The heart and the kidneys share responsibility for maintaining hemodynamic stability and end-organ perfusion. Connections between these organs ensure that subtle physiologic changes in one system are tempered by compensation in the other through a variety of pathways and mediators. In the setting of underlying heart disease or chronic kidney disease, the capacity of each organ to respond to perturbation caused by the other may become compromised. This has recently led to the characterization of the cardiorenal syndrome (CRS). This review will primarily focus on CRS type 1 where acute decompensated heart failure (ADHF) results in activation of hemodynamic and neurohormonal factors leading to an acute drop in the glomerular filtration rate and the development of acute kidney injury. We will examine the scope and impact of this problem, the pathophysiology associated with this relationship, including underperfusion and venous congestion, diagnostic tools for earlier detection, and therapeutic interventions to prevent and treat this complication.

1. Introduction

The heart and the kidneys share responsibility for maintaining hemodynamic stability and end-organ perfusion through a tight-knit relationship that controls cardiac output, volume status, and vascular tone. Connections between these organs ensure that subtle physiologic changes in one system are tempered by compensation in the other. As such, hemodynamic control remains stable through a wide range of physiologic conditions.

Communication between the heart and kidneys occurs through a variety of pathways. These include perfusion pressure, filling pressure, and neurohormonal activity. In particular, some of the key mediators include the sympathetic nervous system, the renin-angiotensin-aldosterone axis, and atrial natriuretic peptide. These agents have receptors in the heart, the kidneys, and the vasculature that affect volume status, vascular tone, cardiac output, and inotropy. A change in the performance of one of these organs elicits a cascade of mediators that affects the other.

In the setting of underlying heart disease or chronic kidney disease, the capacity of each organ to respond to perturbation caused by the other may become compromised.

Acute or chronic heart failure may push the kidneys beyond their ability to maintain glomerular filtration, regulate fluid and electrolytes, and clear metabolic waste. Similarly, acute kidney injury or chronic kidney disease affects cardiac performance through electrolyte dysequilibration, volume overload, and negative inotropy. Clinical, cardiac, and renal parameters associated with dysfunction in the other organ are identified in Table 1.

This special relationship and the interdependence of the kidneys and the heart is well recognized. The manner in which dysfunction of one organ affects the other has recently led to the characterization of the cardiorenal syndrome (CRS). At a consensus conference of the Acute Dialysis Quality Initiative (ADQI), the cardiorenal syndrome was subclassified into 5 types [2] based upon the organ that initiated the insult as well as the acuity or chronicity of the precipitating event. The classification system for the CRS is outlined in Table 2.

This review will primarily focus on CRS type 1, where acute cardiac decompensation results in activation of hemodynamic and neurohormonal factors that lead to an acute drop in GFR and the development of AKI. We will examine the scope and impact of this problem, the pathophysiology

TABLE 1: Risk factors for the cardiorenal syndrome [1].

Clinical
(i) Older age
(ii) Comorbid conditions (diabetes mellitus, uncontrolled hypertension, and anemia)
(iii) Drugs
(a) Antiinflammatory agents
(b) Diuretics (thiazides, loop diuretics)
(c) Angiotensin converting enzyme inhibitors/angiotensin receptor blockers
(d) Aldosterone receptor antagonists
Heart
(i) History of heart failure or impaired left ventricular ejection fraction
(ii) Prior myocardial infection
(iii) New York Heart Association functional class
(iv) Elevated cardiac troponin
Kidney
(i) Chronic kidney disease (reduced eGFR, elevated BUN, creatinine, or cystatin)

TABLE 2: ADQI classification system of the cardiorenal syndrome [2].

	Inciting event	Secondary disturbance
CRS type 1	Acute decompensated heart failure	Acute kidney injury
CRS type 2	Chronic heart failure	Chronic kidney disease
CRS type 3	Acute kidney injury	Acute heart failure
CRS type 4	Chronic kidney disease	Chronic heart failure
CRS type 5	Codevelopment of heart failure and chronic kidney disease	

associated with this relationship, diagnostic clues for earlier detection, and therapeutic interventions to prevent and treat this complication.

