The Maillard reaction is of great significance in food, herb medicines, and life processes. It is usually occurring during the process of food and herb medicines processing and storage. The formed Maillard reaction productions (MRPs) in food and herb medicines not only generate a large number of efficacy components but also generate a small amount of harmful substance that cannot be ignored. Some of the MRPs, especially the advanced glycation end products (AGEs) are concerning humans, based on the possibility to induce cancer and mutations in laboratory animals. Numerous studies have been reported on the formation, analysis, and control of potentially harmful MRPs (PHMRPs). Therefore, the investigation into the formation, analysis, and control of PHMRPs in food and herb medicines is very important for improving the quality and safety of food and herb medicines. This article provides a brief review of the formation, analysis (major content), and control of PHMRPs in food and herb medicines, which will provide a base and reference for safe processing and storage of food and herb medicines. Practical Applications. The formed Maillard reaction productions in food and herb medicines not only generate a large number of functional components but also generate a small amount of harmful substance that cannot be ignored. This contribution provides a brief review on the formation (including the correlative studies between MRs and the PHMRPs, mechanisms, and the main pathways); analysis (major content, pretreatment for analysis, qualitative and quantitative analysis, and structural identification analysis); and control (strategies and mechanisms) of PHMRPs in food and herb medicines, which will provide a solid theoretical foundation and a valuable reference for safe processing and storage for food and herb medicines.

1. Introduction

The Maillard reaction (MR) is also called the amino-carbonyl reaction, nonenzymatic browning, or protein glycation reaction. It is originally described by Louis Maillard [1, 2], concerning a serious of reactions between carbonyl and amino compounds. The MR is occurring in dried, heated, or stored herb medicines, food, and in vivo mammalian organisms. MR usually occurs during the process and storage of food and herb medicines because of the abundant carbonyl and amino compounds contained in them. MR in food and herb medicines processing and storage process not only produces a large number of active ingredients but also generates a small number of potential harm compounds which cannot be ignored. Many contributions reported the formation, analysis, and control of potentially harmful Maillard reaction productions (PHMRPs) in food and herb medicines [3, 4]. Harris et al. [5] reported that some MRPs such as ε-N-2-furoylmethyl-L-lysine (furosine, FML) could degrade to form different advanced glycation end products (AGEs). However, recent evidence shows that MRPs, especially AGEs, have a propensity to generate reactive oxygen species (ROS), and partial MRPs had been proven to be related to some kind of diseases such as Parkinson’s disease [6], chronic diabetes [7], Alzheimer’s disease [8], and also aging (normal aging) [7, 9]. AGEs in bodies of humans are mainly derived from two pathways, in vitro intake and in vivo transformation, and the intake from food and herb...
medicines is the main source of the formed AGEs [10]. During the process, two types of MRPs can generate, and they can be distinguished by the cross-linking structures and fluorescence properties, depending on the temperature, pH, and characters of the reactants (e.g., type of amino acid, sugar, or protein); one is cross-linking and fluorescent MRPs, such as crossline, FML, 2-(2-furoyl)-4(5)-(2-furyl)-1H-imidazole (FFI), methyl-glyoxal-lysine dimer (MOLD), glyoxal-lysine dimer (GOLD), fluorolink, pentosidine, and vespertisines A, B, and C (Figure 1(a)) and another is non-cross-linking and nonfluorescent AGEs, such as argpyrimidine, Ne-(carboxymethyl)lysine (CML), Ne-(carboxyethyl)lysine (CEL), 3-DG-imidazolones, MG-imidazolones, acrylamide (AA), and pyrroline (Figure 1(b)). The maxima excite wavelengths of 340–370 nm and emit wavelengths of 420–470 nm for the compounds concerning the fluorescent MRs; their intensities are related to the level of AGE [11]. The present article reviews the formation, analysis, and control of the MRPs, consisting of formation (pathways and mechanisms), analysis (major content, pretreatment for analysis, qualitative and quantitative analysis, and structural identification analysis) and with an emphasis on control (strategies and mechanisms) of the PHMRPs. The aim of this paper is to search for strategies for preventing or inhibiting the undesired MRPs formation during the storage and processing of food and herb medicines, which will provide a base and reference for the safety of utilization.

