Objective. To assess the value of clinically relevant data for predicting the failure of removal of the urinary catheter within 48 hours after TUERP. **Materials and Methods.** We retrospectively analyzed the medical records of 357 patients who underwent TUERP between January 2015 and July 2018, all of whom stopped bladder irrigation and removed urinary catheter within 48 hours after the operation. According to whether the removal of the catheter was successful, the patients were classified into 2 groups: Group A was successful and group B was a failure. Univariate analysis was performed to determine the association between the failure of removal of the catheter and the patients' preoperative clinical characteristics. Logistic regression analysis and receiver operating characteristic analysis (ROC) were conducted to establish the prediction model. Then the area under the curve (AUC) and the cut-off value were calculated. **Results.** 357 patients were divided into group A ($n = 305$, 85.4%) and group B ($n = 52$, 14.6%). The patients' drug medication ($P = 0.006$), history of acute urinary retention (AUR) ($P \leq 0.001$), smoke ($P = 0.045$), IPSS ($P \leq 0.001$), IPP ($P = 0.006$), PSA ($P = 0.047$), residual urine volume ($P \leq 0.001$), QoL ($P \leq 0.001$), and TPV ($P = 0.043$) were significantly different between the 2 groups. A predictive model using logistic regression was defined as follows: $\text{INDEX} = 10.862 - 1.376 \times (\text{IPSS}) - 1.185 \times (\text{QoL}) - 1.062 \times (\text{drug medication}) + 1.079 \times (\text{history of AUR}) + 0.030 \times (\text{TPV}) - 0.867 \times (\text{IPP})$ with area under the curve of 0.860 obtained from the ROC curve analysis. The predictive model had a cut-off value of 1.7725, and the sensitivity for predicting the failure of removal of the urethra was 74.1% and the specificity was 84.6%. **Conclusion.** This study demonstrated that IPSS, QoL, drug medication, history of AUR, TPV, and IPP are independent factors associated with the failure of removal of the urethral catheter within 48 hours after TUERP.

1. Introduction

Benign prostatic hyperplasia (BPH), which causes lower urinary tract symptoms (LUTS), is a common diagnosis among the aging male population with increasing prevalence [1, 2]. It is a histologic diagnosis characterized by enlargement of the prostate gland from a nonmalignant proliferation of glandular and stromal elements in the transition zone of the prostate [3]. The development of BPH in males is an age-related process. Histologic evidence of BPH is identified in approximately 20% of men in their 40 s, in 50% to 60% of men in their 60 s, and in up to 90% of men in their 70 s and 80 s [3, 4]. Transurethral Resection of the Prostate

(TURP) is the historical gold standard therapy for LUTS secondary to obstruction from BPH [5]. However, it is not a standard anatomical surgery; postoperative complications are still there; for example, it is usually recommended for prostates less than 80 mL [6], postoperative BPH recurrence [7]. In addition, the whole resection process is the repeated opening of the perforator vessels of the prostate, so the treatment of the blood-rich prostate is limited [8–10]. Other complications such as TURP-syndrome and bladder neck contracture were also high [11]. There are a number of clinical studies suggesting that TUERP and TURP have similar efficacy, but TUERP removes hyperplastic glands more thoroughly, with shorter operative time, less bleeding,

and shorter bladder irrigation and catheterization time [12, 13]. The catheterization time varies from study to study [14–17]. This article investigates the risk factors for the failure of removal of the urinary catheter within 48 hours and conducts correlation analysis.

2. Materials and Methods

2.1. Patients. We retrospectively analyzed the medical data of 357 patients who underwent TUERP between January 2015 and March 2018. Inclusion criteria were male patients ≥ 18 years, and/or failed medical therapy, recurrent urinary tract infections, and/or recurrent episodes of urinary retention. Exclusion criteria were previous urethral/prostatic surgery, known prostate cancer or urethral strictures, and urodynamically diagnosed neurogenic bladder, and known bladder stones, bladder diverticulum, or bladder tumor [18, 19]. The urinary catheter was removed within 48 hours.

