Background. Thyroglossal duct cysts (TDC) represent approximately 70% of all congenital neck masses, and up to 1% of them contain thyroid tissue malignancies. Clinical presentation of TDC carcinomas is usually indistinguishable from benign tumors preoperatively, and differential diagnosis can be challenging. We present a rare case of TDC carcinoma concurrent with thyroid cancer in an adolescent. Case Presentation. A 16-year-old Caucasian female, otherwise healthy, was referred with a painless, gradually expanding lump on the neck. Physical examination revealed a well-circumscribed, moderately hard, tender mass of the anterior neck midline anteroinferior to the hyoid bone. Imaging findings suggested TDC as the most likely diagnosis. The patient had a Sistrunk procedure under general anesthesia. Histopathological findings diagnosed a BRAFV600E-positive papillary thyroid carcinoma (PTC) in a TDC. A thyroid gland and neck ultrasound revealed a highly suspicious finding for malignancy right level VI lymph node, which was not confirmed by fine needle aspiration cytology (FNAC). Under general anesthesia, total thyroidectomy and central compartment lymph node neck dissection were performed. Histopathological findings revealed a thyroid parenchymal locus of PTC, as well as three lymph nodes infiltrated by PTC. The patient received adjuvant radioactive iodine ablation (RAI) therapy and is closely followed. Conclusion. TDC carcinomas in conjunction with thyroid carcinomas in young patients are rare. Preoperative diagnosis can be challenging, as the vast majority of neck masses in young patients are benign in nature, and most malignant tumors lack specific clinical features. The diagnostic accuracy of FNAC is considered unsatisfactory due to its frequently cystic nature. Definitive diagnosis is based on histopathological findings. Clinicians should maintain a high level of suspicion for coexisting thyroid malignancies. Although surgical extirpation of the malignancy is considered standard of care, the treatment of TDC cancer should always be individualized by a multidisciplinary team.

1. Introduction

Thyroglossal duct cysts (TDC) represent 70% of all congenital neck masses, with a prevalence of 7% in the general population [1]. They arise from remnants of the thyroglossal duct that failed to regress during gestation. They grow along the embryologic descending route of the thyroid gland, starting at the foramen cecum and ending at the level of the cricoid cartilage and upper trachea [2]. Sixty percent of these masses are present at the level of the hyoid bone, while 24% are suprathyroid and 13% are infrahyoid [3, 4]. Most of these cysts have an average size of 2 to 4 cm [5]. Ectopic thyroid tissue may be present in up to 50% of these, which can be explained embryologically [3, 6]. The vast majority of TDCs are benign; however, up to 1% may contain malignant neoplasms [7]. Most of these cancers are variants of papillary thyroid carcinoma (PTC), with a median age of initial diagnosis at 40 years [8–10]. In 20 to 60% of cases, they coexist...
with a thyroid gland PTC [11, 12]. Therefore, a diagnostic
dilemma exists as to whether a TDC carcinoma is a primary
tumor or metastatic from the thyroid gland.

Identifying a TDC carcinoma is generally in-
distinguishable from benign tumors preoperatively [8, 13].
Currently, there is no established consensus on TDC ma-
lignancy treatment, especially in adolescents [14]. The
universal recommendation for these patients is the Sistrunk
procedure, performed alone in low-risk patients, and only
high-risk patients receive additional treatments [3, 15].
Further surgical management and adjuvant therapy after
primary surgery are contemporary debates among clinicians
due to the lack of data from the literature. [14]. We present
a case of PTC of a DTC coexisting with PTC of the thyroid
gland in an adolescent.

2. Case Report

A 16-year-old Caucasian female, otherwise healthy, was
referred to our institution with a painless, gradually
expanding lump on her neck. ENT examination revealed
a mass located in the neck midline, anteroinferior to the
hyoid bone. The mass was well-circumscribed, moderately
hard, fixed, and tender at palpation and followed swallowing
movements. No other significant findings were found on the
rest head and neck examination, including flexible fiberoptic
upper airway endoscopy. Thyroid function tests were also
normal. Contrast-enhanced computed tomography (CT)
revealed a sizeable (4.38 × 4.26 cm) well-circumscribed mass
anteroinferior to the hyoid bone, showing a moderate
heterogeneous contrast enhancement (Figure 1). The im-
aging findings suggested that the most likely diagnosis was
TDC. Differential diagnoses included other congenital be-
nign masses of mixed composition or a neck tumor of
mesenchymal origin.

The patient had a Sistrunk procedure under general
anesthesia. Intraoperatively, the mass was found adherent to
the hyoid bone, and the middle portion of the latter was
excised along with the entire thyroglossal duct tract. The
patient had an uneventful postoperative course. Permanent
histopathology revealed a BRAFV600E-positive classic PTC in
a TDC (Figure 2(a)), exhibiting tall cell features in ap-
proximately 20% of the tumor cells (Figure 2(b)). According
to the latest WHO classification, the diagnosis of the tall cell
subtype of PTC requires at least 30% of tumor cells to display
tall cell features [16]. A thyroid gland and neck ultrasound
revealed highly suspicious findings for malignancy right
level VI lymph node of 8 mm in size with increased echo-
genicity. Fine needle aspiration cytology (FNAC) of the
lymph node revealed no malignant elements, and FNAC
thyroglobulin lavage (FNAC-Tg) was negative. Under
general anesthesia, total thyroidectomy and central com-
partment lymph node neck dissection were performed with
no postoperative complications. Histopathological findings
revealed a 6 mm parenchymal locus of PTC in the left
thyroid lobe. Furthermore, three lymph nodes were infil-
trated by PTC, none larger than 6 mm and without extran-
odal extension (Figure 3). The patient received 120 mCi of
radioactive iodine (131I) (RAI) ablation therapy as adjuvant
treatment and is now closely followed. One year post-
operatively, there is no clinical or radiological evidence of
disease recurrence.