2. PHMRPs Formation and Mitigation

The MRs are usually concerning three stages: the initial, intermediate, and final stage [12]. So, the obtained MRPs conclude initial MRPs, advanced MRPs, and AGEs (Figure 2). The initial stage starts from a reaction between carbonyl group compounds (such as sugar) and free amino group compounds (e.g., sugars, peptides, or proteins), leading to form an unstable Schiff base, which then generates a stable Amadori product. It is reported that the Schiff base is highly prone to form reactive carbonyl compounds (e.g., oxoaldehydes, glyoxal, and methylglyoxal) [13]. On the other side, reduced sugars such as glucose can autooxidize to form hydrogen peroxide and keto aldehydes in the specific conditions [14] and subsequently to form AGEs. Consequently, the Amadori products react with the amino acids to form CML or regenerate amine and subsequently to form dicarbonyls such as 1-deoxyglucosone (1-DG), 3-DG, and glycolaldehyde. Finally, the final advanced stage of the reaction occurs. In this stage, the highly reactive DG reacts with lysine or lysine residues in proteins to form pralines. Meanwhile, cross-linking and fragmentation formed in the protein molecule, leading to protein denaturation and damage. During the process of the MRs, two types of AGEs are formed: one is cross-linking and fluorescence AGEs and the other one is non-cross-linking and nonfluorescence AGEs. In addition to pentosidine and pyrroline, other types of AGEs such as CML, CEL, FFI, GOLD and MOLD, and melanoids, as well as other compounds, which have not yet been identified, can be generated from the Amadori products. Table 1 concludes the notification, structure, and

source of Maillard reaction productions in food and herb medicines.

3. PHMRPs Analysis

The analysis of PHMRPs is very important for quality and safety evaluation for food and herb medicines. Up to date, various methods have been developed dealing with analysis for MRPs, including pretreatment for analysis, qualitative and quantitative analysis, and structural identification analysis. First, the pretreatment for analysis includes chromatography, extraction, and membrane dialysis methods. Second, the qualitative and quantitative analysis methods include thin-layer chromatography, ultraviolet-visible spectroscopy (UV spectroscopy), high-performance liquid chromatography (HPLC), gas chromatography (GC), mass spectrometry (MS), fluorescent spectrometry (FL), chemiluminescence (CL), and electrochemical detection (ECD). In addition, structural identification and analysis methods include infrared spectrum (IR), MS, and nuclear magnetic resonance (NMR). The analysis of MRPs in food and herb medicines on the current status and the achievements made are included, the existing challenges are addressed, and the future perspectives are provided.

3.1. The Pretreatment for PHMRPs Analysis

At present, the MRPs, especially the PHMRPs in food and herb medicines, cannot be analyzed and detected accurately; one of the most important reasons is that the complex products cannot be purified effectively to obtain the pure substances. So, the pretreatment of MRPs including extraction, separation, and purification is very important for detection. Because most of the MRPs are water-soluble ingredients, the extraction methods include water extraction or water solvent extraction [15].

The separation of MRPs includes chromatography [16], extraction, dialysis, and other methods. Chromatography is a separate and determination method used by isolated MRPs with the differences of physical and chemical properties, such as adsorption, molecular shape, size, molecular affinity, and partition coefficient. Soldo et al. [17] applied a LC method combining with the taste dilution analysis and succeeded in identifying the potential bitter suppressing candidate.

Extraction usually transfers MRPs from one solvent to another by using the different solubility in different solvents. Extraction generally includes liquid-liquid extraction, solid-phase microextraction, and accelerated solvent extraction. Zhang et al. [7] studied the different levels of MRPs in different extract conditions such as aqueous extract, ethanol extract, infusion, decoction, and sterilization. Combined with LH-20 separation, and absorption of UV measurement at 420 nm indicates that steam sterilization can lead to the formation of MRPs [18]. Shi et al. developed the method to extract acrylamide in heat-processed Chinese herb Radix Asparagi using water, and the result indicated that the extract efficiency was good [19]. Zhou and Zheng [20] employed the accelerated solvent extraction (ASE) method
to extract 5-hydroxyethylfuraldehyde (5-HMF) in coked
*Angelica sinensis*. Compared with traditional extraction
techniques such as reflux extraction and ultrasonic extrac-
tion, ASE is more convenient, more effective, and quicker.
The method can also be used for other MRPs analyses in
food and herb medicines, providing an efficient, fast, safe,
and energy-saving extracting method for components
analysis in food and herb medicines.

