(Received 20 January 2000; In final form 4 October 2000)

A new kind of a decision diagrams are presented: its nodes correspond to all types of nonsingular expansions for groups of input variables, in particular pairs. The diagrams are called the Linearly Independent (LI) Decision Diagrams (LI DDs). There are 840 nonsigular expansions for a pair of variables, thus 840 different types of nodes in the tree. Therefore, the number of nodes in such (exact) diagrams is usually much smaller than the number of nodes in the well-known Kronecker diagrams (which have only single-variable Shannon, Positive Davio, and Negative Davio expansions in nodes). It is usually much smaller than 1/3 of the number of nodes in Kronecker diagrams. Similarly to Kronecker diagrams, the LI Diagrams are a starting point to a synthesis of multilevel AND/OR/EXOR circuits with regular structures. Other advantages of LI diagrams include: they generalize the well-known Pseudo-Kronecker Functional Decision Diagrams, and can be used to optimize the new type of PLAs called LI PLAs. Importantly, while the known decision diagrams used AND/EXOR or AND/OR bases, the new diagrams are AND/OR/EXOR-based. Thus, because of a larger design space, multi-level structures of higher regularity can be created with them. This paper presents both new concepts and new efficient synthesis algorithms.

Keywords: Decision diagrams; Technology mapping; Regular layout; FPGA mapping; Nonsingular expansion; Multi-level synthesis

INTRODUCTION

It has been known for few years that the Linearly Independent Logic (LI) [7–9,15,20,22,23,24,26,30] can potentially create circuits that are superior in terms of the number of gates, speed, area and testability to canonical AND/EXOR circuits (both two- and multi-level) [10,11]. The concepts of LI logic have been also used for image processing [16] and encoding [1]. Similarly to the Reed–Muller (RM) logic [36–45] that is a special case of the LI logic, the circuits realized using LI logic are obtained by repetitive expansions of a logic function. Unlikely to RM logic, however, where there are only three expansion types for a variable; Shannon (S), Positive Davio (pD), and Negative Davio (nD) [39], the LI logic uses more expansion types for **sets of variables**, and the number of such expansions is very high even for two variables.

The reason why the LI-logic-based circuits are most often much smaller and never worse than RM-logic-based circuits is simply because they include all canonical AND/EXOR circuits as their special cases, operating in a much larger design space. The circuits generated using LI logic are obtained by expansions with respect to certain nonsingular matrices representing "basis functions". These expansions are called therefore the **nonsingular expansions**. Unfortunately, no efficient algorithms for the calculation of all nonsingular expansions of LI logic have been so far created. The approach from Ref. [26] only outlined efficient approaches for limited types of nonsingular expansions, but no detailed synthesis algorithms were presented. Paper [7] presented a "fast transform" method to find a single expansion for certain polarities of variables, but still the problem of selecting the best polarity (and thus, the best expansion) among all polarities of two-variable nonsingular expansions was not discussed. Therefore, although there exist fast transforms (expansions), still no methods are known to select a good one among a huge number of such transforms. (Applying "fast" transforms successively for all possible polarities would be extremely inefficient and thus have been not

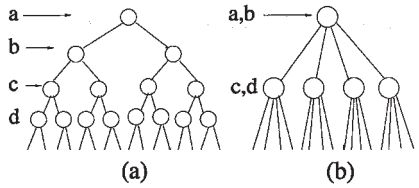

FIGURE 1 Standard and multi-variable expansion trees.

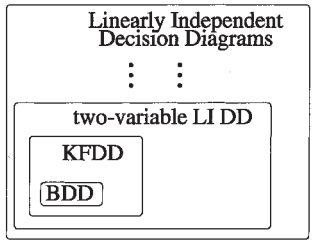

FIGURE 2 Simplified hierarchy of decision diagrams.

proposed.) In conclusion, LI logic despite having a high potential as a powerful generalization of Reed–Muller logic, has not been proven to be practically useful because there were no efficient circuit minimization techniques developed for it.

In this paper, we will develop a general approach to create various types of LI circuits. However, the algorithms for expansion selection will be restricted here to pairs of variables in expansions, similarly to [7].

For the first time, however, it will be presented how good-quality polarities of expansions can be found quite efficiently. Second section will present the very idea of expansions for groups of variables as the generalization to well-known expansions. In the third section we introduce the nonsingular expansions. We illustrate an example of a LI Universal Logic Module with two control variables (corresponding to a node of a tree) and present a theory how to compute the expansion "data input functions" (DI functions, for short) for such two-variable nodes. These expansions are calculated repeatedly in the process of tree creation. Fourth section introduces the LI Trees, and fifth section introduces the LI Decision Diagrams and the LI Forms. Sixth section presents approximate algorithms for the generation of various types of LI Decision Diagrams for multi-output functions. Seventh section describes general principles of creating algorithms to select, for a given set of expansion variables, good polarities (i.e. basis functions) for nodes at a given level of the diagram. Eighth section presents an example of such an exhaustive exact algorithm for completely specified functions, and ninth section presents an approximate algorithm for incompletely specified functions. The algorithm becomes more efficient when the function is weakly specified. Tenth section concludes the paper.

NEW TYPES OF DIAGRAMS FOR MULTI-VARIABLE EXPANSION NODES

Figure 1a shows a standard tree obtained for single expansion variables in nodes. Every level corresponds to a single variable, and every node denotes a single-variable (standard) expansion: Shannon, Positive Davio or Negative Davio. Figure 1b shows the new tree obtained for pairs of expansion variables in levels. Every level corresponds to a pair of variables, and the sets of variables in levels are not overlapping. Every node is a two-variable expansion. It can be shown using the methods outlined below that the total number of such expansions for two variables equals 840. Thus, there are 840 types of nodes in the tree. We will call this tree a LI decision tree, because LI logic is used to create all possible expansion types.

Obviously, as shown in the trees, the forms obtained from flattening of the LI tree for four variables have at most 16 terms (leafs), the same number of leafs as the forms obtained from the standard tree. However, the product terms are no longer products of literals, but of arbitrary functions of two variables; for instance a single term $(a+b)(c \oplus d)$ corresponds to four product terms, $a\bar{c}d, ac\bar{d}, b\bar{c}d, bc\bar{d}$, of the standard tree. Thus, the new forms are three-level and not two-level, and have on average a much smaller number of terms. However, these forms allow to create circuits that are as regular as for the standard forms, allowing to generalize the concept of a PLA.

A simplified hierarchy of decision diagrams that includes our new diagrams is shown in Fig. 2. It shows BDDs with single-variables, one-node-type expansions as the narrowest category, next the Kronecker Decision Diagrams with single-variable, three types of node expansions as a broader concept, next the two-variable LI DDs with 840 node types for pairs of variables, and finally, the LI Decision Diagrams with arbitrary sets of variables in groups (arbitrary sizes of sets, overlapping or not) as the broadest type of decision diagrams. In addition, similarly as in standard diagrams, one may allow to have any combination of expansion types in level nodes, thus leading to "Pseudo-Kronecker type" of the LI diagrams. "Mixed-variable" LI diagrams can have levels corresponding to groups of variables of various sizes. Detailed families of diagrams can be described similarly as it was done in literature for single variables.

LI logic [20,26] allows to uniquely derive data functions SF_i for universal expansion modules from the original function $f(x_1, x_2, \ldots, x_n)$, assuming given sets of LI functions (basis functions, LI functions) of m variables ($m \leq n$). We will review these methods briefly below. We create a $2^m \times 2^m$ matrix $\mathbf{M}$ with rows corresponding to minterms (for a subfunction SF with m variables we have 2^m rows). The columns correspond then to the basis functions. A "1" in the intersection of a column i and row j means that function i covers minterm j. Any subset of columns should be LI with respect to EXOR operation (i.e. columns are bit-by-bit exored). If a set of 2^m columns is LI then matrix $\mathbf{M}$ is nonsingular and there exists one and only one matrix $\mathbf{M}^{-1}$, inverse to $\mathbf{M}$ with respect to the exoring

operation. In such case, the family of Boolean functions corresponding to the columns will be called the "linearly independent family of Boolean functions" (or a set of LI Boolean functions, or a LI set, called also the basis functions [3,24,26]). Here, we will call them *LI functions*, for short. The matrix will be called a *nonsingular matrix*, and the data input functions SF_i will be called the *DI functions*.

THE NONSINGULAR EXPANSION

To introduce the ideas of LI logic in a tutorial approach, we will first present a simple example of a nonsingular expansion.

Example 2.1 Given is function *f*(*A*,*B*,*C*,*D*) from Fig. 3.

Let us assume that we want to find a certain expansion of this function with respect to variables $\{A,B\}$. As the first step, we create an auxiliary equation based of standard Shannon expansion with respect to cofactors of variables A, B. This expansion uses the standard cofactors: $f_{\bar{A}\bar{B}}(C,D)$, $f_{\bar{A}B}(C,D)$, $f_{A\bar{B}}(C,D)$, $f_{AB}(C,D)$. All these cofactors are calculated from the initial function $f(A,B,C,D)$. Thus we can write:

$$\begin{aligned} f(A,B,C,D) =& \bar{A}\bar{B}f_{\bar{A}\bar{B}}(C,D)\oplus\bar{A}Bf_{\bar{A}B}(C,D)\oplus A\bar{B}f_{A\bar{B}}(C,D)\\ &\oplus ABf_{AB}(C,D)\\ =&\bar{A}\bar{B}f(A,B,C,D)|_{A=0,B=0}\\ &\oplus\bar{A}Bf(A,B,C,D)|_{A=0,B=1}\\ &\oplus A\bar{B}f(A,B,C,D)|_{A=1,B=0}\\ &\oplus ABf(A,B,C,D)|_{A=1,B=1}\\ =&\bar{A}\bar{B}(C+D)\oplus\bar{A}B(C\oplus D)\oplus A\bar{B}(C\bar{D})\\ &\oplus AB(\bar{C}D) \end{aligned}$$

(after inserting the values of cofactors (rows) of the Kmap from Fig. 3).

Next, we will show how to find the **nonsingular** expansion of this function for the given "**basis functions on variables**" A and B. Here, we arbitrarily select basis functions as: $f_{A+B}=A+B$, $f_{\bar{B}}=\bar{B}$, and $f_{\bar{A}}=\bar{A}$, and $f_1=1$. Now our goal is to find the unknown "**data functions**" $SF_i(C,D)$:

$$\begin{aligned} f(A,B,C,D) =&(A+B)SF_{A+B}(C,D)\oplus\bar{B}SF_{\bar{B}}(C,D)\\ &\oplus\bar{A}SF_{\bar{A}}(C,D)\oplus SF_1(C,D) \end{aligned} \tag{2.1}$$

Now, in order to calculate the equations of the unknown functions $SF_i(C,D)$ from Eq. (2.1) as some functions on variables C and D, we will compare the expansions for all possible combinations of values of A and B. This will lead to a set of linear logic equations, which after solving will give the values to the unknown functions $SF_i(C,D)$.

