CASE REPORT

ISOLATED GALLBLADDER RUPTURE DUE TO BLUNT ABDOMINAL TRAUMA

(Received 25 April, 1988)

Traumatic injury to the extrahepatic biliary system is rare and usually diagnosed at laparotomy when it is associated with other visceral injuries. Isolated gallbladder rupture due to blunt abdominal trauma is even rarer. The clinical presentation of gallbladder injury is variable, resulting in a delay in diagnosis and treatment. Awareness to the possibility of trauma to the extrahepatic biliary system enables early surgical intervention and eliminates the high morbidity associated with delayed diagnosis.

A 5 year old child with isolated gallbladder rupture caused by blunt abdominal trauma is presented.

KEY WORDS: Gallbladder rupture, trauma, blunt, gallbladder

INTRODUCTION

The gallbladder is a well protected organ, being partially embedded in the liver substance and covered by the rib cage. Consequently, gallbladder rupture due to blunt trauma is rare, and usually associated with additional visceral injuries. Isolated gallbladder rupture in pediatric patients following non-penetrating abdominal trauma is even rarer, causes subtle signs, resulting in delayed diagnosis and treatment. Early explorative laparotomy is recommended to reduce the high morbidity associated with this condition.

Case Report

A 5-year-old boy was admitted to the Pediatric Surgical Service 4 hours after falling to the ground from a 5 meter high balcony.

On admission, he was haemodynamically stable with blood pressure of 140/100 mm Hg. and pulse rate of 100/min. Physical examination was essentially normal apart from tenderness over the right upper abdomen with hypoactive bowel sounds. Laboratory data including serum haemoglobin, haematocrit, glucose, amylase, electrolytes and urine examination were all within normal limits. The white cell count was 18,400/mm³. Radiological studies of the skull, cervical spine, chest and abdomen x-rays (supine and erect) were normal.

Over the next hours, though he remained hemodynamically stable, his abdominal condition deteriorated, with the development of guarding and rigidity over the upper abdomen, necessitating an exploratory laparotomy, which was performed 3 hours

after admission. At laparotomy, blood and bile were found in the infrahepatic region. The gallbladder was collapsed and avulsed from its hepatic bed with a 3cm. longitudinal tear on its posterior aspect (Figure 1). No other abdominal injuries were noted.

A cholecystectomy was performed and intraoperative cholangiography demonstrated a normal extrahepatic biliary tract.

Postoperative course was uneventful and the patient was discharged on the seventh postoperative day.

DISCUSSION

Gallbladder injury due to blunt abdominal trauma is rare, with an incidence of about 2% of all intraabdominal injuries^{1,2,3}. Liver injury is present in up to 83% of cases of gallbladder trauma, and the spleen, stomach, intestine, pancreas, and kidney may also be injured³.

Figure 1 Traumatic partial avulsion of the gallbladder from the gallbladder bed with rupture of the posterior gallbladder wall (arrow).

Isolated gallbladder rupture is of rare occurrence. Review of the English literature since 1900 disclosed 51 such cases¹⁻¹⁸, ranging in age from 3 years⁴ to 73 years², with about 30% of cases in the pediatric age group. Most injuries followed road accidents or direct blows to the abdomen.

Penn et al classified four major groups of gallbladder injury: contusion, avulsion, laceration and traumatic cholecystitis¹. Delayed perforation following blunt abdominal trauma can also occur, following a hematoma of the gallbladder wall developing into an area of necrosis, or a blood clot occluding the cystic duct and precipitating infection, gangrene and late perforation^{1,2}.

A thin-walled normal gallbladder or a distended gallbladder following a meal is more prone to traumatic rupture than a diseased, thick walled one¹⁷. Indeed, only two cases with a ruptured gallbladder containing stones have been reported². It is postulated that gallbladder distention at the time of trauma is a prerequisite for its rupture. A high incidence of traumatic gallbladder rupture is reported in alcohol intoxicated patients. Alcohol intake enhances gastrin and secretin secretion, which in turn stimulate bile flow and high serum level of alcohol elevates the common bile duct pressure by increasing the sphincter of Oddi's tone¹³. This combined effect causes gallbladder distension which makes it more susceptible to injury, especially since alcohol also relaxes the abdominal wall musculature¹⁹.

Though persistent bile leakage causes sequestration of fluids resulting in the intraperitoneal bilious collections^{1,2,9}, the clinical presentation is variable and non-specific, resulting in a delay in diagnosis^{20,21}. Why some patients tolerate intraperitoneal bile leak without short term sequelae, while others develop bile peritonitis, is a mystery²². Both conditions, however, require aggressive surgical intervention^{13,20}, since continuous bile loss into the peritoneal or retroperitoneal space usually has a fatal outcome²³.

Diagnostic procedures are not always helpful. Peritoneal tap or lavage is significant only when it yields bile-stained fluid, yet a high incidence of false-negative results has been reported⁹. Contrast x-rays studies depend upon the ability of the gallbladder to concentrate contrast media which may be disturbed in an injured gallbladder. Ultrasonography and computerized tomography scans are valuable when the bile leak becomes encapsulated yielding a mass, while in the acute phase their contribution is questionable¹⁴. Tc-99m-HIDA cholecystoscintigraphy was advocated by Ryan²⁴ as an accurate means of detecting bile leak. Recently, endoscopic retrograde cholangiography and percutaneous transhepatic cholangiography have been proven useful and accurate in diagnosing bile leakage^{13,25}, but their use as an emergency procedure in a trauma patient is questionable. Despite the availability of diagnostic methods, most reported patients with isolated injury to the extrahepatic biliary system were operated after a considerable delay and without preoperative accurate diagnosis. The need, therefore, for careful sequential clinical monitoring of patients with blunt trauma is reemphasized.

Cholecystorrhaphy or cholecystostomy have previously been suggested for the management of a ruptured gallbladder^{6,7}, but cholecystectomy is now accepted as the treatment of choice². Morbidity of patients with gallbladder injuries is usually due to associated intraabdominal injuries² with an overall mortality between 3.8 and 16%¹⁷. However, no death has been reported in patients with isolated gallbladder rupture treated surgically.

Bearing in mind the possibility of injury to the extrahepatic biliary system and using the modern diagnostic facilities, particularly Tc-HIDA scintigraphy, prompt

diagnosis and treatment may be possible, eliminating the high morbidity associated with delayed diagnosis.
