The evaluation for autonomous capability of ground-attack unmanned aerial vehicle (UAV) comes from the demand of reality, which determines the operational use of airborne equipment authority. It essentially entails a multicriteria decision-making process accounting for evaluation model and uncertainties. Firstly, as for the construction of evaluation model, the index model is proposed from four aspects of observation capability, decision capability, action capability, and security capability, namely, ODAS, which analogizes cognitive behavior mechanism of human based on airborne equipment; then, to solve uncertainties of randomness and fuzziness in the process of autonomous capability evaluation, a cloud model approach is proposed, which expresses uncertainties by the certainty degree distribution. Finally, the cloud model-based approach is tested by evaluating typical UAVs and comparing with Hopfield neural network method. The results show that the evaluation of the autonomous capability based on the cloud model is accurate and more representative than the Hopfield neural network method.

1. Introduction

The ground-attack UAV is ranked as one of the main combat equipment in the future. The complex operational tasks and variable operational environment make it necessary for UAV to have a high degree of autonomous capability [1]. In the actual battle, the completion of tasks requires the effective man-machine division between ground station and UAV system, which depends on the classification of the autonomous capability level. Moreover, with the rapid development of artificial intelligence theory, it has changed the operating rules of the previous unmanned system and made the autonomous system more smart and efficient. For example, machine learning algorithms can analyze and predict sudden communication problems in uncertain and complex scenes. Applying machine learning algorithms to communication systems can make systems more intelligent and autonomous [2, 3]. Therefore, it is of great military significance to scientifically establish an evaluation system for the autonomous capability of ground-attack UAV and

formulate the criteria for grading autonomous systems with the national conditions, which can improve the combat effectiveness of equipment systematically.

At present, the research on evaluation model of autonomous capability is in its infancy both here and abroad. A general survey of evaluation models shows that typical ones include Sheridan's levels of automation (LOA) [4], autonomous control level (ACL) [5], autonomy levels for unmanned systems (ALFUS) [6], four-level model in man-machine division [7], and reference frame of autonomous system [8]. These models apply to particular conditions and have certain limitations. For instance, with the vague classified implication, ACL divides the UAV system into 10 grade standard and only reflects the relative autonomy degree between different UAVs. Although some progress has been made in the evaluation model abroad, there is still a big gap in the quantitative evaluation. It does not analyze autonomous capability for a particular equipment, nor does it elaborate on the source of indicators. Therefore, the ODAS model is proposed for ground-attack UAV by analoging

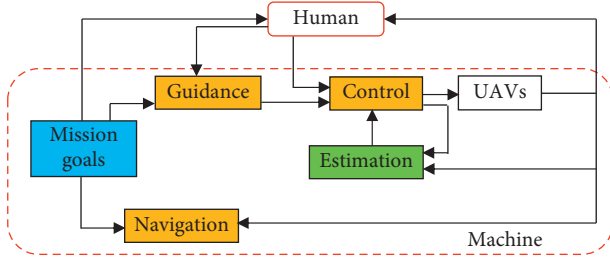

FIGURE 1: Man-machine interaction model.

and security capability in Figure 2. Among them, observation capability and security capability respond to procedural behavior; decision capability responds to the declarative behavior and action capability responds to reflective behavior. Based on the above capabilities, an evaluation model of ODAS is proposed hierarchically.

Based on the ODAS model and previous research on the source of evaluation indicator in detail [9], 31 equipment parameters are selected as evaluation index for autonomous capability of ground-attack UAV. Evaluation index system is established according to the performance parameters of existing airborne equipment, which can distinguish the differences of key technologies. Dividing evaluation index system into three layers, goal layer represents four kinds of capabilities extended by the man-machine cognitive model; subsystem layer represents relative airborne equipment extended by the goal layer, and index layer represents relative performance parameters extended by the subsystem layer. Evaluation index system is shown in Table 1.

2.2. Evaluation Methods

2.2.1. Definition. Cloud model theory is a modern mathematical theory for the study of compound uncertainties, which realizes the transformation between qualitative concepts and quantitative data based on probability statistics and fuzzy set. Let U be the universe of discourse and C be a qualitative concept in U. If $x \in U$ is a random numerical realization of C, which satisfies $x \in N(E_x, E_n'^2), E_n' \in (E_n, H_e^2)$, the certainty degree of x belonging to concept C satisfies

$$u(x) = \exp\left(-\frac{(x - E_x)^2}{2E_x'^2}\right). \tag{1}$$

Then, $(x, u(x))$ is called cloud drop and the distribution of x in the universe U is a normal cloud [20].

