Background. Obstructive sleep apnea (OSA) is a potential cardiovascular risk factor. However, there is currently no prominent screening strategy for its diagnosis in patients with acute coronary syndrome (ACS). The aim of this study was to establish the impact of apneic events in case of OSA associated with ACS. **Methods.** Between January 1st and June 30th, fifty-three subjects with ACS (first acute myocardial infarction) were prospectively evaluated for OSA. Each patient was evaluated by polysomnography (PSG) two months after the ACS. **Results.** Mean age of $59 \pm 9,6$ years, 81,1% males, BMI at $28,5 \pm 4,2$ kg/m², neck circumference of $42,5 \pm 12,6$ cm, and waist circumference of $102,5 \pm 16,5$ cm. The majority of patients (73,6%) had moderate to severe OSA (apnea-hypopnea index (AHI) ≥ 15 /h and arousal index ≥ 10 /h). We defined the apneic coefficient (AC) as the ratio between apnea index (AI) and AHI. We chose as cut-off the median value of apnea coefficient in our population which was at 37%. The patients with a higher AC (AC $\geq 37\%$ versus AC $< 37\%$) had higher levels of Troponin-I ($63,4 \pm 63,2$ versus $29,7 \pm 36,1$ ng/mL, $p=0,016$), higher levels of NT-proBNP ($1879,8 \pm 2141,8$ versus $480 \pm 621,3$ pg/mL, $p=0,001$), higher SYNTAX score ($15,8 \pm 11,5$ versus $10,2 \pm 5,9$, $p=0,049$), and lower left ventricle ejection fraction (LVEF $53,3 \pm 11,4$ versus $59,4 \pm 6,4\%$, $p=0,023$) and were more likely to have a STEMI (21 patients (77,7%) versus 14 patients (53,8%), $p=0,031$). **Conclusion.** An apneic coefficient (AI/AHI) $\geq 37\%$ is correlated with more severe cardiac impairment, as well as higher hypoxemia and arousal index.

1. Introduction

Nowadays, obstructive sleep apnea (OSA) is a common chronic condition, affecting 10% of middle-aged men and 3% of middle-aged women [1].

The clinical guidelines [2, 3] and different other reports highlight that this condition is strongly related to the prevalence and consequences of arrhythmias [4, 5], hypertension [6], stroke [7], and heart failure [8]. The pathophysiological mechanism incriminated in this association is based on endothelial dysfunction [9], coronary plaque burden [10], chronic inflammation, and sympathetic activation [11], secondary to intermittent hypoxemia.

Although the role of OSA as risk factor for cardiovascular disease has been well defined, the description of

this sleep-breathing disorder in acute coronary syndrome is less clear and it is based on small population reports [12–15]. Moreover, a recent large study observed that OSA is a predictor of major adverse cardiac and cerebral events in patients who underwent percutaneous coronary intervention (PCI) for ACS, but there is still no consensus on the effectiveness of OSA treatment for patients with ACS [16]. On the contrary, a study of 136 myocardial infarction patients showed lower levels of troponin among OSA patients, suggesting a cardioprotective role of OSA as a “preconditioning factor” [17]. This protective effect of OSA was recently confirmed in patients with ACS, with a 54% reduction in peak cardiac Troponin-I levels in OSA patients than in those without OSA [18].

A recent expert review, based on the last publications, showed a heterogeneity of breathing disturbances associated with OSA and end-organ damage and that therefore a new definition of different phenotypes is needed, based on polysomnographic, clinical, and outcome parameters and not only on AHI [19]. Likewise, the hypopnea thresholds of 3% and 4% seemed to have different cardiovascular consequences [20] and the oxygen desaturation is more pronounced during apnea compared to hypopnea, with longer event duration [21, 22].

Therefore, we hypothesized that a more apneic profile of OSA defined by the ratio between AI and AHI could be better correlated to the severity of cardiac impairment in ACS compared with AHI alone.

2. Material and Methods

2.1. Study Design. 136 consecutive patients with ACS were referred for PCI, between 1st January 2017 and 30th June 2017. Following a screening procedure, 57 patients were enrolled for complete PSG, 2 months after the ACS (Figure 1).

The inclusion criteria included age > 18 years and the presence of first acute myocardial infarction. The exclusion criteria for the current study included the following: previous treatment with CPAP, inability to complete questionnaires, the presence of any previously diagnosed sleep disorder, patients with > 50% central apneas or Cheyne-Stokes respiration, patients with chronic diseases (neoplasms, severe renal insufficiency, and chronic obstructive pulmonary disease), and patients with cardiogenic shock.