Thus comparing the two expansions for $f(A,B,C,D)$ from Fig. 3 we have:

$$\begin{aligned} &\bar{A}\bar{B}(C+D)\oplus\bar{A}B(C\oplus D)\oplus A\bar{B}(C\bar{D})\oplus AB(\bar{C}D)\\ &=(A+B)SF_{A+B}(C,D)\oplus\bar{B}SF_{\bar{B}}(C,D)\\ &\oplus\bar{A}SF_{\bar{A}}(C,D)\oplus SF_1(C,D) \end{aligned}$$

By substituting in the above equation $A=0$, $B=0$, we get the following Eq. 2.1.1 for cofactor $f_{\bar{A}\bar{B}}(C,D)$:

$$(C+D)=f_{\bar{A}\bar{B}}(C,D)=SF_{\bar{B}}\oplus SF_{\bar{A}}\oplus SF_1 \tag{2.1.1}$$

By substitution $A=0$, $B=1$, we get the following Eq. 2.1.2:

$$(C\oplus D)=f_{\bar{A}B}(C,D)=SF_{A+B}\oplus SF_{\bar{A}}\oplus SF_1 \tag{2.1.2}$$

By substitution $A=1$, $B=0$, we get the following Eq. 2.1.3:

$$(C\bar{D})=f_{A\bar{B}}(C,D)=SF_{A+B}\oplus SF_{\bar{B}}\oplus SF_1. \tag{2.1.3}$$

By substituting $A=1$, $B=1$, we get the following Eq. 2.1.4:

$$(\bar{C}D)=f_{AB}(C,D)=SF_{A+B}\oplus SF_1. \tag{2.1.4}$$

The last four equations for cofactors $f_{A^iB^j}(C,D)$ can be rewritten to the matrix form of equation:

$$\begin{bmatrix} 0 & 1 & 1 & 1\\ 1 & 0 & 1 & 1\\ 1 & 1 & 0 & 1\\ 1 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} SF_{A+B}(C,D)\\ SF_{\bar{B}}(C,D)\\ SF_{\bar{A}}(C,D)\\ SF_1(C,D) \end{bmatrix} = \begin{bmatrix} C+D\\ C\oplus D\\ C\bar{D}\\ \bar{C}D \end{bmatrix} \tag{2.1.5}$$

where we denoted:

$$\begin{bmatrix} f_{\bar{A}\bar{B}}(C,D)\\ f_{\bar{A}B}(C,D)\\ f_{A\bar{B}}(C,D)\\ f_{AB}(C,D) \end{bmatrix} = \begin{bmatrix} C+D\\ C\oplus D\\ C\bar{D}\\ \bar{C}D \end{bmatrix}$$

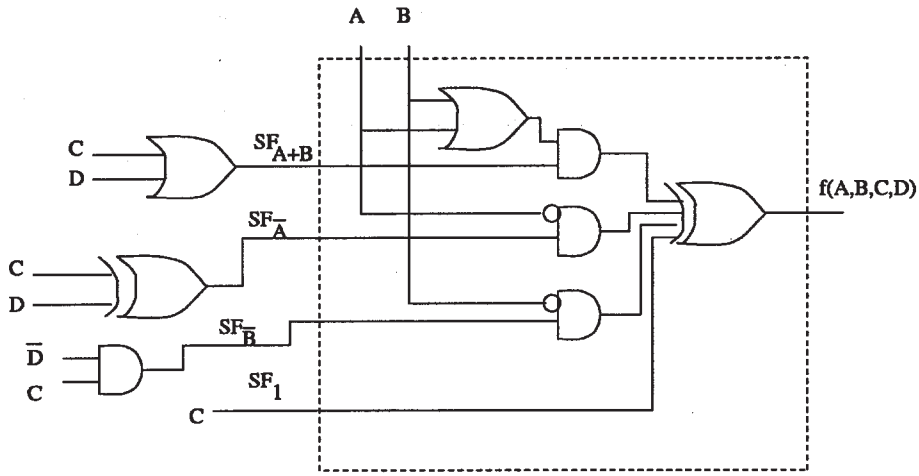

FIGURE 4 Universal nonsingular expansion module for basis functions from Example 2.1, applied to the function from Fig. 3. The data functions $SF_{A+B}, SF_{\bar{B}}, SF_{\bar{A}}$, and SF_1 are from left, and the universal module for basis functions $A+B, \bar{B}, \bar{A}$, and 1 is shown in a dotted rectangle.

Denoting the vector of cofactors by FV and the vector of data functions by CV, the matrix Eq. (2.1.5) can be described in the short form:

$$\mathbf{M} \times CV = FV$$

Therefore, $\mathbf{M}^{-1} \times FV = CV$ which in full form is:

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} f_{\bar{A}\bar{B}}(C,D) \\ f_{\bar{A}B}(C,D) \\ f_{A\bar{B}}(C,D) \\ f_{AB}(C,D) \end{bmatrix} = \begin{bmatrix} SF_{A+B}(C,D) \\ SF_{\bar{B}}(C,D) \\ SF_{\bar{A}}(C,D) \\ SF_1(C,D) \end{bmatrix}$$

Now, that the unknown data input functions SF_i have been found, they are substituted into the nonsingular expansion (2.1) to create the expansion formula (2.2). The coefficients $SF_i(C,D)$ are taken from the above vector CV. From Fig. 3, the function F can be represented by a vector

$$FV^{\mathrm{T}} = [(C+D)\ \ (C \oplus D)\ \ (C\bar{D})\ \ (\bar{C}D)].$$

Thus vector CV is:

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} (C+D) \\ (C \oplus D) \\ (C\bar{D}) \\ (\bar{C}D) \end{bmatrix} = \begin{bmatrix} SF_{A+B} \\ SF_{\bar{B}} \\ SF_{\bar{A}} \\ SF_1 \end{bmatrix}$$

Substituting and simplifying we obtain CV:

$$\begin{bmatrix} (C+D) \oplus (C+D) \oplus (C\bar{D}) \oplus (\bar{C}D) \\ (C\bar{D}) \oplus (\bar{C}D) \\ (C \oplus D) \oplus (\bar{C}D) \\ (C+D) \oplus (C \oplus D) \oplus (C\bar{D}) \end{bmatrix} = \begin{bmatrix} (C+D) \\ (C \oplus D) \\ (C\bar{D}) \\ (C) \end{bmatrix}$$

Then, substituting values from CV to Eq. (2.1), the Eq. (2.1) obtains the form:

$$f(A,B,C,D) = (A+B)(C+D) \oplus \bar{B}(C \oplus D) \oplus \bar{A}(C\bar{D}) \oplus 1(C) \tag{2.2}$$

Concluding, we were able to expand the original function with respect to four basis functions on variables A, B. We will call these functions (in our case, functions $A+B, \bar{B}, \bar{A}$, and 1), the **Linearly Independent Functions,** since the columns corresponding to them in matrix $\mathbf{M}$ are LI with respect to the operation of EXOR-ing columns.

Observe, that a unique expansion was possible because the set of equations had exactly one solution, which is equivalent to matrix $\mathbf{M}$ being nonsingular. Hence, the name "nonsingular" used for our expansion.†

The nonsingular expansion with functional coefficients from Example 2.1 is realized using an "**universal logic module**" with control variables A, B (shown in Fig. 4). We call it an universal logic module, because similarly to a multiplexer with control inputs A and B, all functions of two variables can be realized with this module using constants on its data inputs.‡

This way, for the set of LI functions $\{\bar{A}, \bar{B}, (A+B), 1\}$ there exists only one nonsingular expansion specified by its matrix $\mathbf{M}^{-1}$. The module from Fig. 4 is a generalization of the universal modules: for Shannon Expansion (a multiplexer), for positive Davio Expansion (an AND/EXOR gate), and for negative Davio Expansion (an AND/EXOR/NOT gate with inverted control variable).

Let us observe that formula (2.2) describes only one of the 840 nonsingular expansions for the pair of variables A,

†Moreover, our method of solving this example can be generalized to **arbitrary** sets of LI functions. Such matrices can be nonsingular, or singular. Expansions for singular matrices produce sets of solutions of data functions, the best of which are selected using some additional criteria. The method does not require calculating matrix M.

‡Obviously, the solution from Fig. 4 is not minimal, even assuming the use of LI universal modules. This example has been created to clearly illustrate all principles and matrix calculations. In general, we do not claim that our circuits are always best, only that they are not worse than those obtained from Pseudo-Kronecker diagrams for single variables. The advantages of such circuits become clear for large functions, because of their highly regular realizations with predictable timing, [12,14,25,28,31,32,35].

B [7,24] and thus, 840 different universal modules. (All these universal modules are similar and can be realized by a single switchable universal module). In general, any set of one, two, three, or four variables out of set {*A*,*B*,*C*,*D*} can be selected for the first level expansion of a tree. So, there are very many different trees representing successive expansions. Even if the problem of fast calculating of a single particular expansion was solved, the more important problem remains: how to select the **best one of all the nonsingular expansions** (or the best of nonsingular expansions of certain kind). This problem is difficult, because there are very many such expansions [24]. Here our approach will be to modify some methods known from the Reed–Muller (AND/EXOR) logic, which is a special case of the LI logic. First, we will formally define the representations of Boolean functions that will be next used in functions' optimization.

Now we will adopt the fundamental theorem of LI logic to a special case of binary nonsingular matrix **M**. Let us denote the vector of cofactors with respect to variables $\{x_1, \ldots, x_m\}$ by *FV*. *CV* denotes the vector of coefficients for some given canonical forms represented by nonsingular **M**. Given is an arbitrary LI set of 2^m Boolean functions f_i of m variables. This set can be represented as a $2^m \times 2^m$ nonsingular matrix **M** with basis functions f_i as columns, $i = 0, \ldots, 2^m - 1$.