In this way, the normal cloud model $C = (E_x, E_n, H_e)$ can effectively integrate the randomness and fuzziness of concepts by the three parameters of expectation E_x, entropy E_n, and hyperentropy H_e. As shown in Figure 3, taking the cloud model $C_1 = (6, 2, 0.08), C_2 = (6, 1, 0.08)$, and $C_3 = (10, 1, 0.08)$ as example, E_x represents the highest point in the cloud model, which can represent qualitative concepts in the universe; E_n is the uncertainty measure of E_x, reflecting the acceptable range of cloud drop in the universe;

H_e is the uncertainty measure of E_n, reflecting the dispersion degree of cloud drop [21].

2.2.2. Forward Cloud Generator. Forward cloud generator is a tool that converts qualitative concepts into quantitative values and generates cloud drop in accordance with a probability distribution through parameters (E_x, E_n, H_e). Forward normal cloud model with N drops can be generated by the following steps:

(1) Generate a normally distributed random number x_i with expectation E_x and variance E_n.
(2) Generate a normally distributed random number y_i with expectation E_n and variance H_e.
(3) Calculate $u(x_i) = \exp(-(x_i - E_x)^2/2y_i^2)$; the coordinate of the cloud drop is $(x_i, u(x_i))$.
(4) Finally, repeat step 1–step 3 until N cloud drops are generated.

As shown in Figure 4, considering the importance of different cloud models in the universe, multiple cloud models are combined into a comprehensive cloud model, namely, weighted cloud model. Let $C(E_x, E_n, H_e)$ be the weighted cloud model and $C_1(E_{x1}, E_{n1}, H_{e1})$, $C_2(E_{x2}, E_{n2}, H_{e2})...C_n(E_{xn}, E_{nn}, H_{en})$ be the N cloud models in the domain. The calculation formula is as follows [22]:

$$\begin{cases} E_x = w_1 E_{x1} + w_2 E_{x2} + \cdots + w_n E_{xn}, \\ \\ E_n = \dfrac{w_1 E_{x1} E_{n1} + w_2 E_{x2} E_{n2} + \cdots w_n E_{xn} E_{nn}}{w_1 E_{x1} + w_2 E_{x2} + \cdots w_n E_{xn}}, \\ \\ H_e = \sqrt{w_1 H_{e1}^2 + w_2 H_{e2}^2 + \cdots w_n H_{en}^2}, \end{cases} \tag{2}$$

where $w = \{w_1, w_2, \dots, w_n\}$ is the weight set of cloud model in the universe. When $w_1 = w_2 = \cdots = w_n$, the weighted cloud model $C(E_x, E_n, H_e)$ is the average cloud model. For this article, we use the average cloud model to combine multiple cloud models into a comprehensive cloud model. Therefore, the weight of indicator cloud model is same. We calculate the weight of cloud model from the number of indicator cloud models. The formula is as follows:

$$w_1 = w_2 = \cdots w_n = \frac{1}{n}, \tag{3}$$

where n is the number of indicator cloud models.

3. A Cloud Model-Based Assessment Approach

According to the established evaluation index system in Section 2.1, the cloud model-based assessment approach can be illustrated in Figure 5. However, three outstanding issues exist in the process when employing normal cloud model to quantitative evaluation of autonomous capability:(1) how to define the ideal bilateral boundaries on given levels (I, II, III, IV, and V) of autonomous capability; (2) how to calculate the weight of evaluation index; and (3) how to express the certainty degree of evaluation index.

FIGURE 2: Man-machine cognitive model.

3.1. Bilateral Boundary. The division of bilateral boundary concerning indicator level is the key to confirm parameters (E_x, E_n, H_e) of normal cloud model. Dividing evaluation indicator into five levels, grade I is the lowest level and grade V is the highest level. According to the existing database, 200 data of evaluation indicator are selected by bubble sorting and are divided into five intervals, taking the average value of five intervals as bilateral boundary on given levels (I, II, III, IV, and V). The bilateral boundaries are shown in Tables 2–6 with previous research [9]; it explains the source of evaluation indicator in detail. In order to make the parameters of different airborne equipment comparable, the data are processed dimensionless by means of logarithmic method, weighted arithmetic, and exponentiation. At the same time, the addition rule is used to express the relationship between each capability and underlying indicators.

3.2. Index Weight. Index weight reflects the contribution of evaluation index to autonomous capability, and the difference among index weight is mainly due to three aspects: (1) the experts attach different importance to evaluation index, reflecting subjective differences of experts, (2) the essential function of each index is different, reflecting the objective differences among the indicators, and (3) the reliability of evaluation indexes is different, reflecting the different reliability about information provided by each index. Based on the abovementioned problems, the index weight is calculated by a new method about the combination of distance measure approach and entropy weight method. Distance measure approach considers subjective factors on the index weight of subsystem layer mentioned in Section 2.1; entropy weight method considers objective factors and reliable degree on the index weight of index layer.