3. Discussion

Brentano first described the rare entity of TDC carcinoma in
1911 [17]. Since then, approximately 300 cases have been
reported worldwide [18]. Especially in the pediatric pop-
ulation, this clinical entity is very rare, with approximately
30 previously reported cases [19]. Up to 80% of TDC car-
cinomas are of PTC type [20]. The differential diagnosis
includes a PTC that arises from the rostral end of the py-
ramidal lobe [21]. Most cases of TDC carcinoma are di-
gnosed in the fourth decade of life, and females are affected
slightly more often than males in a 3:2 ratio [9, 10].

Some authors have proposed several high-risk charac-
teristics of TDC carcinoma, such as age over 45 years,
maximum tumor diameter greater than 1.5 cm, previous
radiation exposure, nodal disease, cyst wall invasion, positive
histopathological margins, and a tumor in the thyroid gland
on radiological evaluation [22]. The BRAFV600E mutation
has also been associated with aggressive clinical and path-
ological features [23]. Regarding metastatic disease, regional
lymph node metastases of TDC carcinoma occur at a low
rate, observed in only 7.7% of reported cases [3]. Local
invasion also rarely occurs, and the risk of metastasis is less
than 2% [21]. Recent reports show a favorable prognosis,
with survival rates reported of 99.4–100% and 95.6% at 5 and
10 years, respectively [4, 22].

There is a strong debate about the origin of TDC car-
cinomas. The etiology is explained by either de novo theory
or metastatic theory [13]. Currently, most authors support
the de novo theory, which is based on the carcinogenesis of
ectopic thyroid tissue within the cyst and the absence of
metastatic disease [3, 24, 25]. Metastatic theory suggests the
existence of metastatic disease due to an occult primary
thyroid lesion [14]. Furthermore, the diagnosis of primary
carcinoma of the thyroglossal duct is one of exclusion using
the Widström criteria [26].

The clinical presentation and characteristics of a TDC
carcinoma are generally indistinguishable from benign
TDCs [8, 13], making the preoperative diagnosis challenging
[8, 27]. A detailed clinical history is essential for an accurate
diagnosis before surgery [27]. The findings indicative of
malignancy increased the growth rate and the presence of
a palpable firm mass [28]. While the initial imaging modality
of choice is ultrasound [29], CT and MRI play a critical role
in preoperative diagnosis, staging of malignancy, and
therapeutic approach [28]. Imaging findings can reveal a
solid mass with invasive features indicative of malignancy,
but a definitive diagnosis cannot be made [27, 28]. There is
debate over the utility of FNAC or core needle biopsy
preoperatively [4]. FNAC is a safe, well-tolerated, and cost-
effective procedure for diagnosing thyroglossal duct lesions
[30]. However, the sensitivity of FNAC is relatively low due
to the cystic nature of the lesion [31]. A definitive diagnosis
with FNAC is achieved in about 53–60% of cases [32, 33].
Therefore, FNAC is recommended when characteristics
suspicious for malignancy are present, such as calcifications on ultrasound [11]. In a recent study, Rayess et al. reported that 73.3% of TDC carcinomas were diagnosed as incidental findings in the final histopathology analysis and another 20.6% preoperatively based on the FNAC analysis [4].

Regarding therapeutic strategies, there is no consensus on specific surgical management for a malignant disease that arises from a TDC [14]. The universal recommendation is the Sistrunk procedure, which involves complete excision of the thyroglossal duct tract, as well as the central portion of the hyoid bone [15]. The Sistrunk procedure is performed alone in patients with low-risk tumors and normal thyroid gland ultrasounds, whereas only high-risk patients undergo additional treatments [3]. Furthermore, surgical management and adjuvant therapy, such as RAI, are controversial among clinicians [14]. In the event of a preoperatively diagnosed TDC carcinoma, some authors recommend routinely performing a total thyroidectomy as well, even in cases with normal thyroid gland diagnostic workup [7, 34]. However, total thyroidectomy is not universally accepted as the standard of care for TDC carcinoma, as thyroid gland involvement is present only in 33–45% of cases [18]. In summary, total thyroidectomy and neck dissection should be considered in high-risk patients with concurrent thyroid malignancy or nodal disease [35]. Routine elective neck dissection is not indicated for these patients in the absence of clinically palpable nodes or suspicious findings on ultrasound or CT, due to the low risk of metastatic spread to lymph nodes [14]; it should be reserved for clinically positive nodal disease [14, 18]. Furthermore, there is also no clear

**Figure 3:** The presence of metastatic papillary carcinoma with tall cell features was observed in a lymph node at level VI (H&E stain, 100x magnification).
recommendation on the indications and timing of RAI treatment [14]. However, it is recommended to consider RAI treatment in patients with large tumors and nodal disease or in patients with malignancy in both the thyroid gland and the TDC [14].

4. Conclusion

Reports in the literature of TDC carcinoma coexisting with thyroid gland PTC in young patients are rare. Preoperative diagnosis is challenging due to the fact that the vast majority of congenital neck masses in adolescents are benign in origin, and most cancers lack specific clinical characteristics. The use of FNAC is controversial due to the cystic nature of the lesion. In most cases, the final histopathological findings determine the presence of carcinoma in a TDC. Clinicians should maintain a high level of suspicion for coexisting thyroid malignancies when treating these patients. Complete disease extirpation via a Sistrunk procedure is vital for a favorable outcome. TDC cancer should be further managed according to individualized risk stratification by a multidisciplinary team.