THEOREM 1 Given is a function $F(x_1, \ldots, x_m, \ldots, x_n)$ such that the set of input variables $\{x_1, \ldots, x_n\}$ properly includes the set $\{x_1, \ldots, x_m\}$. There exists an unique expansion

$$\begin{aligned} F(x_1, \ldots x_n) = & f_0(x_1, \ldots, x_m) SF_0(x_{m+1}, \ldots, x_n) \\ & \oplus f_1(x_1, \ldots, x_m) SF_1(x_{m+1}, \ldots, x_n) \\ & \oplus \ldots \oplus f_{2^n-1}(x_1, \ldots, x_m) SF_{2^n-1}(x_{m+1}, \ldots, x_n) \end{aligned} \tag{2.4}$$

where functions f_i are the given basis LI functions of m variables, and the coefficient functions SF_i are the "data input functions" of the remaining input variables and are determined from the coefficient vector $CV = \mathbf{M}^{-1} \times FV$, where $FV(x_{m+1}, \ldots, x_n)$ is a vector of all 2^m cofactors of F with respect to variables from the set $\{x_1, \ldots, x_m\}$.

Proof Omitted. The proof is a formalization of the general case of applying the method for solving the EXOR logic equations, applied in the example. It is space consuming but straightforward. The method as presented in the example works for any basis LI functions as the columns of a nonsingular matrix **M**.

We will call Eq. (2.4), the nonsingular expansion with functional coefficients $f_i(x_1, \ldots, x_m), i = 0, \ldots 2^{n-1}$. This is a unique expansion for the set of variables $x_1, \ldots, x_m$ and the set of functional coefficients. Thus, the data input functions on variables $x_{m+1}, \ldots, x_n$ for given basis LI functions of matrix **M** are uniquely determined by expansion (2.4). This means that this expansion can be used to create canonical trees. These trees are called LI trees and will be introduced in the next section. Of course, separation of input variables to sets $\{x_1, \ldots, x_m\}$ and $\{x_{m+1}, \ldots, x_n\}$ influences the final implementation cost. The important problem of finding good sets is not discussed here. □

LINEARLY INDEPENDENT TREES

Now when we understand that the basic concept of the nonsingular expansion, we can build the theory around all nonsingular expansions in exactly the same way as the RM logic is created based on Shannon and Davio expansions: we first introduce trees, then the decision diagrams constructed from the trees, and finally the flattened forms obtained from the diagrams. Thus, here we use the plan of RM logic (which is a special case of the LI logic) to build the entire body of LI structures, circuits and the respective synthesis/optimization methods. The creation of diagrams from trees is, however, more complex, so it is deferred to the next section.

Let us recall that the (standard) Kronecker Tree has levels that correspond to single (input) variables. Only one of the three types of binary expansions (S, pD and nD) is used in every level of the tree [41]. Kronecker Trees are quite useful to obtain high-quality multi-level circuits by replacing their nodes with respective gates (such as multiplexer realizing the Shannon expansion node). They can be also generalized to *Pseudo–Kronecker Trees* [6,21,38] that lead to even better (i.e. smaller, faster) circuits. The decision diagrams are next created from such Kronecker or Pseudo-Kronecker trees by applying reduction transformations to pairs of nodes of such trees.

It can be observed, however, that a powerful generalization is possible when in the trees one way allow to have nodes for sets of variables, instead for single variables only. These sets of variables will be called *blocks*. The concept of an "expansion tree" is now generalized, and the tree is no longer a binary tree but has *multi-variable* nodes (many children of a node rather than just two). Moreover, **arbitrary nonsingular expansions** are now allowed in the nodes. The number of such expansions is very large, even for small blocks of grouped variables. For instance, let us observe that in the case of two successive levels of a (standard) Kronecker Tree, there are three nodes for a pair of variables, and each level can have S, pD or nD expansion. Thus, the total number of expansions for a pair of variables in the Kronecker tree is $3 \cdot 3 = 9$. In contrast, there are 840 various nonsingular expansions for a pair of variables in a LI tree. (The total number of expansions for a pair of variables on the top of the Pseudo-Kronecker tree is $3^3 = 27$ because the expansions can be mixed in levels.) These simple calculations demonstrate the power of the concept of expansions for pairs of variables.

The new type of a tree introduced here will be called the *Linearly Independent Kronecker Tree* (LIKT). It is a special case of a general LI Tree. A **LI Tree** is a tree that

uses any nonsingular expansions in nodes in a tree level, and any orders of variables, possibly repeated.

DEFINITION 2 The **LI Kronecker Tree** (LIKT) is a tree with multi-variable expansion nodes, created as follows:

(1) The set of n input variables is partitioned into a set of disjoint and nonempty subsets S_j, such that the union of all these subsets forms the initial set. (This is a partition of the set of input variables). The subsets are called *blocks*. In the case that each block includes just a single variable, the LIKT reduces to its special case of the well-known Kronecker Tree. If there is only one block that includes all variables, the tree reduces to the special case of a **nonsingular form** [23,24,26] (called also the LI form or the orthogonal form).
(2) The sets (blocks) are ordered, each of them corresponds to a level of the tree.
(3) For every level, if the block involves a single variable, the type S, nD, or pD expansion is selected for all its nodes. If the block is multi-variable, one nonsingular expansion polarity is selected for the nodes of the tree at the tree level corresponding to this block. For the block with n variables there are 2^n children nodes of a node.

In LIKTs created for paired input variables the set of all input variables is thus partitioned to several disjoint blocks, each corresponding to a level of the tree. For every block with a single variable, the corresponding expansions are for only three types: S, pD and nD. However, for a block with two variables there are 840 nonsingular expansions and 840 matrices **M**. Therefore, for the two-variable nodes there are 840 types of nodes, called LI(2) nodes (expansion types). Each of the expansion types has four columns in matrix **M**, so that the expansion types will be denoted by $LI(2)$-$[n_{1,1},n_{2,1},n_{3,1},n_{4,1}]$,...,$LI(2)$-$[n_{1,840},n_{2,840},n_{3,840},n_{4,840}]$, or by their basis matrices **M**, shown below. Thus, in $LI(2)$-$[n_{1,i},n_{2,i},n_{3,i},n_{4,i}]$ the number $n_{j,i}$ is a natural number corresponding to the binary vector of the j-th column of the i-th matrix **M**. This number is read with the bottom row as the least significant bit. In this way, the (expansion polarity) matrix

$$\mathbf{M} = \begin{bmatrix} 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 1 \end{bmatrix}$$

is represented as a vector of four natural numbers, each corresponding to one LI function, being a column of **M**, starting from the left, and denoted by $LI(2)$-[15,3,10,7]. The name "**polarity**" comes from standard Reed–Muller logic, where it describes a variable or its negation consistently taken in an expansion. It has been generalized there to three polarity matrices, corresponding to all non-singular 0–1 matrices for a single variable: Shannon, Positive Davio and Negative Davio. Here, the situation is much more general, and the polarity for a group of variables is a set of functions on these variables. It will be called the "**basis matrix**". Because, however, it plays the same role as polarity in Reed–Muller logic, it can also be called the "**polarity matrix**". This way, there are as many expansion types as basis matrices. All these matrices are non-singular.

DEFINITION 3 **Linearly Independent Forms** (LI Forms) are obtained by **flattening the LI Trees**. Flattening has the following stages:

1. Find all branches of the tree that lead to constant 1 in terminal nodes.
2. For each such branch make an ordered product term by multiplying the expressions from the edges in the branch.
3. Make an EXOR of these terms.

In other words, flattening to LI forms corresponds to using recursively the flattening rule $a(b \oplus c) = ab \oplus ac$ and rules $a \oplus 0 = a, a \cdot 0 = 0$ and $a \cdot 1 = a$ of Boolean algebra to the tree expressions. An example of LI Form and how it was obtained by flattenings will be presented in Example 5.3.

Observe, that there exist two combinational problems that have to be solved for such trees: variable pairing and pair ordering. In the more general case of trees with both single-variable and pair-variable nodes, there exists also the problem of partitioning to pairs and single variables. These problems are not a subject of this paper.

LINEARLY INDEPENDENT DECISION DIAGRAMS AND FORMS

DEFINITION 4 (Reduced) LI Decision Diagrams (LI DDs) are created from respective types of LI trees by:

(p1) combining isomorphic nodes of any kind, [5],
(p2) performing standard Ordered Kronecker Functional Decision Diagram (OKFDD) transformations [5] on S, pD and nD nodes,
(p3) performing generalizations of standard Ordered Kronecker Functional Decision Diagram (OKFDD) transformation [5] on multi-variable nodes. These generalized transformations remove any node that evaluates to its single argument.

Let us explain the transformations from (p3). We say that a node **evaluates to a single argument function** H_i, when after the following stages:

1. Substitute in the expression describing the expansion of the node the data input functions being constants by these constants.
2. (Constant propagation and Boolean simplification) Simplify this expression using recursively standard

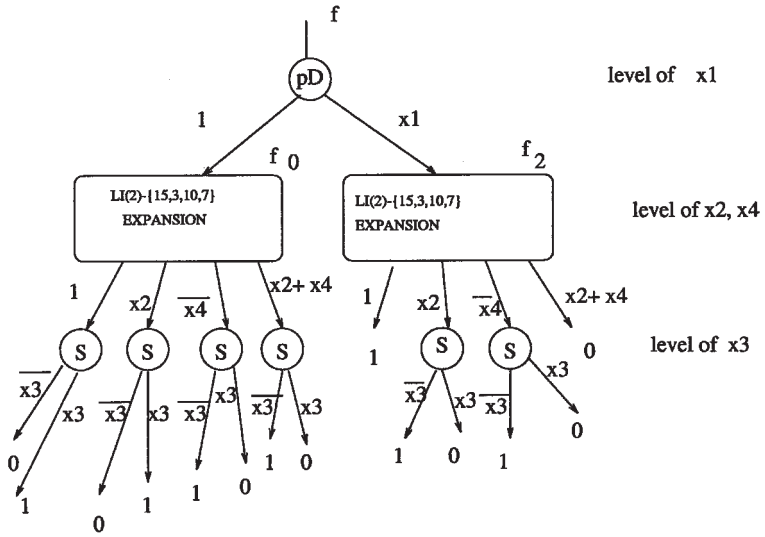

FIGURE 5 Example of a LIKT with blocks $\{x_1\}$, $\{x_2, x_4\}$, and $\{x_3\}$.

Boolean algebra rules: $A0 = 0$, $A1 = A$, $A + 0 = A$, $A + 1 = 1$, $A + A = A$, $AB + \bar{A}B = B$.

the expression becomes H_i.

Observe that in this transformation only those multivariable nodes should be evaluated that their formulas include as arguments some logic constants and/or repeated signals H_i.

For instance, the following examples illustrate the concept of evaluation:

Formula $\bar{a}\bar{b}H_1 \oplus \bar{a}bH_1 \oplus a\bar{b}H_1 \oplus abH_1$ evaluates to H_1
Formula $\bar{a}b0 \oplus ab0 \oplus \bar{b}H_2 \oplus bH_2$ evaluates to H_2
Formula $ab0 \oplus a0 \oplus b0 \oplus H_3$ evaluates to H_3

The above method of creating the reduced LI DD is a generalization of the standard RM logic simplification rules for S, pD and nD nodes that are applied to create the OKFDDs. Two nodes that evaluate to the same arguments become **isomorphic nodes** and as such are combined in a standard way known from the way how DDs are created from trees in RM logic.