MRPs flow by a semipermeable membrane by a dialysis
method, and the unreacted raw materials and the small
molecules flow by the opposite side, which could remove
effectively other substances from MRPs. The MRPs can be
selected with different molecular weights by different dialysis
modalities so that the molecular structure and the com-
position can be analyzed accurately. Melanoidsins generated
in the reactions of glucose and maltose with glycine (MW
>12500 and 3500) was studied by microanalysis. Finally,
the relationship between the molecular weight of the Mela-
noidsins and the elemental composition of amino acids and
sugars was discussed [21]. Cämmerer et al. [22] used mo-
lecular weights of 12000–14000 Da cellulose dialysis mem-
branes to analyze the MRPs before and after the dialysis,
respectively.

3.2. The Analysis of PHMRPs

3.2.1. The Qualitative and Quantitative Analysis Methods.
Up to now, the qualitative and quantitative analysis methods
for PHMRPs include thin-layer chromatography, UV-Vis
spectroscopy, HPLC, GC, MS, FL, CL, and electrochemical
method. Table 2 lists the qualitative analysis of Maillard
reaction productions in Chinese herbal medicine materials
and food.

3.2.2. TLC. TLC is a qualitative analysis method which
compared their retention time (Rf). Jia et al. [36] reported 5-
HMF was separated from the cibot rhizome for the first time.
The silica gel 60 F254 TLC plate was coated by ascending
development in a solution of the cyclohexane-ethyl acetate-
acetone with a ratio of 3:3:1. The results showed that the
established methods had good reproducibility and the spots
were distinct.

3.2.3. UV Spectroscopy. The chromophoric groups, molec-
ular structure, and extinction property in MRPs could be
obtained using the UV-vis spectroscopy method. The UV
absorbance at 280 and 420 nm is due to the formation of
initial MRPs and the AGEs (e.g., melanoidins) for MRPs
individually. Obulesu and Bhattacharya [39] investigated the
color changes of the different stages for Tamarind pulp fruit
development and storage, and the relationship between the
UV absorption properties and pharmacodynamics activity
was also discussed. Yamabe et al. [40] reported the MRs
model experiment using glycine and ginsenoside Re mixture
to investigate the renoprotective role of MRPs from gin-
senosides, and the absorbance at 420 nm was measured for
studying the MRPs level. At the same time, the relationship
between the MRPs level and the possible application as a
renoprotective agent was recommended. Jia et al. [36]
identified the compound by TLC as the 5-HMF and then
detected by UV-vis. The results indicated that the maximum
absorption wavelength was 280 nm, indicating that the MRP s were the initial products. Yu et al. [41] first developed the capillary electrophoresis method to detect five Amadori compounds by UV at 236 nm without separation and derivatization based on the Amadori compound-Cu$^{2+}$ complexes. The results showed that this was a convenient and reliable method for rapid analysis of the Amadori compounds.

</table>
3.2.4. HPLC. HPLC is an effective method to separate and analyze components in a mixture. Gökmen [42] reported a rapid method for the simultaneous determination of HMF and patulin in apple juice. Viñas et al. [43] developed a reversed-phase gradient-elution HPLC method for the simultaneous determination of methyl anthranilate and 5-HMF in honey. The proposed method can be used for both the quality evaluation of honey based on the methyl anthranilate and the quality control based on the 5-HMF.

3.2.5. GC. GC is a good tool to analyze the vaporized compounds without decomposition. Venskutonis et al. [44] used the headspace and gas sensor techniques to detect volatiles (Maillard reaction productions) in the model system. The methods can be used for assessing the volatile compounds generated during the thermal browning process of the glucose-glycine model system. Lojzova et al. [45] analyzed substituted pyrazines and other volatile aromatic compounds formed during MRs in potato chips by an alternative GC-MS method (including gas chromatography-ion trap mass spectrometry, gas chromatography-time-of-flight mass spectrometry, and comprehensive two-dimensional gas chromatography-time-of-flight mass spectrometry), both having the good effect.

3.2.6. MS. MS is a common analytical technique based on their mass-to-charge ratio. Cagliero et al. [46] described a polymeric ionic liquid sorbent coating in direct immersion solid-phase microextraction method for the analysis (especially trace-level) of AA in coffee powder. Pollien et al. [47] investigated the formation of AA during the thermal treatment (120–170°C) of potato as well as in Maillard model systems (composing reducing sugars and asparagus). It was achieved by online monitoring of AA released into the headspace of the samples using proton transfer reaction mass spectrometry. It was found that the level of AA released into the headspace during thermal treatment of potato was positively correlated to temperature.

3.2.7. Chemiluminescence. Chemiluminescence is the emission of light produced in certain chemical reactions without light, heat, or electromagnetic excitation. Lakeev et al. [48] investigated the complex fluctuation dynamics of the MR, that is, a multistage reaction between a carbonyl-containing compound and the nucleophilic amino group of an amino-containing compound at different temperatures, as visualized by chemiluminescence.

