Given the absence of a theoretical formula to analyze the influence of parameters on the contact stress of cylindrical gear with arc tooth, an explicit mathematical model of cylindrical gear with arc tooth between the design parameters and the contact stress is established based on Kriging surrogate model. The parameters of the variation function of Kriging model are optimized by using the whale optimization algorithm (WOA), and the explicit mathematical model accuracy between the design parameters and the contact stress of the gear is in turn optimized by the improved Kriging surrogate model. The influence of design parameters on the contact stress of cylindrical gear with arc tooth is analyzed based on the established mathematical model. The proposed algorithm was realized via the programming platform MATLAB; the simulation results indicate that the precision evaluation indexes (the correlation coefficient ( $R^2$ ), root mean square error (RMSE), and the relative maximum absolute error (RMAE)) of the proposed Kriging model are improved, in addition to the error range which is narrowed from  $(-2, 4)$  to  $(0, 3)$ . As the tooth width, modulus, pressure angle, and tooth line radius increased, the contact stress of the cylindrical gear with arc tooth gear declined, which was negatively correlated with the design parameter. The amplitude of contact stress of the cylindrical gear with arc tooth was the largest due to the change of tooth radius, followed by the change of modulus, while the influence of tooth width was less. Finally, the influence of modulus-tooth line radius interaction and pressure angle-tooth line radius interaction on contact stress of cylindrical gear with arc tooth was significant.

## 1. Introduction

Gears are widely used in various industries [1], and the involute cylindrical gear is widely used at present. However, in the involute cylindrical gear, the bearing capacity of spur gear is limited, the axial force of helical gear subsists, and the processing technology of herringbone gear is complex. In order to solve the problem of involute gear, Japanese scholar Yoshiro Hasegawa and others put forward a new type of circular arc gear transmission device. This new type of gear transmission has the advantages of good meshing performance, high coincidence, no axial force, stable transmission, and so on [2]. For this kind of gear, scholars have carried out in-depth research. Tseng et al. have studied its mathematical model, undercutting conditions, contact, and other aspect

[3–6]. Lei et al. have studied the accurate three-dimensional modeling method of circular tooth profile gear [7]. Dengqiu et al. have studied its contact distribution [8]. The contact performance of gears was studied by Chen Shuai and Wang [9, 10, 11, 12]. Surrogate model is an approximate modeling method that can generate mathematical models with a small number of samples to reduce the number of physical experiments and improve efficiency, and the commonly used surrogate model mainly includes response surface, Kriging, Support Vector Machine, Artificial Neural Network, etc. [13, 14]. In order to study the influence of design parameters on the contact stress of circular arc tooth line gear, this paper proposes using Kriging surrogate model to establish the mathematical model of contact stress between design parameters (tooth width, modulus, pressure angle, and tooth

radius) of cylindrical gear with arc tooth. The Kriging model with the best effect is selected by comparing the prediction effect of these common surrogate model methods on contact stress of cylindrical gear with arc tooth. With a view to improving the modeling accuracy of Kriging model, intelligent algorithm is used to optimize the variation function of Kriging; the commonly used intelligent algorithm mainly includes genetic algorithm, immune algorithm, simulated annealing algorithm, particle swarm algorithm, fish swarm algorithm, ant colony algorithm, cuckoo algorithm, and so forth [15]. In this paper, whale optimization algorithm (WOA) was used for the parameters of the variation function of the traditional Kriging model. The Kriging surrogate model with optimized parameters of the variation function is used to establish the explicit mathematical model between the design parameters and the contact stress of the gear. The influence of design parameters (tooth width, modulus, pressure angle, and tooth radius) on the contact stress of circular arc tooth line cylindrical gear is discussed based on the established mathematical model.

## 2. Mathematical Model of Circular Arc Gear

According to its forming principle [16, 17], the coordinate system of forming principle of circular arc tooth line cylindrical gear is shown in Figure 1. In Figure 1,  $S(O - XYZ)$  is the static coordinate system,  $S_1(O_1 - X_1Y_1Z_1)$  is the solidification coordinate of the gear blank, and  $S_T(O_T - X_TY_TZ_T)$  is the tool coordinate, which moves in relation to  $S(O - XYZ)$  coordinate at the speed of  $V_T = R \times \omega$ .

In the coordinate system  $S_T(O_T - X_TY_TZ_T)$ , the vector expression of the parametric equation of the surface formed in the cutting process is

$$\begin{aligned} \vec{r}_T = & -\left(\frac{\pm q \sin \alpha + R_T \pm \pi m}{4}\right) \cos \theta \vec{i}_T \\ & + \left(\frac{\pm q \sin \alpha + R_T \pm \pi m}{4}\right) \sin \theta \vec{j}_T + q \cos \alpha \vec{k}_T, \end{aligned} \quad (1)$$

$$\begin{cases} \vec{r}_{dq} = \pm \sin \alpha \cos \theta \vec{i}_T \pm \sin \alpha \sin \theta \vec{j}_T + \cos \alpha \vec{k}_T, \\ \vec{r}_{d\theta} = -\left(\frac{\pm q \sin \alpha + R_T + \pi m}{4}\right) \sin \theta \vec{i}_T + \left(\frac{\pm q \sin \alpha + R_T + \pi m}{4}\right) \cos \theta \vec{j}_T. \end{cases} \quad (4)$$

Then, the unit normal vector of the tool surface is

$$\begin{aligned} \vec{n} = \frac{\vec{r}_{dq} \times \vec{r}_{d\theta}}{|\vec{r}_{dq} \times \vec{r}_{d\theta}|} = & -\cos \alpha \cos \theta \vec{i}_T - \cos \alpha \sin \theta \vec{j}_T \\ & \pm \sin \alpha \vec{k}_T. \end{aligned} \quad (5)$$

where  $a$  is the pressure angle of the cutting edge of the cutting tool;  $\theta$  is the angle from the current enveloping point of the gear blank to the middle section; and  $q$  is the length of the enveloping reference point from the point on the cutting surface of the cutting tool along the direction of the generatrix of the cutting cone in the coordinate system.  $R$  is dividing circle radius of gear,  $R_T$  is cutter head radius of machining tool,  $R_n$  is inner edge radius in the tangent direction of dividing circle,  $R_w$  is outer edge radius in the tangent direction of dividing circle,  $R_w = R_T + \pi m/4$ ,  $m$  is gear module,  $\omega$  is cutter head rotation angle speed of machining tool, and  $V_T$  is cutter head moving speed of machining tool.

Transform  $S_T(O_T - X_TY_TZ_T)$  to  $S(O - XYZ)$ , and its coordinate conversion relationship is as follows:

$$\mathbf{T}_{OT} = \begin{bmatrix} 1 & 0 & 0 & R\varphi + R_T \\ 0 & 0 & 1 & R \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \quad (2)$$

Transform  $S(O - XYZ)$  to  $S_1(O_1 - X_1Y_1Z_1)$ , and its coordinate conversion relationship is

$$\mathbf{T}_{10} = \begin{bmatrix} \cos \varphi & -\sin \varphi & 0 & 0 \\ \sin \varphi & \cos \varphi & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \quad (3)$$

If  $S_T(O_T - X_TY_TZ_T)$  is converted to  $S(O - XYZ)$ , then the coordinate transformation matrix is  $\mathbf{T}_{1T} = \mathbf{T}_{10} \mathbf{T}_{OT}$ .

**2.1. Unit Normal Vector of Tool Surface.** The tool surface equation is

**2.2. Relative Speed of Tool and Gear at Meshing Point.** The direction vector can be expressed as

$$\vec{\lambda} = \overline{O_1O_T} = (R\varphi + R_T) \vec{i}_T + R \vec{k}_T. \quad (6)$$

Therefore, the relative speed of the tool and the gear at the meshing point is

FIGURE 1: Coordinate system of forming principle of cylindrical gear with arc tooth.

$$\begin{aligned}
 \vec{v}^{12} &= \vec{\omega}^{12} \times \vec{r}^1 + \frac{d\lambda}{dt} - \vec{\omega}^2 \times \vec{\lambda}, \\
 &= -\omega_1 q \cos \alpha \vec{i}_T - \omega_1 \left( \frac{\pm q \sin \alpha + R_T + \pi m}{4} \right) \cos \theta \vec{k}_T + \omega_1 R \vec{i}_T \\
 &\quad - \left[ \omega_1 R \vec{i}_T - \omega_1 (R\phi + R_T) \vec{k}_T \right], \\
 &= -q \cos \alpha \omega_1 \vec{i}_T - \left[ \left( \frac{\pm q \sin \alpha + R_T + \pi m}{4} \right) \cos \theta + (R\phi + R_T) \right] \omega_1 \vec{k}_T.
 \end{aligned} \tag{7}$$

2.3. *Meshing Function.* Based on the meshing principle, the meshing function is expressed as follows:

$$\Gamma = \vec{n} \cdot \vec{v}^{12} = 0. \tag{8}$$

Because  $\omega_1 \neq 0$ , it can be concluded from the above formula that

$$q = \mp \sin \alpha \frac{\cos \theta (R_T + \pi m/4) + (R\phi + R_T)}{\cos \theta}. \tag{9}$$

2.4. *Conjugate Surfaces.* Combining equations (1) and (9), the contact line equation between the tool and the gear to be machined is as follows:

$$\begin{cases}
 x_T = -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \cos \theta, \\
 y_T = \left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \sin \theta, \\
 z_T = q \cos \alpha, \\
 q = \mp \sin \alpha \frac{\cos \theta (R_T + \pi m/4) + (R\phi + R_T)}{\cos \theta}.
 \end{cases} \tag{10}$$

By converting the coordinates in  $S_T(O_T - X_T Y_T Z_T)$  to  $S_1(O_1 - X_1 Y_1 Z_1)$ , the tooth surface equation of the cut gear can be obtained as follows:

$$\left\{ \begin{array}{l} x_1 = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \cos \theta + R\varphi + R_T \right] \cos \varphi - (q \cos \alpha + R) \sin \varphi, \\ y_1 = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \cos \theta + R\varphi + R_T \right] \sin \varphi + (q \cos \alpha + R) \cos \varphi, \\ z_1 = \left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \sin \theta, \\ q = \mp \sin \alpha \frac{\cos \theta (R_T + \pi m/4) + (R\varphi + R_T)}{\cos \theta}. \end{array} \right. \quad (11)$$

2.5. *Instantaneous Contact Line.* Meshing function  $\Gamma = \Gamma(q, \theta, \varphi)$  is a function of variables  $q, \theta, \varphi$ . As  $\varphi_1 = \omega_1 t$ ,  $\varphi_1$  is regarded as a function of entering  $\Gamma$  in a certain instant, thus the function expression of the instantaneous contact line between the rack cutter and the gear blank can be obtained. If the value  $\varphi_1$  at any time is substituted into equation (7), the contact line equation of the whole surface can be obtained as follows:

$$\left\{ \begin{array}{l} x_T = -\left[ \left( 1 + \sin^2 \alpha \right) \left( \frac{R_T \pm \pi m}{4} \right) + \sin^2 \alpha \frac{R\varphi + R_T}{\cos \theta} \right] \cos \theta, \\ y_T = \left[ \left( 1 + \sin^2 \alpha \right) \left( \frac{R_T \pm \pi m}{4} \right) + \sin^2 \alpha \frac{R\varphi + R_T}{\cos \theta} \right] \sin \theta, \\ z_T = \mp \sin \alpha \cos \alpha \left( \left( \frac{R_T \pm \pi m}{4} \right) + \left( \frac{R\varphi + R_T}{\cos \theta} \right) \right). \end{array} \right. \quad (12)$$

2.6. *Tooth Profile Equation.* In the axial middle section of the gear, from its extended coordinate system, it can be seen that  $b=0$ ; then,  $\theta$  is also equal to zero. Substituting these two parameters into equation (11), the tooth profile equation of the middle section is obtained:

$$\left\{ \begin{array}{l} x_1 = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) + R\varphi + R_T \right] \cos \varphi - (q \cos \alpha + R) \sin \varphi, \\ y_1 = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) + R\varphi + R_T \right] \sin \varphi + (q \cos \alpha + R) \cos \varphi, \\ q = \mp \sin \alpha \left( \left( \frac{R_T + \pi m}{4} \right) + R\varphi + R_T \right). \end{array} \right. \quad (13)$$

According to equation (13), it can be seen that the tooth profile of the axial symmetry surface of the gear is involute.

Similarly, on the axial asymmetric plane, let  $z_1 = b$ ; according to the expressions of  $Z_1$  and  $q$  in equation (11), we can get

$$\varphi = \frac{\{ [(-b/\tan \theta) + (R_T \pm \pi m/4) \cos \theta] / \sin^2 \alpha - (R_T \pm \pi m/4) \cos \theta - R_T \}}{R} \quad (14)$$

Thus, the expression of the tooth profile of the non-intermediate section can be obtained as follows:

$$\left\{ \begin{array}{l} x_T = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \cos \theta + R\varphi + R_T \right] \cos \varphi - (q \cos \alpha + R) \sin \varphi, \\ y_T = \left[ -\left( \frac{\pm q \sin \alpha + R_T \pm \pi m}{4} \right) \cos \theta + R\varphi + R_T \right] \sin \varphi + (q \cos \alpha + R) \cos \varphi, \\ q = \mp \sin \alpha \frac{\cos \theta (R_T + \pi m/4) + (R\varphi + R_T)}{\cos \theta}, \\ \varphi = \frac{\{[-(b/\tan \theta) + (R_T \pm \pi m/4) \cos \theta] / \sin^2 \alpha - (R_T \pm \pi m/4) \cos \theta - R_T\}}{R}. \end{array} \right. \quad (15)$$

### 3. Contact Stress Analysis of Cylindrical Gear with Arc Tooth Based on Finite Element Method

**3.1. Model Material Attribute Definition.** Establish material information in ABAQUS, such as modulus of elasticity ( $E=2.08$  MPa), Poisson's ratio (0.298), and other parameters.

**3.2. Establishing Analytical Steps and Interactions.** Establish analysis steps, which mainly include defining analysis type (static), defining analysis increment step, determining iteration method, creating field variable, and historical variable and determining output parameters. Turn on nonlinearity, and define interaction as contact; then set contact type of finite element analysis of circular arc tooth line gear pair as "friction free." The MPC (multipoint constraint) is established by the rotating centers of the active and the driven.

**3.3. Applying Restraint and Moment.** The torque of magnitude  $6.08 \times 10^4$  N-mm is applied to the driving wheel. At the same time, MPC is added to the driving wheel: the direction of its rotation axis is set as free, and other rotation and translation are set as fixed. In the driven wheel, all directions of MPC constraints are fixed, and no motion is allowed in any direction.

**3.4. Gridding.** The method of sweeping is used to divide the mesh of gear pair, with C3D8I as the mesh type. The overall unit size of the gear is set to 2 mm, while the local subdivision size of the contact area is 0.02 mm. If the requirements are not met, continue to adjust the parameters. In the subsequent calculation, the mesh can be further refined to improve the quality of division. Through multiple trial calculation and comparative analysis results, the grid can be used as the final analysis grid if the calculation result is nearly stable. In the analysis process, due to the local subdivision of

the contact area, the number of grids for each pair of gears is about  $1.2 \times 10^6$ . The result of gear grid division is shown in Figure 2.

**3.5. Solution and Visualization.** Considering that the mesh number of each pair of gears is about  $1.2 \times 10^6$ , a parallel calculation is used in the solution. The calculated stress nephogram of driving wheel and that of driven wheel are shown in Figure 3. Figure 3(a) shows the dynamic contact stress diagram of driving wheel, and Figure 3(b) shows the contact stress diagram of driving wheel.

According to the simulation analysis, contact area is near dividing circle. As shown in Figure 3(a), the driving wheel of the contact area of the above standard pitch circle has a maximum stress value of 503.3 MPa. As shown in Figure 3(b), driven wheel contact area of the below standard pitch circle has a maximum stress value of 501 MPa. Therefore, the maximum contact stress is 503.3 MPa, and the difference in value between active and driven wheel is 2.3 MPa, only equal to 0.4570% of the maximum contact stress, which almost can be ignored. Similarly, it can be seen from Figures 3(a) and 3(b) that the contact area of the gear studied in this paper is an ellipse under the action of load, which confirms the fact that the contact area of point contact gear under the action of load is ellipse.

### 4. The Prediction Model of Contact Stress of Cylindrical Gear with Arc Tooth Based on Surrogate Model

**4.1. Test Design and Response Results.** The common test methods mainly include uniform test design, orthogonal test design, Latin square test design, and other methods. This paper studies the relationship between tooth width, modulus, pressure angle, tooth radius, and contact force. Four factors and three levels are selected for the simulation scheme by using the principle of regression orthogonal test method. The level table of gear design factors is shown in Table 1.

FIGURE 2: Meshing results of gears. (a) Global mesh results. (b) Local mesh results.

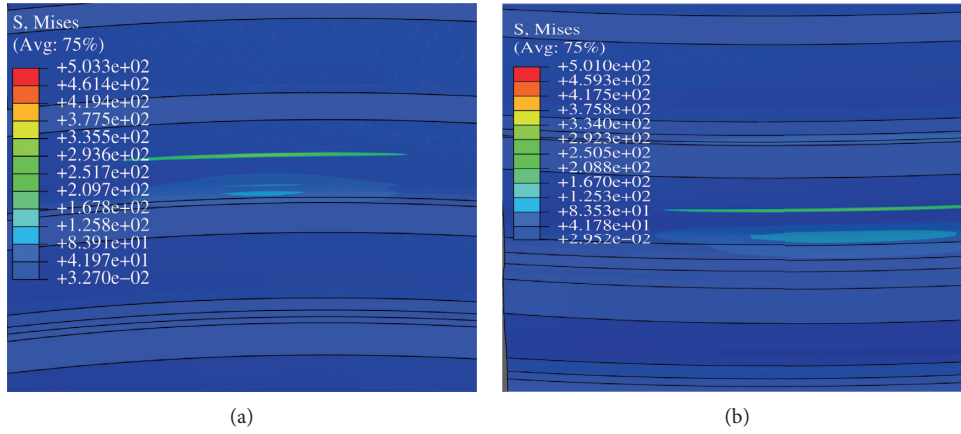

FIGURE 3: Stress neutrogram analysis of driving wheel and driven wheel. (a) Driving wheel. (b) Driven wheel.

TABLE 1: Gear design factor level.

| Level order | Tooth width (mm) | Modulus | Pressure angle (°) | Tooth radius (mm) |
|-------------|------------------|---------|--------------------|-------------------|
| Level 1     | 38.83685         | 2.96737 | 18.83685           | 191.8425          |
| Level 2     | 40               | 3.2     | 20                 | 250               |
| Level 3     | 41.16315         | 3.43263 | 21.16315           | 308.1575          |

In this paper, the orthogonal test is used to sample, and then the finite element method is used to get the gear joint stress under different sample data. According to the orthogonal table, 9 samples were processed, and the contact stress simulation results of  $L9$  (34) orthogonal test arc gear are shown in Table 2.

#### 4.2. Improved Kriging Model

**4.2.1. Kriging Surrogate Model.** Kriging model can obtain ideal fitting results when solving the problem of high nonlinearity. Its interpolation results are defined as the linear weighting of the response value of the known sample function, which is

$$y(x) = \sum_{j=1}^k \beta_j f_j(x) + Z(x). \quad (16)$$

In the formula,  $f_j(x)$  is function,  $\beta_j$  is corresponding coefficient, and  $Z(x)$  is static random process, whose mean value is 0, and its variance is  $\sigma^2$ . The covariance between the random variables corresponding to two different points in the design space is

$$\text{Cov}[Z(x^i), Z(x^j)] = \sigma^2 R(x^i, x^j), \quad (17)$$

$$R(x^i, x^j) = \prod_{l=1}^{N_s} R_l(\theta_l, x_l^i, x_l^j), \quad (18)$$

TABLE 2: Contact stress simulation results of L9 (34) orthogonal test.

| Order | Tooth width (mm) | Modulus | Pressure angle (°) | Tooth radius (mm) | Contact force (MPa) |
|-------|------------------|---------|--------------------|-------------------|---------------------|
| 1     | 38.83685         | 2.96737 | 18.83685           | 191.8425          | 542.7               |
| 2     | 38.83685         | 3.2     | 20                 | 250               | 457.2               |
| 3     | 38.83685         | 3.43263 | 21.16315           | 308.1575          | 396.8               |
| 4     | 40               | 2.96737 | 20                 | 308.1575          | 452.9               |
| 5     | 40               | 3.2     | 21.16315           | 191.8425          | 494.1               |

| 8     | 41.16315         | 3.2     | 18.83685           | 308.1575          | 440.2               |
| 9     | 41.16315         | 3.43263 | 20                 | 191.8425          | 476.7               |

where  $R(x^i, x^j)$  is correlation function, which represents the correlation between random variables at different positions. The commonly used correlation function is Gaussian-type function.

In equation (17), the parameter  $\theta$  of the variation function of Kriging model is determined by the maximum likelihood estimation method to solve the optimization problem:

$$\max \left\{ -\frac{N_s}{2} \ln(\bar{\sigma}^2) - \frac{1}{2} \ln(R) - \frac{N_s}{2} \ln(2\pi) \right\}, \quad \theta > 0, \quad (19)$$

$$\bar{\sigma}^2 = \frac{1}{N_s} (y_s - F\tilde{\beta})^T R^{-1} (y_s - F\tilde{\beta}).$$

In order to minimize the root mean square error (RMSE) between Kriging prediction value and actual function value, the approximate expression of Kriging model can be obtained as

$$\tilde{y}(x) = f_x^T \tilde{\beta} + \left[ R(x, x^{(1)}), R(x, x^{(2)}), \dots, R(x, x^{(N_s)}) \right]^T R^{-1} (y_s - F\tilde{\beta}), \quad (20)$$

where  $F$  is matrix composed of basis function vector  $f_x^T$ ;  $\tilde{\beta}$  is least square estimate of KRG model coefficient;  $R$  is correlation matrix; and  $N_s$  is sample number.

**4.2.2. Whale Algorithm.** The principle of whale algorithm is derived from the "bubble net," foraging behavior of humpback whales. The mathematical expression based on this special strategy is as follows:

$$D = |C \cdot X^*(t) - X(t)|, \quad (21)$$

$$X(t+1) = X^*(t) - A \cdot D,$$

where  $t$  is the number of current iterations;  $X(t)$  is the coordinate vector of the current humpback whale;  $X(t+1)$  is the target coordinate vector after the next iteration;  $X^*(t)$  is the best position vector obtained so far, which is updated with time;  $D$  is the distance between the current humpback whale and the best position; and  $A$  and  $C$  are the number of systems, which are, respectively, expressed as

$$A = 2a \cdot r - a, \quad (22)$$

$$C = 2r,$$

where  $a$  is parameter in the value range (0, 2) and linearly decreasing with the iteration time and  $r$  is random vector in the interval (0, 1).

When  $|A| > 1$ , whales have the behavior of wandering and foraging. Using the random individual coordinates of the population to locate and navigate food, the mathematical expression is as follows:

$$X(t+1) = X_{\text{rand}}(t) - A \cdot D. \quad (23)$$

When  $|A| < 1$ , there were two behaviors of encircling and attacking prey, and the mathematical model is described as follows:

$$X(t+1) = X^*(t) - D \cdot e^{bl} \cdot \cos(2\pi l). \quad (24)$$

In the formula,  $b$  is the constant of the spiral shape and  $l$  is the random number on the interval  $(-1, 1)$ .

Since the contraction and spiral position updating of whales are carried out synchronously, mathematically selecting the same way of probability to update their position, then we can get the following expression:

$$X(t+1) = \begin{cases} X^*(t) - A \cdot D, & p < 0.5, \\ X^*(t) - D \cdot e^{bl} \cdot \cos(2\pi l), & p \geq 0.5. \end{cases} \quad (25)$$

According to the characteristics of Kriging and WOA algorithm, the Kriging surrogate model based on WOA algorithm is used for parameter impact analysis, and the flow chart is shown in Figure 4.

**4.3. Accuracy Evaluation Indexes of Kriging.** Generally, the evaluation indexes of correlation coefficient ( $R^2$ ), root mean square error (RMSE), and relative maximum absolute error (RMAE) are used to evaluate the accuracy of Kriging.

**4.3.1. The Correlation Coefficient ( $R^2$ ).**

$$R^2 = 1 - \frac{\sum_{i=1}^n (f_i - \hat{f}_i)^2}{\sum_{i=1}^n (f_i - \bar{f})^2}. \quad (26)$$

**4.3.2. The Root Mean Square Error (RMSE).**

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^n (f_i - \hat{f}_i)^2}{n}}. \quad (27)$$

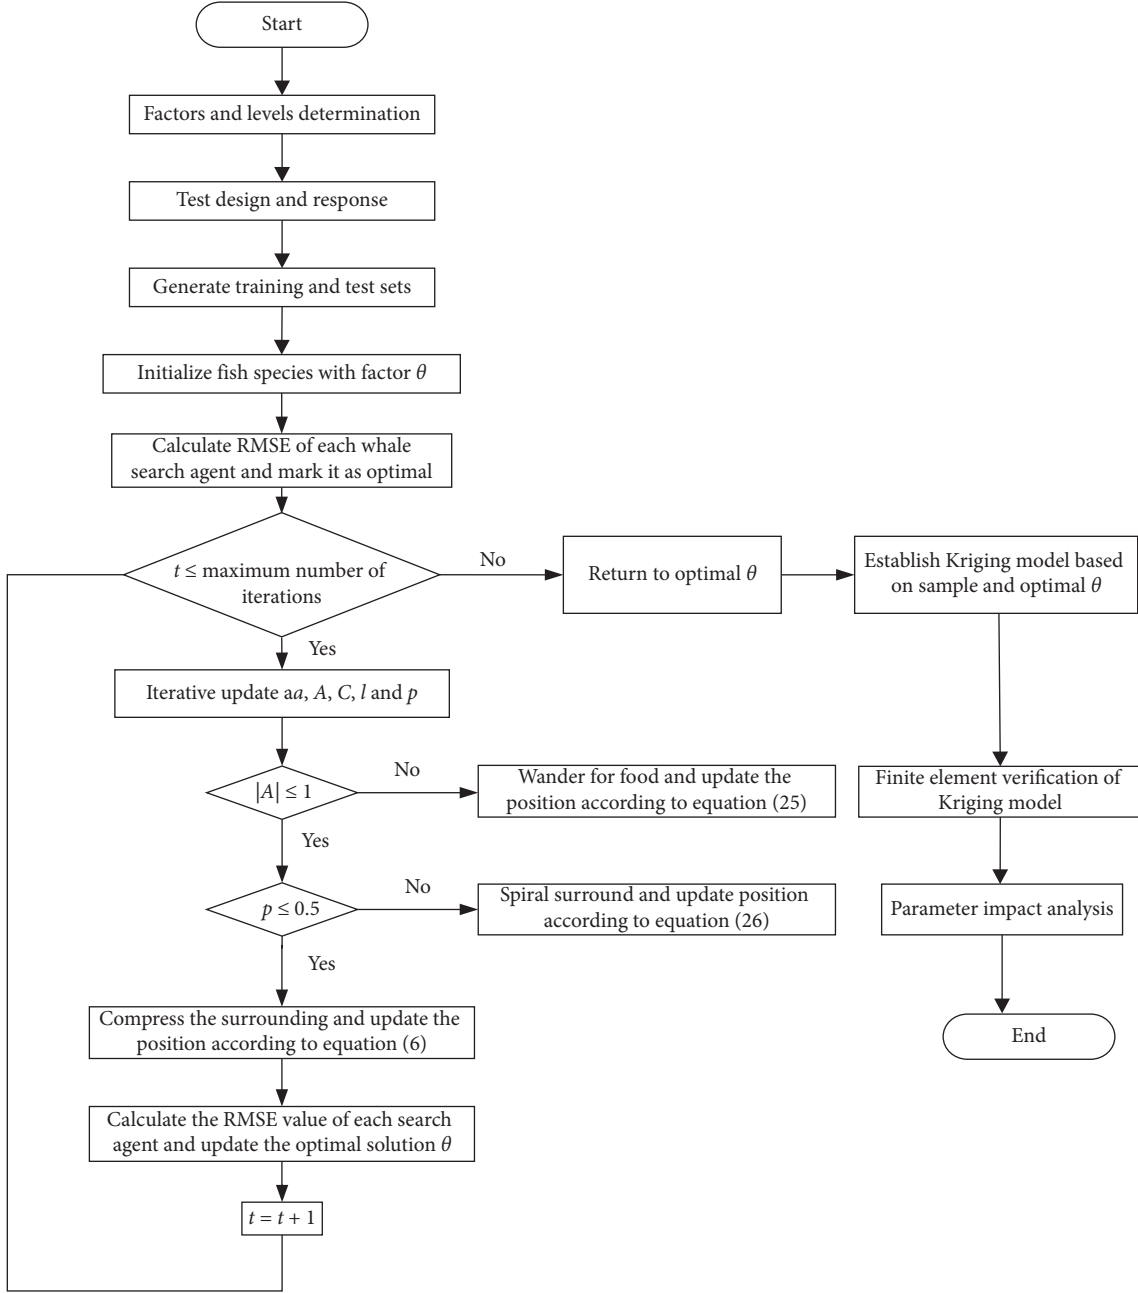

FIGURE 4: Improvement process of Kriging surrogate model based on WOA algorithm.

#### 4.3.3. The Relative Maximum Absolute Error (RMAE).

$$\text{RMAE} = \frac{\max\{|f_1 - \hat{f}_1|, |f_2 - \hat{f}_2|, \dots, |f_n - \hat{f}_n|\}}{\sqrt{1/n} \sum_{i=1}^n (f_i - \bar{f})^2}. \quad (28)$$

In equations (26) to (28),  $n$  is number of test sample points,  $f_i$  is the truth value of the actual model at the  $i^{\text{th}}$  test sample point, and  $\hat{f}_i$  is the predicted value of the surrogate model at the  $i^{\text{th}}$  test sample point. The closer  $R^2$  is to 1, the better the global approximation effect of the surrogate model will be. The smaller the RMSE is, the higher the precision of the surrogate

model will be, and the smaller the RMAE is, indicating that the higher the precision of the surrogate model will be.

4.4. Numerical Simulation. Using the MATLAB digital simulation platform, Kriging and the improved Kriging algorithm based on WOA algorithm are, respectively, used to establish the contact stress prediction model of circular arc gear. The evaluation indexes of the correlation coefficient ( $R^2$ ), root mean square error (RMSE), and the relative maximum absolute error (RMAE) before and after optimization are shown in Table 3.

TABLE 3: Evaluation indexes before and after optimization.

| Indexes | Kriging | WOA-Kriging | Optimization effect (%) |
|---------|---------|-------------|-------------------------|
| $R^2$   | 0.9922  | 0.9974      | 0.52                    |
| RMSE    | 2.8569  | 1.6540      | 42.11                   |
| RMAE    | 0.1322  | 0.0754      | 42.97                   |

It can be seen from Table 3 that the correlation coefficient ( $R^2$ ) has increased from 0.9922 to 0.9974, which is 0.52% higher and closer to 1. The correlation coefficient is closer to 1 implying that the global approximation ability of the optimized Kriging model is better. RMSE is used to indicate the impairment between the estimated value and the actual value. The higher the value of RMSE, the greater the impairment. After optimization, RMSE went from 2.8569 to 1.6540, reducing by 42.11%, which shows that the optimized Kriging model can better estimate the samples. After optimization, RMAE decreased from 0.1322 to 0.0754, which is 42.97% lower and closer to 0. This shows that the local error is less after optimization. Therefore, Kriging algorithm is improved based on WOA algorithm, which enhances the fitting ability and accuracy of Kriging algorithm.

The residual graph histogram of the test set for the contact stress prediction model is established by using Kriging and the improved Kriging algorithm based on WOA, as shown in Figures 5(a) and 5(b).

It can be seen from Figure 5 that the error dispersion of the optimized Kriging based on the improved WOA to establish the contact stress prediction model of the circular arc gear is more centralized, and the optimized error range is reduced from  $(-2, 4)$  to  $(0, 3)$ , which significantly improved accuracy.

**4.5. Finite Element Verification.** In order to further verify the validity of the established mathematical model, the finite element method is used to analyze the gear. The definition of material attribute of the model, the establishment of analysis steps and interactions, the application of constraints and moments, and mesh division are the same as those in Section 3. The gear parameters are shown in Table 4, and the results of the finite element analysis are shown in Figure 6.

As shown in Figure 6, the maximum contact stress of the gear is 472.2 MPa. The mathematical model established in Section 4.3 is used to predict the maximum contact stress of the gear in Table 4.

As shown in Table 5, the mathematical model established in Section 4.3 is used to predict the maximum contact stress of gears in Table 4. Compared with the results of finite element analysis, the maximum error is 3.2013 MPa, which shows that the mathematical model can effectively predict the contact stress of gears.

## 5. Influence of Design Parameters on Contact Stress

In this section, the influence of design parameters on contact stress is discussed based on the explicitly mathematical model between the gear design parameters (tooth width,

modulus, pressure angle, and tooth line radius) and the contact stress of cylindrical gear with arc tooth by using the proposed WOA-Kriging model. When the parameters (tooth width, modulus, pressure angle, and tooth line radius) are changed separately, the influence of tooth width, modulus, pressure angle, and tooth line radius on the contact stress of cylindrical gear with arc tooth is shown in Figure 7.

As seen in Figure 7, with the increase of tooth width, modulus, pressure angle, and tooth line radius, the contact stress of the cylindrical gear with arc tooth gear was in decline, which was negatively correlated with the design parameter, the amplitude of contact stress of the cylindrical gear with arc tooth is the largest due to the change of tooth radius, followed by the change of modulus, and the influence of tooth width is less.

The influence of change in tooth width, modulus, pressure angle, and tooth line radius on contact stress of the cylindrical gear with arc tooth is shown in Figure 8.

As seen in Figure 8, when tooth width interacts with modulus, pressure angle, and tooth line radius, respectively, the variation range of contact stress for the cylindrical gear with arc tooth gear is in decline. The response surface is not large and the complexity of surface is not high, indicating that the influence of tooth width interacting with modulus, pressure angle, and tooth line radius, respectively, on the contact stress is not significant. When modulus interacts with modulus, pressure angle, and tooth line radius, respectively, the complexity of the stress response surface is relatively high, which indicates that the influence on the stress is significant, compared with tooth width interacting with modulus, pressure angle, and tooth line radius, respectively. When pressure angle interacts with tooth line radius, the complexity of the stress response surface is relatively high, which also indicates that the influence on the stress is significant. Influence of modulus-tooth line radius interaction on contact stress of cylindrical gear with arc tooth and influence of pressure angle-tooth line radius interaction on contact stress of cylindrical gear with arc tooth are significant. In the contour map above, the smaller the distance between the contour lines is, the greater the influence of their interaction on the contact stress will be.

## 6. Conclusion

In order to study the influence of design parameters of cylindrical gear with arc tooth on its contact stress, a mathematical model of tooth width, modulus, pressure angle, radius of tooth line, and contact stress of gear is established by using Kriging surrogate model. Meanwhile,

a Kriging model modeling method based on the whale optimization algorithm (WOA) is proposed. The parameters of variation function of traditional Kriging model are optimized by whale optimization calculation to improve the modeling accuracy of Kriging model. Based

on the established mathematical model, the influence of design parameters (tooth width, module, pressure angle, and tooth radius) of cylindrical gear with arc tooth on the contact stress of circular arc tooth line cylindrical gear is discussed.

- (1) Based on the improved Kriging model of WOA algorithm, the correlation coefficient ( $R^2$ ) is increased from 0.9922 to 0.9974, MSE is reduced from 2.8569 to 1.6540, and RMAE is also reduced from 0.1322 to 0.0754. The correlation coefficient ( $R^2$ ) of the improved algorithm is improved, and root mean square error (RMSE) and relative maximum absolute error (RMAE) are improved to some extent, which improves the global approximation ability of the traditional Kriging algorithm, reduces the local error, and improves the fitting accuracy.
- (2) Both the traditional Kriging algorithm and the improved Kriging algorithm based on WOA algorithm can establish the contact stress prediction model of gear, and the accuracy is within the applicable range.

The error range of Kriging is  $(-2, 4)$ , while the error range of Kriging algorithm based on WOA algorithm is  $(0, 3)$ . The accuracy of the improved Kriging has been optimized obviously, and the accuracy of the model is verified by the finite element method, where the maximum error is only 2.5935 MPa.

- (3) Based on the established mathematical model, the influence of design parameters (tooth width, modulus, pressure angle, and tooth radius) on the contact stress of circular arc tooth line cylindrical gear is discussed. With the increase of tooth width, modulus, pressure angle, and tooth line radius, the contact stress of the cylindrical gear with arc tooth gear was in decline, which was negatively correlated with the design parameter, the amplitude of contact

stress of the cylindrical gear with arc tooth is the largest due to the change of tooth radius, followed by the change of modulus, and the influence of tooth width is the least. And influence of modulus-tooth line radius interaction and pressure angle-tooth line radius interaction on contact stress of cylindrical gear with arc tooth is significant.

The stochastic resonance system has the advantage of making the noise energy transfer to the signal energy. Because the existing stochastic resonance system model has the problem of poor performance, an asymmetric piecewise linear stochastic resonance system model is proposed, and the parameters of the model are optimized by a genetic algorithm. The signal-to-noise ratio formula of the model is derived and analyzed, and the theoretical basis for better performance of the model is given. The influence of the asymmetric coefficient on system performance is studied, which provides guidance for the selection of initial optimization range when a genetic algorithm is used. At the same time, the formula is verified and analyzed by numerical simulation, and the correctness of the formula is proved. Finally, the model is applied to bearing fault detection, and an adaptive genetic algorithm is used to optimize the parameters of the system. The results show that the model has an excellent detection effect, which proves that the model has great potential in fault detection.

## 1. Introduction

When the nonlinear system interacts with the signal to be measured and the nonsignal to be measured (noise), resonance will occur. At this time, when the noise intensity increases, the noise will not inundate the signal but will increase the signal-to-noise ratio, and the noise energy will transfer to the signal. This shows that stochastic resonance is a powerful method to extract a weak signal from strong noise [1, 2]. However, a large number of studies have shown that the classical SR theory has obvious detection advantages only in the case of small parameters, i.e., adiabatic approximation. In engineering application, most target signals are not small parameter signals, which greatly limits the application in engineering. In recent years, a series of achievements have been made in the resonance phenomenon of large parameter signals, such as the use of secondary sampling, single sideband modulation, frequency-domain information exchange, and other methods, which can make large parameter signals produce resonance phenomenon [3]. In reference

[4], it is known that the piecewise linear model has better performance than the classical model, and in reference [5], the asymmetric model can obtain better performance than the symmetric model by adjusting the asymmetric factor. Zhang et al. applied a stochastic resonance system for bearing fault detection [6, 7]. Zhang et al. found that the performance of the system is also affected by the system parameters [8], and the selection of parameters will directly affect the quality of the system. Zhang and He obtained better system parameters through an adaptive genetic algorithm and applied them to bearing fault detection [9].

At present, some scholars are committed to exploring the effect of asymmetry on system performance [2, 4]. Some scholars have devoted themselves to the study of piecewise linear systems. Both of them can achieve better system performance [10]. However, there is no research on the combination of them to obtain better performance. Based on this, an asymmetric linear piecewise bistable model is proposed. The analytical expression and signal-to-noise ratio of the model are derived and compared with the symmetrical

bistable piecewise linear stochastic resonance system and the continuous bistable system. At the same time, in order to obtain better performance in the application of bearing fault detection, a genetic algorithm is used to obtain better system parameters. In the second part of the paper, the concrete formula derivation is given. It provides a theoretical basis for the simulation and experiment. In the third part, numerical simulation is carried out to verify the correctness of the formula derivation. In the fourth part, the genetic algorithm is proposed to optimize the parameters, which can improve the system performance to the greatest extent. Finally, it is applied to fault detection. The results show that this method can effectively extract fault feature frequency and has better performance than the symmetric model.

## 2. Theoretical Analysis of Asymmetric Piecewise Linear Model

*2.1. Asymmetric Piecewise Linear Model.* The expression of potential function  $U(x)$  is as follows:

$$U(x) = \begin{cases} \frac{k_3}{r(k_1 - k_2)}(x + rk_1), & x < -rk_2, \\ \frac{k_3}{rk_2}x, & -rk_2 \leq x < 0, \\ \frac{k_3}{k_2}x, & 0 \leq x < k_2, \\ -\frac{k_3}{(k_1 - k_2)}(x - k_1) & k_2 \leq x. \end{cases} \quad (1)$$

where  $D$  is the noise intensity,  $r$  is asymmetric factor,  $k_1$ ,  $k_2$  and  $k_3$  are system parameters. The transition rate  $n_{\pm}(t)$  is generally considered to have an exponential form. Under the action of periodic signal  $s(t) = A \cos(\omega_0 t)$ , it is expanded by Taylor series, as shown in the following equation:

$$\begin{aligned} n_+ &= \tilde{\lambda}_+ \left[ 1 + \frac{Ax_m}{D} \cos(\omega_0 t) + \frac{1}{2} \left( \frac{Ax_m}{D} \right)^2 \cos^2(\omega_0 t) + \dots \right], \\ n_- &= \tilde{\lambda}_- \left[ 1 - \frac{Ax_n}{D} \cos(\omega_0 t) + \frac{1}{2} \left( \frac{Ax_n}{D} \right)^2 \cos^2(\omega_0 t) - \dots \right]. \end{aligned} \quad (3)$$

Under the assumption of adiabatic approximation, the probability equation of the model can be established according to (2) and (3):

Among them,  $r$  is asymmetric factor,  $k_1$ ,  $k_2$  and  $k_3$  are system parameters and are all greater than 0. Under the static condition, the system has two potential wells and one barrier. The bottom of the two wells is  $x_+ = k_2$  and  $x_- = -rk_2$ , respectively, and the barrier height is  $\Delta U = c$ .

When  $r = 1$  is a symmetric piecewise linear model, other cases are asymmetric linear systems. It can be seen from Figure 1 that the width of a potential well varies with the asymmetric factor.

*2.2. System Response and Signal-to-Noise Ratio.* The steady state of the system is  $+x_m$ ,  $-x_n$  and  $rx_m = x_n$ . Let  $W_{\pm}(t)$  be the probability of time  $t$  system in bistability  $+x_m$ ,  $-x_n$  and define  $n_{\pm}(t)$  as the probability of transition from steady state  $+x_m$ ,  $-x_n$  at time  $t$ . Because of the asymmetry of the two potential wells, the transition probability of the two potential wells is not the same, that is,  $n_+(t) \neq n_-(t)$ . When the asymmetry factor is  $r = 1$ , the equation holds. According to the adiabatic approximation theory [2], the escape rate of the asymmetric linear bistable system is as follows:

$$\tilde{\lambda}_-^{-1} = \frac{1}{D} \int_{-rk_1}^{-rk_2} e^{-(1/D)((k_3/r(k_1 - k_2))(x + rk_1))} dx \int_{-rk_2}^0 e^{(1/D)((k_3/rk_2)x)} dx, \tilde{\lambda}_+^{-1} = \frac{1}{D} \int_{-k_1}^{-k_2} e^{-(1/D)((k_3/(k_1 - k_2))(x + k_1))} dx \int_{-k_2}^0 e^{(1/D)((k_3/k_2)x)} dx, \quad (2)$$

$$\frac{dw_-(t)}{dt} = -\tilde{\lambda}_- W_-(t) + \tilde{\lambda}_+ W_+(t), \quad (4)$$

$$\frac{dw_+(t)}{dt} = -\tilde{\lambda}_+ W_+(t) + \tilde{\lambda}_- W_-(t).$$

The equations of solution (4) can be obtained as follows:

$$\begin{aligned} W_-(t) &= \frac{1}{2} \left[ \frac{1}{\tilde{\lambda}_-} + e^{-(\tilde{\lambda}_- + \tilde{\lambda}_+)t} \right], \\ W_+(t) &= \frac{1}{2} \left[ \frac{1}{\tilde{\lambda}_+} - e^{-(\tilde{\lambda}_- + \tilde{\lambda}_+)t} \right]. \end{aligned} \quad (5)$$

The probability distribution function obtained from formula (5) is shown in the following equation:

FIGURE 1: Potential function  $U(x)$ .

$$\begin{aligned} \omega_-(t) &= \dot{W}_-(t) = -\left(\frac{\bar{\lambda}_- + \bar{\lambda}_+}{2}\right) e^{-(\bar{\lambda}_- + \bar{\lambda}_+)t}, \\ \omega_+(t) &= \dot{W}_+(t) = \left(\frac{\bar{\lambda}_- + \bar{\lambda}_+}{2}\right) e^{-(\bar{\lambda}_- + \bar{\lambda}_+)t}. \end{aligned} \quad (6)$$

The frequency-domain probability distribution function can be obtained by Fourier transform of formula (6)

$$\begin{aligned} |w(\omega)| &= |w_-(\omega)| + |w_+(\omega)| \\ &= \frac{\bar{\lambda}_- + \bar{\lambda}_+}{\sqrt{(\bar{\lambda}_- + \bar{\lambda}_+)^2 + \omega^2}}, \\ \varphi(\omega) &= \arctan\left(\frac{\omega}{\bar{\lambda}_- + \bar{\lambda}_+}\right). \end{aligned} \quad (7)$$

Since  $A$  is small, the response of the bistable system can be expressed as follows:

$$\langle x(t) \rangle = \bar{x}(D) \cos(\omega_0 t + \bar{\phi}(D)), \quad (8)$$

where

$$\bar{x}(D) = \frac{(1+r^2)Ax_m^2}{D} \frac{\bar{\lambda}_- + \bar{\lambda}_+}{\sqrt{(\bar{\lambda}_- + \bar{\lambda}_+)^2 + \omega_0^2}}, \quad (9)$$

$$\bar{\phi}(D) = \arctan\left(\frac{\omega_0}{\bar{\lambda}_- + \bar{\lambda}_+}\right).$$

The power spectrum of noise can be written as follows:

$$S_N(\omega) = \left[ 1 - \left( \frac{Ax_m^2}{2D} \right) \frac{(\bar{\lambda}_- + \bar{\lambda}_+)^2}{(\bar{\lambda}_- + \bar{\lambda}_+)^2 + \omega_0^2} \right] \cdot \frac{(\bar{\lambda}_- + \bar{\lambda}_+)^2 (1+r^2)x_m^2}{(\bar{\lambda}_- + \bar{\lambda}_+)^2 + \omega_0^2}. \quad (10)$$

The output power spectrum is obtained by Fourier transform of the autocorrelation function, as follows:

$$S(\omega) = \frac{\pi}{2} \bar{x}^2(D) [\delta(\omega - \omega_0) + \delta(\omega + \omega_0)] + S_N(\omega). \quad (11)$$

Then SNR is as follows:

$$\begin{aligned} \text{SNR} &= \frac{\int_{-\infty}^{+\infty} S(\omega) - S_N(\omega) d\omega}{S_N(\omega_0)} \\ &= \frac{(1+r^2)\pi A^2 x_m^2 (\bar{\lambda}_- + \bar{\lambda}_+)}{4D^2 [1 - (1/2)(Ax_m/D)^2 ((\bar{\lambda}_- + \bar{\lambda}_+)^2 / ((\bar{\lambda}_- + \bar{\lambda}_+)^2 + \omega_0^2))]}. \end{aligned} \quad (12)$$

For the system,  $x_m = b$  and obtained from formula (2):

$$\bar{\lambda}_- = \frac{k_3^2}{r^2(k_1 - k_2)k_2} e^{-(k_3/D)}, \quad (13)$$

$$\bar{\lambda}_+ = \frac{k_3^2}{(k_1 - k_2)k_2} e^{-(k_3/D)}.$$

If the higher order term of the denominator in formula (12) is not considered, the SNR can be approximated as follows:

$$\text{SNR} = \frac{\pi k_2 (1+r^2)^2 k_3^2 A^2}{4D^2 (k_1 - k_2) r^2} e^{-(k_3/D)}. \quad (14)$$

When  $r = 1$ , the SNR formula of the symmetrical piecewise linear model shown in [5] can be obtained. According to reference [2], the formula of signal-to-noise ratio of continuous bistable system is as follows:

$$\text{SNR} = \frac{\sqrt{2}u^2 A^2}{4D^2} e^{-(u^2/4D)}, \quad (15)$$

where  $u$  is the system parameter, the barrier height is  $\Delta U = (u^2/4)$ , and the well bottom is in  $x = \pm\sqrt{u}$ ,  $u = 2$ . Select the system parameter  $k_1 = 1$ ,  $k_2 = 1$ ,  $k_3 = 1$ . The height of the potential well is the same as the position of the potential well, and then the asymmetry factor is changed to make a comparative study. When the input signal and noise are identical, as shown in Figure 2, it is the change of SNR with the noise intensity  $D$ . It can be seen from Figure 2 that with the increase of the noise intensity  $D$  of the piecewise linear system and the classical continuous bistable system, the SNR also increases rapidly to the maximum value, but the noise continues to increase and decreases. The asymmetric piecewise linear system also has the same phenomenon, but in the process of noise intensity from small to large, the system is always larger than the other two systems. It can be seen that the higher SNR can be obtained for the asymmetric piecewise linear system with the same system parameters.