DEFINITION 5 *The Linearly Independent Kronecker DDs* are created from LIKTs as described in Definition 4.

DEFINITION 6 *The Linearly Independent Kronecker Forms* are the forms created by flattening of the LIKTs, (or the *Linearly Independent Kronecker DDs*), where the flattening operation is defined in Definition 3.

The LI Forms are no longer realized in two-level circuits, as is the case of the flattened circuits obtained from AND/EXOR trees and circuits. The LI forms have three levels: the first (from output) level are EXOR gates, the second are AND gates and the third are *arbitrary* Boolean functions defined on blocks of variables. The problem of the best selection of these functions is the subject of this paper. The LI Kronecker Forms can be implemented in a three-level circuit called a **LI PLA**, with ordered pairs of input variables for third level. An example of such a LI PLA will be given in Example 5.3.

Example 5.1 Figure 5 shows an example of the LIKT. The first level of the tree has Positive Davio expansion for variable x_1. It creates an expansion:

$$f(x_1, x_2, x_3, x_4) = f_0(x_2, x_3, x_4) \oplus x_1 f_2(x_2, x_3, x_4),$$

where $f_2(x_2, x_3, x_4) = f_0(x_2, x_3, x_4) \oplus f_1(x_2, x_3, x_4)$ and $f_0(x_2, x_3, x_4)$, $f_1(x_2, x_3, x_4)$ are, respectively, the negative and positive cofactors of f with respect to input variable x_1

The second level has LI(2)-[15,3,10,7] expansion for the set of LI functions on variables $\{x_2,x_4\}$ and the third level has Shannon expansions for variable x_3.

The expansion of the node LI(2)-[15,3,10,7] is described by the following formula:

$$\begin{aligned} f_0(x_2, x_3, x_4) = & SF(f_0)_1(x_3) \oplus x_2 SF(f_0)_{x_2}(x_3) \\ & \oplus \bar{x}_4 SF(f_0)_{\bar{x}_4}(x_3) \\ & \oplus (x_2 + x_4) SF(f_0)_{(x_2+x_4)}(x_3) \end{aligned} \quad (5.1)$$

where notation $SF(f_i)_{\mathrm{LI}_j}(X)$ denotes data function SF_{LI_j}, with arguments from the set X of variables, applied to the argument function f_i. The function in the subscript is thus a basis function of the expansion. SF_{LI_j} is one of the data input functions from the expansion basis matrix **M**, corresponding to the basis function from its subscript. (In our case, these are functions $1, x_2, \bar{x}_4$, and $x_2 + x_4$. Also, in our case $X = \{x_3\}$). Formula (5.1) is a specialization of the nonsingular expansion (2.4) applied to cofactor function $f_0(x_2, x_3, x_4)$ as $F(x_1, \ldots x_n)$, and with expansion variables x_2, x_4 in the LI functions. Subfunctions SF_i of the remaining variable x_3 are calculated for the cofactor function f_0 (so they are denoted as functions

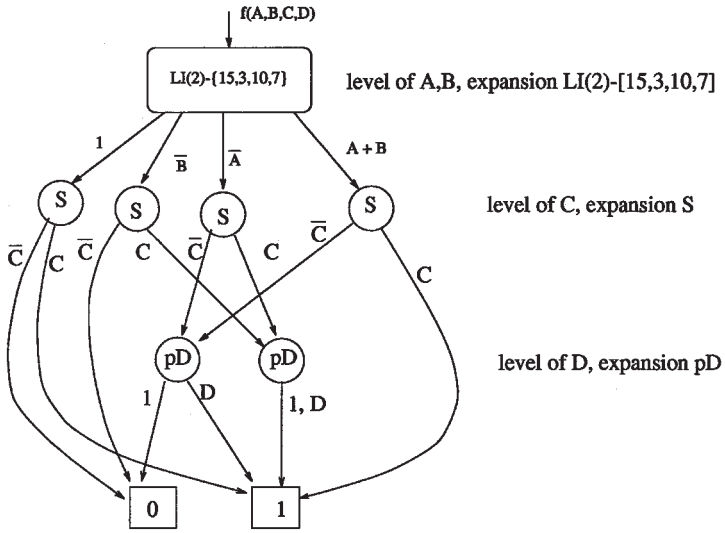

FIGURE 6 A "mixed-variable" LI Kronecker Decision Diagram for function from Example 2.1. Level 1 corresponds to a pair of variables $\{A, B\}$, level 2 to a single variable C and level 3 to a single variable C. Because in every level expansion types are the same, this is a "Kronecker" type of diagram.

$SF(f_0)_1, SF(f_0)_{x_2}(x_3), SF(f_0)_{\bar{x}_4}(x_3), SF(f_0)_{(x_2+x_4)}(x_3)$ in this particular LI(2)-[15,3,10,7] expansion).

Example 5.2 A LI Kronecker Decision Diagram created from a LIKT corresponding to the expansion from Example 2.1 (and the circuit from Fig. 4), is shown in Fig. 6. It was obtained by combining isomorphic nodes.

Now we will generalize LIKTs and LI Kronecker DDs for multi-output functions and "pseudo" data structures. LI "Pseudo" DDs generalize the Pseudo-Kronecker DDs [6,38].

LI Kronecker DDs for Multi-output Functions

DEFINITION 7 A *Single-Polarity Nonsingular Expansion* for a multi-output function is a vector of Nonsingular expansions for its component single-output functions; all of these expansions have **the same polarity.**

DEFINITION 8 A *Multi-Polarity Nonsingular Expansion* for a multi-output function is a vector of nonsingular expansions for its component single-output functions, each of them can have **different** polarity.

Thus, for LI Kronecker DDs for a two-input, three-output function, the *Polarity Vector of a Single-Polarity Nonsingular Expansion* is described by four natural numbers (columns from matrix **M**, as before), and the Polarity Vector of a *Multi-Polarity Nonsingular Expansion* is described by $3{\cdot}4 = 12$ natural numbers. Observe, that in the special case of a multi-output Generalized Reed–Muller (GRM) expansions (realized in multi-variable nodes), Definition 7 is in accordance with the definition of multi-output GRM forms from Ref. [47], which we will call the **single polarity GRMs**. Definition 8 is in accordance with the definition of multi-output GRM forms from Ref. [4] which we will call the **multi polarity GRMs.** Obviously, the minimal DD (or minimal form) obtained with the expansions for multi polarity GRMs is therefore smaller than the one with expansions for single polarity GRMs. There are, however, some advantages of considering single polarity GRMs. They include: faster algorithms, and simpler circuits to create the polarity-defining functions. In case of AND/EXOR forms, these circuits are only invertors in the input level so that these invertors practically do not count to the cost of the realization. However, for general LI circuits, these circuits constitute higher fractions of the total circuit costs, so it is reasonable to assume that for some types of gate/layout realizations the polarities (and their corresponding circuits) are the same for each output function.

DEFINITION 9 A single-output Kronecker DD is specified by a *Single-Output Polarity List*

$$\{[variable\,\text{block}_1, expansion\,polarity_1], \ldots,$$

$$[variable\,\text{block}_r, expansion\,polarity]\}$$

that associates polarities with blocks.

A multi-output Kronecker DD for a function with k outputs is specified by a *Multi-Output Polarity List*

$$\{[variable\,\text{block}_1, expansion\,polarity_{1,1}, \ldots,$$

$$expansion\,polarity_{1,v}, \ldots, expansion\,polarity_{1,k}], \ldots \ldots$$

$$[variable\,\text{block}_r, expansion\,polarity\text{r}, 1, \ldots,$$

$$expansion\,polarity_{r>,v>}, \ldots, expansion\,polarity_{r,k}]\},$$

that associates polarities with blocks, for each output function separately.

LI Pseudo-Kronecker DDs for Multi-output Functions

DEFINITION 10 The *LI Pseudo-Kronecker DD* is defined similarly as the LI Kronecker DD; the only difference is

G,H

FIGURE 7 Six-input, two-output function to Example 5.3.

that in every level, any combination of expansions can be used.

For instance, in LIKDD the expansion LI(2)-[15,3,10,7] is used in the entire level of variables' block $\{x_7, x_8\}$, and in LIPKDD expansions LI(2)-[15,3,10,7], LI(2)-[5,8,10,12], and LI(2)-[3,5,8,15] are mixed in a level. An example of LI DDs will be given in Example 5.3 below.

The relation between the LI Pseudo-Kronecker DD and the LI Kronecker DD is exactly the same as the relation between the Pseudo-Kronecker DD and the Kronecker DD. Similarly, as the Linearly Independent Kronecker Forms and the LI Kronecker Decision Diagrams, the *LI Pseudo-Kronecker Forms* and the *LI Pseudo-Kronecker Decision Diagrams* are defined as flattened forms of respective DDs. Because in case of Pseudo-Kronecker DDs every node can have a different polarity, Definition 7 does no longer apply to Pseudo-type representation of multi-output functions. Polarity lists as for Kronecker DDs are no longer created for Pseudo-Kronecker DDs because of the total freedom of expansion selection for their levels. The name LI DD will be generic to all kinds of LI DDs (LI-Kronecker, LI Pseudo-Kronecker, LI Mixed, LI Ordered, LI Free, etc. [29]).

DEFINITION 11 By a *Shared Ordered Linearly Independent Decision Diagram* (SOLIDD), we will understand an LI Decision Diagram that is Shared and Ordered in the same sense as BDDs are shared and ordered. A *Shared Linearly Independent Kronecker Decision Diagram* (SLIKDD) is a Shared LI Kronecker DD. A *Shared Linearly Independent Pseudo-Kronecker Decision Diagram* (SLIPKDD) is a Shared LI Pseudo-Kronecker DD. A *Shared Ordered Linearly Independent Pseudo-Kronecker Decision Diagram* (SOLIPKDD) is an ordered SLIPKDD.

After defining trees, diagrams, and **LI PLA**s, let us illustrate them by one comprehensive example.

Example 5.3 Given is a six-input, two-output function *G*, *H*(*a*, *b*, *c*, *d*, *e*, *f*) from Fig. 7.

The respective LI Pseudo-Kronecker DDs for blocks {*a*,*b*},{*c*,*d*},{*e*,*f*} is shown in Fig. 8.