2.2. Surgical Methods. Under general or spinal anesthesia the patient was placed in the lithotomy position. The TUERP procedure was performed using a Plasma Kinetic resectoscope (27 F) with 160 W cutting power and 80 W coagulation power, or diode laser system was set at 120 W. The procedure was performed as follows. The ureteral orifices, bladder neck, and verumontanum were identified. The incision was begun close to the verumontanum from the 5 to the 7 o'clock positions, and the urethral mucosa was incised deeply to the level of the surgical capsule. A network of vessels runs on the inner surface of the surgical capsule and sends perforating vessels to the prostatic adenoma. The middle lobe, left lobe, and right lobe were dissected off the surgical capsule in a retrograde fashion from the apex toward the bladder. The adenoma was dissected from the capsule plane. The blood vessels to the adenoma were coagulated at the time of dissection. When the whole adenoma was almost dissected from the capsule, then they were resected into smaller prostatic chips. At the end of both procedures, a 22Fr triple-lumen catheter was inserted into the bladder and irrigation was initiated [20, 21].

2.3. Medical Records. All patients underwent a general and urologic preoperative evaluation, including age, BMI, history of AUR, IPSS, QoL, TPV, IPP, RUV, PSA, drinking, smoking, hypertension, diabetes, drug medication, urine culture, and surgical methods.

2.4. Statistical Analysis. These variables were statistically investigated to identify any factors that might result in the failure of the removal of the catheter. Mann–Whitney's U test for continuous variables and the χ^2 test for categorical variables were applied to identify which preoperative variables are significant. Then multiple logistic regression analysis was performed to select relevant variables, and a P value < 0.05 was considered significant. Finally, the ROC curve was plotted to calculate the predictive value and find the optimal cut-off points of preoperative variables

associated with the persistence of postoperative storage symptoms. All statistical analyses were performed using SPSS 22.0.

3. Results

Of the 357 patients enrolled in the study, 305 (85.4%) had successful urinary catheter removal within 48 hours (group A) and 52 (14.6%) failed (group B). The preoperative clinical characteristics are shown in Table 1. There are significant differences in drug medication ($P=0.006$), history of AUR ($P \leq 0.001$), smoking ($P=0.045$), IPSS ($P \leq 0.001$), IPP ($P=0.006$), PSA ($P=0.047$), RUV ($P \leq 0.001$), QoL ($P \leq 0.001$), and TPV ($P=0.043$) between the two groups; however, there is no significant difference in surgical methods ($P=0.923$), hypertension ($P = 0.181$), diabetes ($P = 0.0916$), drinking ($P=0.437$), urine culture ($P = 0.305$), BMI ($P=0.817$), age ($P=0.770$), creatinine (Cr) ($P=0.294$), or operation time ($P = 0.931$).

Multivariate analysis revealed that drug medication, history of AUR, IPSS, IPP, QoL, and TPV significantly associated with the failure of the removal of the catheter (Table 2). Smoking, PSA, and RUV were excluded from the multivariate analysis.

A predictive model using logistic regression to determine the failure of the removal of the catheter was defined as follows: $\text{INDEX} = 10.862 - 1.376 \times (\text{IPSS}) - 1.185 \times (\text{QoL}) - 1.062 \times (\text{drug medication}) + 1.079 \times (\text{history of AUR}) + 0.030 \times (\text{TPV}) - 0.867 \times (\text{IPP})$ with area under the curve of 0.860 obtained from the ROC curve analysis. The predictive model had a cut-off value of 1.7725, and the sensitivity for predicting the failure of removal of the urethra was 74.1% and the specificity was 84.6%. The ROC curves of preoperative variables significantly related to the catheter are shown in Figure 1. The AUC, cut-off value, sensitivity, and specificity of these variables alone are shown in Table 3.

4. Discussion

BPH is a disease with slow progress. The prostate gland gradually increases and then presses the urethra, resulting in the patient's dysuria, which seriously affects daily life [22]. Treatment for BPH should be based on a comprehensive consideration of the patient's age, symptoms, prostate volume, economic conditions, health status, and other factors. As a first-line treatment for treatment selection, drug therapy is indeed effective and safe for some elderly patients, but long-term use will bring great economic pressure to patients [23, 24]. With the aging of the population structure, the number of patients is increasing year by year. When prostate hyperplasia develops to a certain extent, urinary incontinence, dysuria, and other symptoms may occur. The commonly used first-line treatment in men with symptomatic BPH is the association of α -adrenergic blockers with 5 α -reductase inhibitors. Nonresponders and patients with drug intolerance may require surgical procedures [25, 26].

Although TURP is still considered to be the "gold standard" for surgical treatment of BPH [27, 28], the procedure is not suitable for large prostate and is associated with

TABLE 1: Preoperative clinical characteristics of enrolled patients.