### 3. Numerical Simulation of Asymmetric Linear Model

In order to verify the above results, the symmetrical piecewise linear model has been compared with the continuous bistable system in reference [5], and the

FIGURE 2: Variation of SNR with  $D$  in the three systems.

performance of the piecewise linear model is better. Therefore, only asymmetric and symmetric piecewise linear models are compared. According to formula (1), the system model can be written as follows:

$$\dot{x}(t) = -\frac{dU(x)}{dx} + H(t), \quad (16)$$

where  $H(t) = A \cos(2\pi ft) + \varepsilon(t)$ ,  $\varepsilon(t)$  for noise. Its mean value is zero, and autocorrelation function can be expressed as  $\langle \varepsilon(t) \varepsilon(t + \tau) \rangle = 2D\delta(t - \tau)$ .  $D$  is the noise intensity,  $\tau$  is the delay time,  $f$  is the input signal frequency, and  $A$  is its amplitude. The fourth-order Runge Kutta of (1) is simulated [4], and the resonance behavior of  $r = 1$  and  $r \neq 1$  is compared and explored.

Figure 3 is the input signal frequency  $f = 0.01$ , sampling frequency, and amplitude noise intensity  $fs = 5, A = 0.1, D = 4$ , system parameter  $k_1 = 2, k_2 = 1, k_3 = 0.25$ . Figures 3(b) and 3(d) show the amplitude frequency characteristics of the input signal and the output signal, respectively. It can be seen that the spectrum energy concentrates on the low-frequency component. While Figure 4 is under the condition that other conditions remain unchanged, making the asymmetric factor  $r = 1.5$ , it can be seen from Figure 4(a) that the reduction effect is better than Figure 3(c), and from the frequency domain, it can be seen that the energy concentrated on the input signal frequency is higher.

Figure 5 is a comparison of the average signal-to-noise ratio gain [10] of the asymmetric piecewise linear model and the symmetric piecewise linear model under the same other conditions as Figure 4. It can be seen from the figure that the average signal-to-noise ratio gain of the asymmetric model is always higher than that of the symmetric model with the increase of noise intensity, which is consistent with the conclusion of the formula derivation. Figure 5 shows that the performance of the asymmetric system is not superior to that of the symmetric model because the selection of asymmetric

factors is not optimal. Figure 6 is a three-dimensional graph of noise intensity  $D$ , asymmetric factor  $r$  an average signal-to-noise ratio gain MSNRI under the same conditions as Figure 5. It can be seen that  $r = 2$  is not the optimal case. As you can see, the performance improvement is not very high. This is because the asymmetric coefficient is not very suitable. It is because of this that the adaptive algorithm mentioned below is needed to get the appropriate system parameters.

#### 4. Adaptive Genetic Algorithm

The model proposed in this paper has four parameters, namely  $k_1, k_2, k_3, r$  and the dimension of the genetic algorithm is set as four dimensions [11–13]. The key of the algorithm is to transform the solution into the chromosome needed in a genetic algorithm. There are a variety of “chromosome” transformation methods, which can be divided into real number coding (parameter optimization problem) and integer coding (shortest path problem) according to requirements. The genetic algorithm has a wide range of applications. Usually, some changes will be made according to actual needs. In this study, the range of parameter optimization is determined by theoretical analysis, that is, the range of initial gene in genetic algorithm. By replacing the signal-to-noise ratio with fitness function, the purpose of improvement is achieved. The genetic algorithm can be well applied to the stochastic resonance system. The specific process is shown in Figure 7. Specific steps of the proposed algorithm:

The fitness function of the paper is the output signal-to-noise ratio. Signal-to-noise ratio (SNR) is a common measure in signal processing research. The higher the SNR, the better the fitness. Compared with correlation and average signal-to-noise ratio, the genetic algorithm has lower time complexity and little difference in effect.

Initialize population size and iteration: Random selection of individuals to build an initial population.

The fitness function constructed in step (1) is used to calculate the fitness of all individuals. And keep the best individuals to the next generation.

The individual genes in the population were crossed, and when the crossing process met the variation conditions, the cross was executed (5). The crossover operator of the following formula is used:

$$\begin{aligned} X'_1 &= \lambda_1 X_1 + (1 - \lambda_2) X_2, \\ X'_2 &= \lambda_1 X_2 + (1 - \lambda_2) X_1. \end{aligned} \quad (17)$$

Variation, that is to say, the offspring produced genes that the parents did not have. The construction of the mutation operator is as follows:

$$X' = X + \Delta. \quad (18)$$

Generate offspring and replace any random individual in the offspring with the optimal solution individual in step (3). According to whether the termination condition reaches the maximum number of iterations, the algorithm’s branch flow is determined.

FIGURE 5: Average SNR gain.

FIGURE 6: Three-dimensional graph of MSNRI varying with  $D$  and  $R$ .

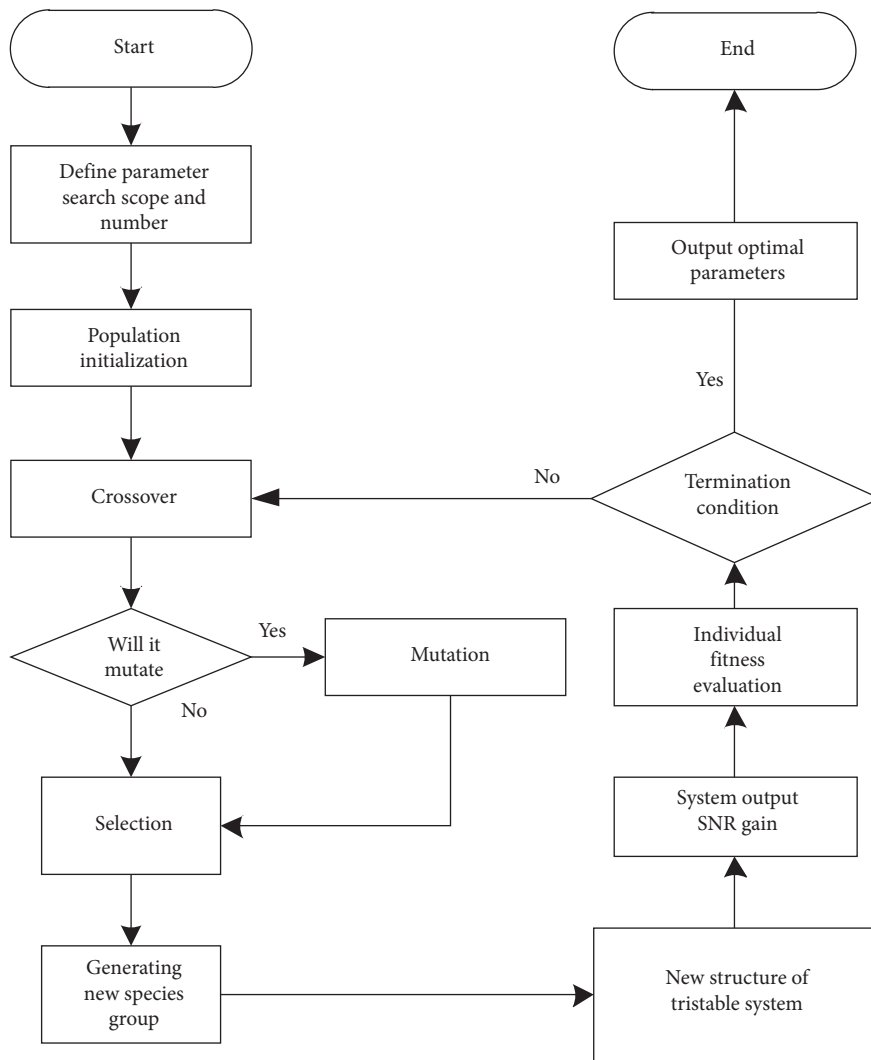

FIGURE 7: Flow chart of genetic algorithm.

Adding optimization parameters to the genetic algorithm will not exponentially increase the time complexity like an ordinary iterative algorithm. The time complexity of the iterative

algorithm is  $o(N^n)$ ,  $N$  is the number of iterations, and  $n$  is the number of parameters. The time complexity of GA is  $o(N * n^n)$ .  $N$  is the genetic algebra,  $n$  is the number of parameters.

TABLE 1: Main parameters of bearing.

| Inner diameter (cm) | Outer ring diameter (cm) | Ball straight (cm) | Thickness (cm) | Stanza (cm) | Number of ball bearings (one) |
|---------------------|--------------------------|--------------------|----------------|-------------|-------------------------------|
| 2.5001              | 5.1999                   | 0.7940             | 1.5001         | 3.904       | 9                             |

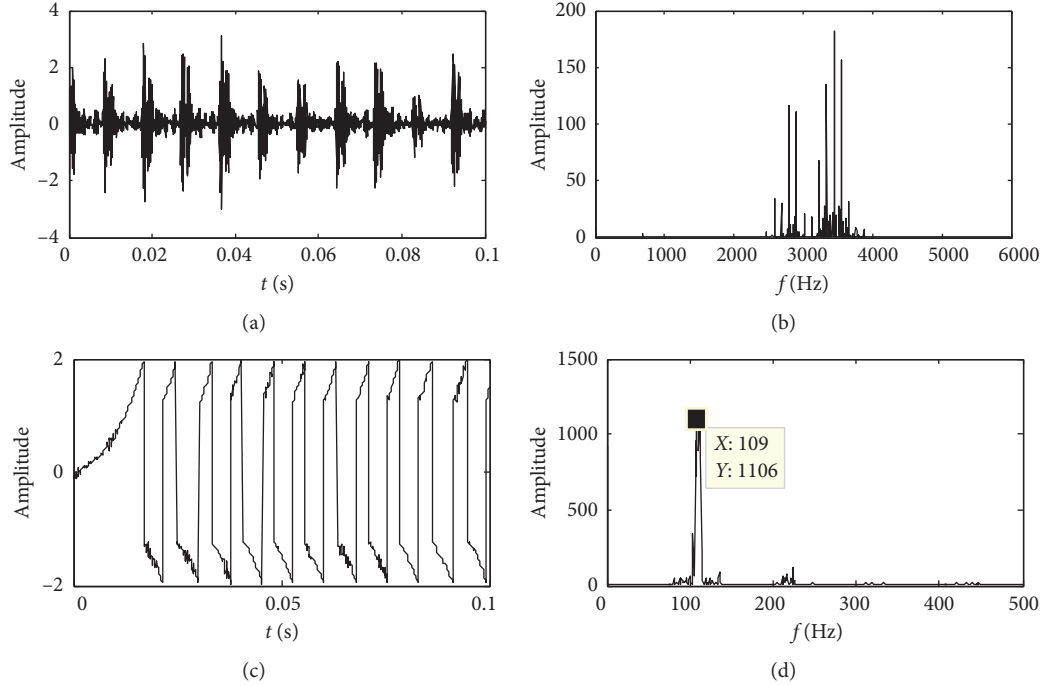

FIGURE 8: Time and frequency-domain diagrams of input and output of outer circle fault detection system ( $a = 0.422000206845763$ ,  $b = 0.01$ ,  $c = 2.645191139445148$ ,  $r = 1$ ).

## 5. Bearing Fault Detection

### 5.1. Fault Characteristics Extraction of the Bearing Type 6205-2RS JEM SKF

**5.1.1. Characteristic Frequency.** The bearing model is 6205-2RS JEM SKF deep groove ball bearing. The main parameters are shown in Table 1. Because the condition of a small parameter is not satisfied, the resonance phenomenon is produced by using the method of second sampling.

Sampling frequency  $f_s = 12000$  Hz, number of sampling points  $N = 10000$ . Here, 5 Hz is selected as the second sampling frequency. The calculation formula of the characteristic frequency is as follows:

$$\begin{aligned} f_{\text{BPFI}} &= \frac{n_r f_r}{2} \left( 1 + \frac{D_1}{D_2} \cos \alpha \right), \\ f_{\text{BPFO}} &= \frac{n_r f_r}{2} \left( 1 - \frac{D_1}{D_2} \cos \alpha \right), \end{aligned} \quad (19)$$

$n_r$  represents the number of rolling elements,  $D_1$  represents the diameter,  $D_2$  represents the bearing, the rotation frequency is  $f_r$ , the contact angle is  $\alpha$ ,  $f_{\text{BPFI}}$  and  $f_{\text{BPFO}}$  are the characteristic frequencies of the inner and outer rings of the bearing, respectively. Substituting the data in the table into equation (19), it is known that the characteristic frequency of

the outer ring fault is 107.28 Hz, and that of the inner ring fault is 162.11 Hz.

**5.1.2. Outer Ring Fault Detection.** Figure 8 shows the input signal of bearing fault to be detected and the output signal of the symmetrical piecewise linear system. It can be seen that the fault signal is completely covered by other high-frequency noises. After passing the SR system, the fault signal is detected. The parameters of this check are all found through the adaptive parameter optimization of the genetic algorithm. The population number of genetic algorithms is 200, the genetic algebra is 200, the crossover probability is set to 0.4, and the mutation probability is set to 0.2. (In the actual natural environment, the crossover probability is much greater than the mutation probability, but in order to jump out of the local optimum, the mutation probability is set to be larger here.)

Figure 9 is an output signal through an asymmetrical piecewise linear system. Compared with Figure 8, it can be seen that the accuracy of amplitude value and inspection at fault frequency is higher than that of the symmetrical segmented system. The time-domain waveforms of the stochastic resonance system are compared. It can be seen that the burr of time-domain waveform of an asymmetric system is obviously less than that of a symmetric system. It is

FIGURE 9: Time and frequency-domain diagrams of the output of outer circle fault detection system ( $a = 1.00619166102941, b = 0.11, r = 1.6, c = 0.284256838355532$ ).

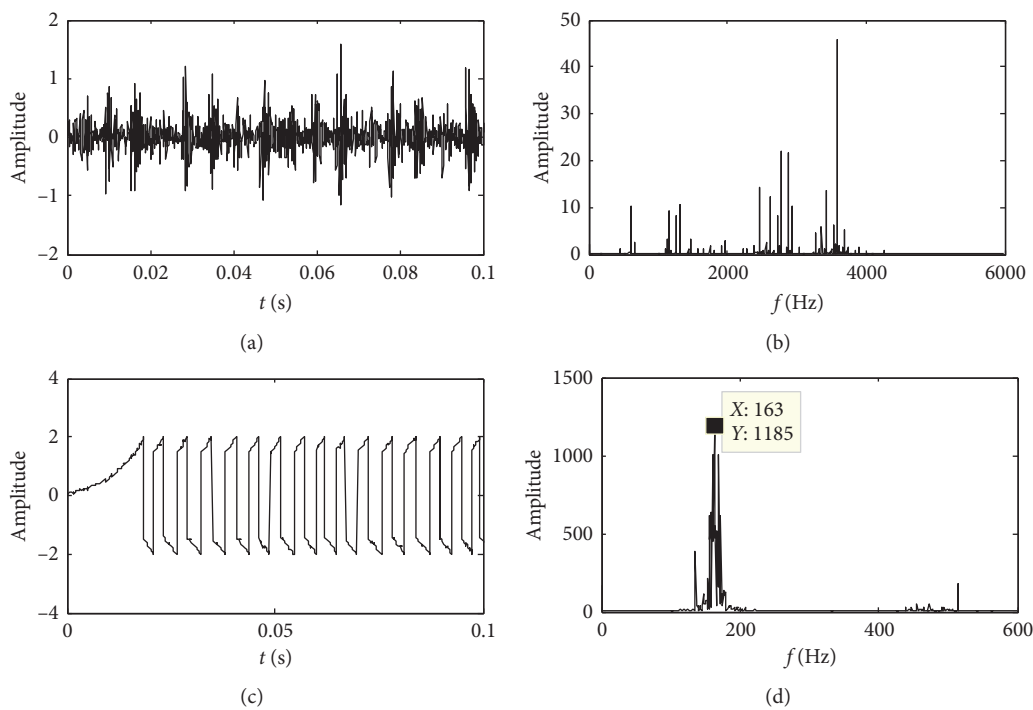

FIGURE 10: Time-domain and frequency-domain diagrams of the input and output of inner-loop fault detection system ( $a = 1.263827550905825, b = 1.226069, r = 1, c = 0.253128458753468$ ).

FIGURE 11: Time and frequency-domain diagrams of the output of outer circle fault detection system ( $a = 0.938548936195951, b = 0.11, c = 2.11048612862940, r = 1.6$ ).

FIGURE 12: The entity diagram of the ID-25/30 test bench.

FIGURE 13: Signal to be detected.

consistent with higher amplitude at fault frequency of frequency-domain waveform.

**5.1.3. Inner Ring Fault Detection.** In order to prove that there is still a lot of room to improve the performance of the system, the number of population and the number of iterations are doubled when a genetic algorithm is used for parameter optimization. Figure 10 shows the signal to be

detected for the inner ring fault and the output signal after the piecewise linear system model. It can be found that the fault signal has been detected, but after a longer time of parameter optimization, the system performance has not been significantly improved.

Figure 11 shows the output waveform of the signal to be detected through the asymmetric piecewise linear model. It can be found that the performance is greatly improved after the time of parameter optimization is increased. It is the

FIGURE 14: Output signal of the piecewise linear system.

FIGURE 15: Output signal of the asymmetrical piecewise linear system.

same as the previous conclusion and proves the superiority of the system.

**5.2. Fault Diagnosis of ID-25/30 Bearing Health Test Bench.** In order to further verify the practicability of the system, it is applied to another group of experimental platform for verification. The physical figure of the ID-25/30 bearing

health test bench is shown in Figure 12. The calculation method of the characteristic frequency signal of bearing fault is the same as the previous one. The frequency of the inner ring and outer ring can be obtained from the formula. The inner raceway frequency of the bearing can be calculated theoretically to be  $f_{\text{Inner}} = 117.14$  Hz.

Figure 13 shows the fault signal to be tested collected by the platform. It can be seen that the fault model is completely

submerged by noise and cannot be detected. Figure 14 is the output graph of the piecewise linear system. It can be seen that the fault signal is detected. This part of the parameters is also optimized by genetic algorithm, which proves the practical value of the system again. Figure 15 shows the output of the asymmetrical piecewise linear system. Figure 15 has a higher amplitude and the frequency doubling has been checked, indicating that the detection effect performance is very good.

## 6. Conclusion

An unsymmetrical piecewise linear system has good efficiency. This paper discusses the performance of the system from three aspects: formula derivation, numerical simulation, and engineering application. The results show that it has a good performance both in theory and in practice, which is consistent with the formula derivation results. Of course, the performance of a system is closely related to its parameters, and it is difficult to find out the coordination between parameters. Therefore, a genetic algorithm is proposed to find better parameters.

The asymmetry mentioned in this paper is the asymmetry of the width of the potential well and the steady state is assumed to be two steady states, which is not explored in the asymmetry of the depth of the potential well and the multisteady state, so we will continue to study in the following work.

In this paper, the forest algorithm and the decision tree algorithm are mainly used to analyze students' physical education information, course exam results, and student learning data and relevant feature attributes from the online teaching platform. We aim to generate decision trees using the decision tree algorithm for the purpose of generating classification rules, based on which we can find factors that are important to students' physical education performance and form data basis for improving teaching quality to help teaching management and teachers improve teaching methods and adjust teaching strategies. We specifically achieved this objective by constructing a model for assessing the effectiveness of student teaching, the steps of which include data collection and preparation, data preprocessing (data cleaning, conversion, integration), model construction (algorithm training), and algorithm optimization, as well as realizing the simulation results of the model. At the same time, the importance of the relevant attributes of the model is analyzed, and some measures are proposed to improve the universities: the standard of physical education teaching and the corresponding strategies for improving teaching methods. The mainstream development environment is chosen to ensure the complete operation of the project system that integrates learning, operation, and evaluation. The sports virtual simulation experimental teaching system realized in this paper has good functionality, stability, and application benefits in operation and use.

## 1. Introduction

The report "Quality Physical Education: A Guide to Action for Policymakers," published by UNESCO, states that physical education is the only way to combine the development of physical motor skills with the learning and communication of values and is the ideal path for students to acquire core competencies [1]. The study of physical education in universities is the final stage of being able to receive formal physical education and is an important way to refine and improve their knowledge of physical education, and the development of physical education in universities is a prescribed requirement imposed by school education, as well as meeting the needs of the development of sports [2]. The results of the survey on the physical health of

adolescents found that the lung capacity of university students from recent years is a declining trend. Students also have poor vision, neurological failure, and cardiovascular disease, and some of the problems have seriously affected physical and mental health. Compared with university students in developed countries of the world, the fitness and health of university students need to be improved [3]. Existing studies have concentrated on the development of the core competencies of physical education and are directed at transforming and teaching the physical education curriculum, and most of them focus on the theoretical aspects of the basic education field. These studies neglect the factors that influence the development of the person himself as well as other aspects [4]. Therefore, this study is not limited to the disciplinary boundaries but is based on the development of

core human sports literacy as the starting point, in addition to the study of the strategies for the development of core human sports literacy in higher education [5]. Based on the development of higher education, on top of the rich experience in implementing quality education and under the accumulation of practical teaching, the college students' sports core literacy has been promoted [6]. Many factors are influencing the development of college students' physical education core quality. First of all, physical education, as one of the important influencing factors, is the main way for college students to participate in physical exercise, which is closely related to the professional quality of physical education teachers as well as the school's implementation policy, management system, sports environment, and organization of extracurricular sports activities [7]. Therefore, to be able to better cultivate students' sports core qualities, the whole school should be placed in the cultivation system, seek the cultivation implementation way, and optimize the cultivation strategy.

Pai et al. based their PageRank model on the performance statistics and ranking of student-athletes in basketball, hockey, and other sports to assess the individual and team performance of students in a more comprehensive way and to promote their participation in learning [8]. The quantitative performance assessment was used to define the students' game performance, and the qualitative assessment of the students was implemented with a personalized interview form to facilitate the participants' perception and experience of the game performance [9]. At the level of the structural design of the physical education curriculum, Martin et al. in their paper analyzed the new concept of physical education curriculum in comparison with traditional teaching [10]. On this basis, they discuss the importance of classroom assessment as it evolves. The research points out that the New Physical Education (NPE) curriculum perspective, based on national development and youth health issues, has significant implications for traditional curriculum design, implementation, and assessment [11]. Furthermore, research on assessment for physical education and learning has focused on communication and linkages between schools, communities, and families; for example, Kim et al. studied parents' perceptions of school assessment and the need to improve the school's curriculum based on parents' views [12]. Dieter et al. have further analyzed the physical education model (SEM) to assess students' motivation from the perspective of self-determination theory, stating that students need a certain time to determine their behavior in an educational environment. One of the most effective means of dealing with classroom assessment is the design and use of rubrics [13]. Mao et al. state that the use of rubrics to determine students' overall learning performance can greatly enhance students' motivation [14].

As can be seen, there are quite several articles and writings on assessment for physical education learning. Whether it is about the relationship between learning assessment and curriculum development or the specific implementation and application of learning assessment, it is evident that physical education learning assessment has become an important hotspot in today's education sector. It

is necessary to establish the educational concept of "health first" and to provide adequate physical education classes, to help students enjoy fun, strengthen their physiques, enhance their personalities, and temper their wills in physical exercise. These important discourses have greatly elevated the status of college sports and are important guidelines for college personnel training. Apply the software theory to the evaluation system functional requirement analysis, design the main functional modules, realize the decision support system based on data mining and simulation, improve the work efficiency of the evaluation department, and provide decision guidance through certain mining analysis. The research proposes a simple and effective data warehouse design and implementation method and uses online analysis and processing technology to analyze the data in the data warehouse and provide basic data for subsequent data mining. After studying and researching the commonly used data mining algorithms and understanding the characteristics of different algorithms, a decision tree algorithm suitable for this data mining is selected based on the data studied in this paper, an improved algorithm is used to establish the mining model, and the mining results are analyzed to extract valuable decision information. According to the problems found by applying the decision tree algorithm, the algorithm is studied in depth, analyzed, and compared, combined with the characteristics of the data of this project, and the analysis of data mining and data warehouse and online analysis and processing techniques are used to obtain useful information to provide a meaningful reference for decision making in the evaluation of physical education.

## 2. Design of a Decision Tree-Based Model for Assessing Teaching Effectiveness in Universities

*2.1. Improved Decision Tree Algorithm and Computer Simulation Design.* As one of the most commonly used methods for data mining, the decision tree algorithm has been widely used in different fields since its introduction. It has undergone a long process of going from shallow to deep and from simple to complex. The decision tree is a top-down, recursive division that uses a top-down, divide-and-conquer approach, and its basic algorithm is essentially greedy [15]. Starting from the root node, each nonleaf node is found to find an attribute in its corresponding sample set to test the sample set, and the training sample set is divided into several subsamples according to the different results of the test. Each subsample set constitutes a new leaf node, and the above process is repeated for the new leaf node so that the loop continues to reach a specific termination condition [16]. The flexible approach to management adopted by teachers and teaching, which is determined by the characteristics of university work, is to go to class when there are classes and then to have free time when there are no classes. While this is conducive to research and learning, it is also likely to keep certain aspects of teaching, such as lesson planning, homework revision, and lab instruction, out of control. The

decision tree adopts a top-down recursive approach to compare and evaluate the attribute values of nodes within the decision tree and determine the branch down from the node based on the different attribute values. One of the biggest advantages of the decision tree-based learning algorithm is that it does not require the user to acquire a lot of basic knowledge during the learning process, as shown in Figure 1.

The process of constructing a decision tree is divided into two steps: tree building and pruning. The first step is the tree building stage, which selects part of the training data and builds a decision tree by the breadth-first recursive algorithm until each leaf node belongs to the same class. The second step is the pruning stage, which uses the remaining data to check the generated decision tree and correct the errors, and it finally prunes the decision tree and adds nodes until a correct decision tree is built. The decision tree building algorithm is a recursive process that ultimately results in a decision tree, and pruning reduces the impact of noisy data on classification accuracy. In general, the greater the information gain, the greater the “purity improvement” obtained by using features to partition the dataset. Therefore, information gain can be used to select attributes for decision tree partitioning, which is to select the attribute with the greatest information gain.

Information gain is the amount of change in the desired information, which mainly reflects the method of sample feature importance, and there is a positive correlation between the two: the importance of the sample feature increases and decreases with the amount of information gain. Information entropy is mainly used to measure the amount of information, so we define the entropy  $w$  of data [17].

$$\begin{aligned} Q_L(w) &= \frac{1}{2} \sum_{i,j} P_{ij} (w^T x_i - w^T x_j)^2 \\ &= \frac{1}{2} \sum_{i,j} P_{ij} (w^T x_i - w^T x_j)(w^T x_i - w^T x_j). \end{aligned} \quad (1)$$

The information gain rate and destination information gain will tend to select the attribute with the larger information gain value. It applies a parameter value to the specification of the information gain, which is calculated as follows [18].

$${}^G D_t^v f(t) = \lim_{h \rightarrow 0} \frac{1}{h^v} \sum_{m=0}^{\lfloor t-a/h \rfloor} (-1)^m \frac{\Gamma(v+1)}{m! \Gamma(v-m+1)} f(t-mh), \quad (2)$$

and based on this, the formula for calculating the gain rate can be obtained as follows:

$$m_i(g) = \frac{\text{fit}_i - \text{worst}(g)}{\text{best}(g) - \text{worst}(g)}. \quad (3)$$

There are many algorithms for generating decision trees in data mining, and several typical decision tree generation algorithms are highlighted below. The ID3 algorithm is the most influential and typical in decision tree mining, which

selects test attributes for each nonleaf node in the tree through a set of rules based on information theory, using entropy as the basis for classification, and finally classifies the data into the form of a decision tree [18]. The basic idea of the ID3 algorithm is to use information entropy as a measure of attribute selection of decision tree nodes; each time it first selects the attribute with the most information, i.e., the attribute that can change the entropy value to the smallest, to construct a decision tree with the fastest decrease in entropy, so that the entropy value at the leaf node is 0 [19]. Currently, the set of instances corresponding to each leaf node belongs to the same class. Since the attribute with the highest gain of information is always selected to divide the rules, the algorithm classifies data quickly, the depth of the tree is average, and the division rules are simple. The ID3 algorithm is important in the process of constructing a decision tree: attribute determination and set partitioning. The process of attribute determination is to select the attribute with the largest value of gain information from the selected data as the root node and construct a branch with the attribute value of this node to divide the selected data into several unrelated subsets; after branching the nonleaf node, it will determine the attribute of the subset value twice and then continue to branch until it branches to the leaf node.

C4.5 is a classification decision tree algorithm in machine learning, which is based on the ID3 algorithm and improves on the advantages of ID3 again. This algorithm uses the concept of information gain or entropy reduction to select the optimal division, to better realize the construction of the decision tree: (1) It selects attribute columns based on the information gain rate, overcoming the deficiency of biased selection of attributes with more values when selecting attributes with information gain. (2) It constructs a decision tree. The tree pruning process is completed in the tree construction process. (3) The data of continuous attributes are processed by applying discretization. (4) The tree pruning construction is also used for incomplete data. The ID3 algorithm can only solve the discrete data attributes, but the C4.5 algorithm can handle the discretized continuous attributes well, with the following procedure.

$$Q(w) = \frac{Q_N(w)}{Q_L(w)} = \frac{\text{tr}(w^T X L_N X^T w)}{\text{tr}(w^T X L X^T w)}. \quad (4)$$

Computer simulation (data visualization), as the name implies, is a simulated representation of data that uses computer graphics and image processing techniques to interpret data through analysis, transformation, and graphic patterns (including animation) in either planar or three-dimensional form, while providing methods, theories, and techniques for interaction [20]. It helps people to view data and the relationships between data more visually. The atlas of computer simulation is composed of a large amount of data. Each data item is the basic unit of the atlas, and the value of each attribute of the data is represented by the multidimensional terms so that the user can observe and analyze the data from different angles to better serve the user and help the user to make decisions. Simulation technology is the data mining results of abstract information, with a

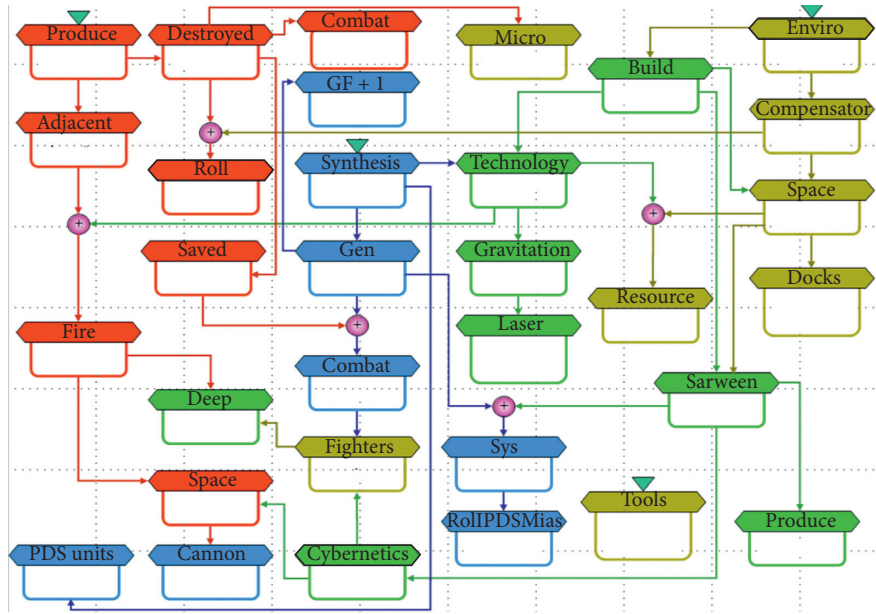

FIGURE 1: Model of improved decision tree algorithm.

simple and intuitive form of expression, to deepen the user's understanding of the meaning of the data, while understanding the interrelationship between the data and development trends. The characteristics of computer simulation technology are as follows. There is strong interaction with the user. The user is no longer simply a receiver of information but can also manage, process, and develop the data. Computer simulation technology can classify, arrange, and present data from multiple perspectives. For example, users can view data time, percentage, rank, and other dimensions. Users can view data and analyze it using simulation charts, histograms, line graphs, puzzles, etc. [21].

Scientific computational simulation refers to the use of computer graphics and image processing techniques to display engineering measurement data, data generated by scientific calculations, and calculation results on the screen and transform them into images. They can also be processed interactively using theoretical methods and techniques. The classification of scientific computing data is relatively extensive and can be divided into structured, unstructured, and mixed data according to different data structures or scalar, vector, and tensor according to data types. Scientific computing simulation technology faces two difficulties in the development process: first, the way to classify the object data by research; second, how to display the simulation object on the screen practically and effectively, making users view it interactively.

*2.2. Evaluation Design of the Effect of Physical Education in Universities.* Model building is at the heart of data mining, which means determining which algorithm to choose to build the decision tree. The implementation of the algorithm requires certain tools for programming. In this paper, MATLAB tools are used to build the CART decision tree. There are three main reasons for this. Firstly, the research

content of data mining is the learning and application of models and algorithms, and MATLAB is particularly suitable for algorithm development. Because MATLAB can directly call a rich library of mathematical functions to quickly implement algorithms according to the flow steps of the algorithm, the programming workload using MATLAB will be greatly reduced when the computational requirements are the same. The syntax of MATLAB is more intuitive than Python or R, and the learning and programming of algorithms are easier. Secondly, MATLAB has efficient and rich scientific computation functions, including calculus, matrix computation, and symbolic computation, and system simulation applications are very extensive. Thirdly, MATLAB itself is a program development tool with a friendly GUI development function [22]. MATLAB was used to learn the principle of algorithms in depth, and then hands-on programming computer programs were deployed to solve many machine learning problems in practical applications. Using MATLAB is more focused, and the toolbox is mostly developed in C. The tools are all interconnected, and it is easier to get started if you have or understand this data mining knowledge and then apply these tools, as shown in Figure 2.

From the above rules, by analyzing the meaning of the rules in detail, some teaching strategies can be adjusted for the problems that arise, such as the need to have relatively effective teaching methods in the online teaching platform, whether to make it mandatory or set open assignments (conscientious students do open assignments, while lazy students do mandatory assignments) and guide students to learn independently. Other aspects, such as out-of-province students with a poor foundation and students with a good foundation who also fail exams, can be predicted pre-intervention can be made; students with good English scores generally have a positive attitude to learning and are encouraged to study professionally. Since the data is not

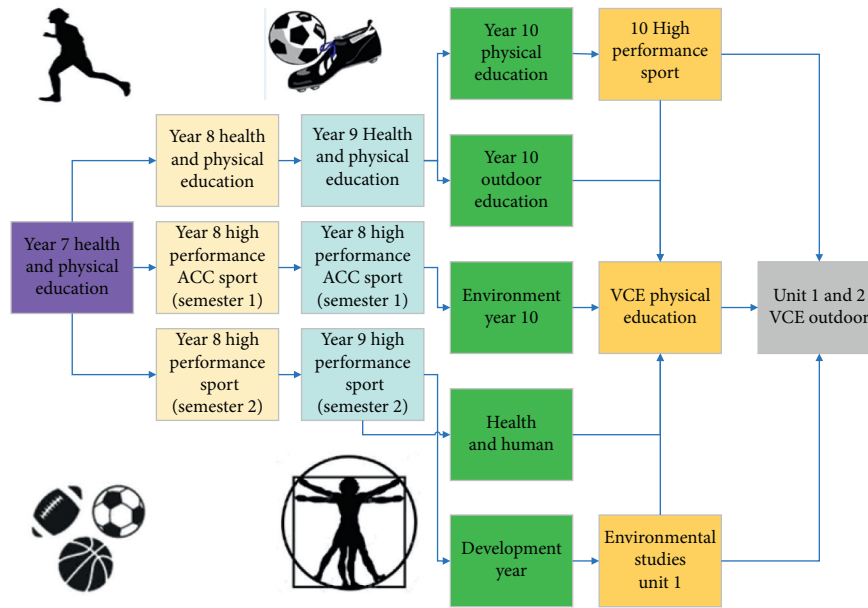

FIGURE 2: The design of physical education effectiveness evaluation.

complete and comprehensive, the results obtained can only serve the major students' local construction advice, but to some extent to make the assessment of student learning effectiveness possible. With the continuous deepening of the new curriculum, curriculum reform is steadily advancing in depth; in the gradual integration of the new curriculum concept and classroom teaching, we have made some achievements and accumulated some experience in the classroom. At the same time, many problems often arise in the classroom, which we did not anticipate in advance, when we must think of a good strategy and find a good way to solve them.

With the development of colleges and universities and the advancement of network technology, the introduction of data mining technology, visualization technology, etc. into the assessment information management system of colleges and universities will provide great convenience and work efficiency. Besides, through data mining technology to analyze student information over the years, you can find some valuable laws and factors that affect the assessment of student reporting, hence more scientific guidance to adjust our plans and decisions. The design of the database system directly affects the quality and operation of the assessment management system. The relative independence, data integrity, and consistency of the database were followed in the design of the database. According to the design features of this system, the traditional database processing mechanism differs greatly from the decision analysis needs and cannot handle online analysis processing, so a data warehouse was established based on the database for the data between different databases. The evaluation management information of this system uses SQL Server 2012 as the software for data storage and management, and this paper only takes the design of the evaluation database as an example, aiming to illustrate the relationship between data tables, databases, and data mining functions and visualization functions.

**2.3. Performance Evaluation Design.** When performing data mining algorithms, to improve the college's reporting success rate, the assessment dataset is used as the object of study; therefore, the decision tree algorithm is used to analyze the key attributes of the assessment data source that may affect the reporting rate and to identify the factors that are most likely to affect the student reporting, so that these potentially relevant influences can be scientifically applied to provide key decisions for future assessment work. The advantages of decision tree algorithms include easy-to-understand analysis, high classification accuracy, and high execution efficiency, making decision tree algorithms well-suited for use in mining large amounts of data. The commonly used decision tree algorithms are ID3 and C4.5, but the two algorithms are very different in the selection of splitting rules. ID3 selects the classification criterion of information gain, which is to select more attribute values as splitting attributes, and it can only mine nonlinear data. C4.5 evaluation classification criterion is the information gain rate, that is, according to information; therefore, C4.5 can effectively circumvent the problems of ID3. Moreover, through the comparative analysis in Section 2.1, the decision tree algorithm of C4.5 is preferred to be used for data mining for better attribute factors, as shown in Figure 3.

The improved algorithm merges branches with higher and lower entropy values, i.e., branches where the division is not important, effectively reducing the fragmentation problem, improving branch efficiency, and limiting the impact of the overfitting problem. In contrast, this paper studies the promotion of assessment in universities, with diverse student sources, but the number of people assessed in each major is relatively small due to local and other reasons, so this requires a more balanced analysis of the diverse assessment channels and student sources, to prevent analysis bias. The improved C4.5 decision tree algorithm makes better use of memory space, balances the selection of

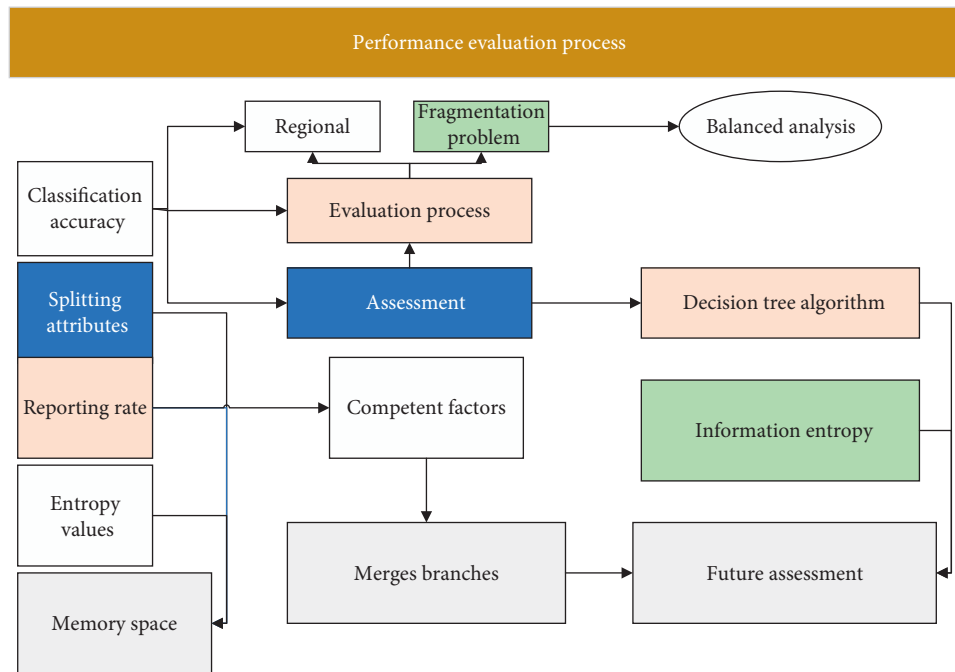

FIGURE 3: Performance evaluation process design.

information entropy, and avoids low or high information entropy caused by the human influence of competent factors, which is more conducive to a more accurate decision tree.

Due to the small data amount selected in the selection of the training set, there may be some deviations in the obtained mining model, and then the training set model is verified through the test set to verify whether the model is accurate, so that the mining model can be further improved and revised, which will be analyzed in the decision tree analysis function module of the system module analysis.

### 3. Results and Analysis

**3.1. Analysis of Assessment Results.** It is found that the more the decision tree base classifiers are, the smaller the generalization error will be. The accuracy of the algorithm is close to 98.25% compared to 8258% for a single base classifier. This is comparable to the accuracy of the CART algorithm. This shows that the decision tree algorithm can predict new data better than the CART algorithm.

In Figure 4, it is found that the prediction error rate of the classifiers is decreasing; i.e., the prediction accuracy rate is increasing. It is more clearly known that the algorithmic accuracy of the decision tree keeps improving with the increase in the number of classifiers. Evaluating the decision tree classification performance cannot be done by simply counting the accuracy of a single breakpoint, but it requires analysis of the classifier's ROC curve, AUC value, and other metrics. The decision tree algorithm is used to validate predictions for 30.25% of the test sample and compare them with the true category. The ROC curve and AUC value are calculated and Figure 5 is obtained. It has an AUC value of

0.7444, although the ROC and AUC metrics are improved by a point over the CART algorithm and the decision tree is more accurate. However, whether the comprehensive performance of this algorithm can still be improved remains to be explored further by the experiment. The ROC (Receiver Operating Characteristic) curve and AUC (Area under the Curve) values are often used to evaluate a binary classifier (the advantages and disadvantages of ROC and AUC (classifier) are discussed here). The ROC and AUC are used in the evaluation of model prediction results when doing medical image computer-aided pulmonary nodule detection in the past. The characteristics of ROC and AUC are briefly introduced here, and how to make ROC plots and calculate AUC values is discussed in more detail.

An analysis of the unsatisfactory experimental results, in terms of the distribution of the dataset, reveals possible causes. One is the problem of data imbalance in the dataset. The target variable classification ratio in the two-category dataset was 586:110 (pass or fail). Afterward, we adjusted the target classification ratio to 407:258 (mean division) for training, made predictions on 30.25% of the test data, and then conducted the ROC curve and AUC value statistics. The expected experimental effect was achieved. The decision tree algorithm can predict the classification more accurately. However, the importance of the attributes of the independent variables cannot be represented as clearly as the decision tree. According to the most important attribute summarized in the decision tree (professional grades), after removing this attribute and retraining the classifier, the false and true rates of the test set can be calculated to obtain the ROC curve Figure 6, which has an AUC value of 0.611 and a decrease of 23.34%, which shows the importance of this attribute. Similarly, the ROC curve and AUC value can be

FIGURE 4: Number of base classifiers and generalization error.

FIGURE 5: ROC of a decision tree on 30% test set.

statistically determined by removing the other attributes. In this way, we can indirectly analyze the characteristics of the most important attributes that affect the target variable.

The AUC of the highest decision tree algorithm is only 0.8441, which is far from excellent performance. The highest decision tree algorithm has an AUC of only 0.8441, which is far from excellent performance. However, the actual classification application in this dataset can predict the classification more accurately and meet the practical application requirements.

The CART and RF algorithms are used to train the data. Firstly, the CART model is used as a single classifier, and the CART classifier is used as a base classifier. The data is trained using the random forest algorithm with different numbers of base classifiers, resulting in four integrated classifiers and a total of five classifiers. The new data table “data” is predicted using each classification model, and the predicted results are compared with the actual classification labels, as shown in Figure 7.

The results show that for both decision tree (CART) and random forest (RF) algorithms, by constructing a random forest algorithm based on CART classifier, the random forest

algorithm integrated with a different number of base classifiers enhances the classification evaluation indexes, in which the true rate, precision-P, recall-R, and F1 value are improved, and the classification performance of the model reaches the expected results. The accuracy of the random forest algorithm is 0.981 for the 5-tree classification model, 0.99 for the 10-tree classification model, and 0.991 for the 20-tree and 100-tree classification models. The classification accuracy has reached the ideal state. As for the comprehensive performance ROC and AUC metrics of the classifier, a comparison has been given in the previous section and will not be repeated here.

In the process of predicting student achievement using classification algorithms, the performance of the final classification model is related to not only the criteria of algorithm goodness and split attribute selection, but also the collection of raw dataset and data preprocessing. The key to classifying and predicting student performance is the need to filter out the main attributes that influence student course performance from the attribute characteristics of the raw data, use this influencing factor as a candidate attribute set, and construct a classification prediction model with student test scores as the target variable. It is found that the attribute set of the raw data may not be very comprehensive and may lack some of the main feature attributes; then, the accuracy of the constructed classification model will not be very high. Therefore, the algorithm is not a panacea; there is no perfect algorithm in the world, and perfect data needs to be collected to implement it. Anomalous data in the dataset can also affect the classification accuracy of the model. It affects a single decision tree model more, while integrated combinatorial models are relatively less easy to affect, and it has a strong generalization ability. However, if multiple trees are trained on the same data, it is also easy to get strongly correlated trees, and then the effect is rather bad, which is all related to the choice of the sample set and attribute selection.