3.2.8. Electrochemical Method. The electrochemical method can be employed as a useful tool for the analysis of Maillard intermediates and final products.Galvanic potentials serve as useful indicators for reductones, Amadori compounds, and pyranones analyzed readily by HPLC-EC techniques. Electrochemical methods provide valuable noninvasive probes to follow the stages of the Maillard reaction and for investigating its mechanism [49]. Rizzi et al. [50] investigated the electrochemical properties of β-alanine/ carbohydate MRPs using a combination platinum/Ag-AgCl (Cl−) redox electrode. Joo et al. [23] detected and quantified redox-active Maillard reaction intermediates and products by a variety of electrochemical techniques. Amperometry in the form of electrochemical detectors was used in conjunction with chromatographic separation to analyze Amadori compounds and pyranones.

3.2.9. Fluorescent Spectrum. Trevisan et al. [51] explored the fluorescent method to investigate the effect of cooking conditions on MRPs in beef. It was found that fluorescence intensity changed consistent with the results of FML levels. Hu et al. [52] reported a fluorescent sensing method based on AA polymerization and the unique photo-physical properties of quantum dots (QDs) detecting AA [53, 54]. The correlation was established between the concentrations of AA and changes of fluorescence intensities after UV irradiation can be used as the base of the detection of AA. The lower sensitivity of this method limits it to be used for detecting AA in various food samples.

3.3. Structure Identification Analysis of PHMRPs. At present, the methods of structure identification analysis for MRPs in food and herb medicines are mainly including infrared spectrum (IR spectrum), nuclear magnetic resonance (NMR), and MS.

3.3.1. IR Spectrum. Because the functional groups are generally associated with the IR spectrum frequencies, it can be used to determine the structures of the compounds or to determine the functional groups. IR spectroscopy is one of the main means to study the structures of organic molecules and has been applied to analyze the molecular structures of the MRPs. Gullón et al. [55] used the IR spectrum to analyze the functional groups and evaluate the introduction of glucose into the chitosan molecule. After reaction, it can be observed that the absorption bands of Chit showed changes from 1697 cm−1 to 1596 cm−1 (C-N double bond), which suggesting it was formed Schiff base between the reducing termination of Glc and the amino groups of Chit [56].

3.3.2. NMR. The most commonly studied nuclei are 1H and 13C NMR. 1H NMR was used to monitor ligand-exchange reactions on the compounds, and 13C NMR was used to investigate the structures of the compounds. Gullón et al. [55] used 1H NMR to analyze the functional groups and study the reaction between glucose and chitosan. Comparing the spectra of the original glucose and chitosan, one of the most important differences is the new signals appearing at 2.09 ppm, indicating the new formation of NH-CH₂ (Amadori product). Wu [57] studied the effect of gamma irradiation on the browning of depolymerized chitosan; the result showed that gamma irradiation was an effective technology to inhibit browning during the depolymerization of chitosan. Lima-Dellamora et al. [18] found that the sodium bisulfite added could cause the absorbance of
Echinodorus grandiflorus at 420 nm dropped comparison with the control.

3.3.3. MS. MS is an analytical tool that makes use of the mass-to-charge ratio (m/z) of particles to determine the molecular formula of a compound. In the lab, the tool is very powerful in making sure of the known and unknown compounds [58]. MS is a key tool to explore the reactions and the different reaction products in food and herb medical field. [58]. Pollien et al. [47] established a PTR-MS method to monitor AA formation online during Maillard reaction systems and processed food. The PTR-MS ion signal at m/z 72 was shown to be exclusively due to protonated AA obtained without fragmentation. Kislinger et al. [59] used matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) to qualitatively study the formation of early Maillard products of lysosome, produced upon incubation with seven different sugars (D-ribose, L-rhamnose, D-glucose, D-fructose, D-galactose, D-lactose, and D-maltose) in solution, in the presence of oxygen. The report first reported the use of MALDI-TOF MS peptide mapping as a quick and highly selective method for the detection of early-stage Maillard products produced upon incubation of lysosome with seven different reducing sugars. Linda et al. [60] prepared MRPs by the reaction of 5-hydroxymethylfurfural (5-HMF) separately with glucose and glycine. The spectra display two responses (one for each isotope) that are separated by a mass number that directly corresponds to the number of nitrogen atoms present in the MRP.