	Group A (n = 305)	Group B (n = 52)	P
Age (years)	70.00 ± 8.98	71.00 ± 7.67	0.770

intraoperative and postoperative hemorrhage, TUR syndrome, postoperative urethral stricture, postoperative recurrence, and other complications [8]. Therefore, safe, minimally invasive, and effective surgical methods have become an important topic in urology.

TUERP combined with the concept of conventional open surgery and transurethral resection of the prostate, can

not only completely remove the gland but can also reduce bleeding; it is less invasive to the body and has been recognized by clinical experts [29]. Although the energies used for enucleation of the prostate by urologists may be different, such as holmium laser [30], thulium laser [31], diode laser [32], or plasma kinetic energy [14, 33], the principle is similar which include identification of the tissue plane between the adenoma and the surgical capsule, and anatomical enucleation of the adenoma, and this technique has the advantage of being an extravesical procedure, better controlling the bleeding and avoiding bladder incision. TUEP can reduce wound repair time, thus shortening bladder irrigation time, catheterization time, and postoperative hospital stay [12, 34].

There is no uniform conclusion for the time of catheterization time after TUEP. The successful removal of the urethra after surgery is affected by many factors. In order to remove the urinary catheter safely and effectively at the early stage, and to avoid the need to reindwell the urinary catheter, this study combines clinical data with multiple factors to establish a predictive model, improves the success rate of removing the catheter within 48 hours after surgery, and tries to avoid repeated indwelling of the catheter after surgery.

FIGURE 1: ROC curves to determine the cut-off values, sensitivity, and specificity of the variables.

TABLE 3: AUC, cut-off value, sensitivity, specificity, PPV, and NPV of each variable.

Variables	AUC	Cut-off value	Sensitivity (%)	Specificity (%)
INDEX	0.860	1.7725	74.1	84.6
TPV	0.588	37.03	75.1	46.2

In our study, 52 patients (14.6%) needed to reindwell the urinary catheter, and it showed that the prostate volume of group A (55.43 ± 44.16) was larger than that of group B (42.31 ± 42.54), and the difference was statistically significant ($P < 0.05$). Prostate volume was an independent risk factor for predicting the failure of catheter removal within 48 hours. We can notice that the smaller prostate has higher PSA, maybe it is because the inflammation of the prostate is more severe. The failure of removing the small prostate's urinary catheter within 48 hours may be caused by congestion and edema of the prostate. The urethra is squeezed and it takes a long time to recover. If the catheter is removed early, the risk of failure is higher. At the same time, drug medication before the surgery is also an independent risk factor, so if patients take medication before surgery, it is safer to remove the catheter within 48 hours after surgery. There is a significant difference between the patients with and without the acute urinary retention history ($P < 0.05$), and the OR value was 2.943 (95% CI 1.024–8.459). It was suggested that the existence of a history of urinary retention was an independent risk factor for catheter removal within 48 hours after operation, and patients with a history of urinary retention were 2.943 times more likely to fail to remove the

catheter. Other clinical indicators, such as PSA, although statistically significant between group A and group B, could not be used as a valid predictor of failure to remove the catheter in multivariate logistic regression analysis.

This study comprehensively used the predictive value of each clinical data to establish a model to improve the success rate of the removal of the urinary catheter within 48 hours. The diagnostic model has a cut-off value of 1.7725. The sensitivity and specificity of this predictive model is 74.1% and 84.6%, respectively. This model takes into account diagnostic sensitivity and specificity. It can improve the success rate of removing the catheter within 48 hours, and at the same time, reduce or prevent the patient from indwelling catheterization again.

Our research also had some limitations: (1) this study is a single-center retrospective analysis, and the results still need to be verified by a prospective randomized multicenter study and (2) the lack of some valuable urodynamic data, such as the extent of detrusor overactivity and urine flow rate.

5. Conclusion

In clinical practice, the combination of various preoperative variables can predict the failure of removal of the catheter within 48 hours in this study. Our results suggest that various preoperative variables with cutoffs are available for the prediction. And further studies are required to test the reproducibility of the data.

Abbreviations

TUERP: Transurethral enucleation and resection of the prostate
 BMI: Body Mass Index
 AUR: Acute urinary retention
 IPSS: International prostate symptom score
 QoL: Quality of life score
 TPV: Total prostate volume
 IPP: Intravesical prostatic protrusion
 ROC: Receiver operating characteristic
 PSA: Prostate-specific antigen
 AUC: Area under the curve
 BPH: Benign prostatic hyperplasia
 LUTS: Lower urinary tract symptoms
 TURP: Transurethral resection of the prostate
 RUV: Residual urine volume.