A Reduced Shared, Ordered LI Pseudo-Kronecker Decision Diagram created from this diagram is shown in

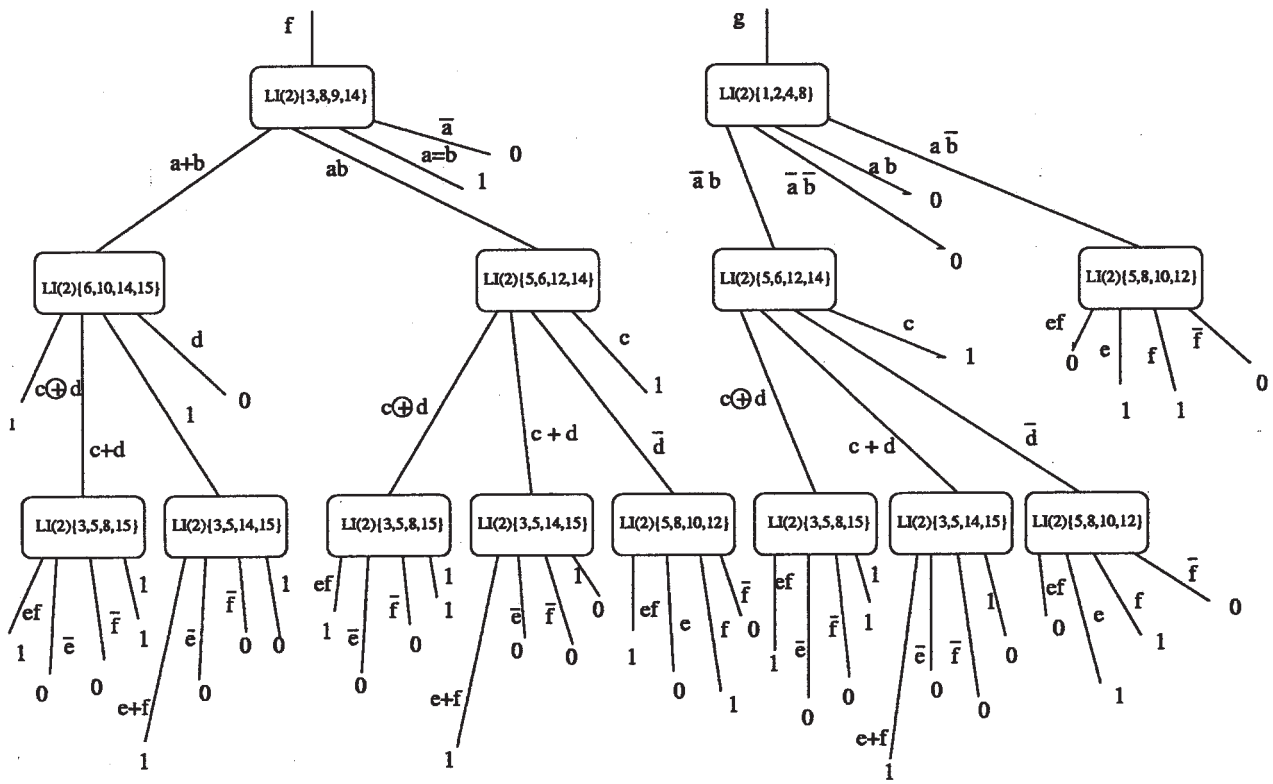

FIGURE 8 A LIPKT for blocks $\{a,b\}, \{c,d\}, \{e,f\}$ to Example 5.3.

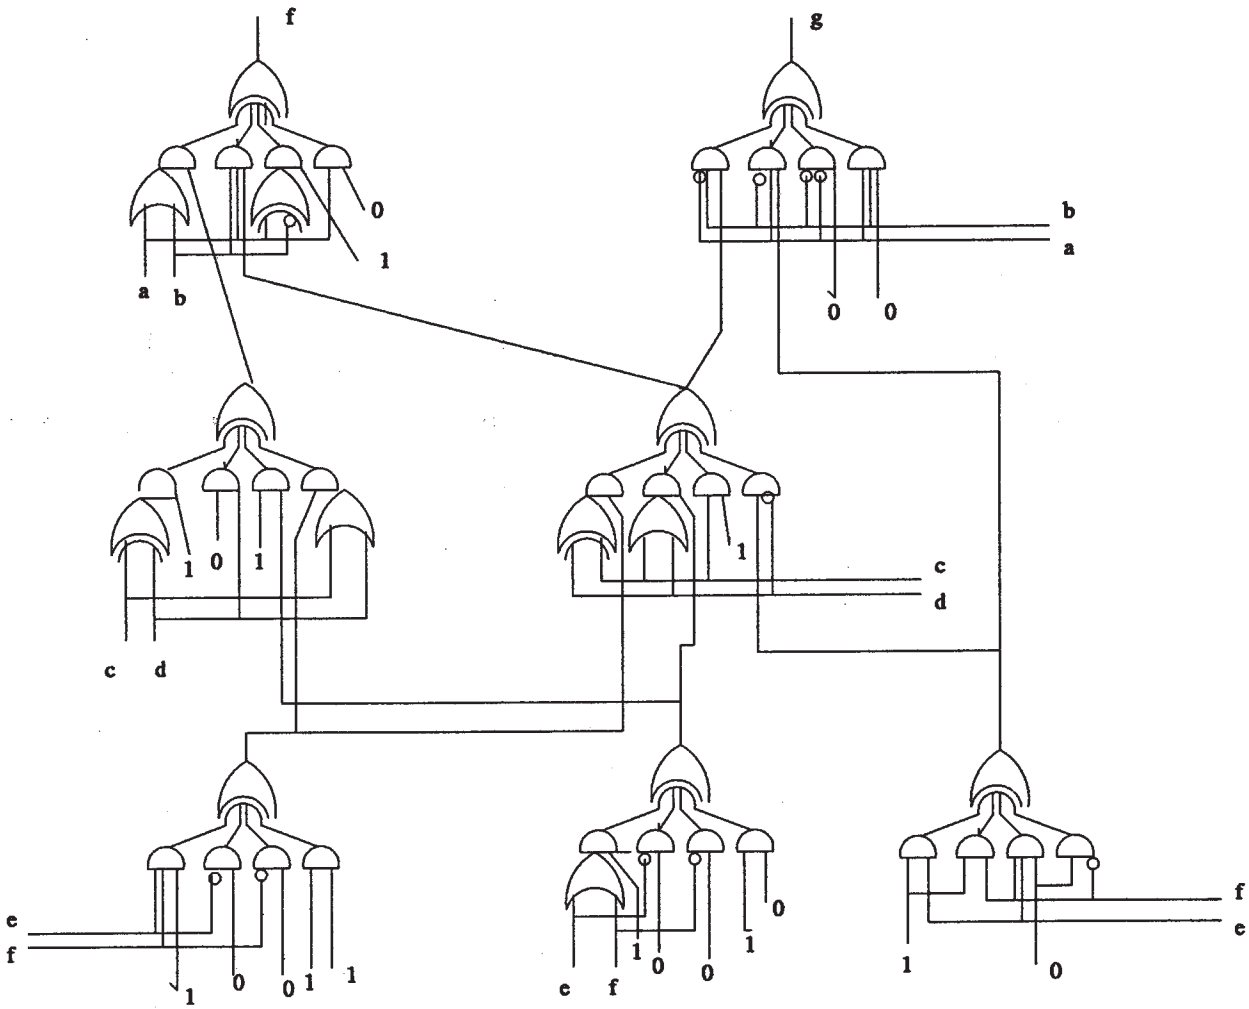

FIGURE 9 A LI Shared and Ordered Pseudo-Kronecker Decision Diagram (SOLIPKDD) for blocks $\{a,b\}, \{c,d\}, \{e,f\}$ to Example 5.3. It is drawn with the expansion nodes substituted by their respective universal module circuits, in order to explain how the final circuit from Fig. 10 can be obtained from such a diagram.

Fig. 9. To enable the reader to analyze the final solutions, in this diagram we show the internal gate-level structure of nodes corresponding to the expansions from Fig. 8.

The multi-level circuit obtained from the SOLIPKDD after the propagation of constants is shown in Fig. 10. Observe for instance the node with output signal *g* from Fig. 9. It has two data inputs being constants 0, so it is transformed to the gate-level circuit from Fig. 10.

The circuit is drawn in a way that enables the reader to observe the effect of propagation of constants. Let us note, that the two EXOR gates that have *c* and *d* as inputs can be factored out, and also the two OR gates with *c* and *d* as inputs can be factored, thus saving two gates. The three-level **LI PLA** for the flattened SOLIPKDD (after constants propagation) is shown in Fig. 11. Again, it can be observed that several operators on variable pairs are repeated, thus can be **factorized**, which would lead to a circuit with less gates. But the PLA regularity would be lost. Observe, that the regular array from Fig. 11 can be directly mapped to fine grain FPGAs such as those from Concurrent Logic/ATMEL [2], Motorola or Xilinx 6000 series. The circuit can also be easily mapped to any architecture with 6-input lookup tables.

From now on, we will assume that **each block has only two variables**. The respective representations will be called *Double-variable LI trees*, *Double-variable Decision Diagrams*, and *Double-Variable LI Forms*, respectively. Although in this paper we discuss LI diagrams for only two variables in each block, all concepts and algorithms can be expanded to blocks of arbitrary size, but the algorithms would become less efficient. Also, in this paper we will consider the LI circuits designed according to Definition 7 (we developed also similar methods for the circuits realized using Definition 8).

