Cutaneous leishmaniasis is of particular importance in southern Iran. This study aimed to investigate the infection of rodents with Leishmania major in an urban area of Fars Province, located in southern Iran. Rodents were trapped and samples from the liver, spleen, and skin were collected. Impression smears were prepared from these tissues and any skin lesions and were examined microscopically. In addition, a portion of the samples were preserved for subsequent DNA extraction. A total of 41 rodents belonging to three species were caught from 10 trapping stations in gardens or houses within the area. The caught rodent species were Rattus rattus (n = 25, 60.97%), Mus musculus (n = 15, 36.58%), and Meriones persicus (n = 1, 2.5%). Leishmania amastigotes were seen in the spleen tissue smear of 6 (2.43%) of the rodents, including 4 of R. rattus and 2 of M. musculus. Skin lesions were observed on the muzzles of two R. rattus and one M. musculus. Samples taken from these lesions tested positive for Leishmania infection. Leishmania DNA was detected in 18 (43.9%) rodents, including 11 R. rattus, 6 M. musculus, and one M. persicus, based on DNA sequencing of the ITS2 gene and PCR of the kDNA. Phylogenetic reconstruction revealed that the parasite infecting the rodents was L. major. This detection of Leishmania infection in these rodents in urban areas raises concerns about the urbanization of cutaneous leishmaniasis caused by L. major. This urbanization poses unique challenges for control and prevention efforts.

1. Introduction

Leishmaniasis, as one of the most neglected tropical diseases [1, 2], is a group of diseases including cutaneous, visceral, and mucocutaneous leishmaniasis caused by infection with protozoan parasites from over 20 Leishmania species. The disease is transmitted through the bite of infected sandflies. Cutaneous leishmaniasis (CL) is the most common form of the disease which causes skin lesions, especially in hands, feet, and faces [3–5]. CL is one of the most important parasitic diseases in Asian and Middle Eastern countries [6–9]. CL is a significant public health concern in Iran, with a long history of reported cases and a high prevalence rate [10–14]. The disease poses a considerable burden on the healthcare system, economy, and overall quality of life for affected people [15, 16]. CL holds particular significance in Fars Province, located in southern Iran. This region has consistently reported a high number of cases, making it one of the most affected areas in the country [8, 17, 18]. The prevalence of the disease in Fars Province is attributed to several factors, including the suitable climate and environmental conditions that favor the breeding and survival of sandflies and the vector responsible for transmitting the parasite [17, 19]. In addition, the presence of rural and agricultural communities in Fars Province increases the risk of exposure to infected sandflies.

Rodents serve as important reservoirs for CL in Iran [20–23]. Several species of rodents, including gerbils and
and rodents, have been identified as reservoirs of the *Leishmania* parasite. These rodents act as hosts for the parasite, allowing it to multiply and spread within their populations. The proximity of rodents to human settlements increases the risk of transmission, as infected sandflies can easily bite both humans and rodents [24, 25].

The existence of suitable environmental conditions for the life of rodents, especially gerbils, is the main reason for the endemicity of CL in southern Iran [8, 26–29]. Shiraz, located in the southern region of Iran, is a heavily populated city and serves as the capital of Fars Province. Until recent years, this city was considered one of the important foci of anthropoontic cutaneous leishmaniasis (ACL), but the epidemiological picture of the disease has changed in this city in recent years, in such a way that zoonotic cutaneous leishmaniasis (ZCL) has become the dominant form of the disease in this urban area [17, 18, 30–32].

Understanding the prevalence of CL in any endemic area is crucial. Equally important is having information related to the disease’s reservoirs, agents, and vectors, as well as understanding the genetic diversity of the parasite. These elements are vital for implementing effective prevention and control measures.

The present study was designed and carried out to investigate the *L. major* infection of rodents, based on the molecular datasets of *Leishmania* kDNA and ITS2 genes, in an urban area (Shiraz city), in southern Iran.