All patients underwent systemic sleep apnea screening with polysomnography, performed 2 months after the resolution of the ACS to ensure that fluid accumulation, as a symptom of acute cardiac dysfunction, would not distort OSA diagnosis.

The main objective was the comparison between the apneic coefficient ($AC = AI/AHI$) and the severity of the coronary disease.

All patients gave written informed consent for the procedures and the research protocol was approved by the Institutional Review Board of the French Learned Society for Respiratory Medicine, Société de Pneumologie de Langue Française (CEPRO 2017-044).

2.2. Procedures. The ACS was defined according to the current guidelines [23] and included first ever-acute myocardial infarction (MI) with or without ST elevation infarction and unstable angina. The following data was recorded during hospitalization in the Cardiac Intensive Care Unit:

(i) angiographic data: the Thrombolysis in Myocardial Infarction (TIMI) score to evaluate the angiographic flow (an occluded infarction related artery was defined by a TIMI flow grade 0-1), SYNTAX score, and the infarction related artery (IRA)

(ii) echocardiographic data: LVEF

(iii) laboratory test: Troponin-I level, NT-proBNP, and cholesterol level

(iv) anthropometric data: BMI, neck circumference, and waist circumference.

(v) Sleep validated questionnaires: Epworth Sleepiness Scale (ESS) and Berlin questionnaire.

2.3. Polysomnography. Two months after the hospitalization for ACS, all 57 patients underwent a full night PSG in our sleep laboratory, using a Cidelec device (CID102L8D) with monitoring of the electroencephalogram (EEG) using frontal, central, and occipital leads, electrooculogram (EOG), electromyogram (EMG), airflow (by oronasal thermistor and nasal air pressure transducer), thoracic and abdominal respiratory movement (inductance plethysmography), and oximetry. A single EKG lead II was used for cardiac monitoring and the snoring was recorded by a microphone.

Three physicians manually interpreted polysomnographic recordings of 30 sec intervals, in accordance with the AASM 2012 guidelines [24]. Obstructive apnea was defined as the absence of airflow lasting ≥ 10 s in presence of abdominal and thoracic movements. Central apnea was defined as the absence of both thoracic and abdominal movements and airflow lasting ≥ 10 s. Hypopnea was defined as a reduction in airflow lasting ≥ 10 s associated with oxygen desaturation or subcortical arousal. OSA was defined as mild if $AHI \geq 5$ and $<15/h$ and moderate to severe if $AHI \geq 15/h$ and arousal index $\geq 10/h$.

We defined the apneic coefficient (AC) as the ratio between AI and AHI. We chose as cut-off the median value of apnea coefficient in our population which was at 37%. Using this cut-off, two groups of patients were formed ($AC \geq 37\%$ versus $AC < 37\%$). All the patients with moderate to severe OSA were proposed to either CPAP therapy or Mandibular Advancement Device (MAD) treatment and we noted the CPAP compliance at 3 months. We defined an optimal adherence to CPAP therapy if the mean duration of nocturnal CPAP therapy was at least 4 hours.

2.4. Statistical Analysis. We used SPSS Statistics version 20 for all statistical analysis. Continuous variables are described as mean \pm SD or median and interquartile range (IQR) as adequate. Categorical variables were described as numbers and percentages. Correlation coefficients were calculated using Spearman's test. Differences in procedural characteristics between patient groups were analyzed using Mann-Whitney *U* test for continuous data and chi square test for categorical data. A *p* value $< 0,05$ was considered significant. All parameters with a *p* value $< 0,20$ were entered into the multivariate linear regression analysis.

3. Results

3.1. Baseline Characteristics. Between January 1st and June 30th, 136 patients with ACS were referred to our Cardiac Intensive Care Unit for primary PCI. 79 patients were excluded according to a priori criteria (34 patients had known history of SAS or ACS, 28 patients declined participation, 14 patients had dementia or hemodynamic instability, and 3 patients had sternotomy or surgical revascularization). Finally, 57 patients were prospectively enrolled to complete the polysomnography study, 2 months after the ACS.