2. Epidemiology

Heart failure is a common chronic condition affecting 2% of the adult population [3] and resulting in over 1 million annual admissions [4], making it the leading cause of hospitalization in the United States among adults over the age of 65. Health expenditures for heart failure in 2008 exceeded \$35 billion dollars [5]. Acute kidney injury may complicate one-third of these admissions, resulting in a three fold increase in length of stay, a greater likelihood for hospital readmission, and a 22% higher mortality rate [6–9]. This reduction in outcomes occurs with increases in serum creatinine of as little as 0.33 mg/dl, regardless of its presence at admission or its development during the course of heart failure treatment [10, 11]

In addition, approximately 25% of patients with chronic heart failure have been found to have reduced GFR [12], independent of their level of left ventricular function [13]. A prospective cohort of 754 patients with chronic heart failure found only 17% of patients had an eGFR > 90 ml/min [14]. In the large Acute Decompensated Heart Failure National Registry (ADHERE), reduced GFR affected 30% of the 107,362 individuals [15]. Furthermore, 21% of patients had serum creatinine concentrations > 2 mg/dl, and 9% had serum creatinine concentrations > 3 mg/dl [16].

This reduction in kidney function has significant impact on both morbidity and mortality [17, 18]. In a meta-analysis of 80,098 hospitalized and nonhospitalized patients, an eGFR < 53 ml/min was associated with a 51% 1-year mortality compared to a 38% 1-year mortality for an eGFR < 90 ml/min. Preserved kidney function with an eGFR > 90 ml/min was associated with a 24% 1-year mortality [19].

3. Physiology of the Cardiorenal Axis

The heart, by way of regulating the systemic circulation, and the kidneys, through their effect on extracellular fluid volume, share responsibility for the hemodynamic balance in the body. The kidneys produce a glomerular filtrate that is dependent upon perfusion pressure and afferent and efferent arteriolar tone. The arteriolar resistance is under intrinsic myogenic control, and responsive to several neurohormonal systems. The renin-angiotensin-aldosterone system (RAAS), the sympathetic nervous system (SNS), and local vasodilators such as nitric oxide (NO), adenosine, and prostaglandins contribute to maintaining the glomerular filtration rate (GFR) through conditions of increased or decreased perfusion pressure. When renal perfusion pressure decreases, angiotensin II (AII) preferentially increases the efferent arteriolar resistance to preserve intraglomerular hydrostatic pressure and maintain GFR. Simultaneously, the afferent arteriole, under control of tubuloglomerular feedback and prostaglandins, dilates to increase the transmission of perfusion pressure into the glomerulus. An elegant system

senses decreased glomerular perfusion from hypovolemia or decreased cardiac output at the macula densa and the juxtaglomerular apparatus, then activates the RAAS, nitric oxide, adenosine, and prostaglandin production to prevent dramatic changes in kidney function.

We will now explore some of the mechanisms that effect kidney function during decompensated heart failure.

3.1. Underperfusion. Acute decompensated heart failure (ADHF) results in reduced effective arterial filling volume (EAFV) [20]. This decreased EAFV diminishes renal blood flow and subsequently renal perfusion pressure. Decreased tubular sodium and chloride delivery is sensed by the macula densa and the juxtaglomerular apparatus, activating the RAAS. RAAS enhances sodium and water retention to increase EAFV and stroke volume, but comes at the detrimental cost of volume overload. Furthermore, norepinephrine is released in response to systemic hypoperfusion sensed by baroreceptors. Whereas angiotensin causes efferent arteriole constriction, norepinephrine induces both afferent and efferent arteriole constriction and increases renal vascular resistance. In a setting of low cardiac output, both angiotensin and norepinephrine cause decreased renal blood flow (RBF), diverting blood to the coronary and cerebral circulations. When the normal compensatory mechanisms such as NO, bradykinin, adenosine, and prostaglandins are unable to maintain GFR in the setting of decreased RBF, the groundwork for renal ischemia is laid. It appears, therefore, that the cardiovascular effects on hemodynamics and the renal effects on extracellular fluid volume are in constant flux.

An imbalance in this relationship results in the CRS. In the setting of heart failure where low cardiac output and an overactive neurohormonal system push the compensatory limits, a simple insult such as NSAIDs or aggressive diuresis can precipitate acute kidney injury [21]. NSAIDs inhibit the protective effect of prostaglandins to dilate the afferent arteriole, while over diuresis might lead to further decreased EAFV. Diuretics are effective when properly dosed to allow reequilibration of fluid from the interstitial compartment into the intravascular compartment. If the rate of diuresis exceeds this shift, then kidney dysfunction occurs. Other observations have suggested that RBF is the most important determinant of GFR in patients with CHF [22].