ALGORITHMS FOR THE GENERATION OF SOLIKDDS AND SOLIPKDDS

Now, that the concept of SOLIKDDs and SOLIPKDDs and the methods for their creation have been explained, we

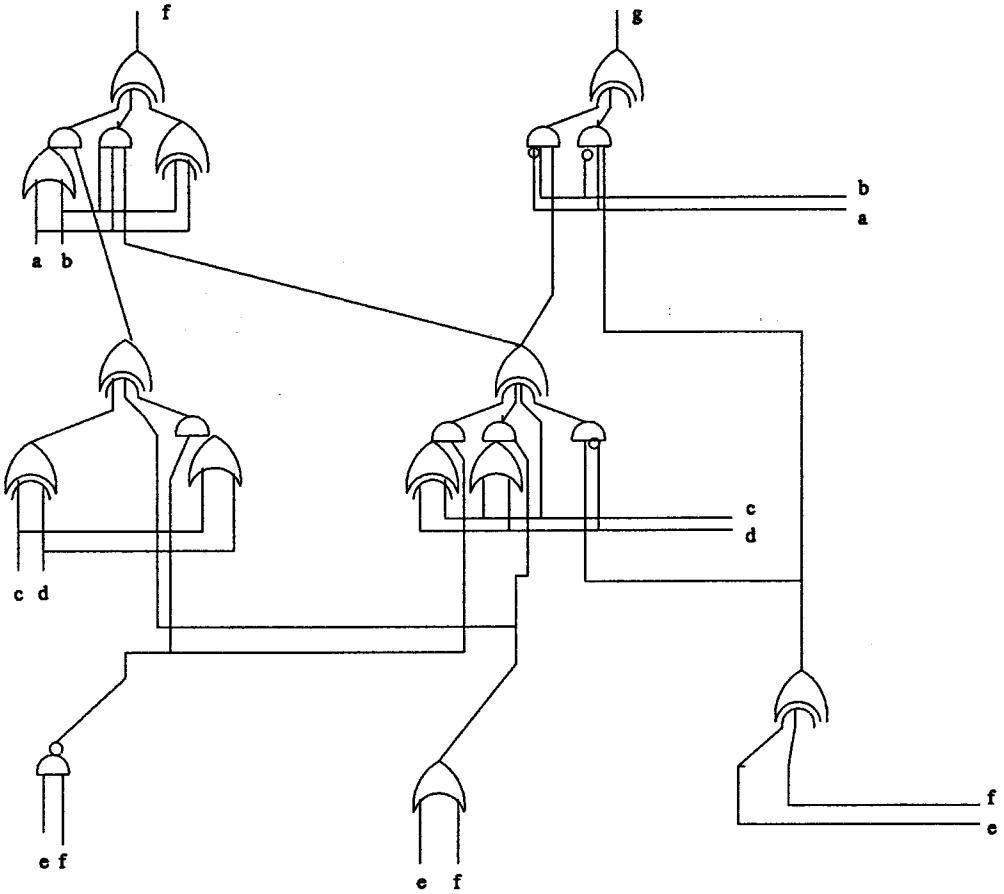

FIGURE 10 A multi-level circuit to Example 5.3 obtained from the LI Shared and Ordered Pseudo-Kronecker DD after substituting circuits of universal modules to nodes of the diagram and propagation of constants.

will turn to generating trees with good expansion type selections for their nodes. We will outline the general algorithms and in the next sections we will discuss approaches to the most important step of selecting the expansion polarities for levels or for individual nodes of LI diagrams. In our considerations, for multi-output functions the algorithms will generate a shared diagram (a Directed Acyclic Graph or DAG) which can be in particular case a **forest of trees**.

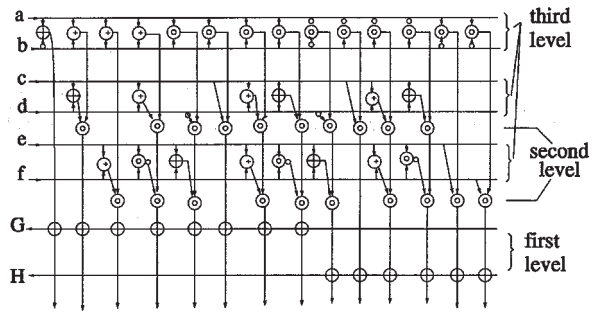

FIGURE 11 A three-level LI PLA for Example 5.3 obtained from the SOLIPKDD from Fig. 9. Large circles denote two-input gates. Small cross in a circle denote an OR gate, and large cross an EXOR gate. Small circle in the large circle denotes an AND gate, and small circle outside large circle denotes an invertor.

PROPERTY 1 In case of SLIKDDs, the order of blocks in the expansions has no influence on the cost of the flattened form that would be found from this diagram.

The same property exists for Kronecker DDs, where the order of expansion variables does not influence the cost of Kronecker expressions obtained from their flattening. Therefore, the minimum form can be found by investigating all LIKDDs for **arbitrary** order of blocks. In contrast, it is not so for the pseudo-Kronecker LI representations, for which all possible permutations of blocks should be calculated in order to find the minimum LI Pseudo-Kronecker Form, thus running the algorithm repeatedly for all possible orders of blocks. Which is, however, not practical for large functions.

While creating a multi-output function of LIKT, the diagrams for all single-output functions are created together, level-by-level from their roots (outputs). In every level, all possible expansions of a block are applied (or some of their subsets) in order to select the best one. Each level of the multi-output diagram corresponds to a block with two elements. Thus, for a two-variable block, **the total of 840 nonsingular expansions** are generated in the exhaustive method which will be described in "Basic principles of efficient algorithms for the selection of the best nonsingular expansion polarity" section. While

calculating the cost function for each expansion, the total cost of nodes of the next level is calculated as the sum of costs of every node in the next level. The best expansion found by the "Polarity Selecting Algorithm" for a level is next applied to all nodes from the level of the multi-output diagram. The next-level nodes that correspond to the same Boolean function are combined to single nodes.

The local optimization algorithm to create the SOLIKDD for multi-output function is the following.

Algorithm 1. Generation of the SOLIKDD for Multi-output Function

1. The set of input variables is partitioned to pairs and single elements (several variable pairing algorithms are known from the literature). In examples below, it is assumed here that all blocks have two elements. Make an ordered list of blocks.
2. Take the first block.
3. Use one of the algorithms from the next section to calculate the best polarity of the expansion for this level of the diagram. Single polarity definition is used for polarity creation.
4. Apply this expansion to all nodes from this level, combine all the isomorphic nodes at the next level (tautology check-see Definition 4).
5. Repeat steps 3 and 4 for all remaining blocks from the list of blocks.

This algorithm is a straightforward generalization of the algorithm from Ref. [42]. We do not discuss the variable pairing and variable ordering problems. The algorithm can also be easily further extended to incompletely specified multi-output functions and to diagrams with inverted edges. Because of a variety of applications, we developed several algorithms to be used in step 3. They are exhaustive or not, for complete and incomplete functions, and for either all nonsingular expansions or only for some of their subfamilies.

The algorithm to create the SOLIPKDDs is very similar to the one presented above. The only difference is in step 3. At each level, the best expansions for each intermediate function (each node of the SOLIPKDD) are chosen separately. So at every level of the diagram, any combination of expansion-node types becomes now possible. These diagrams are no longer canonical, so they cannot be used for function representation in verification processes, but are applicable in circuit synthesis. This way the **Local Optimization SOLIPKDD Algorithm** for Pseudo Diagram is created (not presented here), which finds the best expansion polarity. The difference is that in the Local Optimization SOLIKDD Algorithm, the search is among all polarities for all nodes of the level of the tree together, and for SOLIPKDD the search is performed among all polarities **but for each node of the level separately**.

BASIC PRINCIPLES OF EFFICIENT ALGORITHMS FOR THE SELECTION OF THE BEST NONSINGULAR EXPANSION POLARITY

The most difficult step of the LIDD generation algorithms is how to choose a good polarity. In this section, we consider that problem and propose a solution. Of course, in general one can select any particular polarity of a nonsingular expansion and next create a diagram for these expansion types. Also, one can create a prespecified **Multi-Output Polarity List** and next expand according to it (Such list described polarities for variables in a format shown in "Linearly independent decision diagrams and forms" section). The function representation could be thus calculated for these expansion types as it was illustrated in "The nonsingular expansion" section. If there exists a fast transform, it should be applied, instead of inverting matrix **M** [7]. However, the quality of such an approach cannot be very good because of the random nature of selecting these polarities (Observe that this is an analogous problem as the one known by the name "polarity selection problem" in the area of Functional Decision Diagrams and Fixed Polarity Reed–Muller Forms. It is, however, more difficult to solve in LI logic, because there are many more polarities). Therefore, other methods for finding good expansions must be looked for, unless for some reasons the good polarities can be guessed. Let us then look again to the Reed–Muller logic for an analogy.

One of the interesting and popular concepts of Reed–Muller logic are the **butterfly diagrams** that allow to create all Fixed Polarity RM expansions by transforming iteratively the function under optimization from one polarity form to another polarity form, and doing this just by incremental exoring of some terms from the forms. This way, all forms of certain type are systematically created without even creating their matrices **M** and without calculating their inverse matrices $\mathbf{M}^{-1}$. Gray-code ordering of polarities is usually used. In another similar approach, we applied the concept of Gray-code ordering of all GRM polarities in an algorithm to find the exact minimum GRM form [47]. Below we will demonstrate that such methods are also applicable to LI logic.

PROPERTY 2 In matrix **M**, as well as in matrix $\mathbf{M}^{-1}$, any column can be replaced by a linear combination of itself with other columns and the matrix remains nonsingular, thus it is a base of a new expansion.

On the basis of Property 2, a new *polarity expansion* can be obtained using the Basic Rule (BR), given below, to certain selected columns (i.e. basis functions).

PROPERTY 3 Given is the following rule.

Rule BR:

$$f_1(x_1,x_2)SF_1(x_3,\ldots,x_n)\oplus f_2(x_1,x_2)SF_2(x_3,\ldots,x_n)$$
$$= [f_1(x_1,x_2)\oplus f_2(x_1,x_2)]SF_1(x_3,\ldots,x_n)\oplus f_2(x_1,x_2)$$
$$\times [SF_1(x_3,\ldots,x_n)\oplus SF_2(x_3,\ldots,x_n)]$$

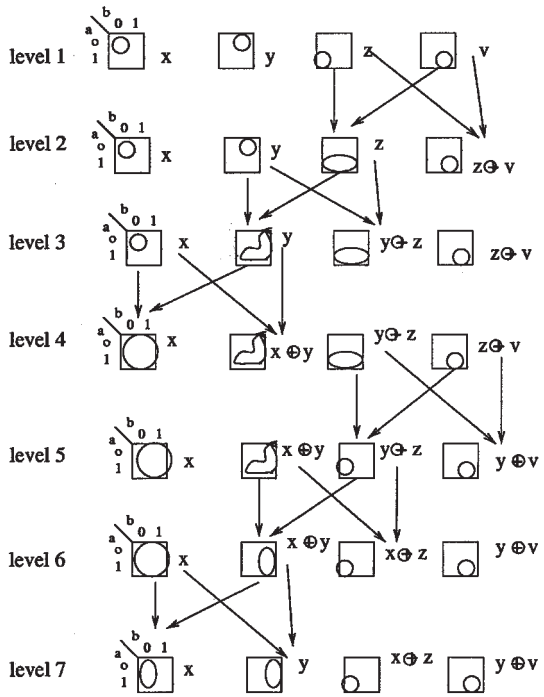

FIGURE 12 An initial segment of a Butterfly Diagram to create nonsingular expansions for all LI functions of *a,b*.

where $f_1(x_1,x_2)$ and $f_2(x_1,x_2)$ are arbitrary LI function, and $SF_1(x_3,\ldots,x_n)$ and $SF_2(x_3,\ldots,x_n)$ are corresponding to them data input functions (DI functions). Any nonsingular expansion formula can be obtained by a repeated application of Rule BR to pairs of LI and DI functions:

$$[f_1(x_1,x_2),f_2(x_3,\ldots,x_n)],[f_3(x_1,x_2),f_4(x_3,\ldots,x_n)].$$

This way, rule *BR* describes simultaneous EXOR-ing of columns in matrix **M** and corresponding columns in $\mathbf{M}^{-1}$. (It is easy to verify that this rule is true, using simple Boolean manipulation and comparing its left and right sides). Observe, that although rule BR assumes pairs of variables in functions f_1 and f_2, it is a general synthesis rule for functions with **arbitrary** numbers of variables.