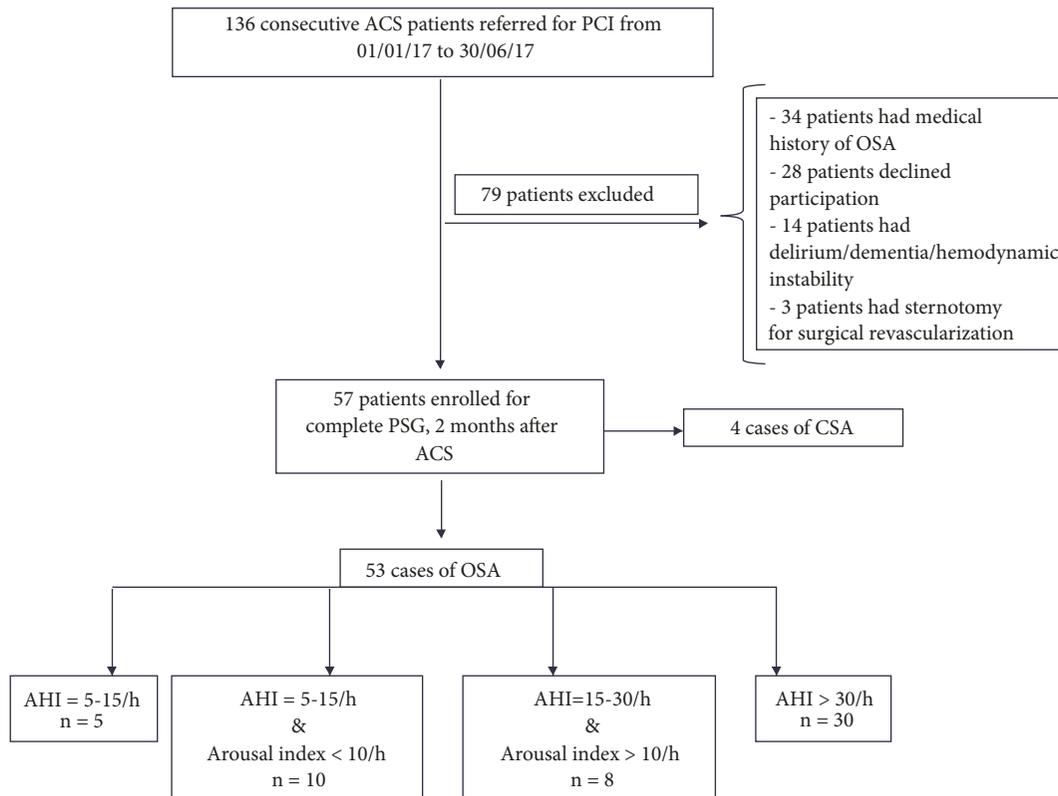

FIGURE 1: Flowchart: ACS: acute cardiac syndrome; CSA: central sleep apnea; OSA: obstructive sleep apnea; PCI: percutaneous coronary intervention; AHI: apnea-hypopnea index; PSG: polysomnography.

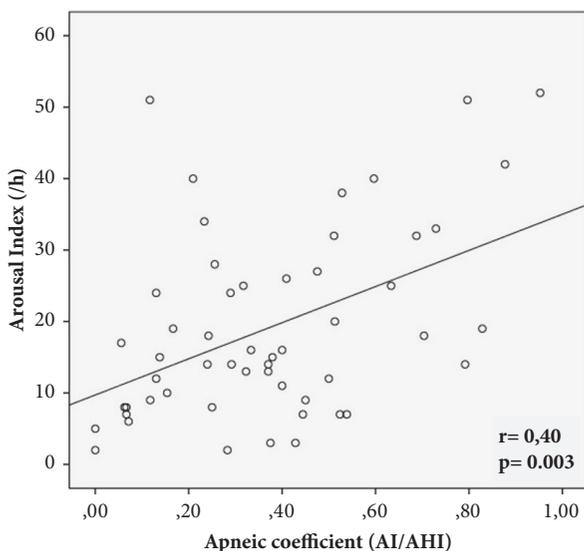

FIGURE 2: Correlation between arousal index and apneic coefficient.

Among them, 39 patients (68,4%) had moderate to severe OSA defined by $AHI \geq 15/h$ with arousal index $\geq 10/h$ and only 4 patients presented central sleep apnea (7%). We included only the 53 patients with OSA in our statistical analysis. The baseline demographic, clinical, and procedural

characteristics from patients with moderate to severe OSA versus mild OSA patients are listed in Table 1. The mean age was $59 \pm 9,6$ years, with a male predominance (81%) and BMI at $28,5 \pm 4,1 \text{ Kg/m}^2$. We did not find any statistical difference between the 2 groups (moderate to severe OSA versus mild OSA patients) in terms of severity of ACS.

3.2. Results of the Sleep Study. The mean and median value of AHI levels were $35,1/h \pm 16,8$ and $31/h$ (range 7 – 77/h), respectively, with 39 patients presenting a moderate to severe OSA (defined by $AHI \geq 15/h$ and arousal index $\geq 10/h$), which represents a prevalence of 73,5% in our population. In terms of screening, we observed that only the Berlin score, completed 2 months after the ACS, was correlated to the severity of OSA (Table 1). We diagnosed only 4 cases of CSA (7% of study population) probably due to the 2 months delay between the ACS and polysomnography.