### 2. Materials and Methods

#### 2.1. Area of the Study and Sampling of Rodents.

The study was carried out in Shiraz City, situated in Fars Province (Figure 1). Fars Province, located in the southern part of Iran, is one of the country’s provinces. Shiraz, the provincial capital, is divided into 10 districts and is positioned between 29° and 30° North and 51.5°–52.5° East (Figure 1). The city is considered as the most populous city in this province and the fifth most populous city in the country [33].

All rodents were captured in 10 stations, in a newly emerged focus of cutaneous leishmaniasis in the northeast of Shiraz, District 6 (Figure 1). To capture rodents for the study, Sherman live traps were used and placed in gardens and houses within the city during the evening (Figure 1). To minimize the pain and distress of the rodents, they were euthanized with CO₂ [34]. External measurements, sex, and other characteristics were recorded before dissection, and samples were taken from the spleen, liver, and skin. If there was a lesion in the skin, an impression smear sample was prepared from the skin lesion. All samples were kept at −20°C for subsequent DNA extraction.

#### 2.2. Smear Preparation and DNA Extraction.

For direct visualization of *Leishmania* amastigotes, multiple slides were prepared from the liver, spleen, sole, and any visible skin lesions of the captured rodents using the stamp-smear method. The smears were air-dried, fixed by methanol, and then stained with 10% Giemsa stain for 20 minutes and examined under a light microscope.

The Favorgen Biotech Corp. Kit (Taiwan) was used to extract total genomic DNA from tissue samples of rodents, including liver, spleen, and skin and patent lesions, according to the manufacturer’s guidelines.

#### 2.3. Polymerase Chain Reaction (PCR).

The LINR4 (5′-GGG GTT GTG GAT AAA TAG GG-3′) and LIN17 (5′-TTT GAA CGG GAT TTC TG-3′) primers [35] were used for the amplification of *Leishmania*-specific kDNA gene. By using these primers, 650-bp [35], 720-bp [35], and 760-bp [17, 28, 36–38] fragments of the kDNA of *L. major*, *L. infantum*, and *L. tropica* are, respectively, detectable. The PCR machine was programmed as follows: pre-denaturation (at 95°C for 5 min), denaturation (35 cycles, at 94°C for 30 s), annealing (at 52°C for 30 s), extension (at 72°C for 45 s), and a final extension (at 72°C for 8 min). A final volume of 25 µL reaction, including 3.5 µL of extracted DNA, 0.5 µL (10 pm) of each primer, 12.5 µL master mix (Ampliqon, Odense, Denmark), and 8 µL of DW was used for PCR amplification [28].

For amplification of the *Leishmania* ITS2 gene, the primers of 5′-AAACTCTC TCTGGTGCTTGC-3′ (forward) and 5′-AAACAAAGGT TGTCCGGGGG-3′ (reverse) [39] were utilized. The length of the fragment amplified by these primers is 420 base pairs for *L. major*. The final volume (25 µL) of PCR reactions included the following: extracted DNA (1 µL, 100 ng/µL), each primer (0.6 µL, 10 pm), Taq DNA Polymerase Master Mix RED (12.5 µL of 1x), and DW (10.3 µL). The PCR machine was programmed as follows: initial denaturation (at 94.5°C for 5 min), denaturation (35 cycles at 94°C for 30 s), annealing (at 55°C for 30 s), extension (at 72°C for 30 s), followed by a final extension (at 72°C for 8 min) [28].

DNA electrophoresis was carried out on a 2% agarose gel for 45 min at 80 V by adding 3.5 µL of the PCR products, a 100 bp molecular marker (SMOBIO, Hsinchu, Taiwan), and positive controls (reference strains of *L. infantum*, *L. tropica*, and *L. major*). The PCR products were sequenced for the ITS2 fragment, using the same pair of primers, used in the PCR assay.