3.2. Venous Congestion. While it is true that decreased forward flow as a result of decreased cardiac output in ADHF can cause acute deterioration in kidney function, there are several reasons why this mechanism fails to completely explain the development of the CRS. First, altered hemodynamics alone are inadequate to explain the mechanism of kidney injury in ADHF as redundant feedback mechanisms exist to prevent it. Second, the CRS has been observed in patients with diastolic dysfunction who have normal left ventricular systolic function [14]. In the ADHERE registry, acute kidney injury occurred at similar rates in patients with both systolic and diastolic dysfunction [23]. And finally, subgroup analysis of the ESCAPE trial showed evidence

that poor forward flow alone was insufficient to explain worsening kidney function. In this trial, an improved cardiac index was not associated with improved renal outcomes, but increased CVP and atrial pressures were associated with decreased kidney function [24].

Observations dating back to the 1930s have suggested that renal venous congestion could also contribute to decreased glomerular filtration. Experiments conducted on canine models revealed that increased venous pressure in the kidneys caused changes in urinary sodium, chloride, and urea excretion similar to decreased arterial pressure. Urine flow decreased when renal venous pressures were increased to 20 mmHg. This also led to a drop in glomerular perfusion pressure, and a reduction in GFR [25]. It is hypothesized that increased venous pressure distends the venules surrounding the distal nephron. This leads to compression of the tubule, increased tubular fluid pressure, and backleak of filtrate into the interstitium. An increased interstitial pressure then results in venous congestion and interstitial hypoxia [26]. Furthermore, as hydrostatic pressure within the Bowman's capsule increases, GFR fails and the RAAS is activated and the SNS is triggered [27]. The sequence of events is shown in Figure 1.

Studies in human subjects have also demonstrated that increased central venous and right atrial pressure are associated with worsening kidney function as well as increased mortality [29, 30]. Damman and colleagues have demonstrated that increased venous pressure is an independent determinant of glomerular filtration in patients with heart failure [28]. In this study the lowest glomerular filtration rate was observed in patients with lowest renal blood flow and highest right atrial pressures.

3.3. Intra-Abdominal Hypertension. Intraabdominal hypertension might be yet another mechanism contributing to the CRS. Elevated intraabdominal pressure from ascites and abdominal wall edema is also prevalent in patients with ADHF, and associated with worsening kidney function [31]. Several studies have suggested that the deterioration in the kidney function is not due to direct parenchymal pressure on the kidneys, but rather due to elevated central venous pressure, arterial underfilling, and renal venous congestion [32, 33]. The decline in kidney function from increased intraabdominal pressure is mechanistically related to the venous congestion described above.

4. Mediators of the Cardiorenal Syndrome

There are a variety of neurohormonal mediators associated with the deterioration of kidney function in ADHF. Understanding these mediators and effectors yields insight into the diagnosis and therapy of CRS.

4.1. Renin-Angiotensin-Aldosterone System. The CRS occurs with both hypoperfusion associated with decreased cardiac output as well as venous congestion. The actions of the RAAS, beyond its role to maintain hemodynamics, may explain this cardiorenal connection.

Erythropoietin is purported to decrease apoptosis in renal cells and cardiac myocytes by decreasing oxidative stress [53]. Small trials have revealed that heart failure patients who received erythropoietin had improved kidney function [54], but their place in the treatment of CRS cannot be confirmed without long-term studies.

Antidiuretic hormone (ADH) levels are elevated in HF due to nonosmotic stimuli from baroreceptor stimulation [55]. Antagonism of ADH would seem to have a role in the CRS, but studies of vasopressin receptor 2 antagonists did not result in improvement in kidney function [56].

There is direct evidence to demonstrate that HF is associated with tubulointerstitial damage. A recent study by Damman and colleagues showed that congestive heart failure is associated with increased markers of tubulointerstitial damage such as N-acetyl-beta-D-glucosaminidase (NAG), kidney injury molecule 1 (KIM-1), and neutrophil gelatinase associated lipocalin (NGAL) [57]. Other studies have also demonstrated renal tubular and interstitial damage as well [58].

In summary, it appears that regardless of whether decreased perfusion occurs as a result of hypoperfusion or venous congestion, the consequent processes resulting in kidney injury are the same. RAAS activation results in increased AII which stimulates NADH and NADPH-oxidases. The resulting NADPH/NADH suppresses superoxide dismutase, and increases reactive oxygen species. This results in the well known cascade of hypoxic ischemic injury, inflammation, apoptosis and cell death as shown in Figure 2.