The excessive daytime sleepiness evaluated by ESS was nonsignificant in both groups of patients (moderate to severe OSA versus mild OSA).

The apneic coefficient was positively correlated with NT-proBNP ($r = 0,31; p = 0,33$) and arousal index ($r = 0,40; p = 0,003$) (Figure 2).

We found a mean and median value of AC levels at $37,3\% \pm 24,2$ and 37% (range 5% – 95%). Using AC levels with a cut-off of 37% we defined two groups: the most apneic patients ($AC \geq 37\%$) versus the least apneic patients ($AC < 37\%$).

| Age | 0,004 | -0,045 – 0,053 | 0,86 |
| CPAP therapy ≥ 4h | 0,364 | -0,899 – 0,207 | 0,19 |

more compliant to CPAP at 3 months with more than 4 hours of CPAP therapy for 19 patients (73%) versus 8 patients (32%); p=0,016 (Table 2). However, all these results are no longer significant after multivariate analysis (Table 3).

4. Discussion

OSA is highly prevalent in cardiovascular diseases. Intermittent hypoxia, the hallmark of OSA, causes oxidative stress, inflammation, sympathetic hyperactivity, and endothelial dysfunction which lead to cardiovascular comorbidities [19, 25].

Recent expert review highlighted that the clinical definition of OSA based on the combination of AHI and sleepiness

is compromised by the high prevalence of elevated AHI in the general population [19, 26, 27] and the ODI may be a stronger predictor of adverse cardiovascular outcomes than AHI [28, 29]. In this context we hypothesized that a coefficient based on the frequency of pure apneic events could be more reliable to predict cardiac impairment for patients with ACS associated with OSA. Therefore, we defined the apneic coefficient (AC) as the ratio between the AI and AHI. We chose the median value of AC as the cut-off (AC=37%) to evaluate the correlation with the cardiac outcomes after ACS. The polysomnographic evaluation was made 2 months after the ACS to ensure that fluid accumulation, as a symptom of acute cardiac dysfunction, would not distort OSA diagnosis.

We found, after univariate analysis, that the most apneic patients defined by an AC \geq 37% had a higher level of Troponin-I, higher level of NT-proBNP, higher SYNTAX score, and lower LVEF and were more likely to have a STEMI and a higher ODI. These results are similar to recent studies which showed that OSA is independently associated with major adverse cardiac and cerebrovascular events [30] and could inhibit the recovery of left ventricular function in patients with acute MI [31]. Unfortunately, all these correlations did not remain statistically significant after multivariate analysis probably because of the limited number of patients in our study.

Also, these patients seemed to be more compliant to CPAP therapy. This is probably explained by a significantly more severe sleeping disorder (AHI 40/h \pm 14,5 versus 31,3/h \pm 16,3 and ODI 28,8/h \pm 15,6 versus 16,4/h \pm 13,8). Similar to our findings, a recent ancillary analysis of the ISAACC trial showed that protective factors against noncompliance with CPAP treatment were the severity of the disease (high value of AHI and ICU stay length) [32].

We did not find any statistically differences between the groups of mild OSA versus moderate to severe OSA, in terms of coronaropathy markers or cardiac dysfunction after ACS.

A recent study reported that gender in OSA influences the severity of ACS [33]. Our OSA-ACS population presented a large majority of men but without any significant gender-related difference in OSA associated with ACS.

We found a very low level of sleepiness in our population and we did not find any correlation between sleepiness scale evaluated by ESS and the severity of OSA based on AHI. The more complex Berlin questionnaire seemed to better define the more severe OSA patients. Contrary to a recent study [34] we did not find that age or BMI were associated with OSA.

The current study has several strengths including a gold standard polysomnographic evaluation for all 57 patients, performed two months after the ACS to exclude a high prevalence of apneic events due to fluid accumulation secondary to acute cardiac dysfunction. Also, we assessed a broad range of anthropometric, biological, clinical, cardiovascular, and therapeutic variables in our analysis.

Moreover, our study has some limitations. This is a single-center study regarding a small population of patients. Because of a short follow-up period we could not analyze the efficacy and the protective role of CPAP-treatment regarding the cardiovascular status. Repeat coronary angiography was not protocol mandated and therefore we could not examine the

follow-up data of the coronary status, regarding the severity of OSA.

In conclusion, in this single-center study we observed that the most apneic patients, defined by an AC \geq 37%, were associated with a more severe coronary and cardiac dysfunction. The apneic status (AC \geq 37%) could be a protective factor against the noncompliance to CPAP therapy.