By repeated applications of rule BR all possible expansions can be found starting from one initial expansion, the canonical SOP/ESOP expansion with disjoint cofactors as basis functions. The methods based on the rule BR will be therefore a fundament of several very general optimization methods of LI logic. But a question remains. "Which pairs of columns to select and how long to continue the application of rule BR?"

These are the possible approaches in LI logic to find good (best) expansions based on rule BR.

A1 Find **all** nonsingular expansions for a function. This problem is important theoretically because it is a generalization of problems such as "find the best FPRM form", or "find the best KRM form", which are classic problems in RM logic. It should be solved in order to create exact algorithms and enumerate all best solutions. However, practically this approach is of less importance, since the number of all nonsingular expansions is very high.

A2 To find not all but **as many as possible** sequences of nonsingular expansions, but such sequences that can be created in very efficient way. This would allow to create efficient multi-level minimizers for those function bases that correspond to some sets of nonsingular expansions for which such sequences can be found.

A3 To find all nonsingular expansions for some limited special families of expansions (such families are defined by matrices **M** having some special properties). This is exactly the approach developed by many researchers for past 40 years in Reed–Muller logic (AND/EXOR logic), which is a proper subset of the general LI Logic. For instance, this was done for Fixed Polarity RM forms, and Kronecker RM forms, which restrict basis functions to ANDs of certain sets of literals. Also, we proposed different families of special functions for the general LI logic as well [7,23,24,26,35]. They are of interest to create highly regular PLA-like structures with short connections for submicron technologies. There exist classes of expansions which are practical for synthesis using Fine Grain FPGAs, but for which fast transforms do not exist. Many fast transforms were identified for various LI classes [7], unfortunately for some of them the applications are not yet known to us. For all these special families, we would be able now to build butterfly diagrams based on rule BR. Our future research goal is to find such families with some interesting and useful properties.

From the point of view of A2 and A3 above, another important observation is that until now, the following classes of LI subfamilies have been of interest in general LI Logic:

C1 Those for which both fast forward and fast inverse recursive transforms exist [7]. This is the easiest class of families to create efficient algorithms based on butterfly concepts. The open problem however remains; "is this a practically useful class for current technologies and gate libraries?" We plan to investigate the properties of circuits created using the approach from Ref. [7].

C2 Those for which only the fast forward recursive transforms exist. This is a wider class than class C1, so there exists a better chance that such transforms exist for the interesting families of expansions. Similar research plans as in C1 can be formulated.

C3 Families that are important practically, such as those used in Generalized AND/OR/EXOR PLAs and can be mapped to Motorola, ATMEL or XILINX Fine Grain FPGAs and other FPGAs. Even if general

solutions will be not found, it is worthy to find specific solutions for limited number of input variables in a block, for instance for two or three variables.

C4 The family of all nonsingular expansions. Even for two variables, this family includes very many expansions that have no fast recursive transforms.

Points A1 – A3 and C1 – C4 above delineate a large body of theory and algorithms that can be developed for various special applications of LI logic. The next two sections will illustrate two approaches based on the butterfly diagram concepts.

EXHAUSTIVE ALGORITHM BASED ON THE PRE-COMPUTED BUTTERFLY DIAGRAM FOR COMPLETELY SPECIFIED FUNCTIONS

Even if in general there exists no recursive method to define a universal Butterfly-like diagram for an *arbitrary* LI matrix or if such a method is not known, a generator of a specific diagram can be created **once for all** for a set of variables with *certain selected* cardinality and for any given set of expansion polarities. This pre-computed diagram can be stored in the computer memory, and next, it can be applied to a given function to calculate all respective expansions together with their costs. We will call this a "**pre-computed Butterfly diagram**". It can be used to find the best polarity for a block in the Algorithm 1. The algorithm goes through all polarities, calculates the cost of each circuit corresponding to the polarity, and returns the polarity with the minimum cost. As an example, let us discuss the method applied to a single-output function $F(x_1, x_2, x_3, \ldots x_n) = F(a, b, c, \ldots)$. The set of all polarities is created as levels (rows) in a butterfly-like diagram from Fig. 12(for the lack of space, only first few levels are shown). Small k-maps correspond to some LI functions $f(x_1, x_2) = f(a, b)$ and functions $x(x_1,x_2,\ldots, x_n)$, $y(x_1,x_2,\ldots,x_n)$, $z(x_1x_2,\ldots,x_n)$, $v(x_1,x_2,\ldots,x_2)$ correspond to the original cofactors $x = F_{a=0,b=0} = = F_{a=0,b=0} = SF_{00}(x_3,\ldots,x_n)$, $y = SF_{01}(x_3,\ldots,x_n)$, $z = SF_{10}(x_3,\ldots,x_n)$, $v = SF_{11}(x_3,\ldots,x_n)$. (see the top row of the diagram). EXOR-ing the LI functions according to BR rule is shown here graphically on Karnaugh maps. EXOR-ing of the respective DI functions is shown on formulas that stand on the right sides of the respective Kmaps to illustrate clearly the principle of this method.

Thus, the first row corresponds to expansion on standard cofactors:

$$\bar{a}\bar{b}x \oplus \bar{a}by \oplus a\bar{b}z \oplus abv$$

with $\text{cost} = 8 + \text{cost}(x) + \text{cost}(y) + \text{cost}(z) + \text{cost}(v)$, where cost($x$) is a literal cost (complexity, total number of literals) of functions x in the expansion, etc.

The second row is:

$$\bar{a}\bar{b}x \oplus \bar{a}by \oplus az \oplus ab(z \oplus v)$$

with $\text{cost} = 7 + \text{cost}(x) + \text{cost}(y) + \text{cost}(z) + \text{cost}(z \oplus v)$, where cost($z \oplus v$) is a cost of function $z \oplus v$ and is calculated only once, together with function $z \oplus v$.

Comparison of expansion formulas from the first and second rows shows clearly how the second expansion formula is created from the first one by applying rule BR to the last two columns:

$$a\bar{b}z \oplus abv \Rightarrow az \oplus abz \oplus abv = az \oplus ab(z \oplus v)$$

where $z \oplus v = z(x_1, \ldots, x_n) \oplus v(x_1, \ldots, x_n)$ is a new function calculated by EXORing functions z and v.

While applying the BR rule, the simplification rule $X \oplus X = 0$ is used as well. For instance, it can be observed that, between rows 4 and 5 in Fig. 12, the law $(x \oplus y) \oplus (y \oplus z) = (x \oplus z)$ is applied. In addition, the DI functions $SF_i(x_3, \ldots, x_n)$ are repeating in the EXOR formulas in the levels of the diagram and do not have to be computed repeatedly in the diagram, whenever their EXOR formulas such as $x \oplus z \oplus v$ are created. Thus, the generator of the diagram for all nonsingular expansions for pairs of variables can be created once and stored in the memory. The generator for the part shown in Fig. 12 is:

REPEAT 2 times {BR(col3,col4),BR(col2,col3), BR(col1,col2)}

Next, the values of EXOR-sums of subsets of functions $f_i(x_3, \ldots, x_n)$ which are calculated one for the given function $F(x_1, \ldots, x_n)$, can be just inserted for any particular initial cofactors also calculated only once. Thus the number of executions of EXOR operation on subsets of cofactors

$$x(x_1, x_2, \ldots, x_n), y(x_1, x_2, \ldots, x_n), z(x_1, x_2, \ldots, x_n),$$

$$v(x_1, x_2, \ldots, x_n)$$

is essentially decreased, because all repeated EXOR-ings have been now supressed. To obtain high speed of the EXOR-ing operation, the cofactors can be represented as BDDS, KFDDS, cube arrays, bit sets, or using any other efficient representation. Observe that because of generality of BR rule, this method can be applied with no change to functions of arbitrary size and only functions x, y, z and v represented by BDDs, will have more variables.

NON-EXHAUSTIVE ALGORITHM BASED ON DYNAMIC CREATION OF BUTTERFLY DIAGRAM FOR INCOMPLETELY SPECIFIED FUNCTIONS

While the algorithm from "Exhaustive algorithm based on the pre-computed butterfly diagram for completely specified functions" section can be applied to find the minimum cost expansion for small completely specified functions, below we will explain a faster approximate algorithm, similar to the Exhaustive Algorithm, for finding a good expansion for multi-output functions. It works especially efficiently with strongly unspecified functions.

The first observation is that the operations of EXOR-ing on functions $f_i(x_3, \ldots, x_n)$ can be done on incompletely specified functions as well. It must be, however, taken into account, that when a do not care value " $-$ " is EXOR-ed with a constant, the values of x and $x \oplus y$ become constrained. It means that if $x = -$ and $y = 0$ then the same value should be taken for x and $x \oplus y$; which means, 0 for both, or 1 for both. The choice of any of these two possibilities is arbitrary, but it is not possible to just write do not care symbols as x and $x \oplus y$, because this would mean the possibility of selecting 0 for one of those do not cares, and 1 for another do not care in next stages. Similarly if $x = -$ and $y = 1$ then the opposite values should be taken for x and $x \oplus y$; which means 0 for x and 1 for $x \oplus y$, or 1 for x and 0 for $x \oplus y$. In all other cases the values are not constrained and the standard rules $0 \oplus 0 = 1 \oplus 1 = 0, 1 \oplus 0 = 1, 1 \oplus - = -0 \oplus - = - \oplus - = -$ should be taken. These rules are used for EXORing any functions, otherwise the application of BR is the same as in "Exhaustive algorithm based on the pre-computed butterfly diagram for completely specified functions" section.

To illustrate the operation of this Approximate Algorithm, assume function $f(a, b, c, d)$ from Fig. 13. The calculation of the first few levels of the butterfly diagram is shown in Fig. 14. The square Kmaps correspond to LI functions and the long-width rectangles to the data functions $SF_i(x_3, \ldots, x_n)$ (in this particular case, the data functions are $SF_i(c, d)$). In the top row of the diagram the rectangular Kmaps correspond to the cofactors with respect to variables a, b of the map from Fig. 13 (i.e. to the rows of the Kmap).