5. Diagnosis

One of the cornerstones of CRS therapy is the early identification of worsening kidney function. This can be accomplished with the use of biomarkers that become detectable before the traditional tests for kidney function, including glomerular filtration rate or serum creatinine (Figure 3). Biomarkers such as NGAL, NAG, and KIM-1 have been implicated in tubulointerstitial damage and have been used to identify acute kidney injury [61–63]. Serum cystatin C is elevated earlier than creatinine. Furthermore, while cystatin C in the serum is a marker of reduced glomerular filtration, urinary cystatin C is a marker of tubular dysfunction [64]. Other biomarkers that have proven useful include BNP, IL-18, and Fatty Acid Binding Protein (FABP). Thus detection of these biomarkers might be used to diagnose CRS at an earlier time point, facilitate targeted therapy for CRS by modifying pharmacologic therapy, and monitor progression of disease. Nevertheless, a higher index of suspicion for identifying patients at CRS is needed as testing for biomarkers at this time is expensive.

Tests for volume status and end-organ perfusion are also useful in the diagnosis of CRS. Bioimpedance vector analysis is effective at assessing hydration status and BNP measurement provides an assessment of cardiac filling, although it is often elevated in patients with AKI without overt fluid overload. Urine sediment examination should be performed in differentiating CRS from other causes

of AKI by excluding pathologic cells, casts, or crystals. Hyponatremia, when present, may indicate excess ADH and portend an overall poor prognosis. Although patients with ADHF have a poor prognosis to begin with, ensuing AKI that accompanies the CRS confers an even more dire condition.

6. Therapies for the Cardiorenal Syndrome

In patients with ADHF who present with worsening kidney function, management is challenging and effective therapies are lacking [66]. This is in large part due to the exclusion of patients with kidney dysfunction in many of the trials analyzing treatment for heart failure. A rational approach would be multi-modal, focusing on the underlying pathophysiology of CRS with the goal of disrupting the cardiorenal connections. Ideally, therapy for CRS would prevent the fulminant decompensation that jeopardizes kidney function. This requires use of biomarkers in appropriate settings to detect early changes in kidney function, and represents an opportunity for initiation of immediate treatment.

6.1. Diuretics. Although diuretics have a major role in the symptomatic treatment of heart failure, their effectiveness is limited due to diuretic resistance in CRS. Although renal hypoperfusion may require a reduction in the dose of diuretics, venous congestion may necessitate additional diuresis. Thus, delicate fluid management may involve monitoring urine flow, central venous pressures, and possible cardiac output to optimize renal physiology. Nevertheless, CVP monitoring is cumbersome and costly. A forthcoming trial, “Determining Optimal Dose and Duration of Diuretic Treatment in People With Acute Heart Failure (DOSE-AHF) study,” is designed to answer these questions with regard to the role of diuretics in CRS [67].

6.2. Natriuretic Peptides. Several studies have explored the pharmacologic properties of natriuretic peptides in the treatment of heart failure. Nesiritide, a recombinant natriuretic peptide, decreases preload, after load, and pulmonary vascular resistance, while inducing diuresis. Because of its natriuretic and aquaretic properties, these agents seem to be an ideal candidate to relieve the venous congestion in CRS. Nevertheless, no studies have shown benefit on kidney function. In fact, a meta-analysis demonstrated poorer renal outcomes with nesiritide [68]. In one study, nesiritide when compared to placebo had no effect on glomerular filtration rate, renal plasma flow, urine output, and sodium excretion in patients with CRS [69]. To address these controversies, the “Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure Trial (ASCEND)” is underway [70].

6.3. Vasopressin Antagonists. By making use of their aquaretic properties, vasopressin (V2 receptor) antagonists have been used in severe heart failure. However, clinical trials such as the “Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study With Tolvaptan (EVEREST)” trial showed

FIGURE 2: Hypothetical vicious circle of decreased glomerular function, endothelial injury, and tubular damage in heart failure. GFR: glomerular filtration rate. NGAL: neutrophil gelatinase associated lipocalin. NAG: N-acetyl-beta-D-glucosaminidase. KIM-1: kidney injury molecule 1. no benefit of tolvaptan, a vasopressin antagonist, on all-cause mortality or the combined end point of cardiovascular mortality or hospitalization for ADHF [56]. Kidney function remained stable throughout this trial, and the use of vasopressin antagonists in the CRS conundrum may be limited to those patients complicated by hyponatremia. Although other studies showed there was some renal benefit [71], the cost of these medications would prohibit them from being used routinely.