**3.2. Analysis of Computer Simulation Results.** According to the system test case design scheme, the virtual simulation experimental system of “Human Movement Ability Assessment and Fitness Path Design” was tested. 48 test cases were set up and the test report is shown in Table 1.

Among them, 18 user interface test cases, 20 functional test cases, and 10 performance test cases passed the test at a rate of 100%, which shows that the system has passed the application test and can be put into teaching application, as shown in Figure 8.

The interaction of the system is the basic characteristic of virtual simulation experiments. According to the constructivist theory, keeping good interaction in the learning process can effectively stimulate learners’ motivation and enhance the learning effect. Ease of use is an important dimension to evaluate the logic and science of the virtual simulation experimental teaching system in terms of functional design, which can provide important instructions for the design and optimization of the system. Besides, the vivid experimental scenarios and easy-to-use operation

FIGURE 6: ROC curve with the main independent variables removed.

TABLE 1: Test cases.

| Test cases | Number of questionnaires issued | Number of questionnaires withdrawn | Number of valid questionnaires | Recovery rate (%) | Efficiency (%) |
|------------|---------------------------------|------------------------------------|--------------------------------|-------------------|----------------|
| Numbers    | 12                              | 16                                 | 20                             | 93.65             | 94.86          |
| Parents    | 14                              | 14                                 | 20                             | 87.47             | 86.74          |
| Total      | 14                              | 15                                 | 19                             | 88.47             | 85.78          |

procedures are also beneficial to the efficient operation of the knowledge learning process, which is an effective extension of the traditional experimental sports education.

The usefulness of the system is one of the indicators to evaluate the teaching effect of sports virtual simulation experiments. The goal of sports virtual simulation experiments is to meet the actual needs of sports experimental teaching and improve the teaching effect of the experiments. By evaluating the usefulness of the system, we can clearly understand the learners' knowledge of virtual

simulation experiments, to provide a basis for the assessment of the practical effect and teaching significance of sports virtual simulation experimental teaching system. The motivation of the system is the psychological feedback of the learners after using the virtual simulation experimental system. The high level of motivation indicates that the learners recognize the value of the virtual simulation experiments in terms of learning effect; on the other hand, it also indicates that the system can dig deep into the learners' learning needs to strengthen their desire for

FIGURE 8: Test report of virtual simulation experimental system.

FIGURE 9: Descriptive statistics of sports virtual simulation experiment.

learning sports knowledge, which reflects the guiding role of the virtual simulation experiments in sports to the learners. The development of virtual simulation experimental teaching in higher education is an important content of higher education informatization. This paper points out the necessity of virtual simulation experimental teaching according to the experimental practice of higher education in China, analyzes the problems of the current virtual simulation experimental teaching project, and proposes the sustainable development mechanism of virtual simulation experimental teaching project.

The application function and teaching effect of sports virtual simulation experimental teaching are evaluated by a Likert five-point scale and the specific results of statistical analysis are shown in Figure 9. The above results show that the test subjects are highly satisfied with the virtual experiment of “Human Movement Ability Assessment and Fitness Path Design,” with an average score of more than 4, which indicates that the four dimensions of interactivity, usability, usability,

and motivation of the system are at a relatively good level, and the system is recognized and praised by the test subjects.

From the evaluation feedback of interactivity, ease of use, usefulness, and motivation, we can see that the system can build a virtual simulation teaching scenario with good interactivity, which enables the test subjects to use the virtual experimental equipment and instruments easily, freely, and fluently to learn and explore sports knowledge independently and improve their sports knowledge, practical application ability, and learning motivation.

In this paper, two decision tree algorithms, ID3 and C4.5, are used to select the same training dataset to construct models of student reporting situations, and then the same test dataset is used to evaluate the performance of these two different models. The best performing algorithm is shown in Figure 10.

The accuracy of the two algorithms was calculated according to the formula for the accuracy assessment index, and Figure 10 shows that the accuracy of C4.5 is significantly higher than that of the ID3 algorithm.

FIGURE 10: Accuracy rate and precision rate.

#### 4. Conclusion

In this paper, the CART algorithm is applied to the analysis and prediction of students' basic information, course test scores, and e-learning platform learning behavior characteristics. In addition, a CART model is constructed based on the improved decision tree algorithm to study the effectiveness of physical education in universities and to study its evaluation model and computer simulation. The CART identifies rules for correlating student learning factors, and some pedagogical strategies can be adjusted, such as the need to have a relatively effective teaching method in the e-learning platform, whether to make it mandatory or set open-ended assignments to guide students' independent learning. In addition to guiding the importance of foreseeing the building of the profession in terms of student and professional teaching, some degree of assessment of the effectiveness of student learning may be achieved. There are many different methods of data mining, among which decision trees and random forests have a very wide range of applications and practical implications. This is because they are theoretically clear, easy to understand, relatively computationally modest, and highly accurate. In this paper, the application of CART algorithms to the analysis and prediction of the assessment of student effectiveness in physical education is significant.

Recently, the development and utilization of industrial heritage resources by using big data has gradually attracted attention. This paper proposes a real-time visualization optimization management simulation of an industrial heritage cloud platform, which realizes the high reliability and diversified storage and utilization of industrial big data by the cloud data distributed storage subsystem. The big data prediction model of the GRU neural network based on a spark distributed framework is constructed to realize the prediction of industrial genetic data. Finally, visualization technology can provide information supporting for industrial production by displaying effective information intuitively. The model's effectiveness and reliability are verified by simulation.

## 1. Introduction

China's industrial development level has reached a new stage due to the gradual improvement and rapid development of today's social and economic system [1]. In order to better adapt to the industrial development environment of modern society, it is imperative to do a good job of industrial heritage information analysis, which is also an important research topic of modern industrial enterprise development [2, 3]. The protection and management of industrial heritage data is of great significance for enterprises to better analyse the industrial development history and the evolution process of industrial development [4]. Therefore, according to the existing big data information technology application, it is necessary to do a good job in the management and integration of industrial heritage resources, so as to provide effective industrial history development content for the development of modern industrial enterprises and make the modern industrial development conform to the development of the social system. The basic demands are of great significance to guide the industrial development [5]. Especially, in the era of big data, people's workload of processing information is increasing [6]. Therefore, in order to

effectively save the time of information processing and improve the efficiency of information processing, more and more fields begin to use visual methods to process data, and the main emphasis is on the comprehensive processing of some large-scale information [7]. The advent of the big data era is both an opportunity and a challenge for information processing. Therefore, relevant staff should strengthen the development of visualization technology so as to provide technical support for actual data processing [8].

At present, many scholars at home and abroad have carried out certain research and exploration on the application of industrial big data at the level of technical tools. The literature [9] has sorted out the current situation of the use of big data in industrial enterprises in the world, elaborated and summarized the current use needs of industrial big data and the difficulties to be overcome, and pointed out the key direction of its application research in the future. The paper elaborates the importance of industrial big data for the development of intelligent manufacturing, as well as the current development status of industrial big data in this field, and puts forward the current lack of industrial data standards, data security problems, and future development suggestions. The literature [10] studies the application status

of big data technology in industrial production workshop and summarizes the importance of big data technology in this field. The literature [11] analyses the current use of big data technology in industrial and mining enterprises from various aspects and analyses the challenges faced by big data in this field and the development direction in the future. In recent years, as a representative of the LSTM algorithm, the time series data prediction and analysis method based on the deep neural network model has accumulated certain research results. ARIMA (autoregressive integrated moving average model) time series model and other neural network algorithms are used to mine and analyse a kind of time series data [12]. However, the ARIMA method has strict requirements for data conditions and needs to meet the stability of the target data and cannot process the nonlinear information in the data to a certain extent. In the literature, the algorithm of combining CNN (convolutional neural networks) and RNN (recurrent neural networks) is used to transform keystroke time data into keystroke vectors so as to complete the learning of personal keystroke vector sequence data [13, 14]. In the literature [15], an improved RNN model based on the time series decomposition backward propagation algorithm is proposed, and a RNN prediction model based on time series decomposition is established, which improves the accuracy of prediction [16]. Although the RNN algorithm has a certain memory ability for the input of the past time, it cannot solve the problem of gradient vanishing or gradient explosion [17]. The LSTM neural network algorithm is used to predict the bus time from the starting point to the target location [18]. A prediction model based on RNN for obtaining information is proposed, which can achieve high accuracy prediction for messages [19]. Although the LSTM algorithm overcomes the problems of RNN gradient vanishing and gradient explosion, its structure is too complex and the model parameters are too many, so the training time is doubled. Especially in the face of large-scale data set analysis and processing requirements, this method is difficult to meet the actual computing speed requirements [20, 21].

Therefore, in order to solve the practical application problems of the above industrial big data technology and the performance problems of data mining algorithms, this paper constructs a small private cloud platform, which is built on the current mainstream Hadoop distributed computing platform. At the same time, to solve the algorithm performance problems of cloud platform analysis, it uses the GRU (gated recurrent unit) recurrent neural network combined with a spark distributed computing engine to realize the prediction and analysis of industrial time series big data, and the effective information is displayed by data visualization method. The simulation shows the effectiveness of the visualization platform.

## 2. Structure and Design of Industrial Heritage Cloud Platform

The industrial heritage big data cloud platform constructed in this paper is an intelligent monitoring and analysis big

data cloud platform integrating real-time monitoring and intelligent prediction analysis. Under the background of big industrial data acquisition and high efficiency [22], it is of great significance to solve the problems of traditional industrial data acquisition and high-efficiency data acquisition which has reference significance.

*2.1. Architecture Design of Cloud Platform.* According to the order of data analysis, the big data technology system is divided into three levels: data integration, data processing, and knowledge visualization, and the data processing process is shown in Figure 1.

The data processing process of the industrial big data cloud platform constructed in this paper can be roughly divided into data collection stage, data persistence stage, and data information processing to the final visual decision-making management. Firstly, in the data acquisition stage, the data from multiple data sources are collected into the industrial big data platform constructed in this paper, and the data are stored in different storage modes according to the characteristics and actual needs of different data. Then, in the data analysis stage, through the relevant data analysis tool components, the data are analysed and mined and further store the results. The analysis results of the previous step are finally visualized for the final decision management.

On the basis of data processing process, combined with the overall requirements, the overall architecture of cloud platform is designed from the perspective of services required in each stage. The overall level service of the cloud platform is shown in Figure 2. Its industrial genetic cloud platform includes data layer, data integration and storage layer, computing layer, data service layer, and application layer.

In the service of industrial heritage cloud platform which is shown in Figure 2, its work can be described as follows: the sensor equipment transmits the monitoring data to the data processing platform through HTTP, TCP, MQTT, and other transmission methods and stores it in MySQL after analysis, providing support for real-time query. The massive historical data use hive storage warehouse to provide large-scale data support for data mining and analysis of the system. In order to improve the query and analysis speed of the system, the query engine based on memory computing is used in statistical query and data mining analysis of historical data. In the application layer, the output of the big data platform layer is used for chart display. Build a web server platform to provide a visual interface for data display and analysis. The data processing of terminal equipment includes real-time monitoring, statistical query analysis, data mining analysis, and data visualization services.

The cloud data distributed analysis subsystem constructed in this paper has the following advantages:

- (1) The efficiency of the algorithm: the prediction algorithm based on the GRU threshold recurrent neural network has less parameters and better stability, which is very suitable for the prediction of industrial time series data.

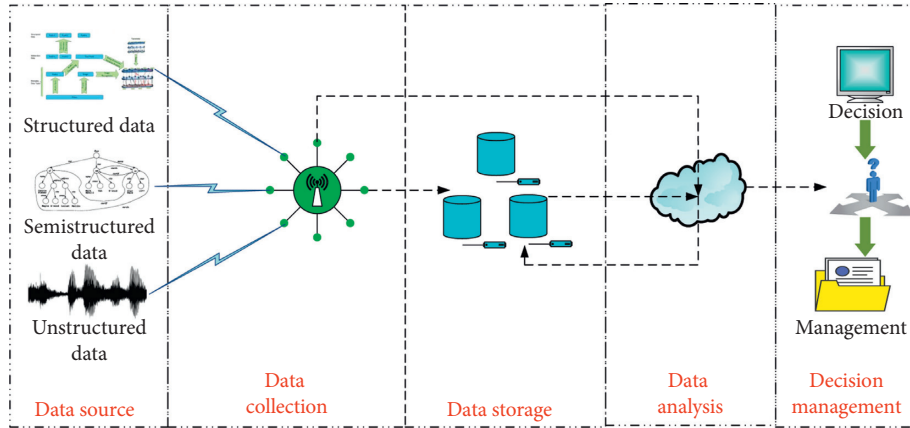

FIGURE 1: Process chart of data mining and visualization on the cloud platform.

- (2) High availability: the GRU threshold recurrent neural network is constructed on the basis of a spark core engine. It makes full use of spark's memory-based computing characteristics while parallel computing on multiple computers so that the algorithm still has high availability in the environment of large amount of data.
- (3) High scalability: the bottom layer of the cloud data distributed analysis subsystem is based on a spark distributed computing framework. In other words, the data analysis subsystem can be integrated with other components of the Hadoop ecosystem, which ensures the high scalability of the cloud platform in future application development.
- (4) Support of the cloud platform for other algorithms in the future: in terms of the data analysis algorithm, the cloud data distributed analysis subsystem itself is based on the design of a spark distributed computing platform, which makes it suitable for spark. At the same time, the subsystem supports the development and application of other types of data mining algorithms in the future

*2.2. Structure Design of Industrial Heritage Cloud Platform Based on Hadoop.* The structure of the industrial heritage cloud platform is shown in Figure 3. The platform is composed of a master node and a group of task subnodes. In the platform, the master node is responsible for the task scheduling and platform management and each subnode is responsible for the task execution, and after the task is completed, the data processing results are fed back to the master node, and the main node presents the results to the user and completes the serialization operation.

Firstly, considering the high reliability and high scalability of the industrial big data cloud platform, the cloud data distributed analysis subsystem is also designed as an independent middleware to provide data analysis services for the cloud platform. Secondly, the cloud data distributed analysis subsystem provides model training and data prediction and analysis functions for the industrial big data cloud platform as a whole. Therefore, the data analysis

subsystem provides two core functions: model training and cloud reserved model library. Finally, from the perspective of the overall performance of the industrial big data cloud platform, when facing the data analysis scenario with large amount of calculation and responsible calculation, the traditional single machine computing mode cannot meet the actual production requirements. Therefore, this part builds the data analysis subsystem on the spark platform and takes spark as the core computing engine. This design can make full use of the characteristics of spark parallel computing and memory-based computing advantages to improve the efficiency of data analysis.

### 3. Research on Big Data Mining Algorithm Based on GRU Network

*3.1. Data Mining Model Based on GRU.* In short-term industrial data forecasting, historical load series is the most important input. It contains rich information to forecast the future load demand and can represent the potential law of load demand. When the traditional machine learning method and single DNN are used to process historical load data, it is necessary to manually select relevant features from the original data, such as the load value of the previous hour and the load value of the same time of the previous day. The features selected according to the correlation will destroy the potential internal relations in the historical load series and affect the accuracy of the prediction results, and this feature selection method also increases the difficulty of prediction. The GRU neural network can effectively avoid this problem. Its internal gating cycle structure can automatically learn the relevant features from historical load data without manual extraction, which makes the prediction method more simple and easy to implement, and can also improve the prediction accuracy. In addition to the historical load series, short-term load forecasting is also affected by weather, holidays, dates, and other factors. The internal potential laws of these features are not obvious, so they are not suitable for the input of the GRU neural network. DNN can effectively deal with these external factors and learn the relationship between these characteristics and load demand so as to improve the prediction accuracy.

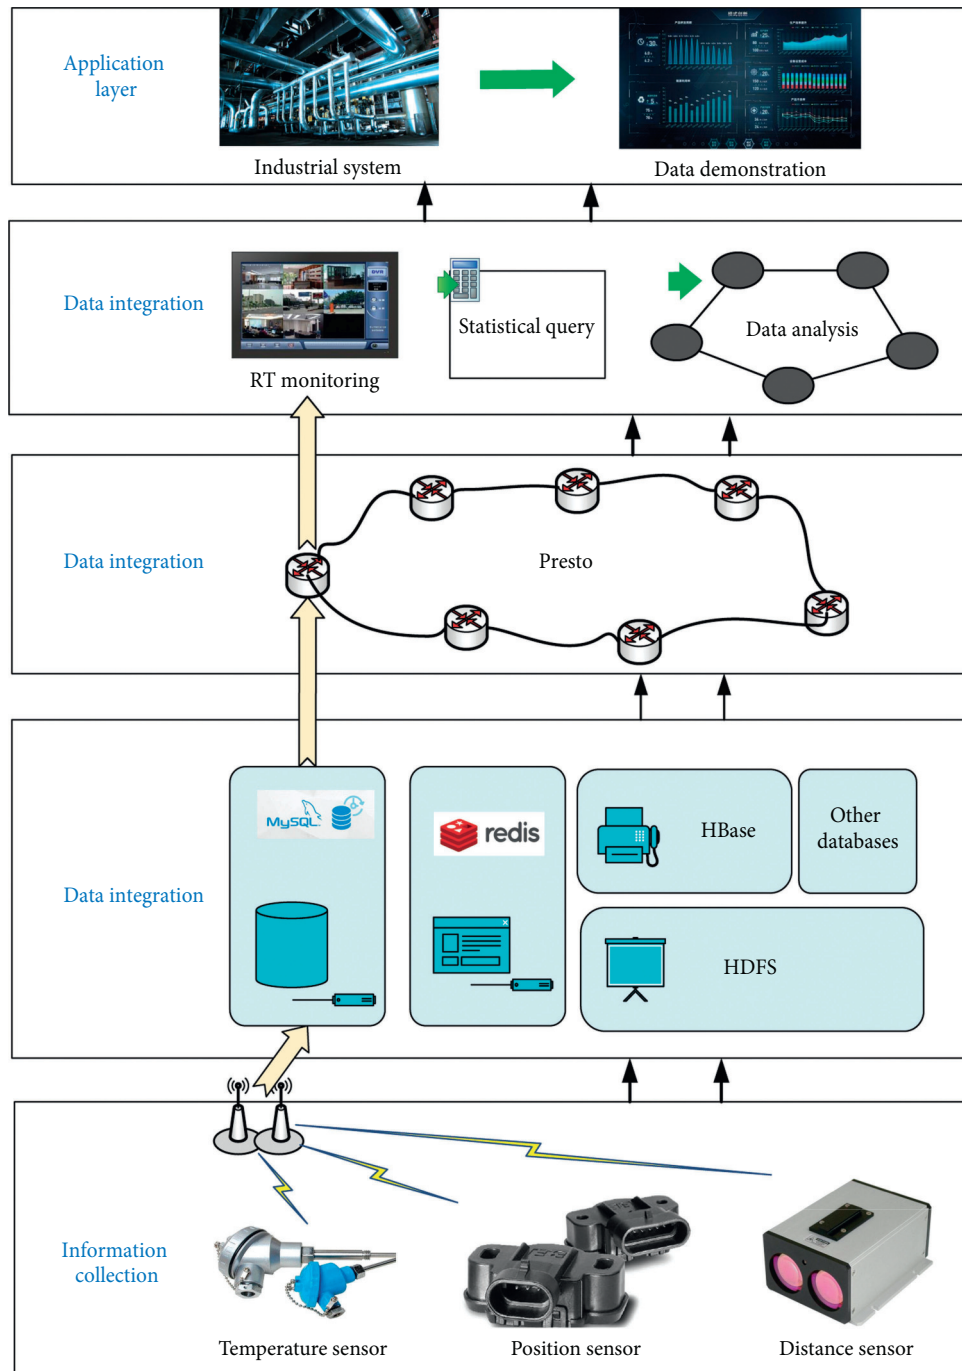

FIGURE 2: Architecture of the industrial heritage cloud platform.

The structure of the GRU prediction model is shown in Figure 4. The historical data input matrix  $T1$  in the model is the input of the GRU network, and the matrix  $TN$  is the output of the GRU network. The description of each layer in the input matrix model composed of other features is as follows.

The model is mainly divided into three layers. The first layer is data processing layer, which mainly normalizes the data and discretizes the normalized data into time series data; the second layer mainly extracts the features with small amount of data to reduce the prediction error; the third layer

mainly uses the prediction model based on GRU unit to send the data and feature extraction data to this layer, where the prediction of data can be realized. GRU unit is the core part of this model, and the detailed information is designed as follows. (1) Preprocess the historical input data and select the input features. According to the characteristics of historical data, external factors with greater influence are selected as other features. The length of historical load data and external characteristics is  $m$ , which needs to be corresponding to each other. In addition, in order to facilitate training, it is necessary to normalize the real value data and code the symbolic

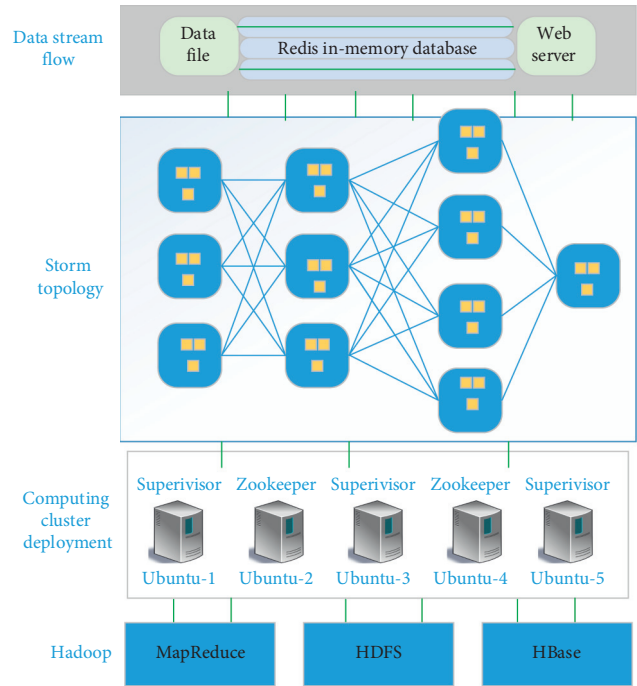

FIGURE 3: Architecture of the industrial heritage cloud platform based on Hadoop technology.

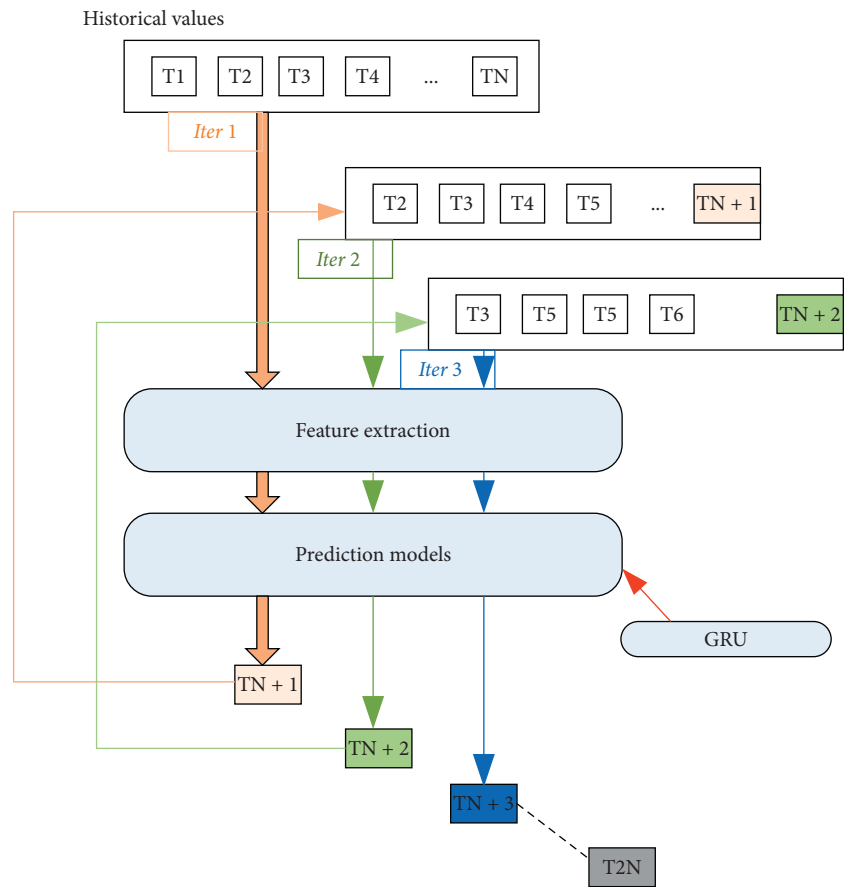

FIGURE 4: Architecture of the industrial heritage cloud platform based on Hadoop technology.

data. (2) The GRU model is trained by the training sample set, and the network parameters are optimized and updated to get the prediction model. The input data samples at the time to be predicted are input into the trained model to obtain the load forecasting value at each time. The output of a neuron in GRU networks is calculated as follows:

$$\begin{aligned} \mathbf{z}_t &= \sigma(\mathbf{W}^{(z)}\mathbf{x}_t + \mathbf{U}^{(z)}\mathbf{h}_{t-1}), \\ \mathbf{r}_t &= \sigma(\mathbf{W}^{(r)}\mathbf{x}_t + \mathbf{U}^{(r)}\mathbf{h}_{t-1}), \\ \tilde{\mathbf{h}}_t &= \tanh(\mathbf{W}\mathbf{x}_t + \mathbf{r}_t \circ \mathbf{U}\mathbf{h}_{t+1}), \\ \mathbf{o}_t &= \mathbf{h}_t = \mathbf{z}_t \circ \mathbf{h}_{t-1} + (1 - \mathbf{z}_t) \circ \tilde{\mathbf{h}}_t, \end{aligned} \quad (1)$$

where  $\mathbf{h}_{t-1}$  and  $\mathbf{h}_t$  are the output of hidden layer at time  $t - 1$  and  $t$ ;  $\mathbf{z}_t$ ,  $\mathbf{r}_t$ , and  $\mathbf{o}_t$  denote the output of update gate, reset gate, and neuron at time  $t$ ; and  $\mathbf{W}^{(z)}$ ,  $\mathbf{U}^{(z)}$ ,  $\mathbf{W}^{(r)}$ ,  $\mathbf{U}^{(r)}$ ,  $\mathbf{W}$ , and  $\mathbf{U}$  represent the weight parameters that we learned during the training process.

**3.2. Evaluation Index of Model.** In the training process, the model parameters are optimized by using the Adam (adaptive motion estimation) [21] optimization algorithm. Adam is a first-order optimization algorithm which can replace the traditional stochastic gradient descent process. In the process of training, the weight and deviation of each neuron node in the network model are updated iteratively to reduce the output value of loss function to the optimal value. The loss function of the model uses the mean square error function:

$$\min_{\theta=\Omega} \text{MAE} = \frac{1}{M} \sum_{i=1}^M |T_e^i(iT|\theta) - T_e^i(iT)|^2, \quad (2)$$

where  $T_e^i(iT|\theta)$  and  $T_e^i(iT)$  represent the predicted engine torque and real engine torque at sample time  $iT$ , respectively,  $i$  is the length of the  $i$ -th time step, and  $M$  is the total number of the sample time that are used to train or validate.  $\Omega$  is the solution space of  $\theta$ .

**3.3. Parallel Distributed GRU Prediction Model Based on Spark.** In order to speed up the training of the model, the spark distributed parallel computing framework is used in the training of the model. The idea of “divide and conquer” is adopted. The training data are distributed to a specified number of cluster worker nodes through the spark parallel computing framework. Each worker node executes its own according to the logic of the actual task. In the model training task, the driver reduces and averages the weight parameters of each node by setting the average frequency of parameters and redistributes the weight results to each node until the predetermined training target of the model is reached. Figure 5 shows the workflow of model parallelization training.

The detailed process is formulated as follows. Spark application communicates with spark cluster through Sparkccmtext in driver program. Spark program applies for the required resources from the cluster resource manager through Sparkccmtext. The cluster resource manager

allocates the resources and creates an exciter on each running node. Sprkcontext distributes the program code and corresponding data trained by the model to the running node, and each work node allocates the current allocation the model training task is parallelized. Finally, the results of each node are collected to the driver program to realize the parallel training of the model.

## 4. Simulation Results and Analysis

**4.1. Simulation Environment of Cloud Platform.** This part mainly introduces the data server and Hadoop cluster server node environment. The relevant environment and configuration information of the data server and cluster server nodes are shown in Table 1. All of our simulations are performed on the parallel cloud platform with one GTX-1080Ti card under CUDA9.0 and cudnnv7. In addition, the Sqoop component can realize the mutual conversion between the traditional relational database data and HDFS, HBase and other data, so as to ensure the efficient and safe import and export of data in different systems. The Spring-Boot OpcUa data acquisition server realizes the real-time data acquisition and monitoring management of remote equipment in the factory. Abp Core server is the basis of cloud platform visual management.

**4.2. Validation of GRU Evaluation Model.** The simulation takes a group as an example, which mainly provides OEM services to famous overseas clothing brand companies. The export revenue has occupied the first place of knitting apparel enterprises for many years and also maintains the first position of export to Japan for many years.

Planned production capacity, planned capacity index, service capacity index, timely delivery rate, order fulfilment rate, and average delivery period are the main indicators to evaluate a company. We use industrial heritage data for evaluation and visualization. In order to compare the advantages of our algorithm, we choose to compare it with SVM (support vector machine algorithm). The comparison results are shown in Figure 6.

As can be seen from Figure 6, external customers and internal management departments can provide reports intuitively and clearly on this unified interface so as to find out the changes of capacity indicators in time. The system will also rely on the interval early warning information to carry out automatic early warning prompt, meet the statistical data support of predictive scheduling, and monitor the manufacturing capacity under the contract. In addition, we can use the prediction model based on the GRU network to accurately predict the operation status of enterprises, and it is consistent with the actual production data. Compared with the SVM-based algorithm, our algorithm has higher prediction accuracy. The detailed prediction results are shown as in Figure 7.

From the results, it can be seen that the industrial heritage cloud platform model proposed in this paper has better prediction effect; it can more accurately capture the law of data change, can predict the trend of data change

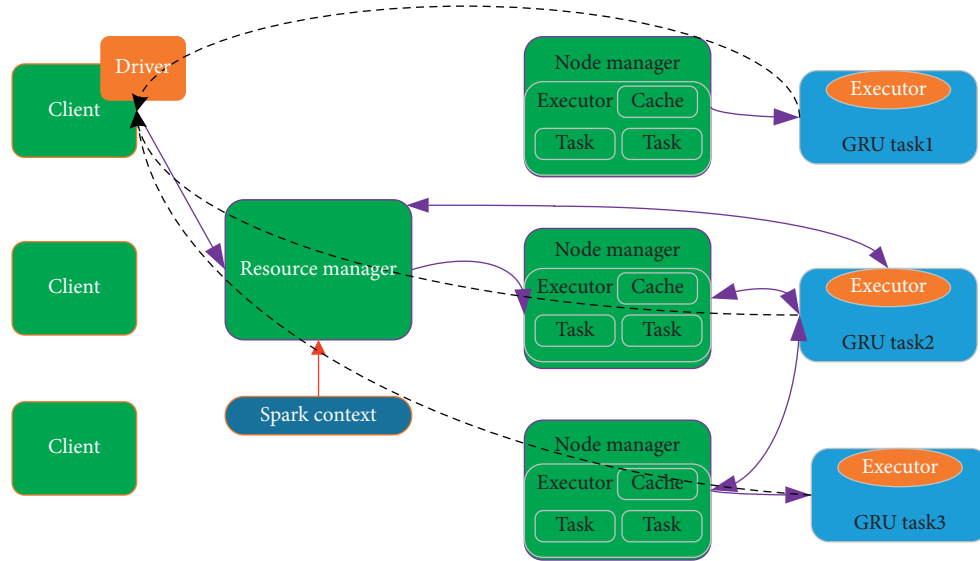

FIGURE 5: Parallel distributed GRU prediction model based on spark.

TABLE 1: Overall deployment of the cloud platform.

| Server type   | OS         | Memory (GB) | IP address   | Other information           |

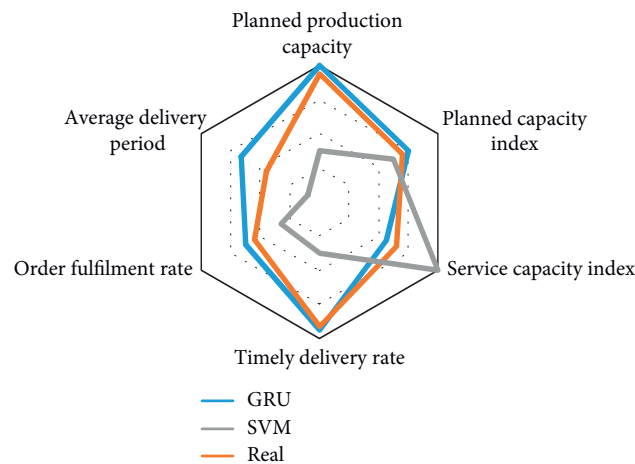

FIGURE 6: Simulation results compared with the SVM algorithm.

faster, can improve the prediction accuracy, and has high accuracy compared with the SVM prediction algorithm.

In addition, the cloud platform of industrial heritage also needs to evaluate the possible risks in the actual production process. This paper mainly shows the risk warning function of the industrial heritage cloud platform, and the results are shown in Figure 8.

Risk early warning was from the material and plan conflict, fabric supply interruption, lack of planning information, abnormal expectations, production progress lag,

and other five aspects of early warning. According to the contract number, the system can import production plan data and execution data according to the contract number, count the execution progress of all unfinished orders in real time, realize the automatic early warning of delivery date delay, and estimate the delayed delivery date under the existing constraints. As shown in the figure, our industrial heritage cloud platform can provide real-time early warning and visualization of possible problems in the production process so that enterprise decision makers can adjust their

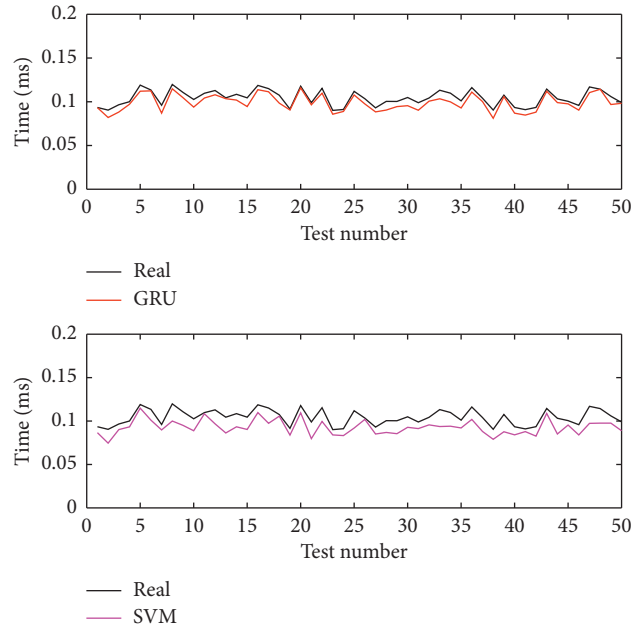

FIGURE 7: Simulation results compared with the SVM algorithm.

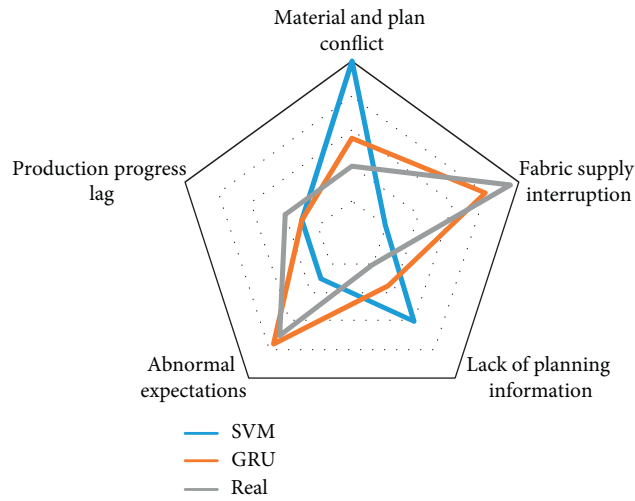

FIGURE 8: Enterprise operation risk prediction compared with SVM model.

own production plans. In addition, the accuracy of our prediction model is much higher than that based on SVM, which achieves good prediction performance.

#### 4.3. Production Data Visualization Based on Cloud Platform.

The process flow of products corresponding to different orders is not completely the same, and the operations required by different products in the same process are also different, so the decision and arrangement of production balance are complex. At the same time, the volatility of orders is also obvious. Orders fluctuate frequently due to the influence of seasons, fashion trends, prices, emergencies, and other factors. In addition, the company's OEM business is also affected by the order fluctuation. Different orders from

different enterprises have different order placing time and delivery time, and the product types and quantities presented in the weekly and daily production plans are also different. Considering the order satisfaction rate oriented production balance adjustment, the factors need to be considered comprehensively are more complex, which is a typical mixed loading balance decision-making problem under uncertain environment.

It can be seen from the figure that the production data are chaotic before processing, complex and disordered, as shown in Figure 9(a). We need to carry out feature extraction and visualization through the cloud platform, and the visualization results are shown in Figure 9(b). Through the full mining of the industrial heritage cloud platform, the relevance of production data began to show. Production data

FIGURE 9: Production data visualization based on the cloud platform. (a) Before processing and (b) after processing.

are a complex high-dimensional and multi-dimensional data, which refer to data variables with multi-dimensional attributes. It widely exists in the application based on traditional relational database and data warehouse. The goal of high-dimensional multivariate data analysis is to explore the distribution rules and patterns of high-dimensional multivariate data items and to reveal the implicit relationship between different dimensional attributes. From the visualization results (Figure 9(b)), we can see that the production data mainly includes five aspects (planned production capacity, planned capacity index, service capacity index, timely delivery rate, order fulfilment rate, and average delivery period); we can figure out which leading force plays a leading role at what time and then deal with it according to the actual changes. Simulation results show that our industrial heritage big data platform has good data mining ability.

## 5. Conclusion

In order to solve the practical application problems of the above industrial big data technology and the performance problems of data mining algorithms, this paper constructs a small private cloud platform, which is built on the current mainstream Hadoop distributed computing platform. At the same time, to solve the algorithm performance problems of cloud platform analysis, it uses the gated recurrent unit recurrent neural network combined with a spark distributed computing engine to realize the prediction and analysis of industrial time series big data, and the effective information is displayed by data visualization method. The simulation shows the effectiveness of the visualization platform compared with the SVM algorithm.

## Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

## Conflicts of Interest

The authors declare that they have no known conflicts of interest or personal relationships that could have appeared to influence the work reported in this paper.

Fine particulate matter with diameters less than  $2.5\ \mu\text{m}$  (PM<sub>2.5</sub>) concentration monitoring is closely related to public health, outdoor activities, environmental protection, and other fields. However, the incomplete PM<sub>2.5</sub> observation records provided by ground-based PM<sub>2.5</sub> concentration monitoring stations pose a challenge to the study of PM<sub>2.5</sub> propagation and evolution model. Consequently, PM<sub>2.5</sub> concentration data imputation has been widely studied. Based on empirical orthogonal function (EOF), a new spatiotemporal interpolation method, EOF interpolation (EOFI) is introduced in this paper, and then, EOFI is applied to reconstruct the hourly PM<sub>2.5</sub> concentration records of two stations in the first half of the year. The main steps of EOFI here are to firstly decompose the spatiotemporal data matrix of the original observation site into mutually orthogonal temporal and spatial modes with EOF method. Secondly, the spatial mode of the missing data station is estimated by inverse distance weighting interpolation of the spatial mode of the observation sites. After that, the records of the missing data station can be reconstructed by multiplying the estimated spatial mode and the corresponding temporal mode. The optimal mode number for EOFI is determined by minimizing the root mean square error (RMSE) between reconstructed records and corresponding valid records. Finally, six evaluation indices (mean absolute error (MAE), RMSE, correlation coefficient (Corr), deviation rate bias, Nash–Sutcliffe efficiency (NSE), and index of agreement (IA)) are calculated. The results show that EOFI performs better than the other three interpolation methods, namely, inverse distance weight interpolation, thin plate spline, and surface spline interpolation. The EOFI has the advantages of less computation, less parameter selection, and ease of implementation, it is an alternative method when the number of observation stations is rare, and the proportion of missing value at some stations is large. Moreover, it can also be applied to other spatiotemporal variables interpolation and imputation.

## 1. Introduction

Fine particulate matter (PM<sub>2.5</sub>) is particulate matter with aerodynamic diameter less than  $2.5\ \mu\text{m}$  in ambient air [1]. Hazy weather will form if PM<sub>2.5</sub> concentration is too high, which has adverse impacts on human health, traffic, and outdoor activities [2], and it will also produce other indirect inestimable economic losses [3]. Therefore, many countries attach great importance to the monitoring and forecasting of PM<sub>2.5</sub> concentration. A large number of ground-based monitoring stations have been established. For example,

1500 monitoring stations have been set up in the United States. In China, around 1500 stations have been set up in 454 cities by 2018, and a new national ambient air quality standard for PM<sub>2.5</sub> was introduced in 2012 [1, 2]. Generally, it is believed that high PM<sub>2.5</sub> concentration has become a prominent challenge for air pollution control in China, which is mainly caused by the industrial combustion of coal and gasoline, traffic emissions, and long-distance transport [4, 5]. The North China Plain, especially the Beijing-Tianjin-Hebei region (Figure 1(a)), is one of the regions most severely affected by the hazy weather [4, 6]. To monitor air

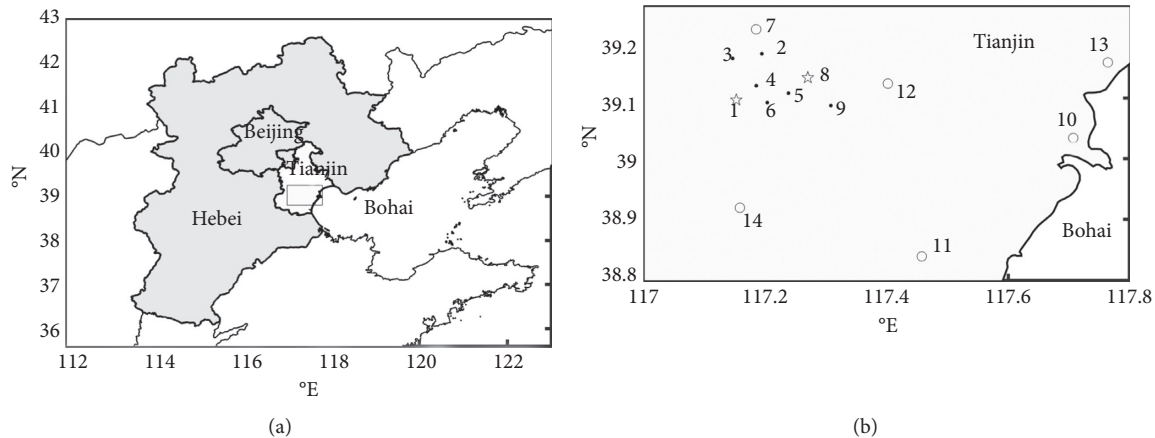

FIGURE 1: (a) Map of the Beijing-Tianjin-Hebei region. The rectangle in Tianjin is the study area of (b). (b) Location of 14 monitoring stations in Tianjin. From 1 to 14, they are located in the city testing center, Nankou Road, Qinjian Road, Nanjing Road, Dazhigu No. 8 Road, Qianjin Road, Beichen Science and Technology Park, Tianshan Road, Yuejin Road, Fourth Avenue, Yongming Road, Hangtian Road, Hanbei Road, and Tuanbowa. The stars represent the missing data stations (stations 1 and 8), the black dots represent the stations used for the interpolation (stations 2, 3, 4, 5, 6, and 9), and the circles represent the stations far from the missing data stations (stations 7, 10, 11, 12, 13, and 14).

pollution, many urban environmental stations have been built in this region, and many researchers have analyzed the causes and behavior of high PM<sub>2.5</sub> concentration recently [3, 7].

There have been many studies on PM<sub>2.5</sub> concentration data analysis methods, such as real-time data space interpolation of monitoring points, weighted regression models, and mixed models [1, 8]. The application of the preceding methods mostly depends on the complete and continuous monitoring data provided by local monitoring stations. However, problem arises when original spatiotemporal PM<sub>2.5</sub> concentration data are incomplete, which hinders further analysis and modelling, such as aerosol-related haze control and environmental health risk assessment [9, 10].

In practice, missing values and data gaps always exist in the original spatiotemporal observation records due to various factors. For example, satellite-based remote sensing may be affected by clouds, rain, aerosols, or incomplete track coverage in atmospheric research [11, 12]; *in situ* observations from land-based stations, shipborne monitoring, offshore buoy stations, and other platforms may suffer unexpected factors such as instrumental malfunction, power supply failure, and Internet outage [10, 13]. Directly ignoring incomplete spatiotemporal observation data should be carefully considered. The reasons include that the some platforms of data acquisition are expensive and irreplaceable (e.g., ocean research vessels and buoy stations), the demanding requirements of data quality (e.g., coastal tidal gauge records), and ignoring missing values sometimes may lead to biased spatial patterns and invalid inferences [10, 13]. Thus, many temporal, spatial, and spatiotemporal data interpolation and imputation methods have been proposed to fill these gaps in records.

Simple methods commonly used to fill gaps in univariate time series include mean value substitution (or median value and mode value), polynomial interpolation (linear, piecewise polynomials, and spline interpolations), and last

observation carried forward (*locf*), but they may result in large deviations when the time gaps are too large [14–17]. Based on a Markovian process, statistical parametric models include autoregressive (AR) models, moving average (MA) models, ARMA models, and linear weighted or exponential weighted MA. Complex machine learning techniques include gradient boosting and artificial neural networks (ANNs), which are computationally intensive [10, 18].

At present, there are also numerous spatial interpolation methods. Common simple methods include inverse distance weighting (IDW) interpolation [19], global polynomial interpolation (GPI), local polynomial interpolation (LPI) [20], surface spline (SS) interpolation [21], Cressman interpolation [22], and radial basis function (RBF). Using different basis functions, RBF includes thin plate spline (TPS), thin plate spline with tension, regularized spline, multiquadric spline, and inverse multiquadric spline. The TPS method does not need to set parameters, while other RBF needs to set parameters [23]. Some statistical-based methods (e.g., Kriging interpolation, optimal interpolation (OI), and Kalman filter) are conventional and classical methods in geoscience [12, 13, 24–27].

Numerous methods have been proposed to deal with spatiotemporal data containing missing values, and a considerable part of them are based on empirical orthogonal function (EOF) (e.g., [28–31]). Compared with other methods, EOF-based methods have the advantages of ease of implementation and less computation costs [32, 33].

EOF is based on the theory of matrix eigenvalue decomposition, and the core step of EOF is to decompose the spatiotemporal matrix into the sums of space-dependent spatial modes multiplied by corresponding time-dependent temporal modes. These EOF spatial and temporal modes can reveal data inherent characteristics or some phenomenon (e.g., ENSO) [13, 28]. EOF is usually used for spatiotemporal data analysis, but it can be also used to fill the missing data gaps.