In contrast to the algorithm from "Exhaustive algorithm based on the pre-computed butterfly diagram for completely specified functions" section, in this algorithm,

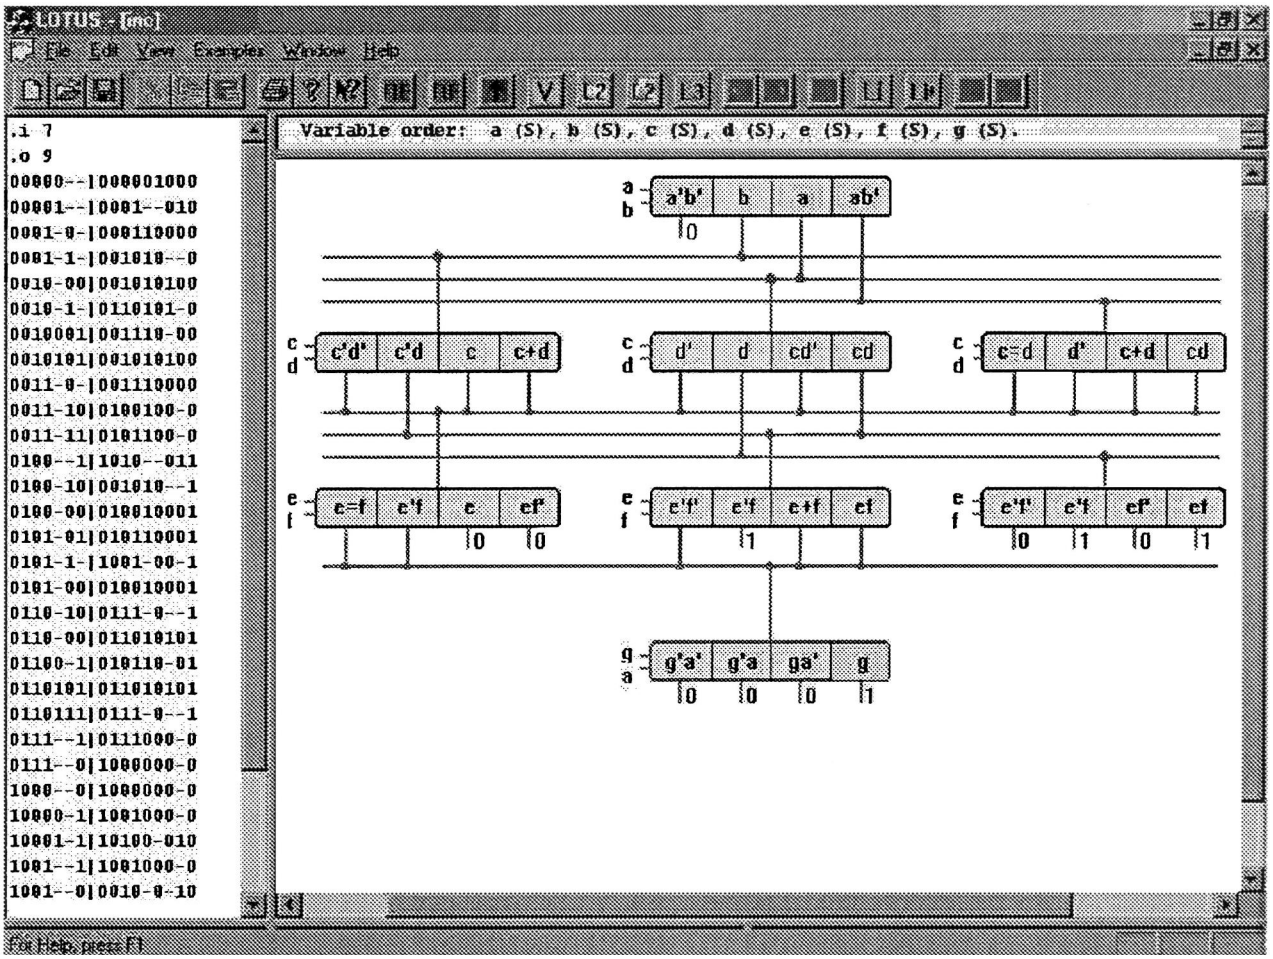

FIGURE 15 Part of a diagram showing setting of individual basis functions in universal modules.

the levels are not pre-computed, but the rule BR is applied to the dynamically selected pairs of functions (i.e. pairs of columns). At every level, the selection is done in such a way that, using the above EXOR-ing rules for incomplete functions within Rule BR, as many as possible of the functions $SF_i(x_3, \ldots, x_n)$ (the long rectangles) will have only symbols 0 and -, which means, as many as possible of these functions will be equivalent to function 0. In general, when it is not possible to create zero-functions $SF_i(x_3, \ldots, x_n)$, the choices must be done in such a way that the functions $SF_i(x_3, \ldots, x_n)$ will have the smallest total cost. Observe that this algorithm can be used without any modification assuming pairs of variables in nodes, but **arbitrary total number of variables**.

Concluding, the above non-exhaustive algorithm to find a good expansion does not visit all possible LI polarities to select the best one but terminates when the curve of best solution cost until now versus the solution number becomes flat for a prespecified number of generated solutions. This value is selected experimentally. The quality of the final solution may suffer, but the algorithm becomes much faster. Using this algorithm in step 3 would allow the SOLIKDD generating Algorithm 1 from "Algorithms for the generation of SOLIKDDS and SOLIPKDDS" section to be applied to larger functions.

CONCLUSIONS

We introduced new concepts of LI Decision Diagrams and shown that they include previously known BDDs, KFDDs and other diagrams. We expect that the LI Decision Diagrams, LI PLAs and LI factorized circuits will find application in Boolean function representation and multi-level logic synthesis with arbitrary gates (AND/OR/EXOR base). The presented methods can be applied to both completely specified and incompletely specified functions; single-, and multi-output. Both Kronecker-like and Pseudo-Kronecker-like generalizations have been shown. Further generalization to Free LI, Forms and DDs are also possible along the line of the approach to free diagrams presented in [13]. Generalizations to Mixed, Ordered, Free and other LI representations following the methods presented in Ref. [29] are also possible.

This paper opens several new interesting research questions in LI Logic. A particularly important open problem is to define generic recursive butterfly diagrams to create *all* expansion polarities of certain practical types and *for arbitrary numbers of variables*. A very practical application of the methods presented and outlined here is for the optimization of various types of lattice diagrams

[14,17,19,25,31,32], such as regular lattices with two, three and especially four inputs/outputs from a node. All methods can be applied to new Xilinx FPGAs, as well as to similar lookup-table architectures. The new representation and algorithms developed in this paper can be used in the first stage of logic synthesis — the "technology independent, EXOR synthesis" phase, which is next followed by the "EXOR-related technology mapping" [10,35,38,42,46], not discussed here.

We have programmed the algorithms to create SOLI-PKDDs and related lattice diagrams and we obtained circuits of small sizes, regular layouts, predictable timing and high testability for functions with tens of inputs and outputs, [18]. Figure 15 shows a regular layout generated.

The advantage of our multi-level synthesis method versus standard approaches for fine grain FPGAs is that our method produces netlists with short and regular connections, which simplifies the phase of technology mapping, placement and especially routing. Our circuits are also highly testable [33,34,46–48]. None of the known approaches has these desirable attributes. The algorithm complexity issues and the discussion of experimental results for FPGA mapping and regular layouts will be discussed in a separate paper.

Authors' Biographies

Marek Perkowski has his PhD in Automatic control from the Technical University of Warsaw, Warsaw, Poland. He served on the faculties of Technical University of Warsaw and University of Minnesota. Currently he is professor of Electrical and Computer Engineering at Portland University, Portland, Oregon. He has been a visiting professor at the University of Montpellier, France, and Technical University of Eindhoven, The Netherlands. He was also a summer professor and consultant at Wright Laboratories of US Air Force, GTE, Intel, Cypress, Sharp, and other high technology and EDA companies. Dr Perkowski was the general chair of International Symposium on Multiple-Valued Logic, 2000, the Vice-Chair for Technical Activities of IEEE Technical Committee on MVL, the Chair of Fourth Oregon Symposium on Logic, Design, and Learning, 2001 and Program Chair for Americas, ISMVL 2002. His recent research interests include spectral decision diagrams, functional decomposition, intelligent robotics, walking robots, robot theatre, axiomatic morality, and all applications of logic synthesis outside circuit design.

Bogdan J. Falkowski received the MSEE degree from Technical University of Warsaw, Poland and the PhD degree in Electrical and Computer Engineering from Portland State University, Oregon, USA. His industrial experience includes research and development positions at several companies. He then joined the Electrical and Computer Engineering Department at Portland State University. Since 1992 he has been with the school of Electrical and Electronic Engineering, Nanyang Technological University in Singapore where he is currently an Associate Professor. His research interests include VLSI systems and design, switching circuits with the use of spectral methods and has published three book chapters and over 150 refereed journal and conference articles in this area. He is a senior member of the IEEE, member of international advisory committee for International Conference on Applications of Computer Systems and was technical chair for IEEE International Conference on Information, Communication and Signal Processing held in December 1999 in Singapore.

Malgorzata Chrzanowska-Jeske received her MS in Electrical Engineering degree from the Technical University of Warsaw, Warsaw, Poland and PhD degree in Electrical Engineering form Auburn University, Auburn, Alabama. She has served on the faculty of the Technical University of Warsaw. Poland, and as a design automation specialist at the Research and Production Center of Semiconductor Devices, Warsaw. Currently, She is a professor of Electrical and Computer Engineering at Portland State University in Portland, Oregon. Her research interests include logic and layout synthesis of VLSI circuits and systems, FPGA synthesis and architecture, and design automation and testing for deep sub-micron technology. She is a member of the IEEE Circuits and Systems Society VLSI Systems and Applications Technical Committee, a senior member of the IEEE, and a member of Eta Kappa Nu.

Rolf Drechsler received his diploma and Dr Phil. Nat. degree in computer science from the J.W. Goethe-University in Frankfurt am Main, Germany, in 1992 and 1995, respectively. He was with the Institute of Computer Science at the Albert-Ludwigs-University of Freiburg im Breisgau, Germany from 1995 to 2000. He later joined the Corporate Technology Department of Siemens AG, Munich and is now with the University of Bremen. He published three books at Kluwer Academic Publisher one on BDD-techniques co-authored by Bernd Becker, one on using evolutionary algorithms in VLSI CAD, and recently one on formal verification of circuits. His research interests include verification, logic synthesis, and evolutionary algorithms.