4. PHMRPs Control

The Maillard reaction paths taking place depend strongly on pH, temperature, and the properties of the reactants (e.g., types of sugar, amino acid, and protein) [61]. It is acknowledged that, in the case of proteins or peptides, the reactive amino groups are available for the MR or the Strecker reaction. In the case of proteins, the MR often leads to cross-link formation [62]. Deoxyosones are considered essential intermediates for the general MRs [63]. An alternative view on the MRs has been given by Yaylayan [64] who considers the initial stage as three primary fragmentation pools arising from sugars, amino acids, and Amadori/Heyns products. Lysine is the major amino acid that contributes to MRs as it has a free amino group that can readily react with reducing sugars [65]. Recent evidence suggests that AGEs have a propensity to generate reactive oxygen species (ROS) [66]. Furthermore, glucose and other aldehydes, free or protein-bound, can undergo autoxidation reactions and generate radicals and other reactive intermediates (e.g., H2O2 and other peroxides) that contribute to AGE formation. Ma et al. [67] reported that acylation of antioxidant of bamboo leaves with fatty acids by lipase and the acylated derivatives’ efficiency in the inhibition of acrylamide formation in fried potato crisps. Wu [57] investigated the effect of oxygen and pH on the browning of chitosan exposed to gamma radiation. It was found that oxygen and pH value could play important roles in inhibiting browning of irradiated chitosan. Przygodzka et al. [68] reported that furosine was decreased in cakes with cloves, allspice, spice mix, and vanilla, which will provide a base for the application.

5. Conclusions and Future Research Outlook

During the past few years, it has been of concern that partial MRPs in food and medicines are harmful to the human body because they have been proven to be closely related to a variety of diseases such as chronic diabetes, Parkinson’s disease, Alzheimer’s disease, and aging and also induce cancer and heritable mutations in laboratory animals. Many contributions reported the formation, analysis, and control of PHMRPs in food and herb medicines; with also some progress being achieved.

As for the outlook of future research, an acknowledged fact is that PHMRPs in the MRs need to be more adequately demonstrated. Overtly, the formation, analysis, and control of PHMRPs in food and Chinese herbal medicine started late, and the structures of the MRPs are complex and varied. First, the preliminary research on the formation of PHMRPs only stays in a single factor or a macrolevel. However, if not studying their formation from a molecular level, it cannot accurately reveal the PHMRPs formation regulation from the raw material, processing conditions, and chemical microenvironment. Second, the separation, purification, qualitative and quantitative analysis, and structure analysis are of great difficulty because of the complexity of the PHMRPs. Furthermore, the contents of some MRPs are very low and cannot be easy to separate, and various related factors bring many challenges to the analysis of PHMRPs in food and Chinese herbal medicines. In addition, the analysis of MRPs is far behind the analysis of sugar, amino acid, and protein in food and Chinese herbal medicines. There have been many theoretical and practical problems to be solved and most of the analysis is still in the laboratory stage of exploration and really can’t be used in actual application, far from being able to meet the urgent need for people’s understanding of its structure and function.

In conclusion, first, we study the PHMRPs formation from a molecular level. Second, we establish a high sensitivity and high accuracy analysis method that is an important issue in the analysis of PHMRPs in the future, with the development of various analytical techniques in the separation and analysis of PHMRPs in pharmacology and other fields. Third, the preliminary research on the formation of PHMRPs limited effective directional control of PHMRPs in food and medicines. MR is consecutive and parallel reaction steps, which is very complex. Therefore, fundamental studies, especially kinetic research during the progress of the MR, need to be further investigated. On the other hand, the optimized processing parameters are important factors to minimize AGEs formation. The ultimate challenge will be to achieve a substantial reduction of PHMRPs while keeping desirable product attributes such as flavor and color, which are generated by similar MR pathways.
Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors’ Contributions

Yali Li designed the manuscript and contributed to the writing of the manuscript. Yanzhu Zhu, Peihe zheng, Zhengyi Qu, Hao Zhang, Xiangmin Piao, and Yingping wang contributed to the proofreading of the manuscript. Wei Hou supported the paper to be published. All the authors read and proofed the final manuscript.

Acknowledgments

The authors sincerely thank the project of the Jilin Provincial Department of Science and Technology China (no. 20190201160JC), the Jilin Province Development and Reform Commission (20190C052-10), the National Science Foundation for Youths of China (no. 31401606), the Innovation Project of Medicinal Plant Germplasm Resources and Breeding Innovation Team, the Chinese Academy of Agricultural Sciences (no.