One of the earliest applications of EOF interpolation is reconstruction of global-scale sea surface temperature (SST) [28]. Based on gridded data (1982–1993) processed by OI, EOF decomposition was performed to obtain spatial modes, and then, the temporal modes were expanded to longer time period (1950–1992) via least squares method when the data coverage was relatively poor; next, the longer time period spatiotemporal SST data were reconstructed. Their work can be considered as another form of optimal interpolation [13, 34]. In 2003, Data INterpolating Empirical Orthogonal Functions (DINEOF), an iterated EOF interpolation method, was proposed to fill the missing data gap [30]. Based on the principle of EOF, DINEOF was successfully used to reconstruct missing data and fill data gaps. Alvera-Azcárate et al. [32] reconstructed missing data of Adriatic sea surface temperature. Sirjacobs et al. [35] used DINEOF to show the reconstruction of complete space-time information for 4 years of surface chlorophyll-*a* (CHL), total suspended matter, and SST over the Southern North Sea and the English Channel. However, DINEOF may fail if the data gaps are too huge.

Similar to the principle of DINEOF, EOF interpolation (EOFI) was proposed to reconstruct spatially continuous water levels in the Columbia River Estuary using limited tide gauges along the river [36]. Their main steps are as follows: firstly, the spatial-temporal data matrix of the river existing observation stations was decomposed with EOF method. Then, Pan and Lv adopt one-dimensional linear interpolation and one-dimensional spline interpolation to estimate the missing data station's spatial modes, respectively; then, EOFI reconstruction sequence is obtained by the estimated spatial modes multiplied by corresponding temporal modes, and this reconstruction sequence was in good agreement with that of the NS\_TIDE method. NS\_TIDE is specially designed and applied to the analysis of river tidal water level, and river flow discharge data are needed [37].

Based on the research of Pan and Lv [36], this study attempts to extend the missing data station's EOFI spatial mode from one-dimensional spatial interpolation to two-dimensional spatial interpolation. The river upstream and downstream sites are nearly one-dimensional distributed, and there is a strong correlation between the upstream and downstream water level records (e.g., when the upstream of a river rises, the water level in the downstream generally rises). Therefore, it is reasonable to apply one-dimensional interpolation to establish the spatial mode's connection between the observation stations and the missing data station. Compared with the river water level reconstruction, the PM2.5 stations' correlation is not so strong and intuitive because the PM2.5 concentration stations are spatially distributed. To establish a connection between variables that two-dimensional distributed in space, a simple idea is using IDW, so EOFI here uses IDW to estimate the spatial modes of the missing data station. Of course, other spatial interpolation methods can also be applied to the establishment of spatial mode relationships, but we will not discuss them in this paper. We consider the simple case (IDW) to verify the usability of EOFI. To the best of our knowledge, our proposed EOFI has not been applied to PM2.5 concentration

data reconstruction currently; therefore, we firstly introduce and use this method to fill the data gaps and compare the result with IDW interpolation, surface spline (SS), and TPS interpolation. The competing methods we choose here are all widely used and easy to implement [38].

Compared with widely used DINEOF- and other EOF-based methods, the novelty of our method is to deal with the case of sparsely distributed observation stations and a large proportion of missing values in some stations' records. In this case, the data of the station with too many missing values are not suitable for EOF decomposition (DINEOF fills these gaps with first guess values and then uses these data for EOF decomposition); otherwise, the accuracy of temporal and spatial modes will be affected. EOFI here only uses the observation data with a small proportion of missing values for decomposition; thus, the EOF decomposed temporal and spatial modes are more accurate and less affected. Then, spatial interpolation is applied to establish spatial modes' connection between observation stations and missing data station, and next, the reconstruction sequence with optimal mode number is determined by root mean square error (RMSE). The EOFI reconstruction sequence can be used as a reasonable first guess value of the missing data station for other methods further EOF decomposition (e.g., DINEOF). In this way, the spatial mode patterns are considered to some extent. Further comparison between DINEOF and EOFI will be explained in Discussion.

The paper is arranged as follows: Section 2.1 describes the study area and data. Then, we revisit the principle of EOF decomposition and introduce IDW, EOFI, TPS, and SS. The evaluation indices of these methods will also be mentioned in Section 2. Four methods (IDW, EOFI, TPS, and SS) are applied to reconstruct two stations' PM2.5 concentrations records, and then, the results are compared with corresponding valid observations in Section 3. EOFI inverse distance weighting power  $P$ , the impact of site number and data time length on the EOFI reconstruction, and comparison between DINEOF and EOFI will be discussed and analyzed in Section 4. Finally, we present the advantages and disadvantages of EOFI in Section 5.

## 2. Materials and Methods

**2.1. Study Area and Data.** There are 14 monitoring stations (Figure 1(b)) located in Tianjin. These stations are distributed in different regions of the city: some stations are located in the urban area (e.g., stations 1, 2, and 3), while other stations are near the Bohai Sea (e.g., stations 10, 11, and 13). The PM2.5 concentration data provided by these monitoring stations come from China National Environmental Monitoring Center (CNEMC). The CNEMC releases near real-time PM2.5 concentration data online, but there are no direct data download interface [10]. Bai et al. used web crawler technology to obtain many cities PM2.5 concentration data from 2014 to 2019. Here, our data sources and acquisition method are the same. In this study, some of the stations provided the hourly PM2.5 data throughout the year of 2015, except for the first 25 hours from January 1st 0:00 AM to January 2nd 0:00 AM. Thus, the total time length is

8735 hours (8760 hours in 2015). The reason for first 25 hours missing values may be web crawler technology failure, or CNEMC did not release the data for that time period. Figure 2 shows the original observation records of several stations used in this study. Among them, the first half year PM2.5 concentration data of station (sta) 1 and station (sta) 8 are reconstructed and compared with their corresponding valid records (Figure 2 (1 and 7)). There are no observed data from June 30th 23:00 PM to the end of the year (near six months) in sta 1 and sta 8. In addition, Bai et al. [10] mentioned that some monitoring stations across China have stopped releasing PM2.5 observations since the middle of 2015, and consequently, observations at these stations for the second half of 2015 are missing. This is the exact case at sta 1 and sta 8 in Tianjin. In sta 1, 10.70% of the data in the first half year are missing, and the percentage of missing data for the nearly whole year record is 55.86% (Figure 2 (1)). At sta 8, the proportions of missing data for the first half year and the nearly whole year are 9.59% and 55.31%, respectively (Figure 2 (7)). It shows that there are still nearly 400 missing values in the first half of the year for both sta 1 and sta 8.

## 2.2. Methods

**2.2.1. EOF Decomposition.** The EOF method was firstly proposed by the statistician Pearson in 1902, and meteorologist Lorenz firstly introduced the EOF method into meteorological and climatic research in 1956 [39]. We consider that there are  $N$  stations providing observation records with data length  $L$ , composing the  $N \times L$  space-time matrix  $\mathbf{X}$ . The column  $\mathbf{x}_i$  consists of  $N$  points records at time  $i$  ( $i = 1, 2, \dots, L$ ). The most important step of EOF is to solve the eigenvalues and eigenvectors of symmetric matrix  $\mathbf{X}\mathbf{X}^T$ ; the results of this decomposition include eigenvalues  $\lambda_k$  and their corresponding eigenvectors  $\mathbf{F}_k$  (normalized orthogonal spatial modes) [13]:

$$\mathbf{X}\mathbf{X}^T\mathbf{F}_k = \lambda_k\mathbf{F}_k, \quad k = 1, \dots, N. \quad (1)$$

The column  $\mathbf{F}_k$  of matrix  $\mathbf{F}$  is arranged from left to right in the descending order of the corresponding eigenvalues  $\lambda_k$  ( $k = 1, \dots, N$ ), the elements of the diagonal matrix  $\mathbf{D} = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_N)$  are also arranged in this order, and thus, equation (1) can be written as follows:

$$\mathbf{X}\mathbf{X}^T\mathbf{F} = \mathbf{F}\mathbf{D}. \quad (2)$$

The  $N \times N$  matrix  $\mathbf{F}$  is called spatial modes coefficient matrix, which is also orthogonal (i.e.,  $\mathbf{F}\mathbf{F}^T = \mathbf{F}^T\mathbf{F} = \mathbf{I}$ ), corresponding to the temporal modes coefficient matrix  $\mathbf{A}$  or principal component (PC). The  $N \times L$  matrix  $\mathbf{A}$  is calculated by the following equation:

$$\mathbf{A} = \mathbf{F}^T\mathbf{X}. \quad (3)$$

The column vector  $\mathbf{x}_i$ ,  $N$  points records at time  $i$ , is reconstructed as

$$\mathbf{x}_i = \mathbf{F}\mathbf{a}_i. \quad (4)$$

Here,  $\mathbf{a}_i$  is the column of  $\mathbf{A}$  at time  $i$ , and obviously,  $\mathbf{X} = \mathbf{F}\mathbf{A}$ . The  $k$ -th row of the matrix  $\mathbf{A}$  is called the temporal  $k$ -th mode, and the element of the  $i$ -th column is the temporal coefficient at time  $i$ . Correspondingly, the column  $\mathbf{F}_k$  is called the spatial  $k$ -th mode, and the elements of the  $j$ -th row of  $\mathbf{F}$  (i.e.,  $\mathbf{F}(j)$ ) represent the coefficients of each spatial mode of the  $j$ -th station. Thus, matrix element  $\mathbf{F}_{jk}$  is the  $k$ -th spatial mode of the  $j$ -th station. The temporal modes are time-dependent, while spatial modes are space-dependent [13]. In addition, different spatial modes and different temporal modes are, respectively, orthogonal (i.e.,  $\mathbf{F}\mathbf{F}^T = \mathbf{F}^T\mathbf{F} = \mathbf{I}$  and  $\mathbf{A}\mathbf{A}^T = \mathbf{D}$ ). Finally, the eigenvalue  $\lambda_j$  of the  $j$ -th mode can be used to calculate the cumulative variance contribution rate of the first  $k$  modes to the total variance:

$$G(k) = \frac{\sum_{j=1}^k \lambda_j}{\sum_{j=1}^N \lambda_j} \times 100\%, \quad (k \leq N). \quad (5)$$

The closer the  $G(k)$  approaches 100%, the more information the first  $k$  modes reflect of the original signals [36]. In spatiotemporal data analysis, we often only care about the first  $k$  modes with large variance contribution and regard them as the dominant modes. However, many EOF-based interpolation methods do not only consider the dominant modes, and the less important modes should also be considered. The optimal number of modes for reconstruction is determined by the root mean square error between the reconstruction sequence and the corresponding valid observation record [40].

**2.2.2. IDW and EOFI.** The IDW formula is given as follows:

$$W_j = \frac{1/d_j^P}{\sum_{j=1}^N 1/d_j^P} \quad (j = 1, \dots, N), \quad (6)$$

$$\tilde{Z}_{\text{IDW}} = \sum_{j=1}^N Z_j \cdot W_j, \quad (7)$$

$$\tilde{X}_{\text{IDW}} = \sum_{j=1}^N \mathbf{X}(j) \cdot W_j, \quad (8)$$

where  $d_j$  denotes the distance between the  $j$ -th station and the target station,  $P$  is the inverse distance power parameter,  $W_j$  is the corresponding normalized weight,  $\mathbf{X}(j)$  denotes the observation records sequence at the  $j$ -th station (i.e., the  $j$ -th row of  $\mathbf{X}$ ), and  $\tilde{Z}_{\text{IDW}}$  and  $\tilde{X}_{\text{IDW}}$  represent IDW estimated value and estimated reconstruction sequence, respectively. IDW is based on Tobler's First Law of Geography: "everything is related to everything else, but near things are more related than distant things" [41]. The feature of this method is to produce "bull's eyes" around the observation points in the nearby area when observation points are rare and distributed sparsely [20]. For IDW, the common values of  $P$  are 1 and 2 (also called inverse squared distance weighting), so we only discuss the influence of these two parameters on IDW and EOFI in the later experiments.

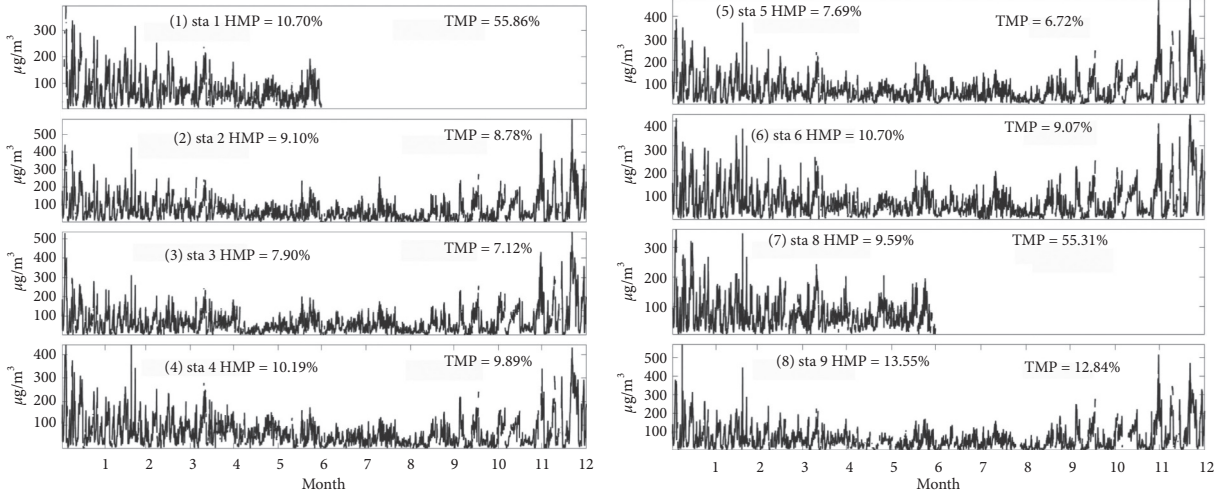

FIGURE 2: The original 12-month-long PM2.5 data records of 8 stations (sta 1, 2, 3, 4, 5, 6, 8, and 9) used in this study. The first half year missing percentage (HMP), i.e., the percentage of missing data in the first 4318 hours, and the total missing percentage (TMP), i.e., the percentage of missing data in 8735 hours, of each station are marked on the subgraphs.

In this study, the EOFI method steps are as follows: the missing data station shares the same temporal modes with observation stations, but the spatial modes  $\tilde{F}$  are estimated by the IDW interpolation of spatial modes of observation stations ( $\mathbf{F}(j)$ ,  $j = 1, \dots, N$ ):

$$\tilde{F} = \sum_{j=1}^N \mathbf{F}(j) \cdot W_j. \quad (9)$$

Here,  $W_j$  is the same as the weight mentioned in IDW (equation (6)). Then, the  $1 \times N$  row vector  $\tilde{F}$  and corresponding temporal mode  $\mathbf{A}$  reconstruct the estimated value  $\mathbf{x}_i^k$  at time  $i$  and estimated reconstruction sequence  $\tilde{\mathbf{X}}_{\text{EOF}}^k$  using the first  $k$  modes:

$$\begin{aligned} \mathbf{x}_i^k &= \tilde{F}(1, 1:k) \mathbf{A}(1:k, i), \quad 1 \leq k \leq N, \\ \tilde{\mathbf{X}}_{\text{EOF}}^k &= \tilde{F}(1, 1:k) \mathbf{A}(1:k, 1:L), \quad 1 \leq k \leq N. \end{aligned} \quad (10)$$

Using first  $k$  modes means that only the first  $k$  columns of  $\tilde{F}$  and the first  $k$  rows of  $\mathbf{A}$  are considered. Finally, the optimal mode number for EOFI reconstruction is determined by the minimizing RMSE between the reconstructed sequence ( $\tilde{\mathbf{X}}_{\text{EOF}}^k$ ,  $k = 1, \dots, N$ ) and the corresponding valid observation sequence  $\mathbf{X}_{\text{vid}}$ :

$$\tilde{\mathbf{X}}_{\text{EOF}} = \min_{\text{RMSE}(\mathbf{X}_{\text{vid}, \cdot})} \left\{ \tilde{\mathbf{X}}_{\text{EOF}}^k, k = 1, \dots, N \right\}. \quad (11)$$

The spatial mode is deemed space-dependent and can reflect the spatial characteristics under the assumption of EOF decomposition. In this study, the estimated spatial mode  $\tilde{F}$  is closely related to the distance from the observation station. If the missing data station and the observation station are close in space, their spatial modes are also close to each other (larger weight, equation (6)); thus, the EOFI reconstruction sequence is also close to the observation sequence, which is consistent with our experience.

Prior to reconstruction, the raw data matrix  $\mathbf{X}$  may contain missing values and cannot be directly EOF decomposed.

Therefore, it is necessary to preprocess the raw data and get the data matrix without missing measured value before decomposition. Here, we first replace the missing values with observed values' space average at missing values time points and then apply linear interpolation to fill all the temporal intervals (i.e., spatial mean value substitution and temporal linear interpolation). Note that the temporal gaps should not be too large, so as to avoid that the interpolation affects the accuracy of dominant temporal and spatial modes [36]. In this study, the data used for EOF decomposition include the preprocessed records of stations 2, 3, 4, 5, 6, and 9 (near one year). Their temporal gaps of original records are short (Figure 2 (2–6, 8)), so we believe that the dominant modes are slightly affected and still reliable. The first half year records of sta 1 and sta 8 are both excluded from EOF decomposition.

**2.2.3. Thin Plate Spline Method and Surface Spline.** The TPS method is a spatial interpolation method based on surface fitting, and it is one of the most frequently compared spatial interpolation methods [38], which was first proposed by Duchon [42]. It is often used to deal with uneven data in geoscience, such as generating continuous smooth elevation surface from discrete and sparse sample point elevation data. By simulating the bending of sheet metal, the TPS method generates a smooth surface with minimum bending energy through all observation points. Its form is as follows:

$$\tilde{Z}_{\text{TPS}} = \sum_{i=1}^N T_i d_i^2 \ln(d_i) + a + bx + cy. \quad (12)$$

Among them,  $d^2 \log(d)$  term is the basic function and  $a + bx + cy$  is the local trend function. The missing data station's horizontal coordinate  $(x, y)$  and its distances from the  $i$ -th ( $i = 1, \dots, N$ ) observation station are needed for TPS. In order to determine the  $N + 3$  unknown parameter  $T_i$  ( $i = 1, \dots, N$ ),  $a$ ,  $b$ , and  $c$  (equation (12)) are subject to the following relations:

$$\begin{aligned}
& \sum_{j=1, j \neq i}^N T_j d_{ji}^2 \ln(d_{ji}) + a + bx_i + cy_i = Z_i, \\
& \sum_{i=1}^N T_i = 0, \\
& \sum_{i=1}^N T_i x_i \\
& \sum_{i=1}^N T_i y_i \\
& d_{ji}^2 = (x_j - x_i)^2 + (y_j - y_i)^2,
\end{aligned} \tag{13}$$

with the  $N$  observation points' horizontal coordinates ( $x_i, y_i, i = 1, \dots, N$ ), distances between each other ( $d_{ij}, i, j = 1, \dots, N$ ), and observation values ( $Z_i, i = 1, \dots, N$ ), a smooth surface ( $N+3$  linear equations and  $N+3$  unknown parameters) is generated, the value at the missing data station is also assumed to be on this surface, and then, the TPS estimated value  $\tilde{Z}_{\text{TPS}}$  is calculated by equation (12). The TPS matrix form was fully described in Bookstein [43], and the coefficient matrix of unknown parameter is only related to spatial attributes (coordinate and distance), but not to time attribute.

The surface spline (SS) method is also a good spatial interpolation method based on surface fitting. It generates smooth surfaces through discrete points too. However, the basic function of the SS method is different from TPS. It does not consider trend term, the fitting function is different, and the radius  $R$  is introduced. Guo et al. [44] used the SS method to interpolate the bottom friction coefficient of the selected independent points to obtain values for the entire Bohai Sea and combined the adjoint assimilation method to invert the bottom friction coefficient of the entire sea. The SS method is also used for the inversion of initial conditions and parameters estimation in the ocean pollutant transport model [21], which is a significant improvement over the Cressman interpolation. Its form is as follows:

$$\tilde{Z}_{\text{SS}} = \sum_{j=1}^N S_j \left( \frac{d_j^2}{R^2} \ln \frac{d_j^2}{R^2} + 1 - \frac{d_j^2}{R^2} \right), \tag{14}$$

$$d_j^2 = (x - x_j)^2 + (y - y_j)^2. \tag{15}$$

Similar to TPS, the  $N$  observation points' spatial attributes and observation values sequences  $\mathbf{z}$  generate a smooth surface, and then, the unknown parameter column vector  $\mathbf{s}$  is solved by the matrix form:

$$\begin{aligned}
\mathbf{D}\mathbf{s} &= \mathbf{z}, \\
\mathbf{D} &= (\mathbf{D}_{ij})_{N \times N}, \\
\mathbf{s} &= (S_1, \dots, S_N)^T, \\
\mathbf{z} &= (Z_1, \dots, Z_N)^T, \\
\mathbf{D}_{ij} &= \begin{cases} \frac{d_{ij}^2}{R^2} \ln \frac{d_{ij}^2}{R^2} + 1 - \frac{d_{ij}^2}{R^2}, & i \neq j, \\ 1, & i = j. \end{cases}
\end{aligned} \tag{16}$$

Here, the elements of parameter matrix  $\mathbf{D}$  are only related to the distance between observation points  $d_{ij}$  ( $i, j = 1, \dots, N$ ) and prescribed radius  $R$ . The radius  $R$  is set to 15 km because the distance between any two stations is within this radius. After solving the unknown sequence  $\mathbf{s}$ , SS estimated value  $\tilde{Z}_{\text{SS}}$  of missing data station is calculated with equations (14) and (15). Note that the value of  $\mathbf{s}$  changes with radius  $R$ , but selecting  $R$  within the appropriate range will not have a great impact on the final interpolation result.

**2.3. Evaluation Indices.** At the end of Section 2.2.2, the preprocessing of the original data has been mentioned. We emphasize that the preprocessed data used for each interpolation method is the same. Therefore, the evaluation of different interpolation methods is persuasive and reliable. Table 1 summarizes their parameter settings. We will list a series of quantitative indices to evaluate these interpolation methods [38]. The evaluation indices listed in this study include mean absolute error (MAE), root mean square error (RMSE), correlation coefficient (Corr), and deviation rate bias, Nash–Sutcliffe efficiency (NSE) [45], and index of agreement (IA) (or Willmott's D) [46].

Among them, MAE (equation (17)) and RMSE (equation (18)) are often used as indicators of the performance of interpolation or models [38]. The smaller they are, the better the interpolation effect is. Corr (equation (19)) and bias (equation (20)) measure the correlation and deviation between simulation value sequence  $S$  and the observation series  $O$ , and  $\bar{S}$  and  $\bar{O}$  are their average values, respectively. Higher degree of correlation and smaller deviation both indicate the better interpolation effect. NSE (equation (21)) is a common index used to measure the performance or interpolation effect in meteorological, hydrological, and environmental models. Its value ranges from negative infinity to 1. The closer to 1, the simulation results are closer to observations; the closer to 0, the result are closer to the observation average values, but the process error is large, while negative NSE indicates that the performance of mean observed values is even better than simulated values and indicates this simulation unacceptable. IA (equation (22)) is referred as the potential error. IA is a nondimensional and bounded index with values closer to 1 indicating better agreement. The above six indices are defined as follows:

$$\text{MAE} = \frac{\sum |S - O|}{n}, \tag{17}$$

$$\text{RMSE} = \sqrt{\frac{\sum (S - O)^2}{n}}, \tag{18}$$

$$\text{Corr} = \frac{\sum (S - \bar{S})(O - \bar{O})}{\sqrt{\sum (S - \bar{S})^2} \sqrt{\sum (O - \bar{O})^2}}, \tag{19}$$

$$\text{bias} = \frac{\sum |S - O|}{\sum O} \times 100\%, \tag{20}$$

TABLE 1: Four interpolation methods parameter setting.

| Method | Parameter setting                |
|--------|----------------------------------|
| IDW    | $P=1$ and $2$                    |
| EOF1   | Spatial mode is dependent on IDW |
| TPS    | —                                |
| SS     | $R=15$ km                        |

$$\text{NSE} = 1 - \frac{\sum (S - O)^2}{\sum (O - \bar{O})^2}, \quad (21)$$

$$\text{IA} = 1 - \frac{\sum (S - O)^2}{\sum (|O - \bar{O}| + |S - \bar{O}|)^2}. \quad (22)$$

In Section 3.2, we calculated the above six evaluation indicators, which reflect the accuracy of these simulations, and the indicators for the EOF1 first  $k$  modes ( $k=1, \dots, N$ ) are also calculated. The results of EOF1 with the optimal mode number will be compared with other three interpolation methods.

**2.4. Site Selection.** To pursue better interpolation performance, here we just choose the data of the five nearest stations for interpolation; that is, the imputation of sta 1 and sta 8 data is based on the data of stations 2, 3, 4, 5, and 6 and the data of stations 2, 4, 5, 6, and 9 (Figure 1(b)), respectively, while the data of other stations are not included. The near one-year records of sta 1 and sta 8 are reconstructed, respectively, by interpolating data of the five nearest stations with four interpolation methods, and then, the reconstructed sequences are compared with corresponding valid observation data in the first half year (Figure 2) to calculate the evaluation index. In Section 4.2 for further validation, multiple sets of experiments in different time periods are implemented, and the RMSE between four interpolation methods' reconstruction sequence and corresponding valid observation records are further compared.

### 3. Results

**3.1. Interpolation Result of Four Methods.** The distances between the observation stations and the target station and the corresponding normalized weight are presented in Table 2. The distance from sta 4 is the shortest, and the weight is the largest in the sta 1 group, while distance from sta 5 is the shortest, and the weight is the largest in the sta 8 group. With the increase in IDW and EOF1 power parameter  $P$  (from 1 to 2), the normalized weights of the nearest stations (sta 4 and sta 5) increase, while the weights of other stations decrease. Therefore, the estimated spatial mode  $\bar{F}$  of sta 1 and sta 8 calculated by equation (9) is more affected by those of sta 4 and sta 5, respectively.

The temporal modes or principal components (PCs) of sta 1 and sta 8 (Figure 3) and the corresponding spatial modes (Table 2) are obtained by EOF decomposition. It can be seen that the variance contribution rate of PC1 in sta 1 and sta 8 is both over 98%, and the spatial 1st modes are all around 0.44. Most of the other modes of PC change around 0

(Figure 3 (a2–a5 and b2–b5)), and the corresponding absolute value of spatial modes is also less than the first mode. Therefore, from the second PC to the fifth PC, these modes play a less important role in reconstructing data than the first mode, but the later indices show that ignoring these less important modes may lead to less perfect performance of EOF1 reconstruction. In addition, Figure 3 (a1 and b1) illustrates that the amplitudes of PC1 in winter months (November, December, January, and February) were significantly greater than those in summer months (April, May, June, and July). It demonstrates that PM2.5 concentration in winter in North China Plain was significantly higher than that in summer [47].

Figures 4 and 5 depict the four interpolation reconstruction sequences and their residuals for sta 1 and 8, respectively. Both power parameters  $P$  (1 or 2) are adopted for IDW and EOF1 reconstruction for sta 1 and sta 8, but the indices show that choosing  $P=1$  for IDW and EOF1 is more accurate in sta 1, while  $P=2$  for IDW and EOF1 is more accurate in sta 8. The optimal mode number for EOF reconstruction is both three in sta 1 and sta 8. In the part of Result Evaluation and Discussion, we try to explain the reasons for this. It can be seen that four methods can roughly reproduce the valid records in sta 1 and sta 8. In sta 1 (Figure 4), the residuals of the four interpolation methods all change near 0, but there are several errors which are quite different from the observed values. For example, they all show errors of more than  $100 \mu\text{g}/\text{m}^3$  around February 20th and mid-March. Regardless of the instrument failure and other factors, the large error at these times may indicate that the PM2.5 concentration varies greatly among different regions of the same city, and it is not accurate to rely on only the adjacent data in this case. In Figure 5 of sta 8, the situation is similar, but the fluctuation magnitude of the residual sequence is significantly larger than that of sta 1, and the large residuals are also more frequently occurred. The performance of the four methods in sta 8 is generally worse than that of sta 1.

**3.2. Result Evaluation.** In this section, we evaluate four interpolation methods with quantified indices. Figure 6 shows a comparison of 4 interpolation methods in terms of MAE, RMSE, and Corr, and Figure 7 shows bias, NSE, and IA. Because many indices of the TPS method are quite different from those of other methods, in order to see their differences clearly, the indicator values of TPS are directly marked on each subgraph. It can be seen that the EOF1 interpolation performance of sta 1 and sta 8 varies with the number of modes, many indices show that the optimal mode number of EOF1 is three (e.g., Figure 6 (a1 and b1)), and the performance of EOF1 is sometimes worse than other interpolation methods when it is not the optimal mode number. We arrange all six indices of the best performing EOF1 and other three interpolation methods in the descending order of performance. It can be seen that, in sta 1, all 6 indicators show that the performance of EOF1 ( $P=1$ ) is the best (red lines) ( $1\text{-EOF1} > 1\text{-IDW} > \text{SS} > \text{TPS}$ ), while in sta 8, all 6 indicators show that EOF1 ( $P=2$ ) is the best (green

TABLE 2: Distances from station 1 and 8 to other five observation stations and corresponding normalized inverse distance weights when power  $P=1$  and 2, respectively.

| Target station         | Station 1 |        |        |         |        | Station 8 |         |        |        |        |
|------------------------|-----------|--------|--------|---------|--------|-----------|---------|--------|--------|--------|
| Observation stations   | 2         | 3      | 4      | 5       | 6      | 2         | 4       | 5      | 6      | 9      |
| Distance (km)          | 9.19      | 7.62   | 3.86   | 7.52    | 4.43   | 7.88      | 7.48    | 3.96   | 7.36   | 6.07   |
| Weight ( $P=1$ )       | 0.1268    | 0.1530 | 0.3018 | 0.1550  | 0.2634 | 0.1560    | 0.1643  | 0.3105 | 0.1669 | 0.2023 |
| $k$ -th mode ( $P=1$ ) | 0.4471    | 0.1179 | 0.0579 | -0.0574 | 0.0592 | 0.4449    | -0.0714 | 0.0192 | 0.0076 | 0.1143 |
| Weight ( $P=2$ )       | 0.0718    | 0.1045 | 0.4066 | 0.1073  | 0.3098 | 0.1124    | 0.1247  | 0.4453 | 0.1287 | 0.1889 |
| $k$ -th mode ( $P=2$ ) | 0.4474    | 0.2282 | 0.0871 | -0.1222 | 0.1191 | 0.4426    | -0.1291 | 0.0332 | 0.0227 | 0.2540 |
| $G(k)$ (%)             | 98        | 98.78  | 99.35  | 99.72   | 100    | 98.14     | 98.78   | 99.38  | 99.76  | 100    |

It is noteworthy that EOF estimated spatial 1st, 2nd, 3rd, 4th, and 5th modes are listed in the 5th and 7th rows (rather than observation station's coefficients). The contribution of the first  $k$  modes to the total variance  $G(k)$  is listed in the last row.

FIGURE 3: Station 1 (a1–a5) and station 8 (b1–b5) temporal variation in EOF modes.

lines) ( $2\text{-EOFI} > 2\text{-IDW} > \text{SS} > \text{TPS}$ ). The IDW performance of many indices is similar; sta 1 prefers  $P=1$ , while sta 8 prefers  $P=2$ . In addition, the indices performance of sta 8 is generally worse than that of sta 1. In Section 4.1, we try to explain why different parameters are chosen at the two sites.

## 4. Discussion

### 4.1. IDW Power $P$ Choice and Sites Number Impact on EOFI.

For the EOFI of this study, we did not take the data of sta 1 and sta 8 into EOF decomposition. The spatial modes of these two stations are calculated by the spatial modes of other 5 stations with IDW, and of course, their spatial modes estimates can also be obtained by other methods, such as Pan and Lv [36] using linear and spline interpolation, respectively, to calculate the spatial modes of river water level measurement points. Next, we try to explain why different  $P$  values are chosen in the two sites as mentioned in Section 3 and discuss the influence of the number of data sites on the EOFI reconstruction.

Firstly, the indices performance of sta 8 is obviously inferior to those of sta 1. There are four same stations (stations 2, 4, 5, and 6) data selected by both sta 1 and sta 8. But the number of missing values at sta 9 for sta 8 imputation is more than that of the sta 3 for sta 1 (the first half of the year missing percent of the sta 9 in Figure 2 reaches 13%), so the completeness of the original data may account for the worse results of sta 8. In addition, for sta 8, when  $P$  is increased from 1 to 2, the EOFI spatial modes and reconstruction sequence will be more dependent on the spatial modes (Table 2) and observation records of the closest station (sta 5), respectively. The adverse impact of the data of sta 9 is reduced, which may be an explanation of sta 8's preference for  $P=2$ .

Furthermore, in previous experiment, data of sta 1 and sta 8 are reconstructed with the data of the other 5 adjacent stations, of which 4 stations (stations 2, 4, 5, and 6) are both used for reconstruction of sta 1 and sta 8. In order to further explore the influence of the remaining station on the interpolation results, another experiment is conducted where the data of sta 3 are not used for sta 1 reconstruction and the

FIGURE 4: 1-IDW (a1),1-EOF1 (b1), TPS (c1), and SS (d1) reconstruction sequence and observations in sta 1 and their corresponding residuals (a2, b2, c2, and d2), 4138 hours after 2015-01-02 1:00. The numbers in front of EOF1 and IDW represent the value of their inverse distance weight  $P$ ; for example, 1-EOF1 represents the value of EOF1's inverse distance weight  $P$  is 1.

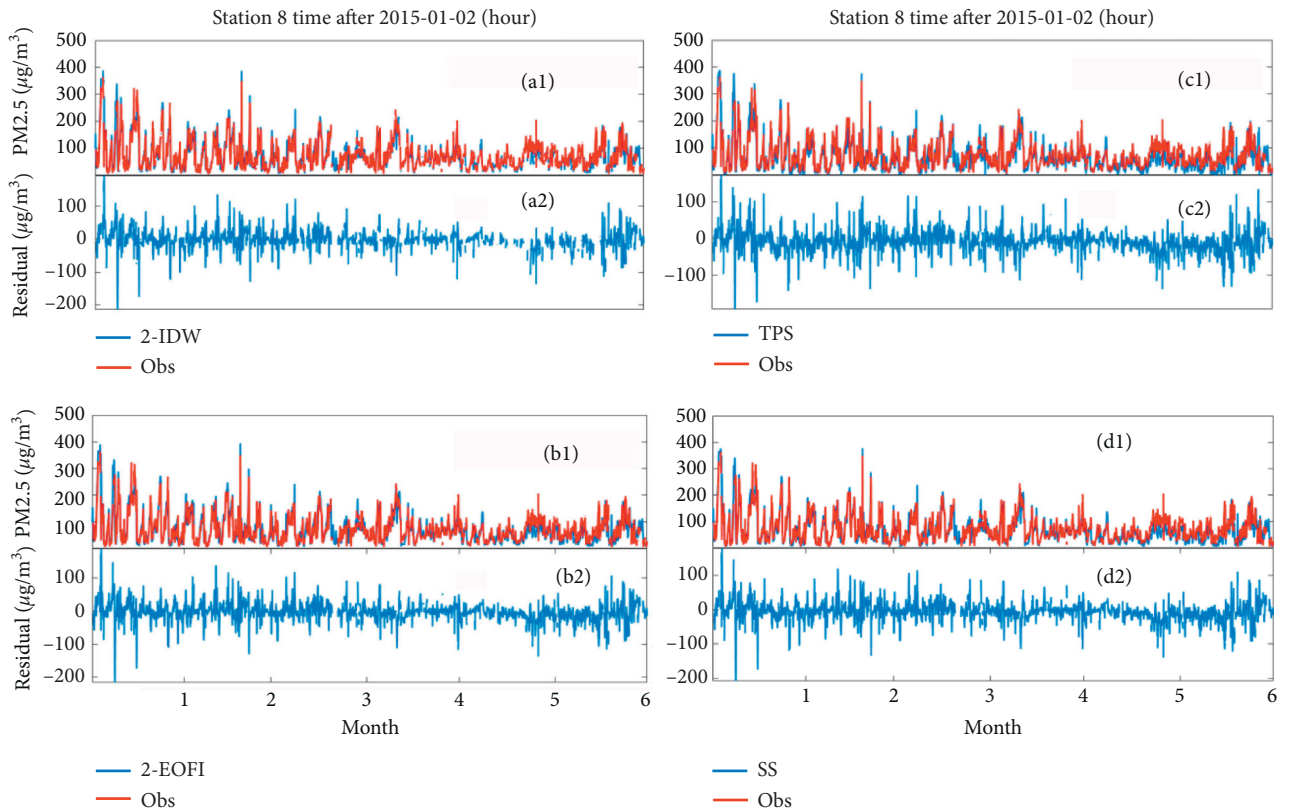

FIGURE 5: Same as Figure 4, but the IDW and EOF1 use  $P=2$  for sta 8.

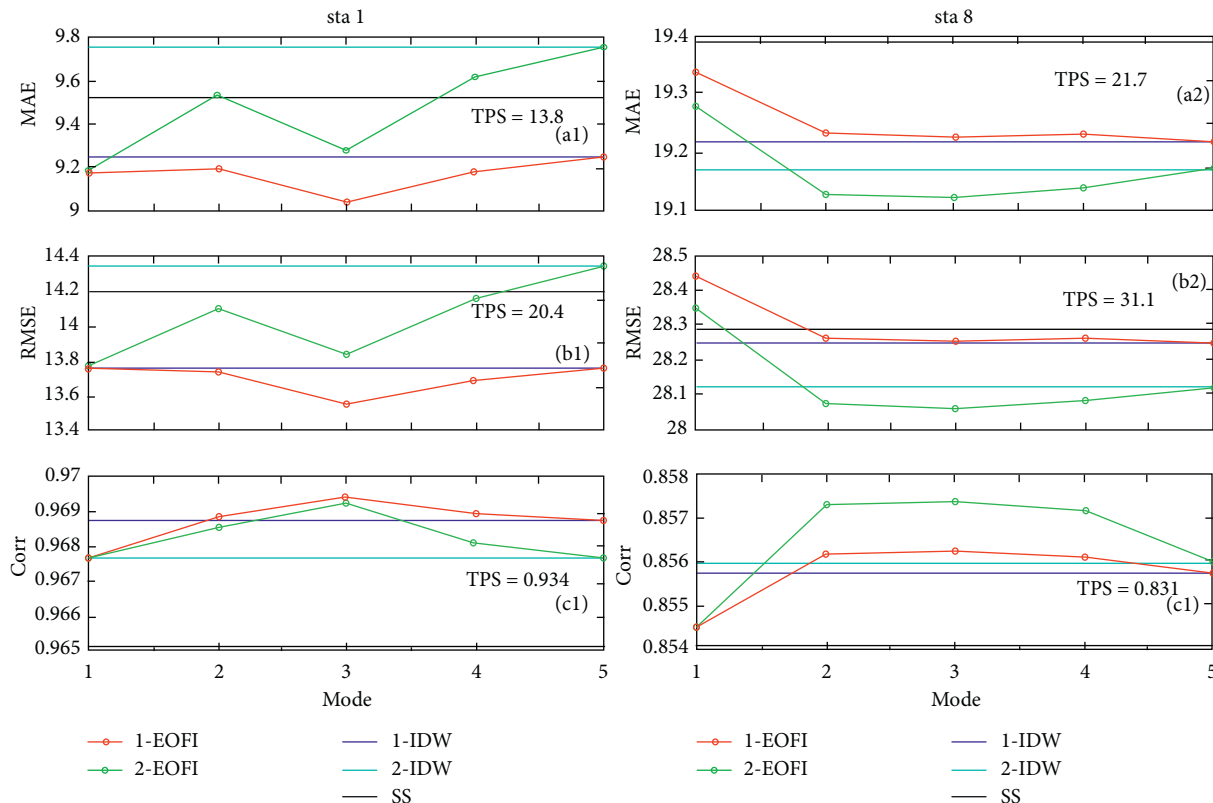

FIGURE 6: MAE, RMSE, and Corr of 4 interpolation methods in sta 1 and sta 8. The horizontal axis is the number of the first  $k$  modes selected in EOFI. The results of the other three interpolation methods are all straight lines and irrelevant to the modes.

data of sta 9 are not used for sta 8. The 4 sites and 5 sites EOFI reconstruction results are shown in Table 3.

It can be seen that, for both sta 1 and sta 8, the EOFI reconstruction with 5 sites is better than that with only 4 sites. In addition, inclusion of data from coastal stations such as sta 10 (Figure 1(b), far away from sta 1 and sta 8) in EOFI is not as good as interpolation with data from only five nearest sites. It is very vital to determine the appropriate number of stations for EOFI according to the feature and quality of the original data. As we can see the performance of using less sites data or adding coastal sites data for EOFI, both of which are worse than that of only five nearest sites data.

**4.2. Further Validation and Impact of Data Time Length on EOFI Results.** In the previous experiment, EOFI selected PM<sub>2.5</sub> data of nearly a full year from five adjacent stations data to perform EOF decomposition and obtained nearly a full year of PC and corresponding spatial modes. In this part, a number of experiments with different lengths of record are implemented to further evaluate and compare the four interpolation methods. Since there are only valid observation records in the first half of 2015 for both sta 1 and sta 8, the reconstruction sequence of four interpolation methods must be compared with valid observations during the same period. Divided by the calendar month, we divided the records in the first half of the year into six one-month sections (Jan, 1; Feb, 2; Mar, 3; Apr, 4; May, 5; and Jun, 6) in

the experimental group E1 and five two-month sections (1-2, 2-3, 3-4, 4-5, and 5-6) in experimental group E2. Four three-month sections (1-3, 2-4, 3-5, and 4-6) are implemented in the experimental group E3. Similarly, E4, E5, and E6 represent the experimental groups with a duration of 4, 5, and 6 months, respectively. There are 21 experiments in total. Since the temporal mode of EOF decomposition is related to the continuity of record, experimental groups with continuous months are set to reduce the inaccuracy of the temporal and spatial modes of EOF decomposition. February in winter and June in summer represents different seasons, and the feature of PM<sub>2.5</sub> concentration is significantly related to the seasons. For example, in winter, more fossil fuels may be consumed for heating; therefore, the PM<sub>2.5</sub> concentration is significantly higher than other seasons.

Figure 8 depicts the main results of EOFI reconstruction sequence of sta 1 and sta 8. It can be seen that, although the spatial 2nd, 3rd, 4th, and 5th modes in different time periods are different, the spatial 1st mode always remains stable at around 0.44, and the corresponding variance contribution also accounts for more than 95% (c1 and c2), which is consistent with the previous results. The RMSE range of EOFI reconstruction for sta 1 is 10–16  $\mu\text{g}/\text{m}^3$  (b1), while the range for sta 8 is 22–36  $\mu\text{g}/\text{m}^3$  (b2). The range is also consistent with the previous results, which shows the stability of the EOFI method. In addition, the number of experiments with the optimal mode number 4 (i.e., using first 4 modes to reconstruct) for sta 1 and sta 8 are both largest,

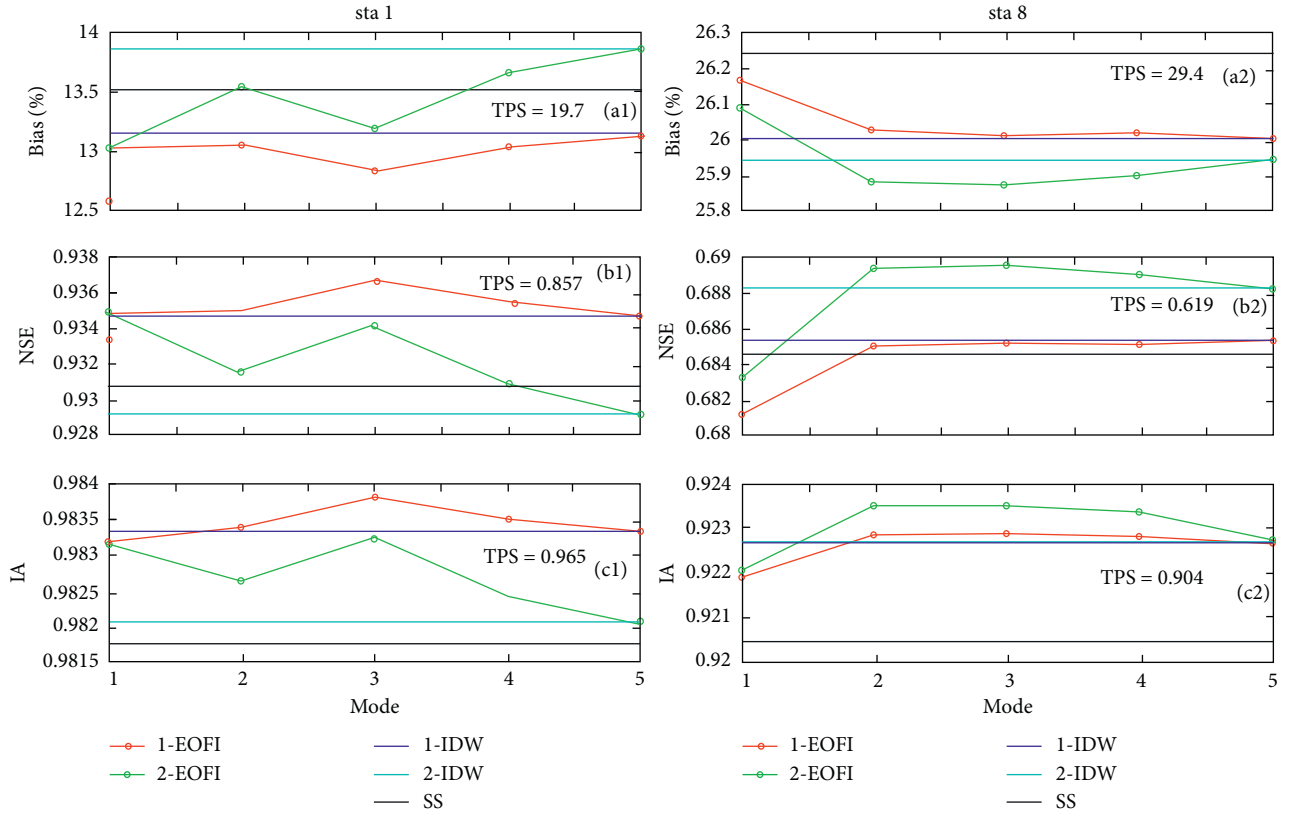

FIGURE 7: Same as Figure 6, but the indices are bias, NSE, and IA in sta 1 and sta 8.

TABLE 3: RMSE between the results of EOF1 reconstruction and the valid observation records of 4 and 5 stations selected by sta 1 and sta 8, respectively.

| RMSE ( $\mu\text{g}/\text{m}^3$ ) | Stations      | Modes  |        |        |        |        |
|-----------------------------------|---------------|--------|--------|--------|--------|--------|
|                                   |               | 1      | 2      | 3      | 4      | 5      |
| sta 1 ( $P=1$ )                   | 2, 3, 4, 5, 6 | 13.759 | 13.739 | 13.558 | 13.686 | 13.764 |
|                                   | 2, 4, 5, 6    | 14.313 | 14.116 | 14.486 | 14.582 | —      |
| sta 8 ( $P=2$ )                   | 2, 4, 5, 6, 9 | 28.344 | 28.072 | 28.061 | 28.082 | 28.119 |
|                                   | 2, 4, 5, 6    | 29.079 | 28.991 | 28.923 | 28.652 | —      |

respectively, but there are still other optimal mode numbers. The optimal mode number can be determined by finding the smallest RMSE [40].