#### 2.4. Phylogenetic Analyses.

The raw nucleotide sequences (forward and reverse directions) and chromatograms were checked and analyzed, and the consensus sequences were aligned, using Clustal W. The final sequences were registered in GenBank with accession numbers of ON398771, ON3987781-87, ON3987789, and ON3987892. The phylogenetic analysis involved 26 partial ITS2 gene sequences of *Leishmania* comprising 19 sequences of *L. major*. A total of 16 sequences were selected from the GenBank database (Table 1). The ITS2 sequence of *Crithidia mellifcae* was considered as outgroup. Phylogenetic relationships between *Leishmania* species were reconstructed using a Bayesian inference (BI) tree in BEAST, version 2.6.7 (https://www.beast2.org/). The reliability of nodes was assessed using Bayesian posterior probability for the Bayesian. The neighbor-joining tree with 100000 bootstrap generations was conducted using the Kimura 2-parameter (K2P) model [46] in MEGA X software [47].
3. Results

3.1. Rodent Fauna and Leishmania Infection. A total of 41 rodents, belonging to three species were caught from 10 trapping stations. The trapping stations were in District 6 of Shiraz (Figure 1) which is not far from a densely populated area in the city. The caught rodent species were Rattus rattus ($n = 25$, 60.97%), Mus musculus ($n = 15$, 36.58%), and Meriones persicus ($n = 1$, 2.5%). Amastigotes of Leishmania were seen in the spleen smear tissue of 6 (2.43%) of the (Figure 2) rodents, including 4 of R. rattus and 2 of M. musculus (Figure 3, Table 2). Skin lesions on the muzzle of two of R. rattus and one M. musculus were seen. Samples that were taken from these lesions were PCR-positive for Leishmania (Figure 4).
Multiple lesions were seen simultaneously on the sole, lip, femur, and other parts of the body of one of the *R. rattus* rodents, while only the sample prepared from the sole was positive for *Leishmania* infection.

*Leishmania*’s DNA was detected in 18 (43.9%) rodents, including 11 of *R. rattus*, 6 of *M. musculus*, and one of *M. persicus*, based on the PCR of kDNA (Figure 4) and sequencing of ITS2 gene (Figure 5). The *Leishmania* infection rate in *R. rattus* and *M. musculus* were 44% and 40%, respectively. Most (81.8%) of the *R. rattus* which were positive for *Leishmania* infection were male while most of the positive *M. musculus* (80%) cases were female (Table 2).

3.2. Phylogenetic Analysis. Phylogenetic analysis revealed the parasite infecting the rodents *R. rattus*, *M. persicus*, and *M. musculus* belongs to *L. major* (Figure 5). The *L. major* group was divided into two main clades with a bootstrap of
Figure 3: *Leishmania* amastigotes (arrows) are seen in the spleen smear of *M. musculus* (a, b) and *R. rattus* (c, d).

Table 2: Molecular and microscopic characterization of *L. major* infection in captured rodents. The parameters considered include species, sex, PCR (kDNA) test results, presence of lesions, and observation of *L. major* amastigotes in the rodent tissues.

**4. Discussion**

Leishmaniasis is one of the important parasitic diseases in different countries of the world, especially in tropical and subtropical regions. Iran is one of the important foci of leishmaniasis in the world, and every year a significant number of patients with cutaneous and visceral leishmaniasis are reported from this country [8, 17]. In the Fars Province in southern Iran, both CL and visceral leishmaniasis (VL) are present [49–55]. Vectors and animal reservoirs of CL are two main affective factors in the spread and emergence of the disease. Previous studies demonstrated ACL type of CL in the city of Shiraz, the capital of...
Fars Province, especially in the center of the city, while the ZCL is mostly reported from the rural areas in the province or from the outskirts of the city [13, 17, 30, 32]. Changes in the profile of CL have been previously reported in a study conducted by Davami et al. in one of the cities of the province, where ZCL has become the dominant form of the disease in the city [56, 57].

In this study, *Leishmania* infection was confirmed in rodents captured in urban gardens and residential areas, indicating a concerning shift in the epidemiology of leishmaniasis. This suggests that the disease, traditionally associated with rural areas, has now permeated into city centers.