6.4. Adenosine Antagonist. Adenosine is generated locally in the macula densa in response to diuretics that block sodium and chloride absorption, resulting in afferent arteriolar constriction and decreased GFR. Antagonizing adenosine might have a role in preserving kidney function in CRS. To this extent, KW-3902, an adenosine A1-receptor antagonist, was found to improve kidney function and decrease diuretic resistance in patients with ADHF and CRS [72].

6.5. Ultrafiltration. Ultrafiltration is usually reserved for diuretic resistance in patients with ADHF. However, in CRS it might have an early role by rapidly reducing venous pressure. In two trials of ultrafiltration in patients with ADHF, the “Relief for Acutely Fluid-Overloaded Patients With Decompensated Congestive Heart Failure (RAPID-CHF)” and “Ultrafiltration Versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive

Heart Failure (UNLOAD),” there was marked weight loss and relief of heart failure symptoms [73, 74], but no improvement of kidney function. Nevertheless, published case reports have shown improved kidney function with ultrafiltration [75]. A final verdict might come with the much awaited “Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF)” study which will assess the effectiveness of ultrafiltration in ADHF and CRS [76].

6.6. Inotropes. Although the use of inotropes in systolic heart failure may improve the EAFV and cardiac output, the inherent adverse effects of these agents, including arrhythmias and myocardial ischemia, have limited their utility. In fact, the “Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF)” trial revealed increased mortality and poorer outcomes in the milrinone arm [77].

Levosimendan, a phosphodiesterase inhibitor, has been studied in CRS. In one study, levosimendan resulted in improved GFR when compared to dobutamine [78]. However, another study of levosimendan and dobutamine did not show any benefit [79]. At this time, the role of inotropic agents in CRS remains unknown.

6.7. Neurohormonal Blockade. The role of RAAS blockade with ACE inhibitors, ARB, direct renin inhibitors, or aldosterone antagonists in CRS is also unclear. While most of these

FIGURE 3: Urinary biomarker profiles in subjects who develop AKI after cardiopulmonary bypass (CPB) surgery. Abbreviations: AKI: acute kidney injury, defined as a 50% increase in serum creatinine from baseline; NGAL: neutrophil gelatinase associated lipocalin; IL-18: interleukin 18; KIM-1: kidney injury molecule 1; L-FABP: liver-type fatty acid binding protein; Cys: cystatin c; creat: creatinine. medications cause an acute drop in GFR through the dilatory effect on the efferent arteriole, they have long-term reno- and cardioprotective effects. Therefore, patients who are prone to develop CRS yet able to tolerate a small reduction in GFR, up to 30% from the baseline, may benefit from these agents. As RAAS has been implicated in oxidative damage, its interruption through ACE inhibition or angiotensin blockade may prevent the development of CRS.

Similar to RAAS blockade, beta blockers through their effect on the SNS may have a role in the long-term prevention of adverse cardiac events and in remodeling. However in CRS, their role is limited by the altered hemodynamics. Unless the underlying etiology of ADHF is myocardial infarction, beta blockers are often held until the patients are hemodynamically stable.

7. Summary

Cardiorenal syndrome represents a disruption of the robust relationship between the kidneys and the heart to preserve hemodynamics and maintain organ function. Despite the ability to adjust filling pressures, afterload, inotropy, cardiac output, and volume status in order to compensate for a wide range of perturbations, dysfunction in either of these organs creates a susceptibility to dysfunction in the other. The mechanisms for worsening kidney function in ADHF are likely due to underperfusion from reduced cardiac output,

venous congestion impairing tubular function and glomerular filtration, and activation of neurohormonal mediators that effect renal blood flow and glomerular autoregulation. The RAAS, SNS, and NO pathways are instrumental in preserving kidney function in compensated HF, but play an aggravating role once HF acutely worsens.

Measures to reverse kidney dysfunction in ADHF require the early recognition and immediate treatment of CRS. Agents that target the physiologic mechanisms of CRS may be effective in restoring kidney function. These include diuretics, natriuretic peptides, or ultrafiltration to reduce venous congestion, inotropes to augment cardiac output, and RAAS and SNS blockade. Despite these interventions, CRS identifies patients at the limits of hemodynamic compensation and most susceptible to increased morbidity and mortality.