3.2.1. Distance Measure Approach. Let evaluation index be $V_i (0 \le i \le 10)$, experts be $K_j (0 \le j \le \lambda)$, and the weight of experts K_j on index V_i be u_{ij}. For qualitative indicator, it is ambiguous for experts to give specific weight value directly. Therefore, u_{ij} is expressed as $C_{ij} = (E_{xij}, E_{nij}, H_{eij})$ by the forward cloud generator and distance measure approach is used to calculate u_{ij}, according to the similarity between cloud model C_{ij} and average cloud model $\overline{C}_i$. The formula of average cloud model $\overline{C}_i = (\overline{E}_{xi}, \overline{E}_{ni}, \overline{H}_{ei})$ is as follows:

$$\begin{cases} \overline{E}_{xi} = \dfrac{\left(E_{xi1} + E_{xi2} + \cdots E_{xij}\right)}{j}, \\\\ \overline{E}_{ni} = \dfrac{E_{x1}E_{n1} + E_{x2}E_{n2} + \cdots E_{xn}E_{nn}}{E_{x1} + E_{x2} + \cdots E_{xn}}, \\\\ \overline{H}_{ei} = \sqrt{\dfrac{\left(H_{ei1}^2 + H_{ei2}^2 + \cdots H_{eij}^2\right)}{j}}. \end{cases} \tag{4}$$

In order to compare the similarity between cloud model C_{ij} and $\overline{C}_i$, the distance measure approach is proposed in the universe. In the cloud model C_1 and C_2, $T (T < N)$ cloud drops are selected in interval $[E_X - 3E_n, E_X + 3E_n]$. According to the bubble sort of index value, the certainty degree $u(x_i)$ of cloud drops is stored in space $drop_1$ and $drop_2$, respectively. Compared to traditional methods [14], the distance between cloud model C_1 and C_2 relies on the distance of cloud drop rather than the ordinate of cloud droplet. The calculation formula of the distance measure between cloud model C_1 and C_2 is as follows:

FIGURE 3: Digital characteristics of cloud model. $C1 = (6,2,0.08)$, blue dots; $C2 = (6,1,0.08)$, red dots; $C3 = (10,1,0.08)$, green dots.
Figure 4: Forward weighted cloud generator.

$$d(C_1, C_2) = d(\text{drop}_1, \text{drop}_2)$$
$$= \frac{1}{T} \sum_{i=1}^{T} \sqrt{(x_{1i} - x_{2i})^2 - (u(x_{1i}) - u(x_{2i}))^2}, \tag{5}$$

where $u(x_{1i})$ is the certainty degree of cloud model C_1; $u(x_{2i})$ is the certainty degree of cloud model C_2. Therefore, the similarity between cloud model C_{ij} and average cloud model $\overline{C}_i$ can be given as follows:

$$\text{sim}\left(\overline{C}_i, C_{ij}\right) = 1 - \frac{d\left(\overline{C}_i, C_{ij}\right)}{x_{\max} - x_{\min}}, \tag{6}$$

where $x_{\max} - x_{\min}$ represents the range of valid universe. Then, the expert weight u_{ij} and average weight u_i given by all experts can be calculated by

$$u_{ij} = \frac{\text{sim}\left(\overline{C}_i, C_{ij}\right)}{\sum_{j=1}^{\lambda} \text{sim}\left(\overline{C}_i, C_{ij}\right)}, \quad \text{s.t.} \begin{cases} \sum_{j=1}^{\lambda} u_{ij} = 1, \\ \\ 0 \leq u_{ij} \leq 1, \end{cases} \tag{7}$$

$$u_i = \frac{\sum_{j=1}^{\lambda} u_{ij}}{\lambda}.$$

3.2.2. *Entropy Weight Method.* Here, a comprehensive weight calculating algorithm coupled with entropy is proposed, which is expected to balance the potential subjective factor of distance measure method. The notion of "entropy" taken from the theoretical foundation of modern information theory means the change degree of evaluation index. Standardizing evaluation index v_{ij} to r_{ij} and forming data matrix, $R = (r_{ij})_{m \times n}$, as

$$r_{ij} = \frac{v_{ij} - \min(v_{ij})}{\max(v_{ij}) - \min(v_{ij})},$$

$$R = \begin{bmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ r_{m1} & r_{m2} & \cdots & r_{mn} \end{bmatrix}, \tag{8}$$

where r_{ij} represents the standard value of ith indicator on jth sample set; m is the number of indicators; n is the number of sample sets. In autonomous capability assessment, entropy under ith indicator can be calculated by

$$\begin{cases} p_{ij} = \dfrac{r_{ij}}{\sum_{j=1}^{n} r_{ij}}, \\ \\ e_i = -k \sum_{j=1}^{n} \left(p_{ij} \cdot Inp_{ij}\right), \quad k = \dfrac{1}{Inn}, \end{cases} \tag{9}$$

where e_i represents the uncertainty of sample data with n potential statements; p_{ij} is the frequency of the jth statement. Now, the combined weight in ith indicator w_i can be attained, based on average weight u_i mentioned in Section 3.2.1 and entropy-based weight in ith indicator b_i, as

$$b_i = \frac{(1 - e_i)}{\sum_{i=1}^{m} (1 - e_i)}, $$
$$w_i = \frac{u_i b_i}{\sum_{i=1}^{m} u_i b_i}. \tag{10}$$