The urbanization of ZCL is an escalating issue in numerous countries, including Iran [17, 27, 58, 59]. As urban areas continue to expand and encroach upon natural habitats, the risk of transmission and spread of the disease increases. This urban growth induces environmental changes that promote the proliferation of both sand fly vectors and reservoir rodents, thereby increasing the potential for disease spread.

One of the main factors contributing to the urbanization of CL is the construction of new settlements and infrastructure. These developments often disrupt natural ecosystems, leading to the displacement of wildlife and the introduction of new habitats for sandflies and their rodent hosts. In addition, the influx of people into urban areas can create overcrowded living conditions, poor sanitation practices, and limited access to healthcare, all of which contribute to the spread of the disease.

Another aspect of urbanization that plays a role in the transmission of CL is the increased movement of people and goods. Urban areas are often hubs for transportation and trade, facilitating the movement of infected individuals and potentially infected animals. This can lead to the introduction of new *Leishmania* strains into urban populations, further complicating control efforts.

The consequences of urbanization on CL are not limited to its transmission dynamics but also impact the burden of the disease on affected communities. Urban areas tend to have better healthcare infrastructure compared to rural areas, which may result in higher rates of diagnosis and reporting. However, the concentration of susceptible individuals in urban settings can also lead to larger outbreaks and more severe disease outcomes if control measures are not effectively implemented.

In Iran, *Rhomobomys opimus* and *Meriones libycus* (Rodentia: Gerbillidae) serve as the main reservoir hosts for ZCL [20–22, 26, 27, 60–62, 65, 66]. In a recent study, we also reported the infection of Calomyscid rodents with *L. major* in the mountainous area of the same area of the current study [28]. In recent years *Leishmania* infection in *Mus musculus*, commonly known as the house mouse, has been reported from different areas of the world including Iran [23, 64, 67, 68]. One study by Parhizkari and colleagues investigated the role of rodents caught in southern Iran as the reservoir hosts for *L. major*. The researchers collected *Mus musculus* from different habitats and examined them for the presence of *Leishmania* parasites. They found that a high proportion of mice (42.9%) were infected with *L. major*, indicating their importance as a possible reservoir host [23]. Moreover, vertical transmission of *L. infantum* in *Mus musculus* has been recently documented [69].

In the present study, *R. rattus* was the most abundant rodent species infected with *L. major*. Although rodents in the subfamily Gerbillinae are the most likely reservoir hosts in the rural area of Fars Province, it seems that rodents of the genera *rattus* and *Mus* are important hosts or probably reservoirs of *L. major* in the transmission of CL in the urban area, in Fars Province.

The newly identified focus of ZCL, as described in this study, is situated in a relatively mountainous and foothill region on the periphery of a densely populated area in the city of Shiraz. This area provides an ideal habitat for the Persian jird (*M. persicus*), which is recognized as a probable reservoir of ZCL in Iran [70]. Therefore, it is not unexpected that *L. major* infection was also detected in this species during our study.

In our research, we not only detected *Leishmania* molecularly but also observed *Leishmania* amastigotes in tissue slides prepared from the spleens of infected *R. rattus* and *M. musculus*. This could serve as evidence for the potential transmission of *L. major* from these rodents to the parasite vector *Ph. papatasi* and subsequently to humans. A comprehensive investigation is required to ascertain the role of these rodents in transmitting *Leishmania* to sandflies. This could help clarify the uncertainties surrounding the role of these synanthropic rodents in the epidemiology of ZCL in this region of Iran.

5. Conclusion

The findings of the current study reveal that rodents captured in urban areas of Fars Province, southern Iran, are infected with *L. major*. Notably, the infection of *Mus musculus* with this parasite has been confirmed in this study. The presence of *Leishmania* infection in these rodents in urban areas signals the potential urbanization of ZCL, caused by *L. major*. This urbanization presents unique challenges for control and prevention efforts. The increased proximity of humans, rodents, and sandflies in urban areas amplifies the risk of transmission. To effectively combat this disease, a multidisciplinary approach is required, focusing on surveillance, vector control, public awareness, and
collaboration between different sectors. Only through these concerted efforts can the urbanization of CL be effectively addressed and its impact minimized.