Table 4 compares the performance (in terms of RMSE) of four interpolation methods reconstruction sequence. Among the 21 experiments, there are 19 experiments in sta 1 and 13 experiments in sta 8 showing the RMSE of EOF1 reconstruction is the smallest, respectively. There are also another 7 groups in sta 8 showing SS performed best in terms of RMSE, and these groups mainly include winter months January, February, and March. We infer that this is due to large PM2.5 concentration difference in different sites in winter, and the accuracy of spatial and temporal modes is not as good as those of other seasons.

**4.3. Comparison between EOF1 and DINEOF.** There have been many EOF-based interpolation methods (e.g., DCCEOF in [10], EOF1 in [36], and VE-DINEOF in [40]).

One of the most widely utilized methods is the iterated EOF method, DINEOF [30]. Therefore, it is necessary to compare DINEOF and EOF1 in this study.

First of all, two methods are both based on the matrix eigenvalue decomposition theory, and they all assume that the short missing value intervals of original spatiotemporal observation records will not affect the dominant temporal and spatial modes significantly. Moreover, the first guess values are given to the missing values to enable matrix decomposition. By calculating the RMSE and other indicators, the temporal and spatial modes of the optimal mode number will be used for final reconstruction.

However, the most significant difference between DINEOF and EOF1 is the original data used for matrix decomposition. In EOF1, the data of sta 1 and sta 8 (the second half of the year data is missing) are not included in the decomposed matrix, but in DINEOF, the data of sta 1 and sta 8 are taken into EOF decomposition; firstly, the missing values are replaced with first guess values and then

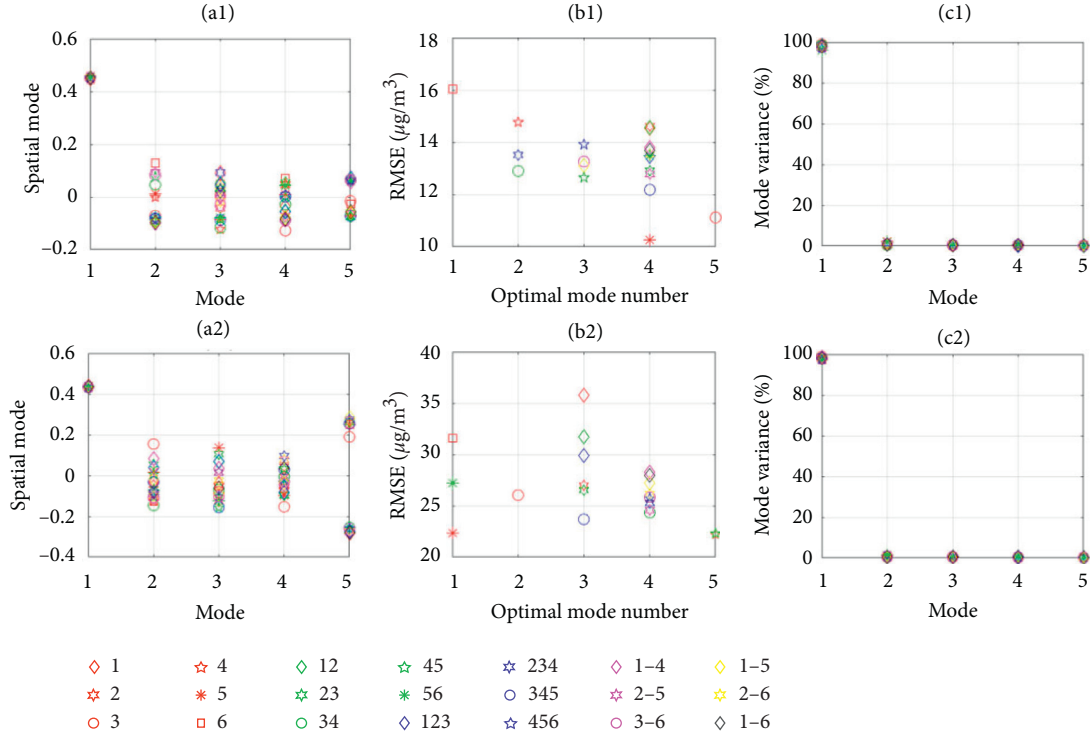

FIGURE 8: EOFI reconstruction sequence's spatial modes, corresponding variance contributions, and the RMSE with optimal mode number of sta 1 (a1, c1, and b1) and sta 8 (a2, c2, and b2) in the first half of the year. The legend color red, green, blue, magenta, yellow, and black represent the experimental groups with durations of 1, 2, 3, 4, 5, and 6 months, respectively.

TABLE 4: RMSE of four interpolation methods in sta 1 and sta 8.

| RMSE Groups | Station Method Month(s) | 1       |         |        |         | 8       |         |        |         |
|-------------|-------------------------|---------|---------|--------|---------|---------|---------|--------|---------|
|             |                         | IDW     | EOF1    | TPS    | SS      | IDW     | EOF1    | TPS    | SS      |
| E1          | 1                       | 14.562  | 14.547* | 23.675 | 15.878  | 36.031  | 35.751  | 38.931 | 35.458* |
|             | 2                       | 14.629  | 14.613  | 20.924 | 13.780* | 27.065  | 26.984  | 28.915 | 26.103* |
|             | 3                       | 11.123* | 11.123* | 13.989 | 11.380  | 26.376  | 26.040  | 27.469 | 25.815* |
|             | 4                       | 15.001  | 14.772* | 22.446 | 15.689  | 22.207* | 22.207* | 24.905 | 22.820  |
|             | 5                       | 10.286  | 10.273* | 16.905 | 10.968  | 22.399  | 22.313* | 27.000 | 24.248  |
|             | 6                       | 16.229  | 16.029* | 23.275 | 16.749  | 32.065  | 31.596* | 36.881 | 33.100  |
| E2          | 1-2                     | 14.596  | 14.557* | 22.308 | 14.840  | 31.889  | 31.688  | 34.317 | 31.159* |

The power  $P$  of IDW and EOF1 is based on the analysis of Section 4.1 (i.e.,  $P = 1$  for sta 1 and  $P = 2$  for sta 8), and the EOF1 reconstruction with optimal mode number is considered. "\*" represents the smallest RMSE of this experiment.

conducted matrix decomposition and iterative replacement until convergence. However, this step may be not suitable for the data processing of a small number of stations because the

first guess values of these missing stations may greatly affect the accuracy of temporal and spatial modes in this case. Even if the final convergent temporal and spatial modes are

obtained through iteration, the calculation resources consumed may be huge. Alvera-Azcárate et al. [32] mentioned that the data points with missing percent more than 95% are removed before data decomposition because they cannot provide effective information. The number of data points involved in their decomposition is huge; therefore, these less-informative points' removal has little impact on the final results. The DINEOF has been widely used for reconstruction of gap-free satellite images where densely sampled and numerous observations are obtained by remote sensing, while in other platforms (e.g., PM2.5 land-based stations in this study and offshore buoy stations array), where observations are relatively rare and sparse sampled, the temporal and spatial modes of iterated EOF methods may be not accurate when there is a large proportion of missing values in the few sites observation data matrix.

Therefore, for the observation records of finite number stations, if we want to make full use of the data of station with large proportion of missing values, EOFI may be more suitable for this kind of interpolation. The superiority of EOFI here is to obtain more reasonable spatial and temporal modes by excluding the records of large missing percent stations before EOF decomposition. All stations share the same time-dependent temporal mode, while the space-dependent spatial mode of the missing data station is estimated by spatial interpolation (IDW is used in this study), and the spatial mode features and patterns are considered. In addition, EOFI can provide more reasonable first guess values for the data of these missing stations, and next, DINEOF is used to iteratively calculate until convergence. For other differences, such as DINEOF iterative decomposition, EOFI can also use iterative decomposition in this study; DINEOF randomly selects a part of observation data as cross validation points, and EOFI here uses the first half year valid observation records and monthly records of sta 1 and sta 8 as check points, both of which can be unified in these aspects.

## 5. Conclusion

In this paper, two-dimensional EOFI is introduced and applied to reconstruct spatial-distributed PM2.5 data as an extension to one-dimensional EOFI in river water level reconstruction. The main step of EOFI here is to calculate the missing data station's estimated spatial modes  $\bar{F}$  by IDW interpolation of spatial modes of the observation sites and then multiply  $\bar{F}$  and the corresponding temporal modes to obtain the EOFI reconstruction sequence, and the optimal mode number of EOFI reconstruction is determined by minimizing RMSE. Compared with the other three interpolation methods (IDW, TPS, and SS), the quantitative indices show that EOFI can improve the interpolation effect. The conclusion is as follows.

TPS and SS have fixed function forms, and their coefficient matrices are space-dependent. The advantage of EOFI is that the spatiotemporal matrix is decomposed into time-dependent temporal modes and space-dependent spatial modes under EOF assumption. Observation stations and missing data stations share the same temporal modes, while the spatial modes of missing data station are estimated by the

IDW of observation stations' spatial modes. The benefit of IDW is that when the distance between the missing station and the observation station is very close, the spatial mode estimated by IDW is very close to that of the observation station; thus, the EOFI reconstruction sequence of the missing station is also close to the data of the observation station, which is consistent with our cognition. More essentially, the IDW weights of neighboring points are generated by statistical estimate of covariance between the observation points. TPS and SS weights do not depend on the statistical features of interpolated fields. EOFI can reduce MAE and RMSE compared with other three methods, and other indices show that the performance of EOFI is better too. This shows that EOFI can improve the interpolation effect with optimal modes. The results of several experimental groups with different data lengths show that the dominant spatial modes of EOF decomposition almost do not change with the time length, which is consistent with the EOF assumption that the spatial modes are independent of time. At the same time, the RMSE of EOFI reconstruction with optimal mode number still shows the advantages over the other three methods.

The proposed method is suitable for interpolation when observations are rare and sparsely distributed, and there are large percent of missing values for some stations' original records. The EOFI reconstruction sequence of missing data station can be a reasonable first guess value for further DINEOF (or other iterated EOF-based method) steps.

EOFI has the advantages of less calculation, less parameter choices, and ease of implementation and can be extended to fill the missing data gaps of other two-dimensional spatial distribution physical variables. The limitation of EOFI is that the missing values' temporal and space gaps should not be too large; otherwise, it will affect the accuracy of spatial and temporal modes. At the same time, the quality of the original data has an impact on the reconstruction results. High quality and complete observation data can produce more accurate spatial and temporal modes, which is conducive to EOFI reconstruction.

## Data Availability

The data (hourly PM2.5 concentration data of 8 stations in Tianjin and station locations) used to support the findings of this study are available from the corresponding author upon request.

## Conflicts of Interest

The authors declare that they have no conflicts of interest.

## Acknowledgments

The authors would like to thank Professor Yang Gao for providing the PM2.5 concentration data. This work was supported by the National Natural Science Foundation of China (Grant no. 41876003) and the National Key Research and Development Program of China (Grant nos. 2017YFA0604101 and 2016YFC1401404).

With the shortage of resources and the increasingly serious environmental pollution in China, green innovation has become a sustainable competition for a region. The Yangtze River Economic Belt (YREB) strategy is one of the most important strategies for the sustainable development of China's economy under the new normal. Green innovation plays a linking role in the resources exchange and trade flow in YREB, and it is also the foundation and guarantee to implement the YREB strategy. The global environmental pollution and the weak recovery of world economy make the traditional extensive economic growth model unsustainable. Sustainable economic growth should focus on the quality of development and its external costs to the environment. In order to implement the concept of sustainable development, the improvement of logistics ecological efficiency is related to the quality of ecological civilization construction. Therefore, it is of theoretical and practical significance to study the measurement, evolution, and driving factors of coordinated development level of regional green innovation system. This paper proposes a super-slack-based measure (super-SBM) data envelopment analysis (DEA) model to measure the green innovation efficiency of 11 provinces and cities in YREB from 2008 to 2017, mastering its spatial and evolutionary characteristics, and conduct empirical analysis on the influencing factors. The empirical results indicate that economic development, government support, and industrial structure upgrading are the leading forces to directly enhance the green technology innovation ability of cities in the Yangtze River Economic Belt and play the core driving role of green innovation. To further enhance the capacity of urban green innovation in the Yangtze River Economic Belt, we will increase the government's support for green innovation, optimize the environmental governance model, promote the green upgrading of industrial structure, and enhance the enthusiasm of enterprises for green innovation.

## 1. Introduction

With the adoption of China's reform and open up policy, the miracle of rapid economic growth is attracting the world's attention. In the meantime, the emerging issues of environment and resource depletion also pose a huge challenge to economic development. Coordinating the relationship between economy and environment is the key to the implementation of sustainable development strategy [1], made in China 2025, and raised the "green innovation-

driven development" strategy to promote the healthy development of national economy.

As an important support belt for China's economic development in the new era, the YREB spans three regions in China, connects the Yangtze River Delta Basin with the most developed economy in China, and together with the coastal economic belt forms the T-shaped model of economy development in China, and it is important in promoting and demonstrating industrial transformation and upgrading and green development. With the diversification of innovation

sources, ecological environment has become an important factor in innovation transformation and upgrading. However, there are many industries with high pollution and high-energy consumption in the YREB. Environmental pollution and resource shortage have become important factors restricting the YREB strategic development. The contradiction of ecological environment and economic society has become extremely acute. Under the rigid constraints of energy and environment, it is urgent to incorporate green development concept into technological innovation [2]. Therefore, as the integration point of innovation-driven and green development, green innovation has become an effective means to break through the constraints of resources and environment and promote sustainable development. It is of great practical significance to improve the green innovation efficiency of the YREB and realize the win-win of innovation efficiency, ecological efficiency, and economic efficiency, so as to enhance the ability of regional sustainable development and promote high-quality economic development [3].

In early 2016, Present Xi Jinping proposed that the ecological environment of the YREB should be placed in an overwhelming position. In March 2016, the meeting of the Political Bureau of the CPC Central Committee presided over by General Secretary Xi approved the outline of the development plan of the Yangtze River Economic Belt, stressing once again that “development should be promoted on the premise of protecting the ecology, enhancing the overall planning, integrity, coordination, and sustainability of development, and improving the efficiency of essential allocation.” In March 2018, it was clearly pointed out in the work report of the 19<sup>th</sup> National Congress of the Communist Party of China that the development orientation of the Yangtze River Economic Belt should be guided by ecological priority and green development, promote the overall layout of “five in one:” innovation, coordination, green, opening, and sharing, accelerate the construction of ecological civilization, and achieve regional coordination and sustainable development. The fundamental way to adjust the regional economic structure, change the mode of economic development, and promote high-quality economic development lies in the continuous green innovation. “Green innovation” is a complex system including resource input, innovation output, and environmental benefits. It coordinates the relationship between economic development and ecological protection, realizes the optimal benefit output with the least resource input, and creates the highest green innovation efficiency.

This paper modifies the super-SBM-DEA model to measure the green innovation efficiency of 11 provinces and cities in YREB from 2008 to 2017, mastering its spatial and evolutionary characteristics, and conduct empirical analysis on the influencing factors. The main contribution is using the undesirable super-SBM-DEA method to avoid any underestimation or overestimation of the green innovation efficiency caused by radial and nonradial DEA. The remainder of this paper is organized as follows. The literature review is presented in Section 2. Section 3 briefly describes the measurement method for green innovation efficiency.

Section 4 presents the data and variables. Empirical results and analysis are reported in Section 5. Section 6 draws conclusions and policy implications. The article structure is shown in Figure 1.

## 2. Literature Review

According to the needs of balanced development in ecology and economy, we need to find a relationship among the rapid development of economy, excessive use of resources, and deterioration of natural environment. By measuring green innovation efficiency, we can find key influencing factors and promote the sustainable development of green ecological economy [4–6]. According to existing literatures, research on green innovation efficiency can be summarized in the following three aspects: (1) research on green innovation efficiency; (2) research on the measurement of green innovation efficiency; (3) research on the influencing factors of green innovation efficiency.

*2.1. Research on Green Innovation Efficiency.* Green innovation has become a popular concept, and it is often known as ecological innovation, sustainable innovation, and environmental innovation [7]. Fussier and James first introduced the term green innovation in the book driving green innovation, defining as new products or processes which provide customer and business value but significantly decrease environmental impacts [8]. Kemp et al. define green innovation as a new process technology, system, and product to avoid or reduce environmental damage [9]. Compared with traditional innovation, green innovation takes both economic and environmental benefits into account and adapts to the improvement of supply side structural reform quality and efficiency of industrial parks. From the perspective of systems theory, green innovation is a combination of industrial innovation system theory and green economy theory, in reference to both green products and green processes [10, 11], including the introduction of any new or significantly improved product, process, organizational change, or marketing solution to reduce the consumption of natural resources and the emission of harmful substances in the product life cycle [12].

In 1951, Kaufman first put forward the concept of “efficiency.” He pointed out that if technology cannot realize the increase or decrease in output or input at the given level of output or input, the input-output vector in this state was defined as technology efficiency. Then, Schumpeter combines the concept of innovation and efficiency and points out that the fundamental purpose of innovation is to maximize regional economic and social benefits. Feng Zhijun defined green innovation efficiency as an input-output efficiency that can promote the unity of “economic benefits, environmental benefits, and social benefits” [13]. The authors in [14] pointed out that green innovation efficiency should not only reflect “green” and “innovation” but also reflect its economic characteristics, that is, economic efficiency. In addition, the authors in [15] believe that green innovation efficiency is a

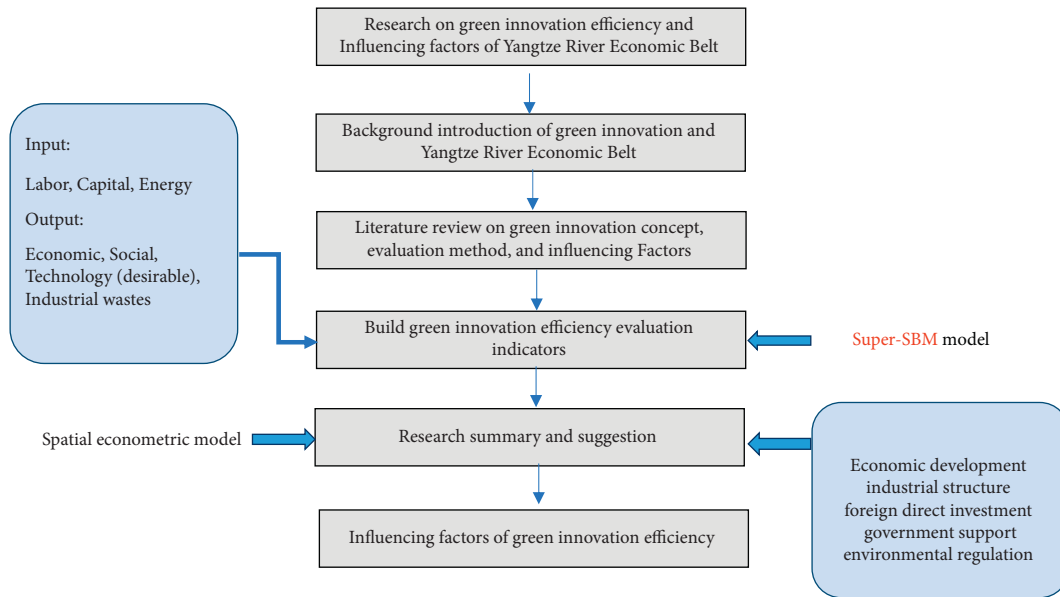

FIGURE 1: Article structure.

comprehensive innovation efficiency considering the cost of resource consumption and environmental pollution.

**2.2. Research on the Measurement of Green Innovation Efficiency.** There are two main methods to measure green innovation efficiency: the parametric analysis method, using SFA, and nonparametric analysis method, using DEA [16, 17]. Parametric analysis assumes that the departure from the frontier of the DMU is the result of a combination of stochastic disturbances and technical inefficiencies. The application of SFA focused mainly on enterprises' efficiency and its influencing factors and on research in the economic field [18, 19]. The authors in [20] measured the green innovation efficiency in China's provinces based on the improved stochastic frontier model and demonstrated the spatial agglomeration characteristics and path dependence of interprovincial green innovation efficiency from a spatial perspective.

The nonparametric analysis method constructs a minimum output possibility set that can accommodate all individual production modes according to the input and output of all decision-making units in the sample and measures the input-output efficiency based on the production possibility set. The authors in [21] compared the innovation efficiency of 185 regions in 23 European countries with the multiobjective DEA model and pointed out that there were differences in the innovation efficiency between different regions and different innovation stages. The authors in [22] used DEA to measure the innovation efficiency values of hospitals in 29 OECD countries between 2000 and 2010 and then applied the panel Tobit model to determine the environmental factors affecting hospital efficiency scores. By decomposing the Malmquist Productivity Index Decomposition, the change in the efficiency decomposition value was analyzed. The authors in [23] used the DEA method to calculate the overall efficiency, patent

production efficiency, and scientific paper production efficiency of 32 Mexican states. The authors in [24] used the SBM model to measure the green innovation efficiency of Chinese industrial enterprises without considering the nonexpected output and analyzed the regional differences of the green innovation efficiency of industrial enterprises in the regions. Luo et al. [3] applied the Malmquist Index and data envelopment analysis to evaluate the efficiency of green technology innovation in strategic emerging industries. Du et al. [25] used a two-stage network DEA with shared input to measure the efficiency of regional enterprises' green technology innovation and explored the regional differences in industrial enterprises' green technology R&D and the efficiency of green technology achievement transformation.

**2.3. Research on the Influencing Factors of Green Innovation Efficiency.** The influencing factors of green innovation efficiency can be classified into direct factors and indirect factors. Direct factors included labor quality, industrial structure, resource consumption, and technological innovation. The authors in [26, 27] conducted a dynamic evaluation on the efficiency of technological innovations in OECD countries and 20 member states of the European Union based on the Malmquist Index. Guan and Zuo [28] applied dual network DEA model to compare technological innovation efficiency of 35 countries. Yu et al. [29] considered the direct factors such as human capital, enterprise nature, and industrial structure when measuring the efficiency of technological innovation in China and found that they all have a significant impact on the efficiency of technological innovation. Wang et al. [30] found that R&D investment intensity has double threshold effect on green innovation efficiency of high-tech industry based on provincial panel data from 2006 to 2012.

The indirect factors included economic development, government funding, regional infrastructure, foreign direct investment, opening up, and environmental regulation. Yu et al. [31] reveal that environmental regulation can significantly improve the green innovation efficiency of the YREB, but different environmental regulation models have different effects on the green innovation efficiency of the YREB. Yang et al. [32] further analyzed the driving mechanism of green innovation efficiency in the YREB and found that the cost of enterprise pollution, the maturity of technology market, and the openness of market are conducive to promoting the efficiency of green innovation in the YREB, while the industrial structure has no significant impact on the efficiency of green innovation. Luo et al. [3] revealed the impact of international R&D capital technology spillover on the efficiency of green technology innovation by building a spatial model. According to the agglomeration effect of FDI, Gong et al. [33] demonstrated the effect and transmission mechanism of industrial green innovation efficiency.

According to the existing literatures on green innovation, there are still some shortcomings: Renyan Long concentrated on the level of enterprises, industrial, or provinces. The research on the efficiency of regional green innovation or specific economic zones and economic basins is of great practical significance for promoting the coordinated development of regional economy. At the same time, factors flow, technology spillover, pollution discharge, and innovation all show spatial interdependence and mutual influence. Existing literatures ignore the spatial correlation of green innovation as data with spatial correlation. Using the 11 provinces/cities' panel data in the YREB from 2008 to 2017, this paper uses the super-slack-based measure (super-SBM) model to evaluate the green innovation efficiency, using Global Moran Index to analyze the spatial correlation and spatial agglomeration characteristics and finally use the spatial measurement model to analyze the influencing factors of green innovation efficiency.

### 3. Materials and Methods

**3.1. Super-SBM Model.** Traditional DEA models, such as the CCR and BCC models, are radial projection constructs by Cook and Seiford [34], which assumes that all the outputs of a production system are valuable and should be maximized for given inputs. Nevertheless, the undesirable output will have significant effects on the efficiency in the whole process [35, 36]. Tone [37] developed a nonradial measurement to solve the problems of input and output slacks by proposing the slack-based measure (SBM). Compared with the traditional DEA, the efficiency value of this method is distributed in the (0, 1) interval, and the efficiency value of the effective DMU is 1. Therefore, when there are multiple effective DMUs, further comparison cannot be made. Then, Tone [38] developed a superefficiency SBM-DEA model which solves the problem of effective sorting and allows the efficiency score to be greater than 1 and can be easily rank-efficient DMUs. Super-SBM model can not only deal with the unexpected output more appropriately but also make further comparison in effective decision-making units, so it is more accurate and

rigorous. Therefore, the super-SBM with undesirable outputs is introduced into measuring green innovation efficiency in this study, and the model is as follows:

$$\min \rho^* = \frac{(1/m) \sum_{i=1}^m (\bar{x}_i/x_{i0})}{(1/(s_1 + s_2)) \left( \sum_{r=1}^{s_1} (\bar{y}_r^g/y_{r0}^g) + \sum_{r=1}^{s_2} (\bar{y}_r^b/y_{r0}^b) \right)}, \quad (1)$$

$$\text{s.t.} \begin{cases} \bar{x} \geq \sum_{j=1, \neq 0}^n \lambda_j x_j, \\ \bar{y}^g \leq \sum_{j=1, \neq 0}^n \lambda_j y_j^g, \\ \bar{y}^b \geq \sum_{j=1, \neq 0}^n \lambda_j y_j^b, \\ \bar{x} \geq x_0, \quad \bar{y}^g \leq y_0^g, \quad \bar{y}^b \geq y_0^b, \quad \lambda \geq 0, \end{cases} \quad (2)$$

where  $\rho^*$  is the green innovation efficiency and  $\lambda$  is the constant vector. The super-SBM model is simultaneously able to measure DMU efficiency and can also calculate DMU input and undesirable output redundancy rates, and it fully considers and effectively solves the problem with undesirable output and is more accurate to evaluate and analyze regional sustainable development.

### 3.2. Spatial Econometric Model

**3.2.1. Spatial Autocorrelation Analysis.** Spatial autocorrelation analysis is a kind of spatial data analysis method that is used for the estimation and analysis of spatial dependency and heterogeneity among objects, which is commonly indicated by Moran Index (Moran's I) [39–42]. Before using spatial econometric methods, it is needed to be constructed to examine whether the green innovation efficiency in YREB has spatial dependence.

Global spatial autocorrelation is used to measure the distribution characteristics of the entire research unit among spatial elements, and it can effectively test the autocorrelation of adjacent units. The global Moran's I value ranges from  $[-1, 1]$ . If  $I < 0$ , there is a negative spatial correlation, which indicates that the efficiency in the study area is in a discrete state. If  $I > 0$ , there is a positive correlation, indicating an agglomeration state. If  $I = 0$ , demonstration is made that the treatment efficiency is random, and the formula is as follows:

$$\text{Moran's } I = \frac{\sum_{i=1}^n \sum_{j \neq 1}^n W_{ij} (x_i - \bar{x})(x_j - \bar{x})}{S^2 \sum_{i=1}^n \sum_{j \neq 1}^n W_{ij}}, \quad (3)$$

where  $S^2 = (1/n) \sum_{i=1}^n (x_i - \bar{x})^2$ ,  $\bar{x} = (1/n) \sum_{i=1}^n x_i$ ,  $S^2$  is the variance value of green innovation efficiency,  $n$  represents the total 11 provinces/cities in YREB,  $x_i$  and  $x_j$  show province  $i$  and province  $j$ 's green innovation efficiency,  $\bar{x}$  represents the average green innovation efficiency, and  $w_{ij}$  is the spatial weighting matrix.

**3.2.2. Spatial Weighting Matrix.** Setting spatial weighting matrix is the basis of the spatial autocorrelation test and spatial econometric model. It reflects the spatial distance between two regions, usually including geographical distance and socioeconomic distance. At present, geographic distance is more common in research. The spherical distance ( $d$ ) between provincial capitals can be used to construct the spatial weighting matrix of geographical distance [43]. It uses the reciprocal of the square of the central distance between regions. The specific formula is as follows:

$$W_{ij} = \begin{cases} \frac{1}{d_{ij}^2}, & (i \neq j), \\ 0, & (i = j). \end{cases} \quad (4)$$

**3.2.3. Spatial Econometric Model.** Following Elhorst and Geogr [44], there are mainly three kinds of spatial econometric models: spatial lag panel model (SLM), spatial error panel model (SEM), and spatial Durbin panel model (SDM). The SLM model hypothesizes that the value of the dependent variable observed at a particular location is partially determined by a spatially weighted average of neighboring-dependent variables.

If the level of green innovation efficiency in the region is not only affected by some variables in the region and by the level of green innovation efficiency in neighboring regions, the spatial lag model (SLM) can be set up, which can be expressed as follows:

$$\ln \text{GIE}_{it} = \alpha_{it} + \rho W \ln \text{GIE}_{it} + X_{it}\beta_{it} + \mu_{it}, \quad (5)$$

where  $\alpha$  is the constant term and  $W$  is the spatial weighting matrix.  $X$  is the variable matrix of the corresponding influencing factors after the logarithmic treatment, and  $\beta$  is the influencing coefficient of the local influencing factors on the local green innovation efficiency.  $i$  represents the corresponding region,  $t$  represents the corresponding year, and  $\mu$  is the random error term.  $\rho$  is the spatial lag variable influence coefficient of green innovation efficiency development, which reflects the spillover effect of green innovation efficiency development on green innovation development in the surrounding areas of the target area.

If the spatial dependence of green innovation behavior is affected by some error disturbance terms which are difficult to observe and have certain spatial structure, and to effectively measure the impact of this error impact on the efficiency of green innovation in this region, the spatial error model (SEM) can be expressed as follows:

$$\begin{aligned} \ln \text{GIE}_{it} &= \alpha_{it} + \rho W \ln \text{GIE}_{it} + X_{it}\beta_{it} + \mu_{it}, \\ \mu_{it} &= \lambda W \mu_{it} + \varepsilon_{it}, \end{aligned} \quad (6)$$

where the parameter  $\lambda$  reflects the regional spillover effects caused by the error term and  $\varepsilon$  is the residual term.

If the level of green innovation efficiency in the region is not only affected by the spatial spillover effect of green innovation efficiency in neighboring regions but also by other variables in neighboring regions, the spatial Durbin model (SDM) can be considered, which can be expressed as follows:

$$\ln \text{GIE}_{it} = \alpha_{it} + X_{it}\beta_{it} + W X_{it}\theta_{it} + \mu_{it}, \quad (7)$$

where  $\theta$  reflects the weighted influence of other regional factors on the efficiency of green innovation in this region, which is defined as other spillover effect in this paper.

**3.2.4. Decomposition of Direct and Indirect Effects.** Due to the spatial correlation in the spatial regression models, the authors in [45] point out that the coefficients of the explanatory variables in the regression model cannot accurately reflect the marginal effect. Spatial spillover effect is an important analysis tool in the spatial econometric model. Because spillover effect has a certain direction of source and source, there will be other spillover effects of other regional influencing factors on innovation efficiency in the region, and there will be other spillover effects of regional relevant variables on green innovation efficiency in the surrounding regions. In the spatial econometric model, the independent variable and the dependent variable will interact. At this time, the marginal effect of the independent variable on the dependent variable cannot be regressed by the linear model. Further deconstruction is needed to simplify the above spatial Durbin model into a vector expression at a specific time point:

$$\ln \text{GIE}_{it} = (1 - \rho W)^{-1} \alpha y_N + (1 - \rho W)^{-1} \cdot (\beta \ln X_i + \theta W \ln X_i) \mu^*, \quad (8)$$

where  $y_N$  is the vector of  $N \times 1$ -order dependent variable,  $\alpha$  is the constant term,  $\mu^*$  is the cross-section, random, and period error term, and  $\ln X_i$  is the  $N \times K$  dimension matrix composed of all independent variables. At a specific time point, the derivative matrix expression of the dependent variable  $\ln \text{GIE}_{it}$  to the independent variable  $K$  is

$$\begin{aligned} \left[ \frac{\partial \ln \text{GIE}}{\partial \ln x_1^k}, \dots, \frac{\partial \ln \text{GIE}}{\partial \ln x_N^k} \right] &= (1 - \rho W)^{-1}, \\ \begin{bmatrix} \beta_k & W_{12}\theta_k & \dots & W_{1N}\theta_k \\ W_{21}\theta_k & \beta_k & \dots & W_{2N}\theta_k \\ \vdots & \vdots & & \vdots \\ W_{N1}\theta_k & W_{N2}\theta_k & & \beta_k \end{bmatrix} &. \end{aligned} \quad (9)$$

The mean value of the elements on the main diagonal of the right matrix in the formula reflects the influence degree of the independent variable on the dependent variable in the province, that is, the effect of a province on the efficiency of

green technology innovation in the region through a certain influencing factor, which is called direct spillover effect. It is expressed as  $\overline{M}_{\text{direct}} = N^{-1} \cdot \text{tra}[X(W)]$ , where  $\text{tra}[X(W)]$  is the trace of matrix  $X(W)$ , and it is the sum of main diagonals. The mean value of other elements on the nonmain diagonal of the right matrix in this formula reflects the spillover effect of a province on the green innovation efficiency of other provinces through its own relevant influencing factors, which is called the indirect spillover effect [46]. In this paper, it is defined as the spillover effect; that is,  $N^{-1} \cdot y \cdot X(W) \cdot y - N^{-1} \cdot \text{tra}[X(W)]$ . Finally, direct spillover effect and indirect spillover effect are summed up as the total spillover effect.

### 3.3. Variables and Data Description

#### 3.3.1. Variables for Green Innovation Efficiency.

According to the principles of comprehensiveness, scientific, and availability of data, the index system for evaluating the efficiency of industrial green technology innovation is constructed by referring to the relevant research of green technology innovation:

- (1) Inputs: including labor input (number of R&D employees), capital input (total investment in R&D), and resource input (total energy consumption), which represent the consumption degree of innovation activities on resources.
- (2) Desirable outputs: including new product sales revenue and patent applications, which, respectively, reflect the economic benefits, living standards, and output level of scientific research achievements of each region.
- (3) Undesirable outputs: industrial pollution is the main source of environmental pollution, so the undesired output variable adopts the industrial wastewater discharge, industrial smoke (dust), and industrial sulfur dioxide discharge of each city in the YREB and uses the entropy method to calculate an environmental pollution index, which is used to explain the comprehensive impact of innovation activities on the ecological environment.

The input-output index system of green innovation efficiency in YREB is constructed in Table 1.

#### 3.3.2. Influential Factors on Green Innovation Efficiency.

There are many driving factors for the coordinated development of green innovation system. These factors will affect the development level of the subsystem invested in the regional green innovation subsystem and then affect the coordinated development level of the regional green innovation system. However, these factors cannot be used as the direct investment of each subsystem, and these factors are often not directly measured [47]. Therefore, in order to systematically and comprehensively study the driving factors of regional green innovation system, the factors that affect the efficiency of green innovation in the YREB are

TABLE 1: Evaluation indicator system of green innovation efficiency in YREB.

| Type                | Indicator        | Description   |
|---------------------|------------------|---|
| Inputs              | Labor            | Number of R&D employees (10,000 people)                         |
|                     | Capital          | Total investment in R&D (Billion yuan)                          |
|                     | Energy           | Total energy consumption (tons of standard coal)                |
| Desirable outputs   | Economic         | New product sales revenue (billion yuan)                        |
|                     | Technology       | Number of patent applications (billion)                         |
| Undesirable outputs | Industrial waste | Exhaust emissions, wastewater discharge, and solid waste (tons) |

summarized as direct and indirect factors, including environmental regulation and industrial structure, and the indirect factors include the level of economic development, the strength of government support, and the level of opening to the outside world [48]. Consider that the YREB, as a strategic region of our country, has different responsibilities and requirements in its upper, middle, and lower reaches. Based on the previous study, the following five factors are used to examine the impact on the green innovation efficiency:

- (1) Economic development (ED): green innovation has a higher threshold than traditional innovation. A higher level of economic development is conducive to the improvement of environmental protection needs and environmental human capital of residents and provides the necessary material basis and social environment for promoting the green innovation achievements. The exhibition has green incentive effect and cumulative effect of innovation ability, and it can promote the promotion of green innovation ability. The YREB is a national key construction inland river economic belt with global influence. Its economic development speed is at the national leading level, which should promote the ability of green innovation and enhance the competitiveness of regional green innovation development.
- (2) Environmental regulation (ER): Porter believes that environmental regulation can drive green innovation, which is the famous ‘‘Porter Hypothesis’’ [49]. Porter believes that appropriate environmental regulations can stimulate enterprises to increase investment in technology research and development, promote green innovation, and achieve a win-win situation of technological progress and environmental protection. Since the ‘‘Porter Hypothesis’’ was put forward, a large number of empirical research results show that environmental regulation is one of the important driving factors of green innovation [50–52]. Under the restriction of environmental regulation, the innovation subject in the region

should increase the investment in technological innovation, promote the improvement of the development level of technological innovation system and then reduce the expected output of the cost of achievement transformation subsystem, and promote the coordinated development of regional green innovation system. Therefore, environmental regulation is also an important driving factor for the coordinated development of regional green innovation system.

- (3) Government support (GS): technology driving factors are considered to be the fundamental cause of green innovation, and the improvement of technology capability triggers green innovation. This paper chooses government support for technology innovation to represent technology driving factors. The government's financial expenditure on science and technology improves the national green innovation ability and promotes economic growth. The government's support for scientific and technological innovation has created a good external environment for regional green innovation. To a large extent, the government's financial support also reflects the strength of the government's policy support. This paper chooses government funds from R&D funds as the indicator of government support for technological innovation. To a large extent, the government's financial support also reflects the strength of the government's policy support. Choose government funds from R&D funds as the indicator of government support for green innovation.
- (4) Foreign direct investment (FDI): the degree of market opening reflects the degree of exchange between a region and other regions in the fields of economy, science, and technology. The impact of market openness on green innovation is still controversial in academia. One of the most famous hypotheses is the "pollution shelter" hypothesis [53]. According to the "pollution shelter" hypothesis, companies in developed countries will transfer their pollution intensive industries to developing countries with relatively low regulation so that developing countries will become "pollution shelter paradise" and bear more environmental pollution [54]. But another hypothesis, pollution halo hypothesis, holds that market opening can reduce environmental pollution [55]. Through the spillover effect of foreign investment, developing countries bring advanced foreign green technologies, which can significantly improve the level of regional technological innovation and the level of regional unexpected output, thus promoting the coordinated development of regional green innovation system [56, 57]. The YREB covers the three major economic zones of the East, the middle, and the West. The introduction of foreign investment may promote the local technological progress, and at the same time, there will be

competition for foreign investment, which will make the surrounding cities backward in production capacity.

- (5) Industrial structure (IS): optimizing the internal allocation of the industry is conducive to stimulating the vitality of industrial innovation and enhancing the capacity of industrial green technology innovation. With the gradual upgrading of industrial structure, the secondary industry with strong pollution production capacity has transformed into a clean and low-carbon service industry, and the secondary and tertiary industries have accelerated the pace of integrated development [58, 59]. The close connection is promoted between green technology R&D services and industrial green transformation and enhanced the technological innovation ability with industrial characteristics. The YREB actively promotes the optimization and upgrading of industrial structure, promotes the integrated development of urban productive service industry and manufacturing industry, and requires enterprises to strengthen the research and development of green production technology to meet the technical requirements of industrial structure upgrading, and low-end production capacity may be forced to move to surrounding areas.

The influencing factors of green innovation efficiency in YREB is constructed in Table 2.

## 4. Empirical Analysis

*4.1. Green Innovation Efficiency of YREB.* Considering that there will be a certain time lag when green innovation input is converted into output, using other research results for reference, the input-output time lag is set as 1 year [60]; that is, the time interval of input index is set as 2008–2017, and the output index is set as 2008–2017. All the data were directly derived from the China Statistical Yearbook (2008–2017), the China Energy Statistical Yearbook (2008–2017), and the China Statistical Yearbook (2008–2017), the carbon dioxide emissions were estimated using the method provided by the Intergovernmental Panel on Climate Change [61]. Descriptive statistics of related variables are shown in Table 3. It can be preliminarily judged that the green innovation efficiency of 11 provinces and cities may also be significantly different, and further empirical analysis will be carried out in the future.

This paper relies on Max DEA PRO 8.0 software by using super-SBM model to measure the green innovation efficiency of 11 provinces in YREB from 2008 to 2017. The results are summarized in Table 4.

From 2008 to 2017, the overall green innovation efficiency of YREB was relatively stable. From 2008 to 2010, there was a slight downward trend. It increased significantly in 2013 and decreased slightly in 2013–2017. There are significant regional differences in green innovation efficiency level and time evolution trend in the upper, middle, and lower reaches of the YREB. During the research period,

TABLE 2: The influencing factors of green innovation efficiency in YREB.

| Variable                        | Description   |
|---------------------------------|---|
| Economic development (ED)       | GDP per capita  |
| Environmental regulation (ER)   | The ratio of total investment in industrial pollutants to GDP                     |
| Government support (GS)         | R&D funds   |
| Foreign direct investment (FDI) | The proportion of foreign investment as a percentage of the regional GDP          |
| Industrial structure (IS)       | Proportion of total output value of tertiary industry to total GDP in each region |

TABLE 3: Descriptive statistics of green innovation efficiency in YREB.

| Index  | Minimum | Maximum | Mean    | Standard deviation |
|--|---------|---------|---------|--------------------|
| Number of R&D employees (10,000 people)          | 12656   | 466735  | 111834  | 134245             |
| Total investment in R&D (Billion yuan)           | 324986  | 4365780 | 4326382 | 6023576            |
| Total energy consumption (tons of standard coal) | 4658    | 30480   | 13762   | 6187               |
| New product sales revenue (billion yuan)         | 3795210 | 7456754 | 7134578 | 7238568            |
| Number of patent applications (billion)          | 1785    | 125784  | 32650   | 33468              |
| Exhaust emissions (10,000 tons)                  | 8730    | 64390   | 23561   | 13652              |
| Wastewater discharge (10,000 tons)               | 14370   | 455321  | 138542  | 100654             |
| Solid waste (10,000 tons)                        | 1450    | 17890   | 8974    | 4376               |

the green innovation efficiency of the middle and lower reaches of the province showed a trend of increasing first and then decreasing slightly, while that of the upper and lower reaches showed a trend of decreasing first and then increasing and then decreasing, but the fluctuation range was small. Since the promulgation of several opinions of the State Council on promoting the rise of the central region in 2005, the industrial undertaking policies to promote the rise of the central and western regions have promoted the inflow of a large number of capital and labor factors, which has led to the economic growth of the central and western regions. However, the industrial undertaking has brought economic benefits as well as unexpected output, making the green innovation efficiency of the middle and upper reaches of provinces at it is low and declining, and only in recent years, does it show an upward trend. In 2014, the policy of building the YREB into a leading demonstration zone of ecological civilization was issued. Since then, the state and local governments of the YREB have successively issued relevant

TABLE 5: Global Moran's I Index of green innovation efficiency.

policies, and the construction of ecological civilization in the YREB has achieved initial results.

#### 4.2. Spatial Autocorrelation Analysis

4.2.1. *Global Spatial Autocorrelation.* This paper uses MATLAB to calculate the Global Moran's I Index of logistics green innovation efficiency in YREB. Table 5 presents the results.

The results show that the Global Moran's I Index of the green innovation efficiency passed the test at 10% significance level in 2008–2017, indicating that the green innovation efficiency displays a positive spatial correlation, it is not distributed randomly, the index is basically between 0.3 and 0.6, and it indicates that the green innovation efficiency shows a weak agglomeration state. In the main, the Global Moran's I Index moves upward along a wave-like curve, this may be related to the macroeconomic environment in which the Chinese economy enters the “new normal,” and the industrial structure is transformed and upgraded.

The high and low efficiency neighboring provinces show a spatial cluster. The higher green innovation efficiency regions were adjacent, and the regions with lower green innovation efficiency were close to each other.

4.2.2. *Spatial Effect of Green Innovation Efficiency.* Because the data used in this paper are panel data, it is necessary to determine whether the fixed effect model or the random effect model should be used before regression analysis of the model. The Hausman test was carried out for SLM and SEM by MATLAB, and the test results are shown in Table 6.

According to Table 6, both SLM and SEM passed the Hausman test at 5% significance level, so the panel model with fixed effect was selected for regression analysis.

According to the test of spatial correlation, Table 7 shows that the test of LM\_lag is greater than LM\_error, so the estimation method of spatial lag model is studied and analyzed.

The general OLS regression coefficient is smaller than the spatial Durbin model (SDM), which shows that OLS regression ignores the spatial interaction between independent variables and dependent variables and overestimates the influence of related variables. From the regression results of the SDM model, the log-L and  $R^2$  of the spatiotemporal fixed model are obvious, and it is larger than the fixed time model and the fixed space model, so the double fixed model has the best estimation results. Table 8 is an analysis of the influencing factors of green innovation efficiency based on the empirical results of the time-space fixed model. The results are shown in Table 8.

- (1) Economic development (ED) has a significant positive role in promoting the green innovation efficiency of the YREB. For every 1% increase in GDP per capita, the efficiency of green innovation will increase by an average of 0.3487%. It shows that economic growth will improve the green innovation efficiency. Economically developed regions in the YREB, on the one hand, will pay more attention to the development of environmental quality; on the other hand, the R&D investment in the field of green innovation will increase, and the investment

\*\*\*, \*\*, and \* represent the significance level at 1%, 5%, and 10%.

subsidies and production subsidies for products and services will be greater. The coefficient of the spatial lag term of economic growth is  $-0.1593$ , and through the 1% significance test, it shows that the economic growth of the neighboring areas in the YREB has negative spatial spillover effects to the green innovation efficiency of the region. This is because the economic development of the neighboring areas will have a certain siphon effect on the relevant innovation elements of the region, which is not conducive to the improvement of the green innovation efficiency of the region.