3.3. *Certainty Degree.* Before calculating the certainty degree of evaluation index, cloud model of each indicator should be generated. According to the bilateral boundary provided in Tables 2–6, the cloud model parameters (E_x, E_n, H_e) are obtained by the following formula (one has [23]):

$$\begin{cases} E_x^p = \dfrac{\left(c_{\max}^p + c_{\min}^p\right)}{2}, \\ \\ E_n^p = \dfrac{\left(c_{\max}^p - c_{\min}^p\right)}{6}, \\ \\ H_e = \beta, \end{cases} \tag{11}$$

where p is the level of autonomous capability; bilateral boundary of the form $(c_{\min}^p, c_{\max}^p)$ is the interval value corresponding to a certain autonomous capability level; β is usually a constant which represents the degree of ambiguity, generally 0.001–0.1 [24]. As shown in Figure 6, the cloud model under given levels (I, II, III, IV, and V) is generated by the forward cloud generator, in which the horizontal coordinate represents the index value and the vertical coordinate represents the certainty degree.

Then, bringing indicator value c_i into generated cloud model, the certainty degree set $\{u(c_i)\}$ is calculated by Section 2.2.2 under given levels (I, II, III, IV, and V). In order to eliminate outliers, the distribution function of certainty degree is approximated by fitting curve. The maximum value of distribution function is taken as the maximum certainty degree of $u_{\max}(c_i)$. Combining index weight w_i with the maximum certainty degree $u_{\max}(c_i)$, the comprehensive certainty degree U_P is given as

FIGURE 5: Evaluation process for autonomous capability of ground-attack UAV.

content of each level being mapped to autonomous capability by referring to literature [25]. The metrics of autonomous capability are shown in Table 7.

4.2. Initial Results. The cloud model-based approach is used to evaluate autonomous capability levels of three representative UAVs. The weights of evaluation index are shown in Table 8.

After calculating index weights, the certainty degree distribution of each level under all indicators is calculated according to Section 3.3. Due to the large number of evaluation indicators, only certainty degree distributions on given levels (I, II, III, IV, and V) of weather threat observation capability are illustrated in Figure 7 as a reference.

From Figure 7, we obtain different distribution patterns of certainty degrees at each level of weather threat observation capability. Not all levels have distributions for most cases and the distribution ranges are also different for those levels which have distributions. Certainty degrees at given levels are determined by the mean of certainty degrees obtained from 2000 simulations. The final autonomous capability levels are calculated by maximum certainty degree indicating the most probable value.

4.3. Results by Reference Method. Based on previous research [26], the Hopfield neural network method is used to compare autonomous capability levels of typical UAVs with cloud model theory. Index coding and simulation result of

test samples based on Hopfield neural network are shown in Figures 8 and 9. Meanwhile, the compared evaluation results are listed in Table 9.

The evaluation method based on cloud model theory provides the membership distribution diagram of evaluation index under index grades, which enables us to feel the difference between standard grade value and evaluation index value more intuitively. However, the Hopfield neural network method directly provides specific evaluation result, which cannot provide more difference in detail. The results show that autonomous capability levels of UAV1, UAV2, and UAV3 are grades III, I, and II. Compared with the Hopfield neural network method, the evaluation method based on cloud model theory is more representative than the reference method.

5. Conclusions

Based on cognitive control behavior, the ODAS model is proposed to select 31 evaluation indicators from airborne equipment affecting autonomous capability of ground-attack UAV. Combining with the weight of evaluation index, a cloud model-based approach is applied to autonomous capability evaluation. Confirming autonomous capability level of ground-attack UAV by certainty degree of cloud model avoids the influence of subjective factors, and cloud model-based approach also reveals the distinction of autonomy at each level, which provides much more information on autonomy status than Hopfield neural network methods. Hence, the autonomous capability level calculated by cloud model-based approach is found to be more actual and representative than Hopfield neural network methods. At present, the findings of this paper are being applied to autonomous evaluation software.

Data Availability

The evaluation index level partition data, the detailed information of generated cloud model data, and the distribution of certainty degrees in concept cloud data used to support the findings of this study are included within the article. The code data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.