- (2) Industrial structure (IS) has a significant positive role at the level of 5%. In the TF model, the coefficient is also significantly positive. This is mainly because in the adjustment and upgrading of industrial structure in the YREB, those high energy consumptions and high pollution situation have improved. However, in the process of promoting the industrial structure to achieve a high degree and rationalization in a certain region in the YREB, it may cause the imitation of neighboring regions and promote the coordinated development of regional green systems in different regions.
- (3) Foreign direct investment (FDI) has no significant effect on the green innovation efficiency of the YREB. At the same time, the corresponding spatial lag has not passed the significance test, which means that when the YREB regions introduce FDI, they neither promote the efficiency of local green innovation nor bring spillover effects to the efficiency of green innovation in the surrounding areas. The reason may be that FDI does not really consider regional environmental technology innovation in most provinces or even occupies the provincial R&D innovation of the YREB and inhibits the technological innovation ability, and the green innovation efficiency of introducing foreign investment is not ideal. This also means that the purpose of most FDI entry is to pursue low cost and tax advantages. It does not really consider environmental technology innovation, and the quality of investment still needs to be further improved.
- (4) Government support (GS) has a significant positive role in promoting the green innovation efficiency of the YREB. The government's support for green innovation activities can improve the development level of scientific and technological research and development subsystem, so as to reduce the unexpected output in the process of achievement transformation, increase the expected output, and promote the coordinated development of green innovation system. The government should continue to increase its support for green innovation in the YREB, especially in the less developed areas such as the central and western regions. By promoting the development of technological innovation, we can develop more technologies that are beneficial to the ecological environment and promote the coordinated development of green innovation system.
- (5) Environmental regulation (ER) has significant positive effect on the green innovation efficiency of the YREB. For every 1% increase in the level of environmental regulation, the green innovation efficiency will increase by an average of 0.005%, which means that the more stringent the environmental regulation is, the stronger the environmental pollution cost constraints enterprises bear, so that they have the motivation to pay attention to the

production of clean, ecological, and recycling, and the enterprises that take the lead in technological innovation have the first mover advantage in pollution control. It is helpful for enterprises to seize market share and gain competitive advantage, and it is also helpful for enterprises to improve their green innovation performance. The coefficient of the spatial lag term of environmental regulation is  $-0.003$ , and through the 1% significance test, it shows that the environmental regulation of the neighboring areas has negative spatial spillover benefits to the green innovation efficiency of the region. This may be due to the deterrence effect of environmental regulations on enterprises, which forces enterprises to increase investment in environmental governance, so that the corresponding low-tech pollution links are transferred to other areas with relatively low environmental standards, leading to the "pollution shelter" effect and inhibiting green innovation.

#### 4.2.3. Spatial Spillover Effects of Green Innovation Efficiency.

Based on the SDM model, this paper analyzes the direct, indirect, and total effects of various influencing factors, among which the total effect represents the average impact of influencing factors on green innovation, while the direct effect and indirect effect represent the decomposition of the total effect, which, respectively, represents the impact of influencing factors on the region and adjacent regions. Table 9 are the results.

The indirect effect of the level of economic development is negative, which shows that, in general, the level of economic development is not conducive to the spatial spillover of green innovation efficiency in the period under investigation, especially in the provinces with the higher level of economic development, the lower the spatial spillover effects of green innovation efficiency, which highlights that the more developed provinces pay more attention to "protect" the efficiency of green innovation in their own provinces in the YREB. Under the requirements of national green development, the economically developed regions in the YREB make use of their own advantages in capital, and the economically underdeveloped regions are eager to improve the local economic level and transfer some high energy consumption, high pollution, and high emission industries to the economically underdeveloped provinces, which to some extent causes the green innovation efficiency to show negative spatial spillover effects.

The total effect, direct effect, and indirect effect of industrial structure are all positive. The optimization of industrial structure is conducive to the transformation of development mode, reduction of energy consumption, and environmental pollution, so as to improve the efficiency of green innovation.

FDI in this region has no significant impact on the green innovation efficiency of surrounding areas in the YREB. It shows that there are corresponding regional technical barriers in the process of promoting the

TABLE 9: Spatial spillover effects of green innovation efficiency.

|       | Direct effect    | Indirect effect   | Total effect     |
|-------|------------------|-------------------|------------------|
| LnED  | 0.244***<br>5.20 | -0.232***<br>4.48 | 0.012***<br>8.82 |
| LnIS  | 0.038***<br>1.29 | 0.047***<br>0.89  | 0.085***<br>1.27 |
| LnFDI | 0.162*<br>1.45   | 0.414<br>3.68     | 0.576<br>2.87    |
| LnGS  | 0.025***<br>2.56 | 0.034<br>3.28     | 0.059**<br>2.62  |

\*\*\*, \*\*, and \* represent the significance level at 1%, 5%, and 10%.

efficiency of green innovation in all regions of YREB. On the one hand, they are unwilling to cooperate and share the technical innovation; on the other hand, they are easy to transfer the cost of environmental pollution to the surrounding areas.

The direct effect regression coefficient is positive under the significance of 5%, and the indirect effect regression coefficient fails to pass the significance test. Government support is a strong backing to enhance the capacity of green innovation, especially along with the transformation and upgrading driven by green innovation in the YREB, and the government has given strong support in building basic innovation platform and increasing investment in innovation and R&D. The guiding effect of green innovation policy is significant, laying a solid foundation for the high-quality development of the YREB.

The direct effect of environmental regulation on the spatial spillover of green innovation efficiency is positive and passes the significance test; the indirect effect and the total effect on the productivity of green innovation pass the significance test of 5% but has a negative impact on the change in green innovation efficiency. This shows that, on the one hand, environmental regulation has a positive role in promoting the efficiency of green innovation in our province, but at present, it has not fundamentally changed the level of green development in China, so it cannot significantly improve the efficiency of green innovation in China. On the other hand, when China's green innovation capacity is insufficient, the imbalance of the intensity of interprovincial environmental regulation is likely to lead the environmental pollution industry in the provinces with high intensity of regulation to enter the provinces with low intensity of regulation in the YREB.

## 5. Conclusions and Discussion

*5.1. Conclusions.* This study used super-SBM model to consider undesirable outputs, measuring the green innovation efficiency in YREB from 2008 to 2017. Since green innovation efficiency has spatial spillover effects, therefore, a spatial econometric model SDM model is applied to analyze the influencing factors of green innovation efficiency. The green innovation efficiency empirical results indicate the green innovation efficiency is developing slowly, and the

green innovation of the eastern part of YREB is significantly better than that of the lower reaches in the west. From the spatial autocorrelation result, it shows that there is a significant spatial autocorrelation of green innovation efficiency in YREB regions. From the spatial econometric of SDM analysis, indicating that the level of economic development, foreign direct investment to the outside world and environmental pollution control has positive effects on the green economic efficiency of the YREB, while the proportion of the secondary industry has negative effects. The green economic efficiency of the YREB has a significant spatial correlation. The provinces with high level of economic development and environmental pollution control have a significant positive role in promoting the green economic efficiency of the neighboring provinces. The provinces with high proportion of the secondary industry and high government support have a negative inhibitory effect on the green economic efficiency of the neighboring provinces.

*5.2. Discussion.* According to the empirical results, this study put forward proposals to enhance green innovation efficiency.

First, the optimization and upgrading of industrial structure is promoted. Industrial structure has a significant negative inhibitory effect on the green innovation efficiency of the YREB, so it is necessary to speed up the pace of industrial structure adjustment and new industrialization. We will bring superiority into full play of industry and intelligence intensity in the YREB, vigorously implement innovation-driven development strategy, add to new momentum of reform, innovation, and development, subtract from the elimination of backward production capacity, and accelerate industrial transformation and upgrading. We will build a manufacturing innovation system, improve the ability to develop key systems and equipment, and foster and expand high technology industries, emerging sectors of strategic importance, equipment manufacturing, and other industries. We will optimize the layout of strategic emerging industries, accelerate the construction of regional characteristic industrial bases, give free rein to radiation driving and leading demonstration, and form a national strategic emerging industry development highland.

Second, the quality of opening up is improved. The technology spillover effects of FDI in the YREB are more than the environmental pollution effect. The introduction of FDI can improve green economic development level in the YREB, but improvement effect is not significant, so we should further improve the quality of opening up. We should further promote the improvement of the negative list of market access in the YREB, improve the project access mechanism, promote the formation of an institutionalized, standardized, green, transparent, and procedural system for foreign capital introduction system, vigorously introduce new green technologies and industries, attract environmentally friendly enterprises to settle down, give full play to the technology spillover effects of green foreign capital industries, and improve the green production of local

enterprises to build a green ecological industrial chain and improve the level of green development and ecological quality.

Finally, we will intensify efforts to prevent and control environmental pollution. Environmental pollution control in the YREB has a positive role in improving green innovation efficiency, but it has not produced significant results, so the efforts of environmental pollution control need to be further strengthened. We should strengthen the joint prevention and control of environmental pollution; establish and improve the emergency response mechanism for cross department, cross region, and cross basin environmental emergencies; strictly control industrial pollution; dispose of urban sewage and garbage; control agricultural nonpoint source pollution; prevent ship and air pollution; strengthen the collaborative protection of ecological environment; establish a negative list management system; strengthen daily monitoring and supervision; and strictly implement the ecological environment. The system of responsibility investigation for environmental damage should be improved, the proportion of resource utilization rate, environmental pollution prevention and control, and quality evaluation system of economic and ecological development should be increased, and the performance evaluation system reflecting the requirements of ecological civilization should be improved.

The Internet of Things (IoT) is an information carrier based on network communication, and it can make all general physical objects which can be independently addressed from an interconnected network. Controller Area Network (CAN) is a kind of serial communication network which can effectively support distributed control or real-time control. This paper proposes the design of an IoT-oriented universal CAN bus. In order to build a complete CAN communication simulation model, message sending and message receiving models are constructed, respectively. The simulation experiment proves that the IoT-oriented network communication model designed in this paper not only has low power consumption, but it can also solve the front-end compatibility problems caused by different communication protocols.

## 1. Introduction

Internet of Things technology has been listed as one of the emerging industries with strategic significance in the world and has developed rapidly. IoT is an object-oriented Internet. Its three major technologies, sensor technology, communication technology, and embedded system technology, correspond to its three attributes of perception, transmission, and control [1]. Among these three technologies, embedded system technology is the foundation, sensor technology is the function expansion, and the communication technology is the core connection technology of IoT [2]. The communication technology of IoT includes four types: wire transmission, wireless transmission, traditional Internet, and mobile air network. The IoT system does not need every device to be connected to the Internet; it can have one device as the control core, to which the other devices are connected through wireless communication technology and this device is connected to the Internet for communication [3]. This method can lower the

application cost of IoT. CAN bus is a serial communication network that can effectively support distributed control and real-time control and it has been widely applied in the field of automatic control with its high performance and reliability. The CAN protocol has multimaster control and it also has the functions of error detection, error notification, and error recovery. All units can detect error and the unit which detects the error will notify all other units immediately [4]. Besides, CAN bus has many connection nodes, and it can be connected to the bus with multiple units. Theoretically, there is no limit for the number of connectable units. Besides, it has a fast communication speed and a long communication distance. The fastest speed is 1 Mbps (with the distance less than 40 m) and the longest distance is 10 km (with the speed slower than 5 kbps) [5]. In field bus, CAN bus has obtained extensive support of computer chip makers, who have released microcontroller unit (MCU) chip with direct CAN interface one after another. With the development of CAN bus technology, it has already become one of field buses that has been widely applied in many fields,

including agriculture, robot, computer numerically controlled machine tool, medical apparatus and instruments, vehicles, vessels, and national defense [6].

The special contributions of this paper include the following:

- (i) It has firstly elaborated the significance and background of this paper, analyzed the research status at home and abroad of IoT and CAN bus, and expounded the related theoretical foundation.
- (ii) It has introduced the technological architecture and logical architecture of industrial equipment IoT platform, analyzed CAN real-time communication technology, and studied the network communication, socket mechanism, and breakpoint resume with reliable time sequence.
- (iii) It has proposed an IoT-oriented universal CAN bus and explored some problems to which attention should be paid in application. It has also proposed the design method for CAN bus interface circuit for its highly integrated communication controller.
- (iv) It has effectively simulated and constructed CAN communication, constructed the complete model structure, and conducted simulation and operation to check its effect. It has proven that the CAN communication design scheme of this paper is effective.

The remainder of this paper is organized as follows. Section 2 discusses related works, and IoT-oriented CAN communication design is outlined in Section 3. Experimental procedure is presented in Section 4. Section 5 shows the experimental simulation results, and Section 6 concludes the paper with a summary and proposed directions for future research.

## 2. Related Work

With the development of IoT, communication technology, and control technology, conventional industrial control field has been experiencing an unprecedented reform and the networked industrial control has expanded the development space for industrial control field and brought new development opportunities [7]. In a wide range of industrial fields, CAN bus can be taken as the field device-level communication bus and compared with other buses, which has high reliability and cost performance. This will be a main direction for CAN technology open for the development and applications of IoT [8]. CAN is a multimaster serial communication bus and according to its basic design specifications, it has a fast bit rate and high anti-electromagnetic interference, and it can detect any error. Firstly, the CAN controller works in a variety of modes, and each node in the network can adopt bit-by-bit arbitration of lossless structure and send data to the bus contention according to the bus access priority and message identifier. Besides, CAN protocol has replaced station address coding with communication data coding, enabling different nodes to receive the same data at the same time [9]. These characteristics have led

to strong real-time data communication among network nodes formed by CAN bus and the easiness to constitute a redundant structure and improved the reliability and flexibility of the system. The data communication of CAN bus has outstanding reliability, timeliness, and flexibility. Due to its excellent performance and unique design, CAN bus has attracted more and more attention. Most automobile manufacturers have adopted CAN bus to realize the data communication between internal control system and various test and execution institutions. Meanwhile, because of the characteristics of CAN bus, its application is no longer restricted to auto industry, but it also develops towards IoT and other fields. CAN has become an international standard and it has already been considered as one of the most promising field buses [10, 11].

In as early as 1998, Massachusetts Institute of Technology in the United States had come up with the idea of IoT at that time, i.e., EPC system, and one year later, the concept of IoT had been deemed as the logistics network based on Radio Frequency Identification (RFID) [12]. IoT has not had a formal definition: IoT is the network that makes all objects which have and can implement independent functions achieve interconnection, until 2005 when the International Telecommunication Union (ITU) released "ITU Internet Report 2005: Internet of Things" [13]. CAN bus is one of the field buses which have been applied the most in the world. It was first launched by Bosch, a German company, and used in the data connection protocols between internal measurement and execution units. The application of CAN bus ranges from high-speed networks to low-cost multiline network and it is widely applied in the data communication between various detection and execution agencies in the control system [14]. CAN bus can mount many communication nodes, the signals between which are transmitted via the bus so as to realize between-node communication. The use of RS-485 can only constitute a master-slave structural system and the communication can only be conducted by means of master station polling. Worse still, the system has poor timeliness and reliability [15].

In theory, as long as the bus has enough load, the number of nodes is not limited, and the repeater can improve the load. CAN bus can effectively reduce the number of wires and it has flexible communication, excellent timeliness, and high reliability. However, the communication quality of CAN is related to many factors, mainly including the distance between communication nodes, the type and impedance of communication lines, crystal oscillator error of various communication nodes, and the deviation caused by external environment [16]. In practical engineering field, the preset CAN sample point may not be able to guarantee the data receiving and dispatching quality of communication nodes and there may be frame loss and receiving and dispatching abnormalities in data which affect the normal operation of product functions due to the impact of the above factors. To solve the problems in existing technology, this paper provides an IoT-oriented scheme used in CAN bus message management and the hardware design method

of CAN bus interface circuit of highly integrated communication controller so as to guarantee the safety of network communication [17].

### 3. IoT-Oriented CAN Communication Control Design

**3.1. Key Issues in Interface Circuit Design.** Any node in CAN can take an initiative and send a message to other nodes in the network irrespective of master and slave at any moment. It adopts nondestructive bus arbitration technology. When two nodes send a message to the network at the same time, the node with low priority voluntarily stops data transmission while the one with high priority continues to transmit the data insusceptibly. In addition, it has the functions of point-to-point, one point to multipoints, and global broadcast data transmission and reception. Every frame of message has CRC check and other error detection measures with an extremely low error rate and high reliability. When a serious mistake occurs in message transmission, the node can automatically cut its connection with the bus so that other operations in the bus are not affected [18].

**3.1.1. Optoelectronic Isolation Circuit.** Although optoelectronic isolation circuit can strengthen the antijamming capability of the system, it also increases the propagation delay time of CAN bus effective loop signal and decrease the communication speed or distance. CAN transceiver itself has instantaneous anti-interference, radio frequency interference (RFI), and the ability to achieve thermal protection; additionally, its current limit circuit has also provided further protection to the bus. Therefore, in case of short field transmission distance and little electromagnetic interference, optoelectronic isolation may not be adopted to make the system reach the maximum communication speed or distance and simplify the interface circuit. If optoelectronic isolation is needed in the field environment, high-speed optoelectronic isolation device should be selected to reduce the propagation delay time of effective loop signal of CAN bus. The propagation delay time is short and it is approximate to the level of TTL circuit propagation delay time [5].

**3.1.2. Power Isolation.** The power  $V_{dd}$  and  $V_{cc}$  used in the two sides of optoelectronic isolation device must be completely isolated. Otherwise, optoelectronic isolation will not play its due role. Power isolation can be achieved through low-power DC/DC power isolation module.

**3.1.3. Bus Impedance Matching.** The terminal of CAN bus must be connected with  $n$  resistors, which have a significant role in bus impedance matching; otherwise, it will greatly reduce the reliability and anti-interference performance of bus data communication and it may even make it impossible to carry out communication. In order to improve the antijamming capability of interface circuit, the following measures can also be taken into consideration: connect  $n$

parallel capacitors between CANH and CANL of the transceiver and the earth to filter the high-frequency interference in the bus and prevent electromagnetic radiation [19].

**3.2. CAN Bus Synchronization Mechanism.** CAN communication is an asynchronous serial communication. Its synchronization method is not achieved by providing extra clock signals but by realizing read-write synchronization through bit timing, fixed message frame structure, and hard synchronization and resynchronization operations. The condition for communication between various nodes in CAN bus network is that they have the same normal bit rate (NBR), i.e., the bits are transmitted every second. Its reciprocal is called normal bit time  $t_{bit}$  which is composed of four nonoverlapping time periods: reciprocal period, transmission period, phase buffer period 1, and phase buffer period 2. The normal bit time can be defined as follows:

$$t_{bit} = \frac{1}{NBR} = t_{SyncSeg} + t_{propSeg} + t_{PS1} + t_{PS2}. \quad (1)$$

Every period of time in normal bit time is made up of multiple time quanta TQ, the length of which depends on the frequency of oscillator  $f_{OSC}$ . The relation between them is as follows:

$$TQ = \frac{2BRP}{f_{OSC}}. \quad (2)$$

In which, BRP is the Baud rate prescale coefficient and for the device that adopts the same clock frequency of the master oscillator in CAN bus network, the normal bit rate NBR can be adjusted to the same numerical value only by setting BRP and the TQ in every time period [20, 21].

When IoT conducts wireless communication and if the transport layer has a high packet loss speed-up rate or the data is blocked, the channel protection mechanism starts automatically. Assume that  $S(v_j, v_{DAPi})$  is the link communication of transmit data and  $v_0, v_{DAPi}$  represents the data source and destination aggregation node. In other words, when the system accesses any aggregation point, stop the transmission if at the time of  $t_0$  and the forward node  $v_i$  in the congestion point will find the homologous data continuously accumulated in the buffer zone and meanwhile conduct self-inspection and abandon. The backward node will not delete the link in the transport layer. So, there is no homologous data in the buffer zone. Therefore, the node can make a judgment according to whether the connection channel is congested or not so as to start the multiagent dynamic additional channel protection mechanism [22, 23].

With regards to protection mechanism, the node goes along the transmission channel in this technology. During the traverse, the proxy includes two parameters in composite measurement: the vacancy and surplus bandwidth rate of the receiving node. In the composite measurement, the corresponding equation to calculate the queue occupancy rate of the receiving node is as follows:

$$\mu_k(t) = 1 - \frac{q_k - \int_{t_{0-}}^{t_0} v_k^1(t) dt + \int_{t_0}^{t_{0+}} v_k^x(t) dt}{B_k} + \xi. \quad (3)$$

In which,  $\mu_k$  is the receiving node,  $v_k$  is the vacancy of queue,  $q_k$  is the current queue length of node  $v_k$ , and  $v_k^1(t)$  and  $v_k^x(t)$  represent the velocities for communication buffer zone of the node at  $t$  phase to send and receive grouping, respectively.  $\xi$  is the buffer zone of the queue and it is used to control the transmission of “flow” over message and  $\xi \in [0.01, 0.08]$ .  $B_k$  represents the size of the communication buffer zone of node  $v_k$  [24].

The composite measurement of proxy travel restoration is defined as follows:

$$M(e_{hk}) = a\mu(t) + b\gamma(e_{hk}) + 0.5. \quad (4)$$

In which,  $\alpha$  and  $\beta$  represent weight coefficient and  $a + b = 1$ . It controls the transmission of real-time message through low  $a/b$  rate as data flow will generate low jitter during the transmission. So, the rate shall increase properly.

There are two main types of CAN physical layer. The CAN communication network in Figure 1 is a high-speed, short-distance “closed-loop network” that complies with the ISO11898 standard. Its maximum bus length is 40 m, and its communication speed is up to 1 Mbps. Each end requires a 120  $\Omega$  resistor [25].

Figure 2 is a low-speed, long-distance “open-loop network” that follows the ISO11519-2 standard. Its maximum transmission distance is 1 km, and its maximum communication rate is 125 kbps. The two buses are independent and do not form a closed loop. Each bus is required. There is a 2.2 k $\Omega$  resistor in series on each [26].

## 4. Experimental Procedure

**4.1. Create the Message Transmission Model.** This section is about creating the part which transmits CAN message in the model. It sets and connects with each module by using the relevant modules in Simulink library.

**4.1.1. Create the Model.** Start Simulink in MATLAB software platform, select “Blank Model”  $\rightarrow$  “Create Model,” and complete the creation of a new blank model window.

**4.1.2. Add Related Modules.** Click the button of “Library Browser” in the toolbar and open Simulink module library. In the left side is the available module library. Select the related modules from “Vehicle Network Toolbox”  $\rightarrow$  “CAN Communication” and use them in the transmission of CAN communication in this instance.

Move the modules of “CAN Configuration,” “CAN Pack,” and “CAN Transmit” to the editing interface, respectively, and create one instance for each of them. The related module descriptions are shown in Table 1.

Select different types of modules as data source. In this paper, constant is used as the data source to verify the CAN communication model.

**4.1.3. Connect Modules.** The above modules are connected through wires: the output port of Constant is connected with the input port of CAN Pack, the output port of which is connected to the input port of Transmit and CAN Configuration is not connected with any other modules. In this module configuration, CAN channel is used for communication.

**4.1.4. Set Module Parameters.** Double click CAN configuration to configure its parameters. The specific parameter description is shown in Table 2.

Double click CAN Pack to configure its parameters, the specific descriptions of which are shown in Table 3.

Double click CAN Transmit to configure its parameters, the specific description of which can be found in Table 4.

The model structure after various modules are connected and configured in the transmission part is shown in Figure 3.

**4.2. Create the Model to Receive Message.** This section is used to create the part which receives CAN message in the model. It sets and connects various modules by using related modules in Simulink library.

**4.2.1. Add Related Modules.** Select related modules from “Vehicle Network Toolbox”  $\rightarrow$  “CAN Communication” and use them to receive CAN communications in this instance. Select the module of “Simulink”  $\rightarrow$  “Sinks”  $\rightarrow$  “Scope” to display the data received.

Move the modules: “CAN Configuration,” “CAN Receive,” “CAN Unpack,” and “Scope” to the editing interface, respectively, and create one instance for each. The related module descriptions are shown in Table 5.

**4.2.2. Connect Modules.** Create CAN message pack subsystem with the module of “Function-Call Subsystem” in “Ports & Subsystems” module library and move CAN Unpack to this subsystem.

In CAN Receive, CAN Msg (output port) is connected with In1 (input port) of CAN Unpack subsystem [27]. In CAN Receive,  $f()$  (output port) is connected with function() (input port) of CAN Unpack subsystem and in CAN Unpack subsystem, CAN Msg(output port) is connected with the input port of scope [28]. CAN Configuration1 is not connected with any other modules and it configures CAN channel for communication [29, 30].

**4.2.3. Set Module Parameters.** Double click CAN Configuration1 to configure its parameters and their descriptions are indicated in Table 6.

Double click CAN Receive to configure its parameters. The related descriptions of these parameters are demonstrated in Table 7.

Double click CAN Unpack to configure its parameters. Refer to CAN Pack for the related parameters’ description.

The model structure of the reception part after various modules are connected and configured is shown in Figure 4.

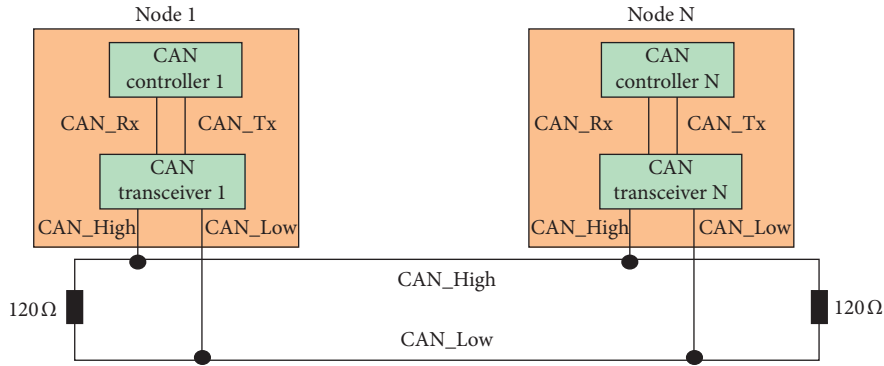

FIGURE 1: CAN closed-loop bus communication network.

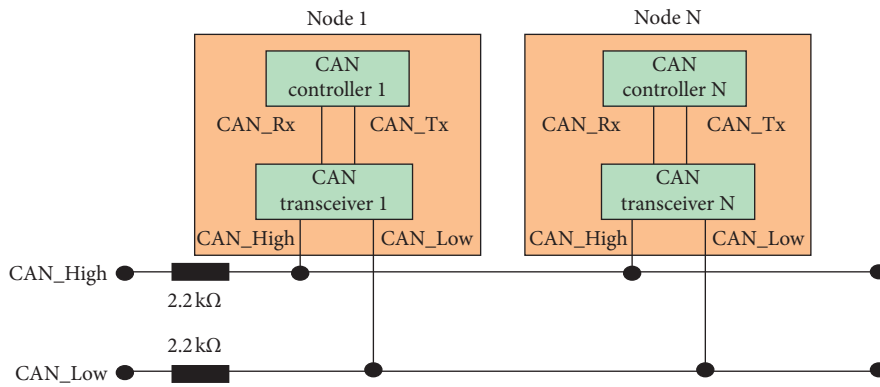

FIGURE 2: CAN open-loop bus communication network.

TABLE 1: Description of modules in CAN communication transmission.

| Module            | Diagram | Description   |
|-------------------|---------|---|
| CAN Configuration |         | It is used to configure the parameters of CAN device which is used in transmitting and receiving message and it uses one CAN Configuration module to configure every device that sends and receives message in the model. |
| CAN Pack          |         | It is used to upload signal data at a designated interval to a message during the simulation. The number of module inputs depends on the dynamic adjustment of the number of specified signals. It has an output port.    |
| CAN Transmit      |         | It is used to send and transmit data to the virtual CAN channel, and it can transmit a single message or message array. There is no output port in this module.   |

TABLE 2: Description of parameters of CAN Configuration.

| Parameter        | Value                           | Description   |
|------------------|---------------------------------|---|
| Device           | MathWorks Virtual 1 (Channel 1) | Select from list CAN device and its necessary channel. The device is used to transmit messages.   |
| Bus speed        | 500,000                         | Set the bus speed attribute for the device selected above with bits per second as the unit.   |
| Acknowledge mode | Normal                          | Check whether the designated channel is in normal mode (normal) or silent mode (silent). If normal, the channel can normally both receive and transmit message while if silent, the channel can only receive message. |

TABLE 3: Description of parameters of CAN pack.

| Parameter        | Value                        | Description   |
|------------------|------------------------------|---|
| Data is input as | Raw data                     | It selects the input signal. The raw data input the data in the form of uint8 vector array; manually specified signals can assign the definition of data signal; and CANdb specified signals can assign the CAN database file which includes the definitions of message and signal. |
| Name             | CAN Msg                      | The name of CAN message can be assigned with the default value of CAN Msg.  |
| Identifier type  | Standard (11-bit identifier) | It assigns whether the identifier of CAN message is standard or extended.   |
| Identifier       | 500                          | It assigns the ID of CAN message. For standard identifier, the figure must be any positive integer from 0 to 2047; and for extended identifier, it must be any positive integer from 0 to 536870911.  |
| Length (bytes)   | 8                            | It assigns the length of CAN message, the scope of which ranges from 0 to 8 bytes.  |

TABLE 4: Description of parameters of CAN transmit.

| Parameter | Value                           | Description  |
|-----------|---------------------------------|--|
| Device    | MathWorks Virtual 1 (Channel 1) | It selects the CAN device and channel which are used to transmit CAN message to the network. |

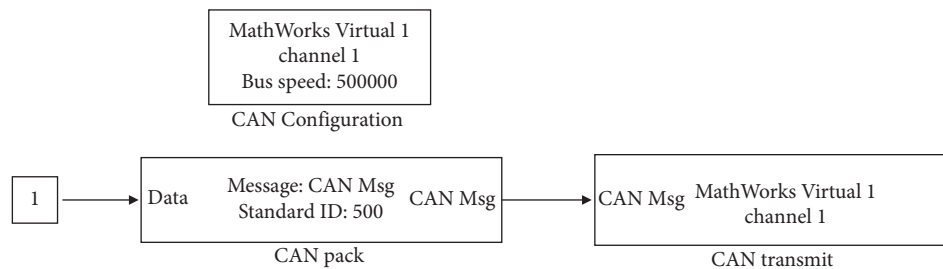

FIGURE 3: Transmission part model structure.

TABLE 5: Description of modules in the reception part of CAN communication.

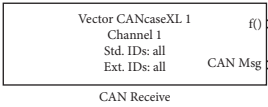

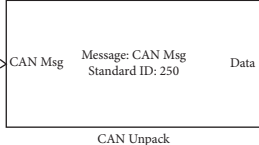

| Module      | Diagram   | Description   |
|-------------|---|---|
| CAN Receive |  | It is used to receive messages from CAN and transmit them to Simulink model. In this module, there are two output ports: $f()$ is a trigger to function-call subsystem and CAN Msg includes the CAN messages received during the specific timestep. |
| CAN Unpack  |  | It is used to unpack CAN message by using designated output parameters in every timestep into signal data and the data is output as a single signal.  |
| Scope       |  | It is used to display time-domain signal.   |

TABLE 6: Description of parameters of CAN Configuration1.

| Parameter | Value                           | Description  |
|-----------|---------------------------------|--|
| Device    | MathWorks Virtual 1 (Channel 2) | Select from list CAN device and the necessary channel and use this device to receive messages. |

4.3. *Operate the Model.* Select in the Toolbar the button of “Run” and click it to simulate. When operating simulation, CAN Transmit will obtain message from CAN pack. Then it will transmit the message through virtual channel 1 and the

CAN Receive in virtual channel 2 will receive this message and transmit it to CAN Unpack subsystem to unpack the message. Finally, double click scope to check the transmission result.

TABLE 7: Description of parameters of CAN Receive.

| Parameter                                    | Value                              | Description   |
|--|------------------------------------|---|
| Device                                       | MathWorks Virtual 1<br>(Channel 2) | It is used to select CAN device and channel to receive CAN message from this device.  |
| Sample time                                  | 0.01                               | It is used to assign the sample time of modules during the simulation and it is defined as the operating frequency of CAN receive during this time.   |
| Number of messages received at each timestep | All                                | It is used to select the number of messages the module receives at each designated timestep. All is to transmit all messages in the buffer zone to model and 1 is to transmit one message to the model. |

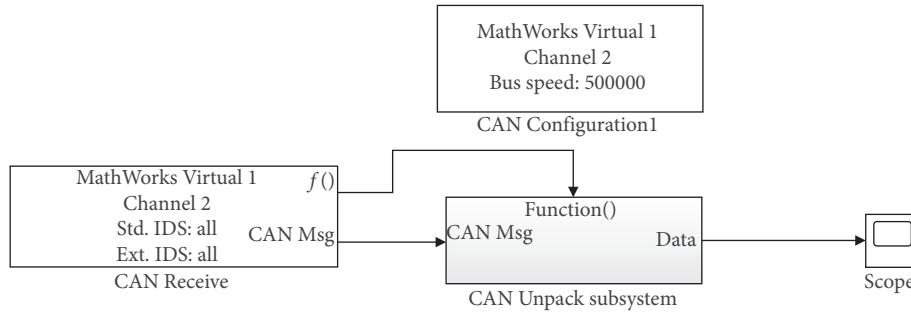

FIGURE 4: Receiving part model structure.

## 5. Simulation Experiment and Results Analysis

After the above links, the model structure which includes such links as transmission, reception, and operation are basically built. In this section, different types of modules will be selected as data sources so as to verify the CAN communication Simulink model.

Use “Constant” as the data source and add a Constant to the model from Simulink → Sources. Constant generates real-number or plural constant-value signal, and it is used to provide the input of constant signal. Among them, the parameter of “Constant value” is set as [1 2 3 4 5 6 7 8]. The final output result of CAN communication is shown in Figure 5.

Use “Sine Wave” as the data source and add a Sine Wave to the model from Simulink → Sources library. Sine Wave takes simulation time as the time source to generate sine wave and outputs sinusoid wave. The equation of wave function is

$$y = \text{amplitude} \times \sin(\text{frequency} \times \text{time} + \text{phase}) + \text{bias}. \quad (5)$$

In this instance, the value of each parameter is set as follows: amplitude is 1, bias is 200, frequency is 1, and phase is 0. The final output result of CAN communication is shown in Figure 6.

Use “Repeating Sequence” as the data source and add a Repeating Sequence to the model from Simulink → Sources library. Repeating Sequence is used to generate periodic signal of any shape and it can output periodic scalar signal with wave shape designated by parameters: time values and output values. Among them, Time values assign the output time vector and Output values specify the corresponding signal amplitude vector to output time. In this instance, the

values of various parameters are set as follows: Time values within [0 5], and Output values within [0 100]; in other words, starting from simulation, repeat one sawtooth waveform with the maximum amplitude of 100 every 5 seconds. The final output result of CAN communication is indicated in Figure 7.

Use “Step” as the data source and add a Step Module to the model from Simulink → Sources library. Step is used to generate step function and it can provide 2 steps which can define level during the designated time. If the simulation time is less than the parameter value of Step time, the parameter value of Initial value will be the output and if it is bigger than or equal to Step time, the output is the parameter value of Final value. In this instance, various parameters are set as follows: step time is 15, initial value is 5, and final value is 100. The final output result of CAN communication is shown in Figure 8.

Use “Pulse Generator” as the data source and add a module of Pulse Generator to the model from Pulse Generator library. Pulse Generator is used to generate square-wave pulse at a fixed interval and its waveform parameters, Amplitude, Pulse Width, Period, and Phase delay, and determine the shape of output waveform. In this instance, the values of various parameters are set as follows: phase delay is 0, amplitude is 100, pulse width is 20, and period is 5. The final output result of CAN communication is shown in Figure 9.

Take “Ramp” as the data source and add a “Ramp” module to the model from Simulink → Sources library. Ramp is used to generate the signals that constantly increase or decrease, and it can generate the signal which changes at a designated speed starting from designated time and value. Its parameters of slope, start time, and initial output decide the features of output signal. In this instance, the values of these

FIGURE 5: Output result of CAN communication in constant.

FIGURE 6: Output result of CAN communication of sine wave.

FIGURE 7: Output result of CAN communication of repeating sequence.

parameters are set as follows: slope is 5, start time is 15, and initial output is 5. The final output result of CAN communication is shown in Figure 10.

Use “Signal Generator” as the data source and from Simulink → Sources library, add a model of Signal Generator to the model. Signal Generator can be used to generate four different waveforms: sine wave, square wave, sawtooth wave, and random wave. The equation of wave function is

$$Y(t) = \text{Amp} * \text{Waveform}(\text{Freq}, t). \quad (6)$$

In this instance, sine wave is selected, and the values of parameters are set as follows: amplitude is 1 and frequency is 1. The final output result of CAN communication is shown in Figure 11.

Use “Chirp Signal” as the data source and from Simulink → Sources library, add a “Chirp Signal” to the model.

FIGURE 8: Output result of CAN communication of step.

FIGURE 9: Output result of CAN communication of pulse generator.

FIGURE 10: Output result of CAN communication in ramp.

This module is used to generate the waves, the frequency of which constantly increases. The parameters of initial frequency, target time, and frequency at target time decide its output. In this instance, the values of parameters are set as follows: initial frequency is 0.1, target time is 100, and

frequency at target time is 5. The final output result of CAN communication is shown in Figure 12.

Through the above experimental results, it can be observed that the IoT-oriented network communication model not only has low consumption, but also solves the front-end

FIGURE 11: Output result of CAN communication of signal generator.

FIGURE 12: Output result of CAN communication of chirp signal.

communication compatibility issues caused by different communication protocols.

## 6. Conclusions

IoT is an extension of the Internet, which extends to the communication network between objects through wireless network. It goes through various sensor devices and it can perform real-time collection, remote monitoring, connection operations, and interaction information on the device. It can constitute a new-type network with Internet technology. Interface circuit is an important link in CAN bus network and its reliability and security have directly affected the operation of the entire communication network. This paper has summarized several key issues to be noted in the design of CAN interface circuit, grasped the key in the design, and proposed an IoT-oriented universal CAN bus design, which has enhanced the quality and performance of multi-interface circuit and ensured the secure and reliable operation of CAN bus. The simulation experiment has proven that the proposed design scheme is effective.

## Data Availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also form part of an ongoing study.

## Conflicts of Interest

The authors declare that they have no conflicts of interest regarding the publication of this paper.

Imperfect information games have served as benchmarks and milestones in fields of artificial intelligence (AI) and game theory for decades. Sensing and exploiting information to effectively describe the game environment is of critical importance for game solving, besides computing or approximating an optimal strategy. Reconnaissance blind chess (RBC), a new variant of chess, is a quintessential game of imperfect information where the player's actions are definitely unobserved by the opponent. This characteristic of RBC exponentially expands the scale of the information set and extremely invokes uncertainty of the game environment. In this paper, we introduce a novel sense method, Heuristic Search of Uncertainty Control (HSUC), to significantly reduce the uncertainty of real-time information set. The key idea of HSUC is to consider the whole uncertainty of the environment rather than predicting the opponents' strategy. Furthermore, we realize a practical framework for RBC game that incorporates our HSUC method with Monte Carlo Tree Search (MCTS). In the experiments, HSUC has shown better effectiveness and robustness than comparison opponents in information sensing. It is worth mentioning that our RBC game agent has won the first place in terms of uncertainty management in NeurIPS 2019 RBC tournament.

## 1. Introduction

Game theory is the mathematical study of interaction among independent, self-interested players, providing a very simple but powerful paradigm to capture decision problem. The classical category divides games into perfect information games (PIGs) and imperfect information games (IIGs). In PIGs, players can obtain complete information of game environment. However, pervasively existing in real world, players cannot sense complete or reliable information of games. IIGs address these cases and model strategic interactions among agents with only partial or unreliable information. Thus, the exploitation of imperfect information of IIGs is one of the most critical challenges for game solving since how well players understand the game environment greatly influences the effectiveness of their strategies.

In this paper, we focus on a recently introduced IIG, reconnaissance blind chess for research of imperfect information exploitation. Reconnaissance blind chess is actually a

family of games, and we only focus on one variant, which we will refer to as RBC for simplicity [1]. RBC was designed intentionally to add a certain amount of uncertainty by adjusting some rules of chess and adding an explicit sense step.

Furthermore, we utilize the algorithm of MCTS in this paper. Monte Carlo (MC) method has been used extensively in PIGs [2] and IIGs [3] which uses random simulations to approximate the true value of states in IIGs. Furthermore, Upper Confidence Bound for Trees (UCT) is the most popular MCTS algorithm, using upper confidence bounds, a formula trying to settle the exploitation-exploration dilemma, as a tree policy for selection and expansion [4]. UCT converges to Minimax, the optimal algorithm used for two-player zero-sum games [5], given enough time and memory. However, the reality is that time and memory are limited. Hence, one severe challenge of the MCTS + UCT structure is the contradiction between the accuracy of states' estimation and limited simulation time both of which are critical for a competitive game program.

The contribution of this paper is twofold. First, we introduce a novel sense method, HSUC, to effectively exploit and manage the uncertainty of the game environment. Our method is no longer entirely dependent on the accuracy of opponents’ actions prediction which severely relies on plenty of simulation time. Instead of that, the key idea of HSUC is focusing on reducing the whole uncertainty of the environment, which is characterized by real-time information set in the game solving process. Second, we realize a practical framework for RBC game that incorporates HSUC with MCTS + UCT. NeurIPS 2019 tournament contains a final win rate rank and several ranks of different indicators. Our agent constructed with this framework has ranked the 7<sup>th</sup> in the final rank and won the first rank in terms of uncertainty management in particular.

## 2. Environment and Preliminaries

In this part, we will briefly introduce the rules of RBC, explain why RBC is a problem worth studying, and point out the difficulty of research. And then, we provide some preliminaries for later discussion.

*2.1. Environment: RBC and Its Challenges.* The major difference between RBC and standard chess is that RBC players are not informed of the opponent’s actions in the process of the game. For managing this hidden information, an additional step called “sense” is embedded prior to the move step. During the sense step, a player selects a square of the chessboard and learns all pieces and their types within the square, and that action is invisible to another player. This step is the most important way for the player to obtain real information about the opponent. That means players should consider their sense strategies to choose a region to review an unknown part of the board. In addition, some changes have been made to other rules, for example, the player wins by capturing the opponent’s king, but, in chess, a win occurs when the King is in under attack or in “check” and every possible move by the King will also put it in check. Since the player cannot see the opponent’s chess pieces, some invalid actions may occur when the player moves. For details, please check the description of the website (<https://rbc.jhuapl.edu/gameRules>). The game tree of RBC is shown in Figure 1.

The past decades have witnessed rapid progress in the ability of AI systems to play increasingly complex games, such as go of PIGs [6] and poker of IIGs [7]. Not long ago, Brown et al. proposed poker agent Pluribus to solve the problem of multiplayer poker [8]. But RBC, as an IIG, is even more complex in certain aspects than multiplayer poker. We will discuss challenges in RBC in the following two aspects: the game size and the number of possible states in the information set.

Generally speaking, the game size can be measured by the number of states that players may encounter in the game. A practical method to measure the game size proposed by Shannon in 1950 [9] is widely adopted. According to the method, the game size of Lim 2-P Poker (Lim 2-P Poker

FIGURE 1: Game tree of RBC. One turn in RBC containing two phases cannot be observed by the opponent: sense and move. In the sense phase, a sense square (area in the red box) is chosen based on sense strategy firstly. Then, positions in the sense square of the chessboard are checked and conflicting states are removed from the information set based on sense result. After sense, a move is selected based on the move strategy. Move action (c7, c5) means that moving the piece of pawn from positions c7 to c5 and (b8, c6) means moving the knight in b8 to c6.

refers to Limit Heads-Up Texas Hold’em) is  $10^{13}$ , the game size of chess is  $10^{43}$ , and that of RBC is  $10^{139}$  [10]. Table 1 lists the number of states for several representative games and it denotes that RBC can approximately achieve a level similar to No-Limit Poker and go in terms of game size.

IIGs’ complexity can be measured by another metric: the average number of possible states in the information sets. In RBC, this metric represents how difficult it is to evaluate a given perceived state. Poor sense strategy may lead to an exponential growth of the scale of information sets. Thus, the key property of RBC is the information asymmetry, that is, the uncertainty about the opponent’s information. Table 2 shows that Jared Markowitz et al. [10] have calculated that the approximate average number of states of real-time information set in RBC is  $1.3 \times 10^{68}$ , which is even larger than Six-Player-No-Limit Poker.

### 2.2. Preliminaries

*2.2.1. Extensive-Form Games.* Sequential games are normally formalized as extensive-form games in which one or more agents or players perform sequential interactions. The extensive-form game can be described as a conceptual mode of six-tuple  $\langle P, H, Z, A_m(h), \sigma_c(h, a), u_p(z) \rangle$ :

- (1)  $P$ : the set of players.

TABLE 1: Approximate size of games.

| Game          | Size       |
|---------------|------------|
| Lim 2-P Poker | $10^{13}$  |
| Chess         | $10^{43}$  |
| RBC           | $10^{139}$ |
| No-Lim Poker  | $10^{162}$ |
| Go (19×19)    | $10^{170}$ |

TABLE 2: Approximate means the number of possible opponents' states in an information set.

| Game                | Game states          |
|---------------------|----------------------|
| Heads-Up No-Limit   | 1083                 |
| Chess               | 1                    |
| RBC                 | $1.3 \times 10^{68}$ |
| Six-Player-No-Limit | $6.4 \times 10^{14}$ |
| Go (19×19)          | 1                    |

- (2)  $H$ : a finite set  $H$  of sequences, the possible histories of actions, such that the empty sequence is in  $H$  and every prefix of a sequence in  $H$  is also in  $H$ .
- (3)  $Z$ : the set of all terminal states, corresponding to all leaf nodes in the game tree.
- (4)  $A(h)$ : the set of legal actions from state  $h$  ( $h \notin z$ ), corresponding to all edges starting from node  $h$  in the game tree.
- (5)  $\sigma_c(h, a)$ : the probability that chance will take action  $a \notin A(h)$  from state  $h$ .
- (6)  $u_p(z)$ : the payoff for player  $p$  if the game ends in state  $z$  ( $z \in Z$ ).

We can further define the notations in RBC based on the mode as follows.

The behavior of players in RBC is similar to that of chess, except that an additional sense step is added before the move step. Thus, each player's strategy in one turn contains two phases, sense and move.

In each turn, player  $i$  chooses actions (a sense action and a move action), by its strategy  $\sigma^i = (\sigma_s^i, \sigma_m^i)$ ,  $\sigma_s^i$  is player  $i$ 's sense strategy, and  $\sigma_m^i$  is move strategy.

Furthermore, action set  $A(h)$  in RBC is generated from the set of legal sense actions  $A_s(h)$  and the set of legal move actions  $A_m(h)$ ,  $A(h) = A_m(h) \times A_s(h)$ . Specifically, a sense action  $a_s = s \in A_s(h)$  locates a  $3 * 3$  area centered on  $s$  to be sensed.

**2.2.2. Information Set.** For IIGs, information set  $I_p$  for each player  $p$  is a partition of  $H_p$ . For any information set  $I \in I_p$ , any two states  $h, j \in I$  are indistinguishable to player  $p$ . Figure 2 uses RBC to give an example of information set.

In a game tree,  $I_p$  is a set of decision nodes of player  $p$ , which meets the following two conditions:

- (1) Each decision node in  $I_p$  is the decision node of player  $p$

- (2) When the game reaches a decision node in  $I_p$ , player  $p$  knows that it is in  $I_p$  but does not know which decision node of  $I_p$  it encounters

### 3. Heuristic Search of Uncertainty Control

A heuristic method is an approach for problem solving or self-discovery, which is not guaranteed to be optimal, perfect, or rational, but sufficient for reaching a feasible solution. While finding an optimal solution is impossible or impractical, heuristic methods can be used to speed up the process of finding a satisfactory solution. Heuristic search refers to a search strategy that attempts to optimize a problem by iteratively improving the solution based on a given heuristic function or a cost measure [11].

The heart of heuristic search methods is the idea of "continual researching" where a sound local search procedure is invoked whenever the agent must act without retaining any memory about how or why to reach the current state [12]. Our method for RBC game can be seen as a kind of heuristic search methods, using some measure function for better information exploitation. For solving RBC game, we divide the problem into two subproblems: how to control the explosive growth in scale of information sets and how to choose the most beneficial move action under imperfect information during the game. These two parts make up our heuristic search strategy.

**3.1. Heuristic Search for Sense Strategy in RBC Game.** The characteristic of RBC brings several difficulties to heuristic search in game solving. Firstly, since we cannot definitely know the opponent's knowledge and strategy, unreliable information may lead to an incorrect search direction. Secondly, how to control the growth of game states in information sets is another challenge. In order to ensure that the subsequent search is performed correctly, we must retain all possible states of the opponent as the current information set and cannot casually abandon any state. In addition, the player has a variety of action options. These two aspects have led to an information set of space rapid explosion and brought difficulty to storage.

Considering the above difficulties, we propose a novel sense method, HSUC, to prevent scale of real-time information set from exponential growth. Although RBC rules provide some extra information, such as notification of sense results, move results, and whether the player captures pieces, which can be employed to help reduce the uncertainty, HSUC is the major method to exploit all hints of RBC in our game system.

In this section, we will discuss how HSUC works to minimize the scale of the information set in RBC. An ideal way is to predict the opponent's next move action  $(s_f, s_t)$  and then take sense action  $a_{s_t}$  to get the sense result. A practical method for predicting opponents' actions is to absorb the idea of self-play, which is to use our own strategy to simulate the opponents' actions. Whenever we act sense action, we obtain the opponent's most likely action for every

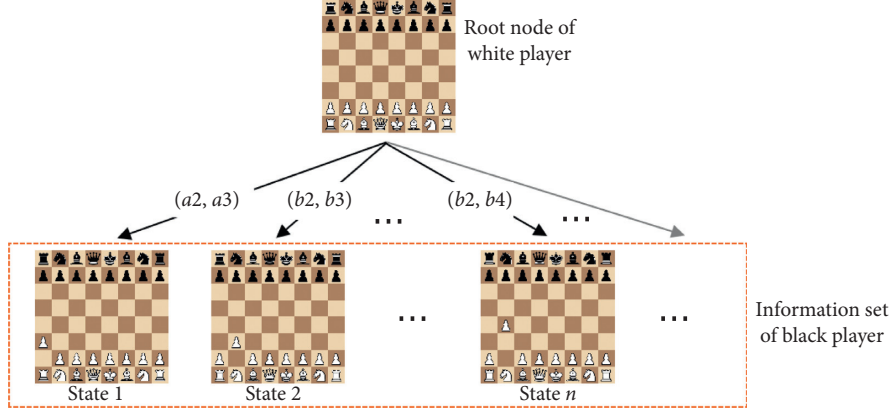

FIGURE 2: An example of the information set in RBC game. The root node is a white turn node. After the white player moves, the black player faces many indistinguishable possible states that are created by the opponent's unknown move; e.g., (a2, a3) and (b2, b3), are all possible move actions. These indistinguishable states in the dotted box form an information set of the black player.

remaining situation after the previous turn by move action selection strategy.

Unfortunately, the above approach is prone to bias. First of all, the initial premise of self-prediction is that the opponents adopt similar strategies to ours. When dealing with some specific agents, such as random or more powerful ones, sense actions will be severely misled which causes crashed performance of the whole system. Moreover, since the information set contains more than one state, plenty of sampling is required during the game tree search in order to guarantee the accuracy of state value evaluation.

HSUC focuses on estimating and reducing the whole uncertainty of the environment. Specifically in RBC, HSUC tries to find out the best sense square to minimize the number of possible states in real-time information set. Considering the game tree given in Figure 1, after the white player moves, the black player expands the game tree to form its real-time information set, which is the foundation of the next phase's strategy. To describe sense actions, the information set in the  $k$ -th turn is described as  $I_k: I_k = \{h_0, h_1, \dots, h_n\}$ ,  $|I_k| = n$  is the number of possible states in  $I_k$ . Each sense action reveals a  $3 \times 3$  sense square and helps eliminate some impossible states from  $I_k$ . For example, if the sense action reveals no piece in the sense square, all states with pieces in the sense square can be determined as "impossible states" and removed from  $I_k$ . Let  $A_s(I_k) = \{a_0, a_1, \dots, a_t\}$  and  $I_k(a_i)$  denote the reduced information set by taking sense action  $a_i$ . Then,  $I_k(a_i) \subseteq I_k$ ,  $m_i = |I_k(a_i)|$ . Employing  $g_k = (|I_k| - |I_{k+1}|) / |I_k| = 1 - (m_i/n)$  as the representative decay radio of sense action  $a_i$ , the target of heuristic search can be formalized as

$$a_i = \arg \max_{a_i \in A_s(I_k)} g_k = \arg \max_{a_i \in A_s(I_k)} \left(1 - \frac{m_i}{n}\right). \quad (1)$$

Here,  $g_k$  is employed to trace the tendency of game uncertainty. In this sense, the goal is to choose a sense action to maximize  $g_k$  for each turn of the game. However, there is no guarantee that the exact value of  $g_k$  can be found under the condition of imperfect information. So what should be done is to design a proper heuristic function  $H$  to evaluate  $g_k$ .

Firstly, we introduce how to evaluate the sense action's efficiency. Let  $D_i(h_1, h_2)$  indicate whether sense action  $a_i$  can distinguish between states  $h_1$  and  $h_2$  in  $I_k$ . As long as one of the 9 positions in the  $3 \times 3$  sense square is different (existence or types of pieces),  $D_i$  is set to 1; otherwise, it is set to 0. Figure 3 shows a specific example. The formula description is as follows:

$$D_i(h_1, h_2) = \max_{s_1 \in h_1(a_i), s_2 \in h_2(a_i)} L(s_1, s_2), \quad (2)$$

where  $s_1$  and  $s_2$  are the corresponding position in  $h_1$ 's and  $h_2$ 's sense squares of  $a_i$ .  $L(s_1, s_2)$  is defined as

$$L(s_1, s_2) = \begin{cases} 1, & P_{s_1} \neq P_{s_2}, \\ 0, & \text{otherwise,} \end{cases} \quad (3)$$

where  $P_{s_1}$  and  $P_{s_2}$  mean the pieces in positions  $s_1$  and  $s_2$ .

In this sense,  $D_i(h_1, h_2) = 0$  means states  $h_1$  and  $h_2$  cannot be distinguished by sense action  $a_i$ . Let  $H_{D_i}$  be the maximum subset of the current information set which contains the largest number of indistinguishable states given the sense action  $a_i$ .  $H_{D_i}$  satisfies the following three constraints:

- (1)  $H_{D_i} \subseteq I$ .
- (2)  $\forall h_1, h_2 \in H_{D_i}, D_i(h_1, h_2) = 0$ .
- (3)  $\forall h_i \in H_{D_i}, \sum_{h_j \in H_{D_i}} D_i(h_i, h_j) > 0$ .

We define that

$$C(a_i, I) = |H_{D_i}|. \quad (4)$$

Note that, in some cases, there may exist more than one maximum subset and the indistinguishable states they contain are different, but values of  $C(a_i, I)$  are the same. In this way, given sense action  $a_i$  and current real-time information set  $I_k$ , the sense efficiency can be described by the following heuristic function:

$$H(a_i, I_k) = n - C(a_i, I_k) = n - C(a_i, I). \quad (5)$$

```

Input: Information set of agent in turn  $k$ :  $I_k$ , The set of legal sense actions:  $A_s$ 
Output: Sense action:  $a_s$ 
(1) for each  $h_j$  in  $I_k$  do
(2)   Perform every legal move action for  $h_j$  to get successors
(3) end for
(4)   Combine all successors to update  $I_k$ 
(5)   Let  $T = 0, a_s = \text{None}$ 
(6) for each  $a_i$  in  $A_s$  do
(7)   for each two states  $(h_1, h_2)$  in  $I_k$  do
(8)     Calculate  $D_i(h_1, h_2)$  using formula (2)
(9)   end for
(10)  Find  $H_{D_i}$  and calculate  $C(a_i, I_k)$  using formula (4)
(11)  Calculate  $H(a_i, I_k)$  using formula (5)
(12)  if  $T < H(a_i, I_k)$  then
(13)     $a_s = a_i$ 
(14)     $T = H(a_i, I_k)$ 
(15)  end if
(16) end for
(17) return  $a_s$ .

```

ALGORITHM 1: HSUC algorithm.

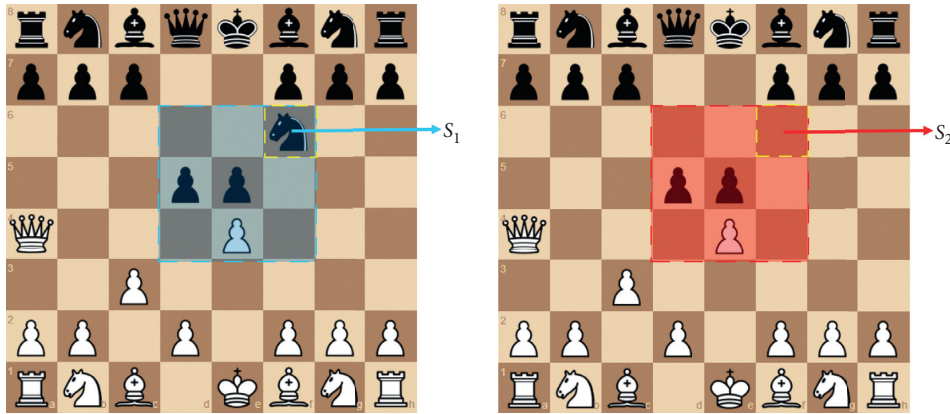

FIGURE 3: An example of evaluating sense efficiency. The two chess boards above denote two different states  $h_1$  and  $h_2$  in the current information set. As shown in the shaded part of the figure, when sense action  $a_i$  is adopted, a difference between the upper right corners  $s_1$  and  $s_2$  appear. In this case,  $L(s_1, s_2) = 1$  and  $D_i(h_1, h_2)$  is set to value 1.

By using the heuristic function  $H(a_i, I_k)$  to evaluate  $g_k$ , sense action can be searched in  $A_s(I_k)$  as follows:

$$a = \arg \max_{a_i \in A_s(I_k)} H(a_i, I_k). \quad (6)$$

By now, we have presented the details of HSUC method which adopts a heuristic searching approach to minimize the information sets' scale. The whole algorithm is shown in Algorithm 1.

**3.2. Foundation of the RBC Game System.** In this section, we will introduce the framework of our RBC game system incorporating the HSUC method. As shown in Figure 4, our architecture contains two main parts, HSUC for sense strategy and MCTS for move strategy.

When it is our turn in the RBC game, for example, at step  $t$ , firstly, we keep an information set of step  $(t-1)$  which contains all possible board states formed by our last move action. Then, we simulate all legal opponent's move actions on these board states to form the initial information set of step  $t$ . Generally, the scale of the information set will increase rapidly at the rate of dozens of times in this stage. And then, we apply our sense action provided by the HSUC algorithm. Powerful sense strategies will effectively eliminate impossible states as many as possible to get a reduced information set. At last, each remaining state will be solved as a root node by MCTS method and all of the returned solutions will be counted and the move strategy is determined by the statistics result. MCTS consists of four steps per iteration generally: selection, expansion, simulation, and backpropagation [13]. To control the iteration time, we use Stockfish to speed up

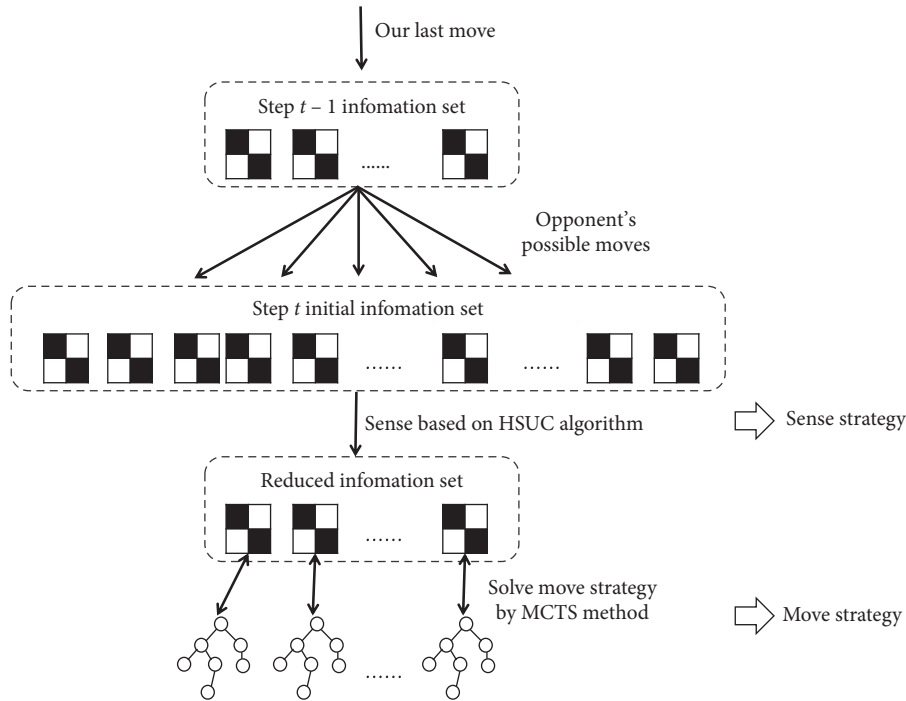

FIGURE 4: Architecture of our RBC game.

FIGURE 5: Result of different sense strategies.  $N$  is the number of states in the information set of RBC.

the termination of iterations and we constrain the depth of iterations based on the remaining time.

#### 4. Experiments

In this section, we evaluate the effectiveness of HSUC and the RBC game-solving framework mentioned in the previous section. During the experiment setting, we choose one agent from the NeurIPS 2019 tournament, Strangefish (<https://github.com/ginop/reconchess-strangefish>), as a comparison baseline. Strangefish ranks the first place in the tournament, which makes the comparison in the

experiments much more convincing. We conduct two experiments to verify the effectiveness of our proposed sense method HSUC (Section 4.1) and the performance of the overall RBC Game System (Section 4.2). The experiments are based on the package provided by the tournament's organizer, and the agents we implement all comply with the competition rules and restrictions.

*4.1. Performance of HSUC in RBC Sense Phase.* To illustrate the growth rate of the number of states in RBC's information set and the importance of a good sense method in solving

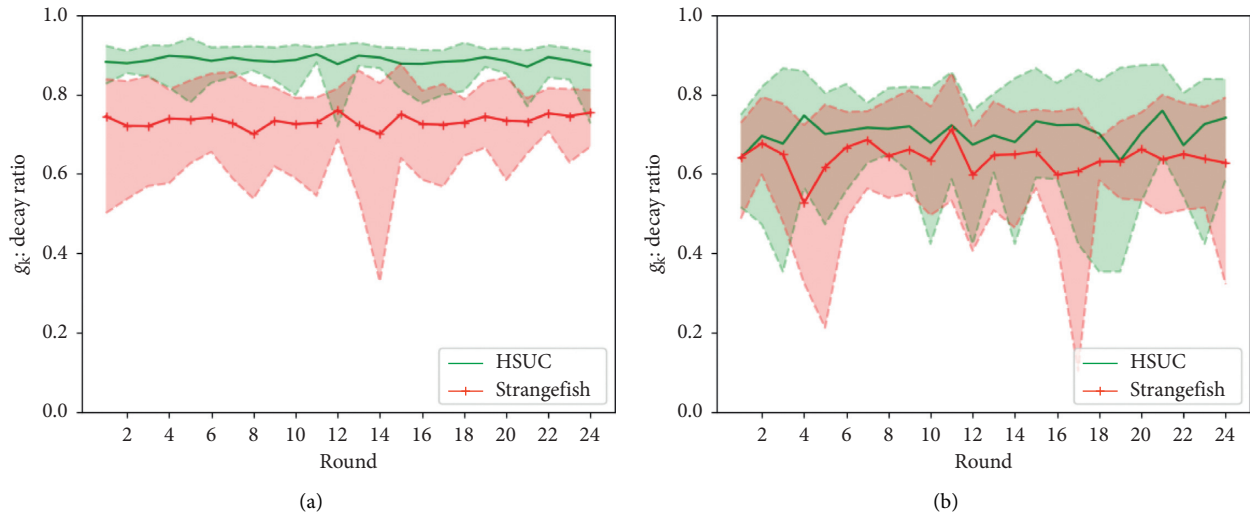

FIGURE 6: Efficiency of HSUC compared with sense method of Strangefish. Curves show the decay ratio  $g_k$  of the game during our agent with HSUC and Strangefish playing against different bots, respectively. The curve of our agent is higher than Strangefish in a large margin, which means that HSUC can maintain an obviously higher decay ratio of game uncertainty than Strangefish. (a) Against Random bot. (b) Against Trout bot.

IIGs like RBC, we conducted a comparative experiment of different sense methods firstly. In the experiment, agents with different sense methods play against the same opponent agent. During the game, the number of states in the real-time information sets after each sense action of each agent is tracked to obtain the experiment result.

As shown in Figure 5, the number of states in the information set of RBC increases exponentially without sense, and the problem of the exponential explosion of information sets can only be slightly alleviated with random sense actions. HSUC from our system and the sense method of Strangefish both perform better than the other two sense methods. We can conclude that the use of good sense methods can greatly reduce the scale of information set in RBC game.

The second experiment aims to verify the empirical advantages of HSUC. We let our RBC game system with HSUC compete with the baseline system at the platform of the NeurIPS 2019 tournament for 10 batches of games to obtain a statistical result. Each batch contains 24 rounds of games and each agent plays 12 rounds as black and 12 as white.

A robust sense method should satisfy the requests of efficiency and stability at the same time. First, decay ratio  $g_k$  mentioned in Section 3.1 is used to describe efficiency. The higher decay ratio denotes the method can reduce more impossible states by sensing. Second, the performance of the sense method should not fluctuate too much when facing opponents from different levels, which can be evaluated by the average scale of real-time information sets. The average scale of real-time information sets of turn  $j$  is  $N^j$ , which is calculated as follows:

$$\text{avg } N^j = \sum_{i=1}^T \frac{N_i^j}{T}, \quad (7)$$

where  $N_i^j$  denotes the average number of states of turn  $j$  in batch  $i$  and  $T$  is the total number of batches. We use the same experimental settings as above for the experiments.

The sense strategy of the Strangefish system is employed by scoring each move action to predict for sense area. The Strangefish method picks up the move with the highest score as the most likely action of the opponent and selects sense area based on the move action. It is similar to the method we introduce in Section 3.1.

The specific implementation of the experiment is to employ another agent as the opponent of our agent with HSUC and Strangefish, respectively, to collect data for calculating the indicator  $g_k$  for efficiency and  $\text{avg } N^j$  for stability during the game.

In Figure 6, we compare HSUC and the sense method of Strangefish by the decay ratio  $g_k$ . Figure 6(a) shows the result of playing against Random bot and Figure 6(b) is about the result of playing against Trout (another bot using Stockfish which performs better than random in the tournament). It can be seen that HSUC maintains a better performance against different bots than sense method of Strangefish. Moreover, HSUC shows more obvious advantages when playing against agents with a higher degree of randomness by reducing no less than 90% of uncertainty. The effective decay of uncertainty will bring great advantage to follow-up and can avoid the risk of failure due to timeout in game which is suffered by the agents maintaining a large number of states in the real-time information sets.

Figure 7 shows the average scale  $\text{avg } N^j$  of the real-time information sets of HSUC and Strangefish. The curves in the figure obviously indicate that our method performs better on managing scale of information sets than the method of the Strangefish against both of the rivals. In Figure 7(b), the maximal average scale of information sets of Strangefish even

FIGURE 7: Stability of HSUC compared with the sense method of Strangefish. Curves show the average scale  $\text{avg } N^j$  of game during our agent and Strangefish playing against different bots, respectively. The curve of HSUC is lower and smoother than Strangefish plainly, which means that HSUC can control the scale of information sets more stably than Strangefish. (a) Against Random bot. (b) Against Trout bot.

TABLE 3: Uncertainty management rank.

| Bot name     | Institution         | Median state space size |
|--------------|---------------------|-------------------------|
| HSUC         | HIT (OUR)           | 12                      |
| Oracle       | JHU/APL             | 13                      |
| Wbernar5     | JHU                 | 18                      |
| La Salle Bot | La Salle University | 19                      |
| MBot         | SRC/Leela Chess Dev | 574                     |
| Random       | JHU/APL             | 50k+                    |

reached 6000 while that of HSUC is about 1000. The number of states of HSUC fluctuates smoothly while that of Strangefish fluctuates violently. Besides, considering Figure 6, we can conclude that the performance of HSUC is pretty stable for each turn and against different opponents from different levels.

By the way, the result of the NeurIPS 2019 tournament can also be a reference for the effectiveness of the sense method. As shown in Table 3, our sense method performs best on uncertainty management rank (<https://slideslive.com/38923177/reconnaissance-blind-chess-competition>).

**4.2. Performance of Our RBC Game System in NeurIPS 2019 Tournament.** In the NeurIPS 2019 tournament, each agent will fight against all the other opponents in turn by 24 rounds, and each agent begins with a cumulative 15-minute clock to make all their actions including sense and move. Our agent *A\_bot*, constructed with HSUC for sensing information and MCTS + UCT for move selection which incorporates new evaluation function Stockfish, achieves good result against many competitive opponents (such as agents from Microsoft and Google). For more details, please check here (<https://rbc.jhuapl.edu/tournaments/26>).

## 5. Conclusion

This paper introduces a novel method of uncertainty management in IIGs called HSUC. HSUC adopts a heuristic search process to guide sense actions to reduce the environment uncertainty of IIGs like RBC by minimizing the number of possible states in the real-time information sets. That is, HSUC can help agents to well understand the environment under imperfect information which enhances the effectiveness of game strategies. Furthermore, a viable RBC game system is realized by combining HSUC for sensing information and MCTS + UCT for selecting move actions. The experiments about HSUC and the RBC game system show that the scale of information sets is reduced effectively and efficiently through our method, providing convincing verification for the superiority of our method in terms of the uncertainty management in IIGs. In the future, we will conduct further research on factors affecting the uncertainty of the game environment and enrich the methods family of uncertainty management in IIGs.

Data gathering is the basis of monitoring applications in an underwater sensor network, and excellent network coverage and data transmission reliability are the guarantees for the quality of monitoring tasks. However, the energy consumption of the nodes is too fast due to the heavy load of the cluster heads closer to the sink when data is transmitted between cluster heads (CHs) and the sink by multihop, which leads to an energy hole problem in an underwater sensor network of clustering technology. Aiming to address this problem, we propose a dynamic hierarchical clustering data gathering algorithm based on multiple criteria decision making (DHCDGA) in a 3D underwater sensor network. Firstly, the entire monitoring network is divided into many layers. For selecting a cluster head in each layer, multiple criteria decision making of an intuitionistic fuzzy Analytic Hierarchy Process (AHP) and hierarchical fuzzy integration is adopted. Furthermore, a sorting algorithm is used to form a clustering topology algorithm to solve the problem that there is the only node in one cluster. Then, an energy-balanced routing algorithm between clusters is proposed according to the residual energy of the node, the depth, and the number of neighbor nodes. Finally, the simulation results show that DHCDGA can not only effectively balance the energy consumption of the network and prolong the network lifetime but also improve network coverage and data gathering reliability.

## 1. Introduction

With the development of science and technology, the ocean, which covers 70% of the earth's surface area, plays an important role in the development of smart city [1, 2]. With the rise of the marine economy, countries all over the world pay more and more attention to the rights and interests of the ocean, and humans urgently need new technologies to observe and develop the ocean [3]. Underwater sensor networks are one of the hot ocean observation technologies that have emerged in the recent years [4, 5]. Underwater sensor networks have broad applications in many military and civilian fields, for example, for ocean exploration and development [6], for disaster warning and forecast [7], for environmental monitoring [8], and submarine detection [9]. Therefore, the

underwater sensor network has attracted widespread attention from domestic and foreign researchers.

Compared with traditional sensor networks [10], the main feature of underwater sensor networks is the use of underwater acoustic communication [11]. The absorption rate of radio signals in the water is very high, the signal propagation distance is limited, and the distance of underwater radio communication is generally not more than 100 meters. Therefore, it is not suitable for the needs of long-distance communication in underwater sensor networks [12]. Besides, the optical signal cannot be transmitted over long distances in seawater, its medium has a high absorption rate, and it is easily blocked, refracted, and reflected by various creatures and obstacles in the sea [13]. Therefore, underwater sensor networks use acoustic communication [14, 15]. The underwater acoustic channel has the

remarkable characteristics of high delay, high bit error rate, and low communication bandwidth [16, 17]. This makes the traditional sensor network communication protocol not directly applicable in underwater, which brings challenges to the protocol design of the underwater sensor network. In summary, the environment of underwater acoustic communication is harsh and the data transmission rate is very low. Therefore, it is of great significance to study the data gathering of underwater sensor networks.

There has been a lot of research studies on the data gathering strategy of underwater sensor networks. DBR [18] was a flat data gathering algorithm that provided a solution for the networking of underwater sensor networks in the early years. However, flat data gathering algorithms are often used in smaller networks. If the network scale is large, nodes close to the sink will undertake too much data forwarding and consume a lot of energy. This causes the nodes near the sink to die prematurely and form an energy hole. The death of these nodes will cause the rapid death of the surrounding nodes. Therefore, delaying the appearance of energy holes helps to prolong the network lifetime. Compared with the flat data gathering algorithm, the clustering data gathering algorithm can balance the energy load of the network. Hence, to adapt to a large-scale network environment, the use of clustering data gathering algorithms can alleviate the appearance of energy holes and effectively prolong the network lifetime.

At present, clustering data gathering algorithms are mainly focused on traditional ground wireless sensor networks. Its network topology is a two-dimensional flat network. These algorithms cannot be directly applied to the environment of a 3D underwater sensor network. Regarding the clustering data gathering algorithm of the 3D underwater sensor network, some theoretical research studies have been studied by many researchers. However, most of the algorithms are based on the clustering data gathering algorithm of the two-dimensional ground sensor network. These two-dimensional clustering algorithms have been transplanted into the three-dimensional underwater sensor network environment. They do not consider the mobility of nodes and unknown location information so that they cannot solve the problem of clustering data gathering in underwater sensor networks. The main deficiencies are as follows:

- (1) Little consideration is given to the impact of node mobility on the network. The clustering data gathering algorithms of two-dimensional sensor networks mostly use flat static sensor networks as the research premise, ignoring the impact of node movement on the network topology.
- (2) A two-dimensional sensor network can use GPS to determine the distance between nodes, but GPS cannot be used to locate an underwater sensor network. There is a large error in the way of wireless measurement distance, and underwater measurement distance has become another hot issue.
- (3) At present, most clustering data gathering of underwater sensor networks use energy as a measure to select cluster heads or design clustering algorithms

based on underwater characteristics. They rarely consider coverage and data transmission reliability. Hence, this is difficult to ensure network coverage and data collection reliability, which is a fatal defect for monitoring applications in underwater sensor networks. Accordingly, some scholars have begun to study cluster algorithms for sensor network coverage preservation and data gathering reliability. The data gathering algorithm with coverage preservation and reliability can reduce the rate of the decline of network coverage, at the same time, and the reliability of data gathering is guaranteed. Current research focuses on data gathering algorithm with the coverage preservation and data gathering reliability in traditional wireless sensor networks [19]. Little work on the clustering data gathering algorithm is suitable for coverage preservation and data gathering reliability in underwater sensor networks.

In this paper, we propose a dynamic hierarchical clustering data gathering algorithm based on multiple criteria decision making in 3D underwater sensor network. Aiming at these problems, the contributions of this paper are as follows:

The entire monitoring network is divided into layers. In each layer, multiple criteria decision making of an intuitionistic fuzzy AHP and hierarchical fuzzy integration is adopted in the phase of selecting a cluster head.

A sorting algorithm is used to form a clustering topology algorithm to solve the problem that there is only one node in one cluster.

According to the residual energy of the node, the depth, and the number of neighbor nodes, an energy-balanced routing algorithm is proposed between cluster heads.

In the simulation, DHCDGA is compared with leach-coverage-U and NULCPR, in terms of network lifetime and other five performances. The simulation results show that DHCDGA can not only effectively balance the energy consumption of the network and prolong the network lifetime but also improve network coverage and data gathering reliability.

The remainder of this paper is organized as follows. The related work of the field is introduced in Section 2. After introducing the network model and energy consumption model, in Section 3, a detailed description of the proposed clustering data gathering algorithm is presented in Section 4. In Section 5, we analyze the DHCDGA theoretically. Section 6 presents and analyzes six performance metrics of the DHCDGA in comparison with two other data gathering algorithms, and we conclude the paper in Section 7.

## 2. Related Work

By now, some work has been finished on improving energy efficiency or coverage preservation or data gathering reliability for 2D wireless sensor networks. However, there are

only a few clustering algorithms improving the above-mentioned three factors in a joint way for 3D underwater wireless sensor networks. Some clustering algorithms have been introduced in Section 1. In this section, we only briefly review some other typical clustering algorithms and considering coverage preservation and data gathering reliability.

Leach-coverage-U [20] was modified from the LEACH and the virtual grid routing protocols. The CPCHSA algorithm was added based on LEACH to achieve the best sensing coverage. Different nodes were assigned different probabilities of being a cluster head to maximize the network sensing coverage. However, Leach-coverage-U does not focus on data gathering reliability in underwater sensor networks. NULCPR [21] was a distributed unequal cluster size and hierarchical coverage-preserving routing algorithm. Spatially, the network was gradually built up from the sink node to the outside. Logically, a downward tree structure with the sink node as the root was constructed. The farther the node was from the Sink, the lower the level in this tree structure. Each layer ran the NCPR algorithm independently to complete the cluster head election, and each layer of the cluster head established a connection link with the upper node to ensure network connectivity. At the same time, the communication radius of nodes in each layer gradually increased as the number of network layers increased. In this way, the communication radius of the node was smaller and the cluster density was larger in the area close to Sink, and the communication radius was larger and the cluster density was smaller in the area far away from Sink. Hence, the energy consumption was balanced and the network lifetime is prolonged. However, NULCPR only considers energy efficiency and coverage preservation and ignores the reliability of data gathering.

CBEER [22] was an event-driven energy-efficient routing approach called clustering-based energy-efficient routing. In CBEER, a BS was responsible to run the routing scheme to optimize the cluster head (CH) selection for cluster creation. By cluster head selection, dynamic clusters were established. In this way, finding the shortest routing paths and consuming energy uniformly became possible in the entire network. Otherwise, a novel evolutionary algorithm based clustering was used to realize the reduction of energy consumption. For avoiding energy consumption of the same CHs, the CHs included in the current routing path were deleted from the other paths in the routing table. However, CBEER does not focus on coverage preservation and data gathering reliability. HENPC [23] was an energy-efficient clustering algorithm for magnetic induction-based underwater wireless sensor networks. The clustering protocol included two main parts. First, the jellyfish breathing algorithm was constructed based on the node contribution density to optimize the cluster size. Second, a node adjustment was built based on the Voronoi diagram to obtain an appropriate number of selected CHs. However, HENPC only focuses on energy efficiency, and it is not suitable for network scenarios with the request of high network coverage and data gathering reliability.

SMO [24] was a clustering approach based on spider monkey optimization. It resolved the node mobility caused

by the water current. Due to the node mobility, it led to transmission errors, link loss, collisions, and congestion, if not well handled. SMO was fit for heterogeneous underwater wireless sensor networks. There were three different roles in the network. They were cluster heads, local leaders, and global leaders. They worked together to provide energy-efficient data gathering. However, CBEER does not focus on coverage preservation and data gathering reliability. QERP [25] was a Quality-of-Service (QoS) aware evolutionary routing protocol for underwater wireless sensor networks. It addressed the challenge caused by reliable data delivery. For example, impairments of the acoustic transmission were caused by excessive noise, extremely long propagation delays, high bit error rate, low bandwidth capacity, multipath effects, and interference. QERP could improve the packet delivery ratio and reduce average end-to-end delay and overall network energy consumption. However, QERP is not suitable for network scenarios with the request for high network coverage. CUWSN [26] was an energy-efficient routing protocol selection for a cluster-based underwater wireless sensor network. In CUWSN, the multihops communication technique was adopted to reduce network energy. For further reducing energy consumption, CUWSN selected the cluster coordinator node and cluster head. The proposed CUWSN reduced power consumption by selecting the cluster coordinator node and cluster head to get a maximum lifetime of the network. However, CUWSN only considers energy efficiency, and it is not suitable for network scenarios with the request of high network coverage and data gathering reliability.

In [27], a fuzzy- and PSO-based clustering scheme using energy and distance parameters was proposed. The nodes were clustered by fuzzy clustering algorithms based on the geographical locations and the probability of belongingness of the sensor nodes. An improved PSO was used to select a cluster head. The process of cluster head selection considered multifactors to minimize energy consumption. However, the clustering scheme does not consider other factors, such as network coverage ratio and reliability of data gathering. MLCEE [28] was a multilayer cluster-based energy-efficient protocol for UWSNs. The goal of MLCEE mainly addressed the issue of a hotspot, high error rate, and high consumption of energy. In MLCEE, the entire network region was firstly divided into different layers from the surface to bottom and in every layer. Then, the second stage was the clustering of the nodes at the same layers. Finally, the cluster head selected the next-hop among the CHs based on the greater fitness value, small Hop-id, and small layer number. Although MLCEE has improved energy efficiency and data gathering reliability, it does not consider network coverage. FCMMFO [29] was a hybrid clustering method based on fuzzy c means and the moth-flame optimization method to improve the performance of the network. FCMMFO adopted FCM to divide the network. Theoretically, the optimal number of clusters could be determined by the elbow method. By MFO, the optimal locations of the cluster heads could be obtained. However, the clustering factor does not consider other factors, such as network coverage ratio and reliability of data gathering in an underwater sensor network.

### 3. System Model

In this section, we will introduce three models used in our clustering data gathering algorithm. They are the network model, the energy consumption model, and the node motion model.

*3.1. Network Model.* This paper assumes that there are the following properties in the underwater sensor network:

- (1) Sensor nodes are randomly deployed to form a three-dimensional underwater network, and the communication link between the nodes is reliable and two-way symmetrical.
- (2) There is a sink on the water. Its computing power and energy are not limited, and it can carry out wireless transmission.
- (3) The node moves within a certain range under the influence of water flow. We assume that the maximum offset distance is  $r$ .
- (4) Nodes can obtain their depth value, and each node is equipped with low-cost depth-sensing hardware.
- (5) The distance between nodes can be calculated according to the signal transmission strength.
- (6) DHCDGA is a periodic data gathering service. The nodes periodically gather data from sensors to sink in the underwater sensor network.

*3.2. Energy Consumption Model.* The algorithm in this paper adopts the same energy consumption model for underwater acoustic communication as in [30]. For underwater sensor nodes, the energy consumption of sending a message is about ten times that of receiving a message and idle listening. Therefore, the energy consumption of sending messages accounts for a large proportion of the total energy consumption, and reducing the energy consumption of sending messages means that the total energy consumption of the entire network can be reduced. The algorithm in this paper uses the energy consumption generated by sending the message as the main parameter to measure the total energy consumption of the entire network. Assume that  $P_o$  is the minimum power required by the node to receive messages normally; if the power attenuation function for the broadcasting distance  $x$  is  $A(x)$ , the transmission power should at least reach  $P_o A(x)$  to ensure that the node can receive the message. Assuming that the sending delay of a node sending  $l$  bit data is  $T_p$ , the energy consumed by sending  $l$  bit data  $E_{tx}(l, x)$  is

$$E_{tx}(l, x) = T_p P_o A(x), \quad (1)$$

in which  $A(x)$  is a function variable related to the underwater acoustic propagation model and the transmission frequency, which can be expressed as

$$A(x) = x^k a^k, \quad (2)$$

in which  $k$  is the related parameter of the underwater acoustic propagation model. When  $k$  is 1, it is a cylindrical

propagation model, and when  $k$  is 2, it is a spherical propagation model. Usually,  $k$  is 1.5 to represent the actual underwater acoustic propagation model.  $a$  is related to frequency  $f$  and can be obtained from the energy absorption coefficient  $\partial(f)$ .

$$a = 10^{\partial(f)/10}, \quad (3)$$

in which the energy absorption coefficient is

$$\partial(f) = 0.11 \frac{f^2}{1 + f^2} + 44 \frac{f^2}{4100 + f^2} + 2.75 \times 10^{-4} f^2 + 0.03. \quad (4)$$

*3.3. Node Motion Model.* To be able to simulate the motion state of the node in the water more accurately, the following conditions need to be considered when establishing the node motion model. Since the node is fixed at the bottom of the water, the depth of the node can be changed by adjusting the length of the anchor chain. The nodes in this state are affected by the water flow and the traction of the anchor chain and move within a certain range [31]. Figure 1 shows the node force in the underwater environment.

As shown in Figure 1, the force analysis of the node shows that the node is subjected to the lateral impact force  $F$ , buoyancy  $f$  of the water flow, and the tensile force  $T$  of the anchor chain to the node (ignoring the gravity of the node). These three forces constitute a set of balance forces. We set that the maximum angle between the anchor chain and the vertical direction is  $\alpha$ ,  $\tan \alpha = F/f$ . It is worth noting that we do not research on fluid mechanics. For simplification, the maximum offset distance of node movement is given in Section 6. Nodes perform random waypoint movement within this offset distance [32].

## 4. DHCDGA

Firstly, after the network is initialized, it will be layered according to the initial information. DHCDGA is implemented in each layer. The time unit of DHCDGA is round. Each round is divided into a cluster topology establishment phase and a data transmission phase. In the cluster establishment phase, multiple criteria decision making of an intuitionistic fuzzy AHP and hierarchical fuzzy integration is adopted to select cluster head so that cluster topology of unequal size is established. Namely, the cluster farther from the sink on the water surface has a larger cluster size, and the cluster closer to the sink has a smaller cluster size. In the data transmission phase, according to the remaining energy of the node, the depth, and the number of neighbor nodes, an energy-balanced routing transmission between cluster heads is proposed. The schedule architecture of DHCDGA is shown in Figure 2.

*4.1. Cluster Selection.* In this subsection, the cluster head nodes in the network are selected. Multiple criteria decision making of an intuitionistic fuzzy AHP and hierarchical fuzzy integration is adopted to select the cluster head. To achieve energy efficiency while taking into account service quality requirements, the main criteria for cluster head selection are

FIGURE 1: Node force.

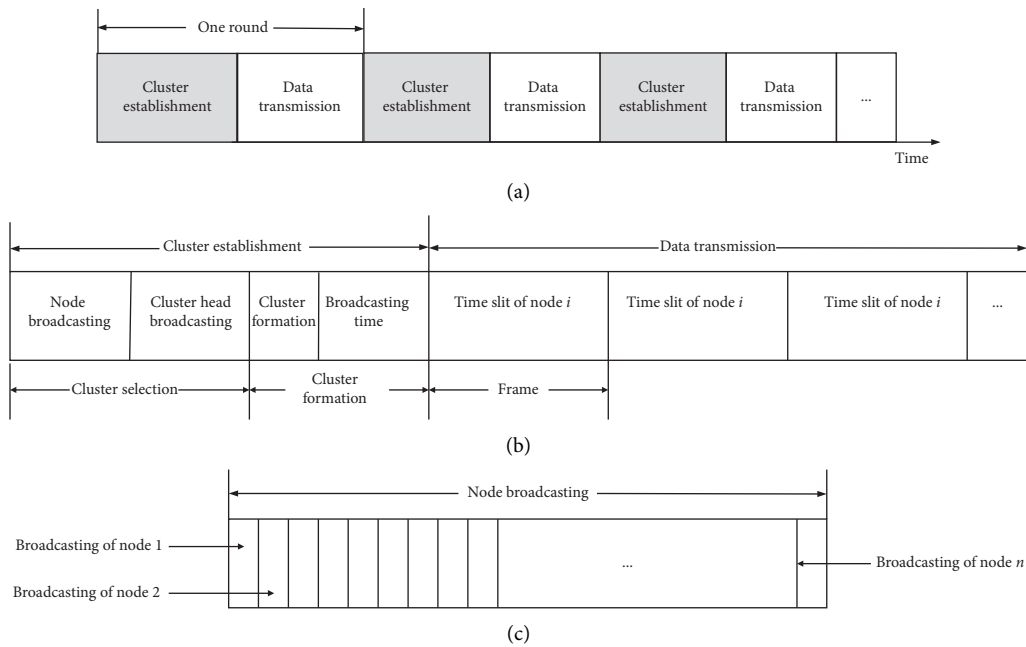

FIGURE 2: Schedule architecture of DHCDGA.

defined as energy status, service quality status, and node location status. Furthermore, each main criterion has two subcriteria. They are residual energy, message cost, coverage factor, link reliability, number of neighbor nodes, and depth factor. According to multiple factors affecting the selection of cluster heads, we have established a comprehensive evaluation hierarchical structure showed in Figure 3. It is mainly for a comprehensive evaluation of various indicators selected by cluster heads.

4.1.1. *Comprehensive Attribute Evaluation Value of the Cluster Head (h).* In the initialization phase, each node broadcasts an initialization message *INITIAL\_UN\_MES* to the network, which includes the node's ID, remaining energy, communication radius, and the distance between layers. The

node can locate the depth in the water to determine the level of the node. Nodes can estimate the distance between nodes based on the strength of their received signals. After the initialization phase is completed, each node can calculate the maximum and minimum residual energy of neighboring nodes, the number of neighboring nodes, and other information according to the neighbor node table. In this way, each node can obtain the evaluation value of each attribute in the comprehensive evaluation hierarchy of the cluster head.

(1) *Residual Energy.* In a clustered topology network, there is a huge difference in energy consumption between cluster heads and member nodes because the cluster head is responsible for receiving data from member node, fusing data, and relaying data to other cluster heads. In the underwater sensor network, the power supply cannot be replaced due to

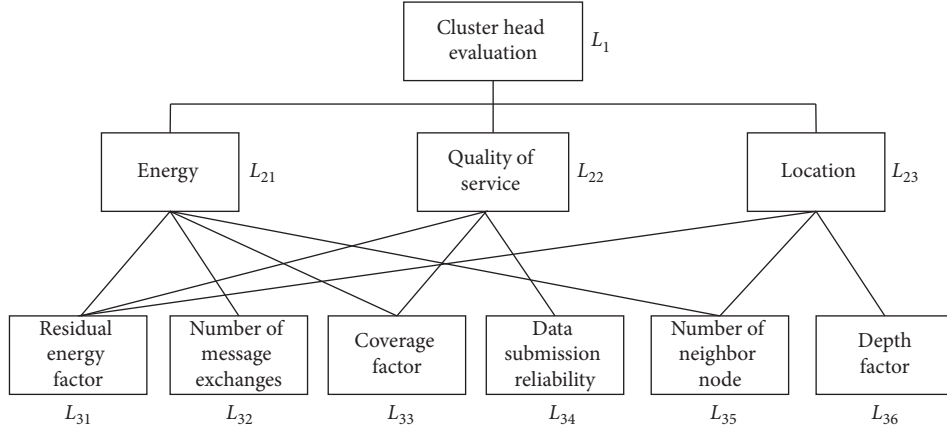

FIGURE 3: Comprehensive evaluation hierarchical structure of the cluster head.

environmental restrictions. Hence, energy is the most important and scarce resource. The evaluation value of residual energy is defined as follows:

$$E_i = \frac{E_r - E_{\min}}{E_{\max} - E_{\min}}, \quad (5)$$

in which  $E_r$  is the residual energy of node  $i$ .  $E_{\max}$  and  $E_{\min}$  are the maximum and minimum residual energy in the neighbor nodes of node  $i$ , respectively. The higher the value of  $E_i$  is, the more the residual energy is and the smaller the energy limit of the node is.

(2) *Number of Message Exchanges*. The number of message exchanges is mainly reflected in the total number of messages sent and received by nodes from the beginning of the network initialization stage to the establishment of the cluster topology. Since both sending and receiving messages consume the energy of the node, the number of exchanges of messages directly affects the energy consumption of the node. The evaluation value of the number of message exchanges is defined as follows:

$$M_i = \frac{M_T - M_C}{M_T}, \quad (6)$$

in which  $M_T$  is the total number of messages received and sent by all its neighbor nodes and  $M_C$  is the total number of messages received and sent by node  $i$ . The smaller the  $M_C$  value is, the higher the message cost  $M_i$  is.

(3) *Coverage Factor*. Coverage preservation is one of the most basic issues to ensure the Quality-of-Service (QoS). Selecting a node with better coverage as the cluster head can effectively prolong the functional time and make the residual energy of the node more. In a three-dimensional underwater sensor network, the coverage factor is the main factor to judge the QoS of a node. Its evaluation value is defined as follows [18]:

$$r(i) = \frac{\text{volume}\left(\left(\bigcup_{j \in N(i)} a_j\right) \cap (a_i)\right)}{\text{volume}(a_i)}, \quad (7)$$

in which  $a_i$  represents the perception area of node  $i$ .  $a_j$  represents the perception area of node  $j$ . Node  $j$  is the

neighbor node of node  $i$ .  $r(i)$  is the ratio of the volume intersection of the perception area of node  $i$  and its neighbor nodes to the perception area of node  $i$ . The larger the value of  $r(i)$  is, the larger the volume of intersection between node  $i$  and its neighbors is. Namely, the larger  $r(i)$  indicates that the node  $i$  is more likely to become the cluster head.

(4) *Data Transmission Reliability*. Data transmission reliability is an important issue to be considered for QoS because any node failure or packet loss will cause a large amount of packet loss in data transmission. In this way, more reliable requirements of data gathering are put forward for network scenarios with data collection reliability. The cluster head as the leader of the cluster unit is responsible for forwarding and receiving data more often in the network of clustered data gathering. Therefore, the probability of a highly reliable node as the cluster head should be greater. The evaluation value of data transmission reliability is defined as follows:

$$R_i = \frac{B_{\text{ava}}(i)}{B_{\text{total}}(i)}, \quad (8)$$

in which  $B_{\text{ava}}(i)$  is the available buffer space for node  $i$  and  $B_{\text{total}}(i)$  is expressed as the total buffer space of node  $i$ . We can observe that the smaller the available space of the node's buffer is, the lower the reliability of node  $i$  is.

(5) *Number of Neighbor Nodes*. In the network initialization, the number of current neighbor nodes can be determined according to the information in the neighbor information table. In an underwater sensor network where nodes are randomly deployed, the sink will calculate the optimal number of cluster heads in each layer when the energy is the smallest based on the global information of the nodes to obtain the optimal number of cluster members. According to this information, the closer the number of neighbor nodes is to the optimal number of cluster members, the greater is the probability that the node will become the cluster head. The evaluation value of the number of neighbor nodes is defined as follows:

$$N = \frac{|N_i - N_o|}{N_o}, \quad (9)$$

in which  $N_i$  is the number of neighbor nodes of node  $i$  and  $N_o$  is the best number of cluster members.

(6) *Depth Factor*. The depth of the node will affect the possibility of the node becoming the cluster head. The data gathering algorithm proposed in this paper is suitable for large-scale hierarchical underwater sensor networks. Since the selection of cluster heads is carried out in the same layer, the depth factor  $D(i)$  is calculated as the ratio of the relative height of the current node in the layer to the height of the layer. The depth factor is defined as follows:

$$D(i) = \frac{l \times L_{ni} - h_i + d \times \text{mod}(n-1, l/d)}{l}, \quad (10)$$

in which  $l$  is the height of the layer;  $h_i$  is the current depth information of the node  $i$ ;  $d$  is the downward adjustment distance of each network layer; and  $L_{ni}$  is the network layer of the  $n$ th round of node  $i$ . The calculation equation is as follows:

$$L_{ni} = \lfloor \frac{h_i + l - d \times \text{mod}(n-1, l/d)}{l} \rfloor. \quad (11)$$

*4.1.2. Determining the Attribute Importance Degree of the Cluster Head ( $g$ )*. In the previous section, the comprehensive attribute evaluation value of a cluster head has been obtained. This section determines that the attribute importance degree ( $g$ ) of the comprehensive evaluation of cluster heads will be determined according to the fuzzy integral. To be consistent with the actual selection of cluster heads in underwater sensor networks, it is necessary to use the intuitionistic fuzzy AHP that is closer to human thinking to select cluster heads because it can represent the neutrality of the expert's scoring. DHCDGA uses the cluster head selection comprehensive evaluation hierarchical structure in Figure 3 and the fuzzy analytic hierarchy process proposed in [33] to obtain the attribute importance degree ( $g$ ) of the cluster head. Firstly, many experts are asked to compare the importance of the indicators in the criterion level and the subcriteria for the upper-level target level. Based on the opinions of experts, the distance of intuitionistic fuzzy complementary judgment is established, where the intuitionistic fuzzy complementary judgment matrix of all attributes of the second layer to the target layer is shown as follows:

$$L_1 - L_2 = \begin{bmatrix} 0.5 & (0.7, 0.9) & (0.8, 0.9) \\ (0.1, 0.3) & 0.5 & (0.7, 0.8) \\ (0.1, 0.2) & (0.2, 0.3) & 0.5 \end{bmatrix}. \quad (12)$$

The intuitionistic fuzzy complementary judgment matrix of the attributes of the third-level subcriteria layer to the attributes of the second-level criterion layer is shown as follows:

$$L_{21} - L_3 = \begin{bmatrix} 0.5 & (0.8, 0.9) & (0.5, 0.8) & (0.8, 0.9) \\ (0.1, 0.2) & 0.5 & (0.1, 0.2) & (0.6, 0.7) \\ (0.2, 0.5) & (0.8, 0.9) & 0.5 & (0.7, 0.8) \\ (0.1, 0.2) & (0.3, 0.4) & (0.2, 0.3) & 0.5 \end{bmatrix}, \quad (13)$$

$$L_{22} - L_3 = \begin{bmatrix} 0.5 & (0.5, 0.8) & (0.3, 0.7) \\ (0.2, 0.5) & 0.5 & (0.5, 0.6) \\ (0.3, 0.7) & (0.4, 0.5) & 0.5 \end{bmatrix}, \quad (14)$$

$$L_{23} - L_3 = \begin{bmatrix} 0.5 & (0.3, 0.5) & (0.5, 0.7) \\ (0.5, 0.7) & 0.5 & (0.4, 0.7) \\ (0.3, 0.5) & (0.3, 0.6) & 0.5 \end{bmatrix}. \quad (15)$$

Furthermore, the fuzzy approximation judgment matrix of the abovementioned four matrices is obtained as follows:

$$F_{L1} = \begin{bmatrix} 0.5 & 0.875 & 0.889 \\ 0.125 & 0.5 & 0.778 \\ 0.111 & 0.222 & 0.5 \end{bmatrix}, \quad (16)$$

$$F_{L21} = \begin{bmatrix} 0.5 & 0.889 & 0.714 & 0.889 \\ 0.111 & 0.5 & 0.111 & 0.667 \\ 0.286 & 0.889 & 0.5 & 0.778 \\ 0.111 & 0.333 & 0.222 & 0.5 \end{bmatrix}, \quad (17)$$

$$F_{L22} = \begin{bmatrix} 0.5 & 0.714 & 0.5 \\ 0.286 & 0.5 & 0.556 \\ 0.5 & 0.444 & 0.5 \end{bmatrix}, \quad (18)$$

$$F_{L23} = \begin{bmatrix} 0.5 & 0.375 & 0.625 \\ 0.625 & 0.5 & 0.571 \\ 0.375 & 0.429 & 0.5 \end{bmatrix}. \quad (19)$$

Then, we realize Algorithm 1 in [33] by Matlab R2013 (b). The consistency test of the abovementioned four fuzzy complementary judgment matrices was performed, where  $\lambda = 0.5$ . After checking and adjusting the consistency of the matrix, a satisfactory consistency matrix is obtained as follows:

$$F'_{L1} = \begin{bmatrix} 0.5000 & 0.5521 & 0.5843 \\ 0.4479 & 0.5000 & 0.5464 \\ 0.4157 & 0.4536 & 0.5000 \end{bmatrix}, \quad (20)$$

$$F'_{L21} = \begin{bmatrix} 0.5000 & 0.8914 & 0.6512 & 0.9380 \\ 0.1086 & 0.5000 & 0.2466 & 0.5722 \\ 0.3488 & 0.7534 & 0.5000 & 0.7974 \\ 0.0620 & 0.4278 & 0.2026 & 0.5000 \end{bmatrix}, \quad (21)$$

$$F'_{L22} = \begin{bmatrix} 0.5000 & 0.5670 & 0.5132 \\ 0.4330 & 0.5000 & 0.4851 \\ 0.4868 & 0.5149 & 0.5000 \end{bmatrix}, \quad (22)$$

$$F'_{L23} = \begin{bmatrix} 0.5000 & 0.4516 & 0.5484 \\ 0.5484 & 0.5000 & 0.5710 \\ 0.4516 & 0.4290 & 0.5000 \end{bmatrix}. \quad (23)$$

Finally, the weight vector can be calculated by the (1) in [33]. After obtaining the satisfactory consistency matrix, the weight of all attributes in the second layer to the target layer can be obtained as  $W = (0.2879, 0.3352, 0.3769)$ . In the same way, the weights of the attributes subcriteria layer in the third level to the second level in the comprehensive hierarchy and the final combined weights of the attributes of the subcriteria layer in the third level relative to the elements of the target layer can be obtained. These weights are as shown in Table 1.

By the previous sections, the evaluation value ( $h$ ) of each attribute and its corresponding importance degree ( $g$ ) are obtained. Next, the overall evaluation value of the node can be obtained by the comprehensive evaluation hierarchical structure of the cluster head according to Figure 3. The process of calculating the overall evaluation value adopts the same tree structure as in [34]. Firstly, the attribute evaluation value is calculated from the leaf node. Then, the evaluation value of the previous layer can be obtained by the fuzzy integral to integrate the attribute evaluation value of the node and the weight of this layer. For instance, by the fuzzy integral, the evaluation value of the second layer L2 can be obtained by the evaluation value ( $h$ ) of the third layer L3 and the weight ( $g$ ) of the third layer. In the same way, by the fuzzy integral, the evaluation value of the first layer L1 can be obtained by the evaluation value ( $h$ ) of the second layer L2 and the weight ( $g$ ) of the second layer. By analogy, the evaluation value of the upper layer and the weight of this layer are calculated by fuzzy integral, and the comprehensive evaluation score of the node becoming the cluster head can be obtained.

## 4.2. Establishment of the Cluster Topology

**4.2.1. Cluster Head Broadcast Time.** In this section, the mapping relationship between the comprehensive evaluation value and cluster head broadcast time is illustrated. The cluster head broadcast timing method of the final cluster head adopts the method in [16]. Its core is to map the comprehensive evaluation score of the candidate cluster head to trigger the message of being a cluster head on the timeline. The time for publishing the competing cluster head message is shown in (24). Its purpose is to broadcast the message  $FIN\_CH\_MES$  for the cluster leader election quickly with high comprehensive evaluation scores.

$$T_i = \gamma \times (1 - CS_i) \times T_{ini}, \quad (24)$$

in which  $\gamma$  is a random number from 0.8 to 1;  $CS_i$  represents the comprehensive evaluation score calculated by the hierarchical fuzzy integral; and  $T_{ini}$  is the preset clustering time.

**4.2.2. Competition Radius of the Cluster Head.** After the cluster head is selected, the node needs to broadcast the

TABLE 1: Weights based on intuitionistic fuzzy AHP ( $g$ ).

| Attribute | $L_{21}$ | $L_{22}$ | $L_{23}$ | Weights |
|-----------|----------|----------|----------|---------|
|           | 0.2879   | 0.3352   | 0.3769   |         |
| $L_{31}$  | 0.0866   | 0.3066   | 0.3333   | 0.2533  |
| $L_{32}$  | 0.3454   | 0.0000   | 0.0000   | 0.0994  |
| $L_{33}$  | 0.1833   | 0.3606   | 0.2935   | 0.2843  |
| $L_{34}$  | 0.0000   | 0.3328   | 0.0000   | 0.1116  |
| $L_{35}$  | 0.3846   | 0.0000   | 0.0000   | 0.1107  |
| $L_{36}$  | 0.0000   | 0.0000   | 0.3731   | 0.1406  |

message in the range of the cluster head competition radius. Hence, clusters closer to the sink have the smaller cluster size, and clusters farther from the sink have the larger cluster size. The specific regulations are as follows.

We set that the network layer  $i$  starts from 0 and is numbered with increasing from the top to bottom. In the initial stage of the network, the NO.0 layer does not exist, and the network number starts from 1. The network number starts from 1. After that, the 0th layer of the network is within the communication range of Sink, so the 0th layer is required to not cluster and send data directly to Sink. The cluster head at other levels needs determination of its level according to (10), and then, the cluster head competition radius is determined by the following equation:

$$CH(i).cr = CH(i).br + level(j) \times initial\_range, \quad (25)$$

in which  $CH(i).cr$  is the competition radius of the cluster head  $i$ ;  $CH(i).br$  is the broadcast radius of the cluster head  $i$ ;  $level(j)$  is the number of layers; and  $initial\_range$  is the initial range value. From (25), it can be seen that the larger the cluster head is, the larger the competition radius is.

**4.2.3. Cluster Topology Formation.** In cluster topology formation, if a node loses the opportunity to become the cluster head, it will join a cluster as a common member node. In joining a cluster, there are two very important parameters, namely, the distance from the node to the cluster head and the density of the cluster head. If there is more than one cluster head in the communication range of a node, the node will calculate the score of joining each cluster head node according to the following equation:

$$Sort_{CH} = \alpha \cdot distance_{itoCH} + \beta \cdot Density_{CH}, \quad (\alpha + \beta = 1). \quad (26)$$

The node's decision to join which cluster head mainly depends on its lower score. Then, this node sends a message  $JOIN\_CH\_MES$  to the cluster head with the lowest score to join it. The cluster topology formation of other rounds is similar to this process. Algorithm 1 shows the pseudocode of the member nodes joining the cluster unit.

**4.3. Data Transmission.** After establishing cluster topology, the nodes begin to transmit data steadily. When the energy value of a node is lower than the threshold  $E_0$ , it means that the node is dead, and then, the network starts to reconstruct.

Input: the distance between node  $i$  to CH; the density of CH;  
Output: cluster topology

- (1) **for** each node  $i$  ( $i$  is not CH)
- (2) Receive message with the distance between node  $i$  to CH; the density of CH
- (3) Calculate  $\text{Sort}_{\text{CH}} = \alpha \cdot \text{distance}_{i\text{toCH}} + \beta \cdot \text{Density}_{\text{CH}}$
- (4) Select Min ( $\text{Sort}_{\text{CH}}$ )
- (5) Send request message  $\text{JOIN\_CH\_MES}$  to the CH which has the minimum score.
- (6) **end for**

ALGORITHM 1: Cluster topology formation.

In the data transmission phase, each cluster member node periodically gathers data from the sensing area and transmits the data to its cluster head according to TDMA timing allocated by the cluster head to avoid message collision in the same cluster. When all the data of the cluster members are transmitted to the cluster head, the cluster head will fuse the data and transmit the fused data packets to Sink. Therefore, data transmission can be divided into two stages: intracluster communication and intercluster communication. Cluster members sense the data in the gathering environment and transfer the gathered data to their cluster head. This process is intracluster communication. Direct transmission is adopted to simplify the communication between member nodes and cluster heads. In intercluster transmission, a multihop inter layer routing algorithm is proposed. The cluster head with a large layer number is transmitted to the smaller layer number and, finally, to Sink. This can not only ensure the direction of data transmission but also prevent the generation of routing loops. Before selecting the next-hop node, the cluster head or node  $i$  calculates the set of neighbor nodes in the upper layer according to the location information of the sink and establishes a table of neighbor nodes, including node ID, node depth, sink location, current remaining energy, and the number of neighbor nodes. The cluster head  $i$  calculates the routing cost of its upper neighbor nodes and selects the next-hop node of the cluster head with the lowest routing cost. When the cluster head  $j$  is selected as the next-hop node, the relay node of the next-hop is selected according to the depth information. The cost function is shown as follows:

$$\text{cost}(i, j) = \alpha \frac{d_{j\text{-Sink}}}{d_{i\text{-Sink}}} + \beta \frac{\bar{E}_{\text{above-Nei}}(i)}{E_{\text{residual}}(\text{CH}_j)} + \gamma \frac{\bar{N}_{\text{above-Nei}}(i)}{N(\text{CH}_j)}, \quad (27)$$

in which  $d_{i\text{-Sink}}$  is represented as the depth information of the node  $i$ ;  $d_{j\text{-Sink}}$  is the depth information of the upper neighbor node  $j$ ;  $\bar{E}_{\text{above-Nei}}(i)$  is the average residual energy of the neighbor nodes in the upper layer of the node  $i$ ;  $E_{\text{residual}}(N_j)$  is the current residual energy of the cluster head  $j$ ;  $\bar{N}_{\text{above-Nei}}(i)$  denotes the average number of neighbor nodes in the upper layer of the node  $i$ ; and  $N(\text{CH}_j)$  is the number of neighbors of the node  $j$ .  $\alpha$ ,  $\beta$ , and  $\gamma$  are weighted coefficients, and the sum of the three weighting coefficients is 1. The cluster head or node  $i$  selects the node whose cost function is the least among its neighbors, namely,  $k = \text{armincost}(i, j)$ .

When designing this cost function, a relay node closer to the sink may be selected in the first term of (27). Since the transmission range of the node is fixed in this paper, choosing a relay node closer to the sink can reduce the number of relays and reduce the energy consumption of the node.

In the second term, the node with higher remaining energy may be selected as the next-hop relay node. Because the energy of the underwater sensor network is limited, it consumes energy during transmitting data, receiving data, or selecting cluster heads. Therefore, the residual energy of the node is the main factor in selecting the relay node.

In the third term, the node with more neighbor nodes may be selected as the next-hop relay node. This factor is considered because the nodes are randomly deployed in this paper, namely, some nodes are deployed densely and some nodes are deployed sparsely. When the nodes are dense, the selected next-hop relay nodes are more scattered, and the energy consumption is more balanced. When the nodes are sparse, the selected next-hop relay nodes are more concentrated. This brings the nodes with the largest energy consumption to appear prematurely, which shortens the network lifetime.

It is worth noting that if there are multiple same minimum routing costs in the neighbor node table toward the water surface, a node is selected randomly as the next-hop relay node. If the set of neighbor nodes of the upper level of the cluster head  $i$  is empty, the fallback mechanism in [14] is adopted. Namely, this node is deleted from the neighbor information table, and the node with the second smallest cost function in the upper-level neighbor node set of  $\text{CH}_i$  is reselected as the next-hop relay node.

## 5. DHCDGA Theoretical Analysis

**Proposition 1.** *The message complexity of DHCDGA is  $O(N)$  in the clustering phase, where  $N$  is the number of sensor nodes in the network.*

*Proof.* Because the energy consumption of sending messages is much greater than that of receiving messages, the complexity of sending messages as the message complexity of DHCDGA is discussed only in the clustering phase. Firstly, in the initialization phase,  $N$  sensor nodes broadcast initialization messages and establish the neighbor table of the nodes. Furthermore, DHCDGA is executed in each layer

to form clustering topology. Because three communications are required between nodes, the total number of messages sent is  $N + N + N$ . Otherwise, assuming that  $M$  nodes in the network become the final cluster heads,  $M$  nodes broadcast, at least,  $FIN\_CH\_MES$  messages. There are  $(N - M)$  non-cluster heads, and they broadcast  $(N - M)$   $JOIN\_CH\_MES$  messages to the cluster head with the smallest score to construct a clustering topology. In summary, the total message overhead is  $4N + M + (N - M)$ . Therefore, the message complexity is  $O(N)$  in the clustering phase.  $\square$

**Proposition 2.** *In DHCDGA,  $(2K + l/d_1 - 1)$  hops are required, at most, for any data packet transmitted to Sink, where  $K = \lfloor D/l \rfloor$ ,  $D$  is the area radius of the underwater sensor network;  $l$  is the width of the layer; and  $d_1$  is the average distance of a hop in the first layer.*

*Proof.* Assuming that the node  $S_i$  is located in the  $K$ th layer, the node in its cluster has one cluster head. There are two transmission methods for a data packet transmitted from the  $K$ th layer to the Sink. Namely, the second layer to the  $K$ th layer is clustered, and the flat multihop transmission mode is used in the first layer.

Firstly, the number of transmission hops is calculated from the  $K$ th layer to the second layer. The data packet of node  $S_i$  is transmitted to its cluster head, and the cluster head is transmitted to the cluster head in the  $(K - 1)$  layer after data fusion. Keeping this way, data packets are transmitted until the second layer. Therefore, the number of hops for data packets of  $(2K - 1)$  nodes is  $(2K - 2)$  in data transmission.

Secondly, the number of hops is calculated for flat multihop transmission in the first layer. When data packets are transmitted from the second layer to the first layer, different transmission methods will be used. In the first layer, the flat multihop data transmission is used, and the number of hops for the data packet transmitted to the sink is  $l/d_1$ . Another hop is from CH in the second level to the nodes in the first layer.

Accordingly,  $(2K + l/d_1 - 1)$  hops are required, at most, for any data packet transmitted to the sink in DHCDGA.  $\square$

**Proposition 3.** *When the cluster head transmits data to Sink, there is no routing loop.*

*Proof.* Proof by contradiction is adopted for Property 3. We assume that there is a routing loop  $\{CH_1, CH_2, \dots, CH_K, CH_1\}$ .  $D_i$  represents the depth of  $CH_i$ . According to the network model in this paper, the depth  $D_{i-1}$  of  $CH_{i-1}$  is shorter than  $D_i$ , namely,  $D_1 < D_2 < \dots < D_L < D_1$ . However, the depth  $D_L$  of the node  $CH_L$  is longer than the depth  $D_1$  of the cluster head  $CH_1$ . This contradicts the actual situation. Accordingly, it is guaranteed that no routing loop will occur when the cluster head transmits data to Sink.  $\square$

## 6. Simulation

**6.1. Simulation Scenarios and Parameter Setting.** The simulation environment is the Intel Pentium dual-core processor (2.2 GHz), 2G memory, and the experimental platform is Matlab R2013 (b). To analyze the effectiveness of DHCDGA, three clustering data gathering algorithms, DHCDGA, NULCPR, and LEACH-Coverage-U, are implemented.

We analyze and compare the six performances of three clustering data gathering algorithms whose network lifetime, the number of alive nodes, the average remaining energy, the number of cluster heads, coverage ratio of the network, and the total amount of data are received by Sink. In the simulation, 1000 sensor nodes are randomly deployed in  $100\text{ m} \times 100\text{ m} \times 100\text{ m}$  of the underwater three-dimensional monitoring area  $A$ . The coordinates of the sink are (50, 50, 100) (m). For calculating the coverage ratio, area  $A$  is divided into  $100 \times 100 \times 100$  small cubes, and the size of each cube is  $1\text{ m} \times 1\text{ m} \times 1\text{ m}$ . The simulation result is the average of twenty experiments, and other parameters are shown in Table 2.

**6.2. Network Lifetime.** The network lifetime of three data gathering algorithms is shown in Figure 4. FDT (First node Died Time) is the time when the node is dead first in the network. LDT (Last node Died Time) is the time when the last node is dead in the network. FDT is one of the most important indicators investigated by underwater sensor network data gathering algorithms. However, when the first node died in the network, if the node has strong coverage, it will not have a great impact on the data gathering of the whole network. Therefore, it is not enough to observe only FDT but also LDT of three clustering algorithms.

As shown in Figure 4, we can observe that the FDT of the Leach-coverage-U algorithm appears the earliest, while the LDT appears at the latest. This result can be explained by the fact that Leach-coverage-U transmits data from CH to the sink by a single hop in the data transmission phase. The cluster head consumes more energy.

Otherwise, in Leach-coverage-U, the cluster structure must be rebuilt in each round. The message is expensive and consumes a lot of energy. Therefore, the FDT of the lease-coverage-U algorithm appears the earliest. Also, single-hop data transmission will bring that the nodes far away from the sink are not able to transmit data to the sink due to insufficient transmission range until their energy is exhausted. Hence, the LDT of Leach-coverage-U appears the latest. NULCPR and DHCDGA are unequal clustering data gathering algorithms. The FDT of DHCDGA is about 18.71% longer than that of NULCPR. The LDT of DHCDGA is about 15.38% longer than that of NULCPR. This result can be explained by the fact that the multihop routing path constructed takes into account factors such as residual energy, depth, and the number of neighbor nodes during the data transmission. But, NULCPR only focuses on the distance between cluster heads.

TABLE 2: Simulation parameters.

| Parameters                              | Value       |
|---|-------------|
| Node throughput                         | 0.25 (kB/s) |
| The initial energy of the node          | 20 J        |
| Lowest receiving power ( $P_o$ )        | 3 (mW)      |
| Size of a data packet ( $l$ )           | 4000 (bits) |
| Communication radius ( $R$ )            | 600 (m)     |
| Sense radius                            | 15 (m)      |
| Carrier frequency ( $f$ )               | 10 (kHz)    |
| Energy diffusion                        | 1.5 (K)     |
| Energy consumption of data fusion       | 5 (nJ/bit)  |
| Maximum offset distance of node ( $r$ ) | 10 (m)      |
| Initial radius                          | 10 (m)      |

FIGURE 4: Network lifetime.

6.3. *Number of Alive Nodes.* The number of alive nodes represents the change in the number of nodes with energy from the beginning of work to the exhaustion of energy. This indicator is to examine the stability of the data gathering algorithm. The number of alive nodes for the three data gathering algorithms is shown in Figure 5.

As shown in Figure 5, the stability of DHCDGA is slightly better than that of Leach-coverage-U and NULCPR. Although DHCDGA occurs FDT, the number of alive nodes decreases linearly until all the nodes die instead of the network split causing the data gathering function paralysis. Since the message timing mechanism adopted by both DHCDGA and NULCPR replaces the message negotiation mechanism of Leach-coverage-U, energy consumption in the clustering phase is less than Leach-coverage-U. Otherwise, NULCPR only focuses on the factor of distance in selecting CH and data transmission; however, DHCDGA integrates multiple attributes for cluster head selection and routing path construction so that it is more suitable for underwater sensor networks with nonuniform node distribution. In summary, DHCDGA has better stability than the other two data gathering algorithms.

6.4. *Average Residual Energy of the Network.* The average residual energy of the network is the ratio of the current

FIGURE 5: Number of alive nodes.

residual energy of each node in each round to the total number of nodes, which mainly examines the balance of energy consumption. The average residual energy of the three data gathering algorithms is shown in Figure 6.

As shown in Figure 6, DHCDGA consumes less energy than NULCPR. This result can be explained by the fact that DHCDGA considers six factors in CH selection and the competition radius has two factors when network forms cluster topology. These are results in the cluster structure more uniform and reasonable when nodes join in cluster units. Meanwhile, the intermultihop route algorithm takes into account factors such as the residual energy, depth information, and the number of neighbor nodes in the interdata transmission, which makes the selection of the next-hop relay node more reasonable and reduces energy consumption.

Otherwise, the nodes of Leach-coverage-U that is an equal size cluster algorithm have a less average remaining energy because the equally clustered data gathering algorithm does not use an effective balance mechanism for reducing energy consumption. The data gathering algorithm with equal cluster size may produce clusters with only one CH and no member nodes, which leads to an unbalanced node load and huge differences in energy consumption. Besides, Leach-coverage-U may cause CHs to be concentrated in certain areas. More edge nodes are generated, which is a result when all CHs are not within their communication range. Long-distance communication is required between edge nodes and sink, which increases energy consumption.

6.5. *Number of Cluster Heads.* The number of cluster heads is the total number of cluster heads in the network in different simulation times. This indicator is mainly to investigate the stability of the clustering algorithm in the data gathering algorithm. The number of cluster heads with changes in network time is shown in Figure 7.

FIGURE 6: Average residual energy.

FIGURE 7: Number of cluster heads.

As shown in Figure 7, compared with NULCPR and Leach-coverage-U, the number of CH for DHCDGA is relatively stable. Because the number of CHs in the DHCDGA mainly depends on the number of neighbor nodes of  $CH_i$ 's every layer, network coverage, and other information, the cluster head competition radius of each layer is relatively fixed.

Therefore, the number of cluster heads in the DHCDGA does not change significantly, so its clustering algorithm has a better stability. NULCPR algorithm is the data gathering algorithm with coverage preservation. After around, there are no nodes to die, so the network topology has not changed so that the coverage redundancy of each node has not changed. NULCPR can continue to keep the cluster topology of the previous round, and the number of CH is relatively

stable. However, the number of CHs fluctuates sharply for Leach-coverage-U since Leach-coverage-U is a random clustering data collection algorithm. Cluster topology must be rebuilt in each round, and candidate CHs will be randomly assigned according to the proportion of alive nodes, which will generate a cluster with a single node. Accordingly, the number of CHs in Leach-coverage-U fluctuates sharply.

**6.6. Network Coverage Ratio.** Network coverage refers to the percentage of the total area of the node gathering range to the entire network area. The network coverage ratio for three data gathering algorithms is shown in Figure 8. Because the coverage ratio is closely related to the number of alive nodes, Figures 5 and 8 are observed together.

As shown in Figures 5 and 8, comparing with NULCPR and Leach-coverage-U, DHCDGA has certain advantages. Furthermore, the coverage ratio decreases approximately linearly after occurring FDT of three data gathering algorithms. Besides, there is no network fragmentation caused by the simultaneous death of a large number of nodes. The coverage rate of the NULCPR algorithm is higher than that of Leach-coverage-U.

As shown in Figure 5, Leach-coverage-U has more alive nodes than NULCPR before the network runs 265 rounds. Leach-coverage-U and NULCPR have the same alive nodes in the 265th round. As shown in Figure 8, in the 265th round, although Leach-coverage-U has more alive nodes at this time, the coverage ratio of NULCPR is about 8.62% higher than the Leach-coverage-U. At the same time, the coverage ratio of DHCDGA is about 39% higher than that of the Leach-coverage-U. Assuming that the expected coverage ratio of the monitoring area is about 70%, the number of running rounds that meet the requirements for Leach-coverage-U, NULCPR, and DHCDGA is about 212 rounds, 253 rounds, and 384 rounds, respectively. Compared with Leach-coverage-U, the network lifetime of NULCPR and DHCDGA has been prolonged by about 41 and 172 rounds, respectively.

**6.7. Total Amount of Data Received by Sink.** The total amount of data received by the sink refers to the total amount of data received by the sink in each round. The total amount of data received by the sink for three algorithms is shown in Figure 9.

As shown in Figure 9, The data packets received by the sink for three data gathering algorithms increase steadily as the running time increases. Near the end of the simulation, the slope of the curve gradually decreases, which is caused by the continuous death of nodes as time increases.

Besides, the total amount of data received by the sink for DHCDGA is more than that received by the other two algorithms, since DHCDGA considers the reliability of data gathering in CHs selection. Otherwise, neither NULCPR nor Leach-coverage-U considers the reliability of data collection, and NULCPR receives more data than Leach-coverage-U. Because NULCPR is a data gathering algorithm with unequal cluster size, Leach-coverage-U is a data gathering algorithm with equal cluster size. The network lifetime of an unequal clustering algorithm is longer than that of an equal

FIGURE 8: Network coverage ratio.

FIGURE 9: Total amount of data received by sink.

clustering algorithm. Therefore, NULCPR receives more data than Leach-coverage-U.

## 7. Conclusions

In this paper, a dynamic hierarchical 3D underwater sensor network clustering data gathering algorithm based on multiple criteria decision making is proposed. Firstly, the entire monitoring network is divided into layers. For selecting a cluster head in each layer, multiple criteria decision making of an intuitionistic fuzzy AHP and hierarchical fuzzy integration is adopted. Furthermore, a sorting algorithm is used to form a clustering topology algorithm to solve the problem that there is the only node in one cluster. Then, an energy-balanced routing algorithm between clusters is proposed according to the residual energy of the node,

the depth, and the number of neighbor nodes. Finally, the simulation results show that DHCDGA can not only effectively balance the energy consumption of the network and prolong the network lifetime but also improve network coverage and data gathering reliability.

Although DHCDGA shows good performances, it does not focus on fault tolerance, security, and other application scenarios in underwater sensor networks. We will study clustering technology in a more comprehensive application scenario in the underwater sensor network.

Coronary artery aneurysms (CAAs) have been reported to associate with an increased risk for thrombosis. Distinct to the brain aneurysm, which can cause a rupture, CAA's threat is more about its potential to induce thrombosis, leading to myocardial infarction. Case reports suggest that thrombosis risk varied with the different CAA diameters and hemodynamics effects (usually wall shear stress (WSS), oscillatory shear index (OSI), and relative residence time (RRT)) may relate to the thrombosis risk. However, currently, due to the rareness of the disease, there is limited knowledge of the hemodynamics effects of CAA. The aim of the study was to estimate the relationship between hemodynamic effects and different diameters of CAAs. Computational fluid dynamics (CFD) provides a noninvasive means of hemodynamic research. Four three-dimensional models were constructed, representing coronary arteries with a normal diameter (1x) and CAAs with diameters two (2x), three (3x), and five times (5x) that of the normal diameter. A lumped parameter model (LPM) which can capture the feature of coronary blood flow supplied the boundary conditions. WSS in the aneurysm decreased 97.7% apparently from 3.51 Pa (1x) to 0.08 Pa (5x). OSI and RRT in the aneurysm were increased apparently by two orders of magnitude from 0.01 (1x) to 0.30 (5x), and from 0.38 Pa<sup>-1</sup> (1x) to 51.59 Pa<sup>-1</sup> (5x), separately. Changes in the local volume of the CAA resulted in dramatic changes in local hemodynamic parameters. The findings demonstrated that thrombosis risk increased with increasing diameter and was strongly exacerbated at larger diameters of CAA. The 2x model exhibited the lowest thrombosis risk among the models, suggesting the low-damage (medication) treatment may work. High-damage (surgery) treatment may need to be considered when CAA diameter is 3 times or higher. This diameter classification method may be a good example for constructing a more complex hemodynamic-based risk stratification method and could support clinical decision-making in the assessment of CAA.

## 1. Introduction

A coronary artery aneurysm (CAA) is a localized swelling in one of the coronary arteries that supply oxygen to the heart. It is typically defined by a diameter at least 1.5 times that of

the adjacent normal segments of the artery. It is called the giant CAA when the diameter of a CAA exceeds four times the diameter of its adjacent coronary artery [1]. The incidence of CAAs has been reported as 0.3%-5.3% [2]. However, the prevalence of CAA in different literature varies due

to statistical data, [3–6], lack of standardization for diagnosis on angiography [5, 7], and different CAA definitions [8]. CAA is generally associated with the risk of complications such as infarction, ischemia, and thrombosis, with the thrombosis being the most common [9]. Unlike other types of aneurysms, which pose a risk of rupture, the main risk caused by CAA is thrombosis rather than rupture [1].

Current American Heart Association (AHA) guidelines for risk stratification rely on aneurysm size alone as the criterion for initiating systemic anticoagulation; however, studies suggest risk may also depend on hemodynamic parameters such as low wall shear stress (WSS), high oscillatory shear index (OSI), and high relative residence time (RRT), which are not available through image data alone [10–13]. Indeed, CAAs' complex geometries, such as the diameter, may contribute to abnormal hemodynamics and correlate with patient outcome. Considering the other risks, doctors may be confused about the dilemma of whether to adopt the watch-and-wait approach, with the risk of sudden deterioration, or to expose the patient to the risks of treatment if just based on the image data alone. Therefore, it is necessary to evaluate the relationship between CAA diameter and level of thrombosis risk based on the hemodynamic study which could provide support for the doctors.

Patient-specific hemodynamic simulations by using computational fluid dynamics (CFD) can non-invasively supply informative hemodynamic parameters for better thrombotic risk assessment; however, existing studies have been limited and struggle to quantify effects of aneurysm shape on local hemodynamics. With such limitations in mind, existing patient-specific models can be augmented by introducing artificial aneurysms of specified diameter, to achieve a systematic evaluation of the relationship between CAA size and the local hemodynamics. Ultimately, elucidating the relationship between hemodynamics and aneurysmal size characteristics may underlie more powerful risk stratification methods to support clinical decision-making. Usually, these treatments include high-risk surgical treatment and conservative treatment regarding initiation of anticoagulant therapy. Surgery has multiple risks such as the risk of anesthesia, postoperative complications, and the like. Due to the large changes in the cardiovascular structure of the operation, even if the surgical operation has complete risk management, some postoperative complications such as weakened cardiac function and arrhythmia cannot be completely avoided.

CFD has been used widely in the research of vascular diseases in recent years [14–16] and can be used to estimate important hemodynamic parameters including mass flow, WSS, OSI, and RRT. The mass-flow rate can usually be calculated based on speed measurement using non-invasive ultrasonic velocimetry. However, other parameter, WSS, OSI, and RRT, measurements are much more complicated and cannot be accurately measured directly. The indirect calculation method of in vitro experiments, which means the need to build an experimental system and need to consider every potential problem in the system, also has high cost. The advantages of CFD, such as gaining insight into systems that might be difficult to test through

experimentation and lower costs, can overcome the shortcomings of other measurement methods mentioned above. Simulations have played important roles in other studies, such as bypass grafts [17, 18] and abdominal and cerebral aneurysms [19–21], but this technique has rarely been applied to CAAs. One of the important factors is that the characteristics of the coronary artery make its simulation difficult. In the human physiological environment, the resistance of the coronary arteries changes repeatedly; during systole, the resistance of the coronary circulation increases considerably due to the contraction of the heart. In contrast, during diastole, the pressure decreases, which reduces coronary microcirculation resistance. As a consequence, the coronary blood supply increased. In order not to lose the characteristics of the coronary artery, we have adopted a circuit model called lumped parameter model (LPM) to simulate the coronary artery to provide the boundary conditions for the CFD simulation work [22].

The aim of the study was to estimate the relationship between hemodynamic effects and different diameter of CAAs. We quantified hemodynamic parameters of likely clinical relevance for assessing the thrombotic risk including WSS, OSI, and RRT. We created virtual models by artificially constructing models of normal coronary and different diameter of CAAs to compare normal and pathological hemodynamics. This study will allow us to estimate the risk of thrombosis of CAAs from a hemodynamic perspective and provide more comprehensive support for doctors' decisions.

## 2. Materials and Methods

*2.1. Model Development and Simulation Methods.* A patient-specific anatomy model was constructed, based on patient data provided by Anzhen Hospital. All patient information for this analysis was anonymized. This study has been approved by the Medical Ethics Committee of Beijing Anzhen Hospital and Tohoku University. The images used for the 3D model reconstruction were obtained by CT. A personalized real 3D anatomic geometry model was built with manual and threshold segmentation by using Mimics processing software (Materialise NV, Leuven, Belgium). The single fusiform CAAs of different diameters were added to the left anterior descending artery by using the PHANTOM Desktop in Freeform software (3D Systems, USA). We have only changed the diameter of CAA and have not changed the length of CAA along the coronary artery. The link between CAA and normal coronary artery was smoothed. All the changes have been confirmed by the medical doctor. CAA models were constructed with diameters two, three, and five times that of the normal segments of the coronary artery, as well as a model of a normal coronary artery without an aneurysm (Models 2x, 3x, and 5x, respectively; Figure 1), so that we can study hemodynamics on both regular and giant size (Figure 1).

The computational models were generated by 3D model meshing, using a hexahedral mesh controlled by size control using ANSYS Meshing software (Swanson Analysis Systems, Inc., USA). The grids of the regions local to the CAA were refined to allow more precise simulation calculations in these areas for more accurate results.

FIGURE 1: Three-dimensional models with a normal coronary artery (Model 0) and with coronary artery aneurysms with diameters two, three, and five times that of the normal diameter (Models 2x, 3x, and 5x, respectively). (a) Model 0. (b) Model 2x. (c) Model 3x. (d) Model 5x.

To confirm the reliability of the simulation results, we performed a grid independence test on the number of elements and nodes [22]. See Figure 2 to check more information of the independence test. It can be found that the simulation results tend to be stable when the number of grids exceeds a certain standard. The total numbers of nodes and elements for the four models differed (Table 1), but they were all of the same order of magnitude number. Blood flow simulations were performed by using the Navier–Stokes solver in the ANSYS-CFX software (Swanson Analysis Systems, Inc.). The simulation calculation assumed that the artery wall was rigid and stationary, the blood flow was Newtonian, and the density and viscosity were  $1050 \text{ kg/m}^3$  and  $0.0035 \text{ Pa s}$ , respectively. Based on the Reynolds number, the fluid is set as laminar flow. The simulations were run for three cardiac cycles. We selected a time step of  $0.0025 \text{ s}$  to satisfy the calculation of stability conditions. The maximum residual of momentum and continuity of the iterative calculation was set to  $0.0001$ .

**2.2. Lumped Parameter Boundary Conditions.** The coronary artery blood flow simulation required careful consideration of the physiological function of the coronary circulation and microcirculation, especially the drastic change in microcirculatory resistance due to heart contractions. This could be simulated appropriately by using an LPM. The LPM construction method for the boundary conditions was based on previous research [22, 23]. The LPM system comprised a heart left ventricle module, coronary artery modules, and arterial modules. These modules were developed based on the concept of the three-element Windkessel RCR (resistor-capacitor-resistor) model [24], a simple circuit model in which blood flow and blood pressure were considered to be analogous to electrical current and voltage, and the resistance and compliance of blood vessels were characterized by resistance and capacitance, respectively. The entire multiscale model is shown in Figure 3. The heart module can be built using some components such as power source and variable capacitor on the basis of the RCR model. The power can simulate the

FIGURE 2: The result of grid independence test and the trend line of the results.

TABLE 1: The numbers of nodes and elements of the grid in the four computational models.

|          | Model 0   | Model 2x  | Model 3x  | Model 5x  |
|----------|-----------|-----------|-----------|-----------|
| Nodes    | 1,098,996 | 940,577   | 1,047,183 | 936,749   |
| Elements | 1,437,901 | 1,231,913 | 1,370,433 | 1,230,434 |

blood pressure and the variable capacitor can simulate the volume change of the ventricular during the systole and diastole. The inlet flow via the ascending aorta was provided by the LPM heart module, and the LPM heart model was connected to the LPM coronary artery models through intramyocardial pressure. The components of this module included resistors, capacitors, inductors, and diodes, which were used to simulate coronary resistance, vascular compliance, blood flow inertia, and the heart valves, respectively. The pressure–volume relationship representing the vascular compliance was calculated as follows:

$$C(t) = \frac{V(t) - V_0}{P(t)} = \frac{1}{E(t)}, \quad (1)$$

FIGURE 3: Details of the multiscale model used in the study, showing the coupled interface between the lumped parameter model (LPM) and the three-dimensional model. *an*, coronary arteries; A1A4, arteries; AAO, ascending aorta; DAO, descending aorta; RCR, resistor-capacitor-resistor.

where  $V(t)$  and  $P(t)$  are the pressure and volume of the ventricle and  $V_0$  is the reference pressure.  $E(t)$  characterizes the time-varying elastic properties and was calculated as follows:

$$E(t) = E_{\min} + (E_{\max} - E_{\min}) \cdot E_n(t_n). \quad (2)$$

The units of  $E$  used were mL and mmHg. Normalized time-varying elasticity  $E_n(t_n)$  was calculated using a method based on previous research [25] as follows:

$$E_n(t_n) = 1.55 \left[ \frac{1}{1 + (t_n/1.17)^{21.9}} \right] \left[ \frac{(t_n/0.7)^{1.9}}{1 + (t_n/0.7)^{1.9}} \right]. \quad (3)$$

In the present study, we set  $E_{\min} = 0.002458$  and  $E_{\max} = 2.0$ .  $t_n = (t / (0.2 + 0.15t_c))$ . The cardiac cycle  $t_c$  was set to 0.8 s.

Compared with normal arterial blood vessels, the coronary artery module required the addition of a microcirculation module to take account of the special physiology of coronary arteries. This module comprised a resistor ( $R_{v\text{-micro}}$ ) and a capacitor ( $C_{i\text{-micro}}$ ), with the cathode of the capacitor coupled to the internal pressure of the heart module to simulate changes in systolic pressure. The target mean flow of every branch of the LPM coronary arteries was determined by the area of each branch [23, 26]. Based on previous studies [22, 27], we assumed that the total perfusion of the coronary arteries was 4% of the cardiac output and that the total perfusion of the left and right coronary arteries was 60% and 40% of the total perfusion of the coronary arteries, respectively. As shown in Figure 2, the simulation of coronary microcirculation is to add a module on the basis of the common artery to simulate the pressure from the left ventricle and the resistance change caused by the pressure change. The debugging of the entire circuit model parameters is based on previous research [22], in which the pressure adjustment needs to match the patient's blood pressure.

The RCR model can be used to directly simulate arterial blood vessels because these do not undergo drastic changes in resistance. The RCR boundary conditions were set as the outlets of the descending aorta and supra-aortic arteries.

The CFD boundary conditions provided by the LPM for the inlet and outlets of the computational model corresponded to different modules, known as the 0D/3D multiscale coupled method [22, 23]. The important reasons for adopting LPM are the easy-to-deploy circuit model and the characteristics of not requiring a mainframe computer. The easy-to-deploy circuit model means that a complex circuit model composed of many different components can be simulated by programming. All four 3D models shared the same LPM, because, apart from the CAA lesion, the peripheral vascular geometry did not change between the models; this ensured changes in the geometric structure of the CAA were the main cause of the different simulation results. Clinical observation has shown that the coronary structure of the distal end of the coronary artery is not affected by the CAA; this was important evidence supporting the selection of this method.

### 3. Results

**3.1. Mass Flow and Pressure Waveforms.** Figure 4 shows the computed mass flow and pressure over a cardiac cycle for the ascending aorta (the inlet to the model), the descending aorta, an outlet artery, and a coronary artery branch (examples of outlets from the model) for the four 3D models. The results confirmed that, except for the mass flow at the coronary artery boundary, mass flow in the outlets peaked during systole. The coronary mass flow peaked during diastole. These results confirmed that the expected life-like characteristics of the coronary circulation, which blood supply mainly occurred during diastole, were successfully captured in the model [22]. High systolic intra-myocardial pressure resulted in increased distal downstream resistance

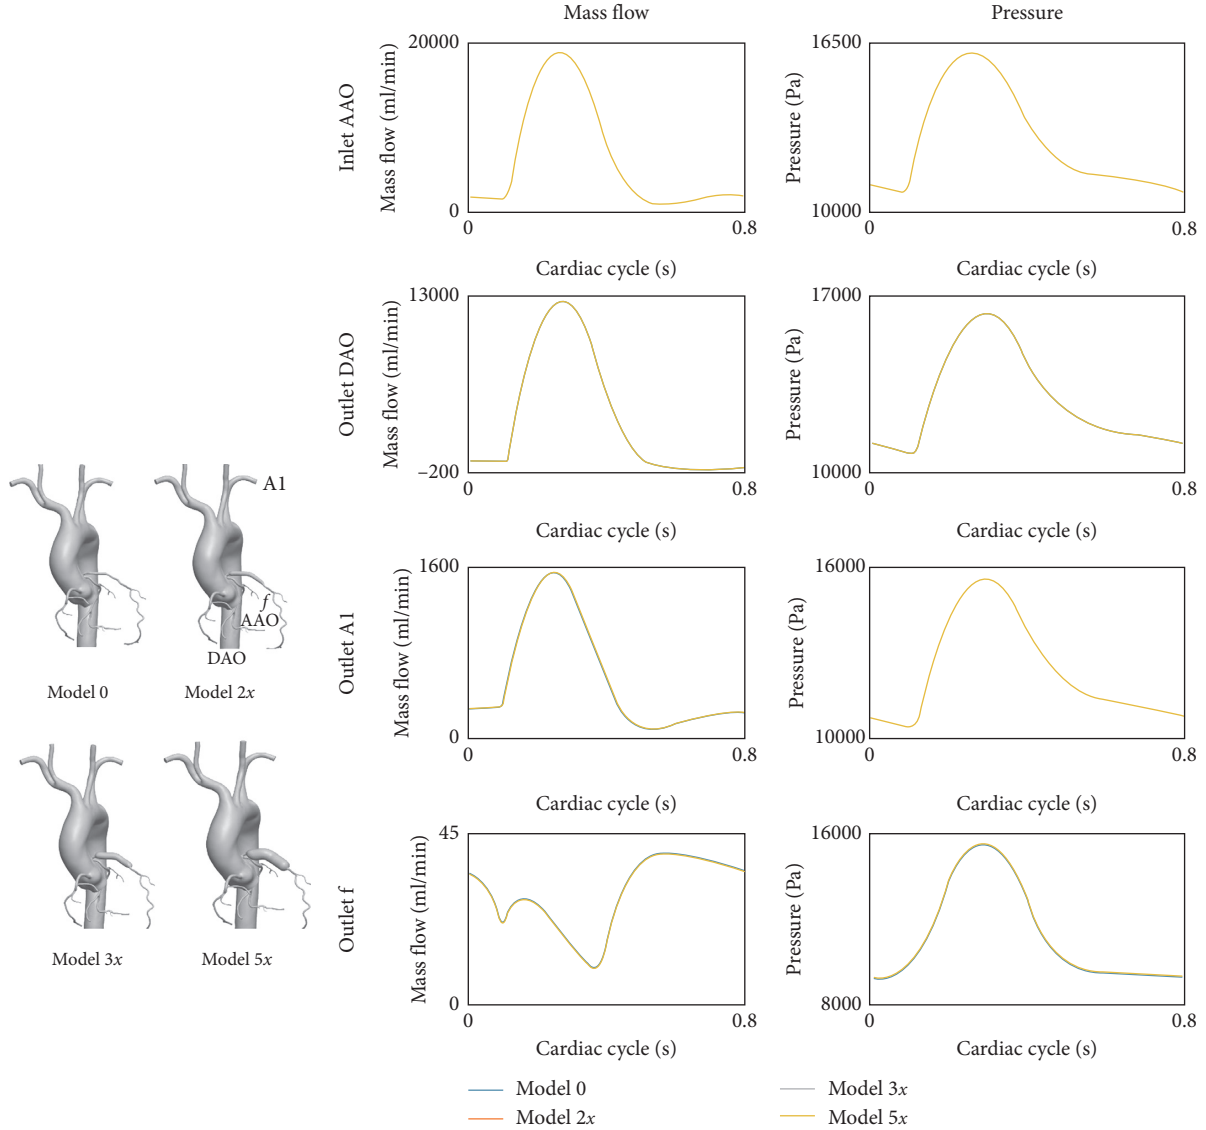

FIGURE 4: Mass flow and pressure curves for the inlet (ascending aorta, AAO) and three outlets (descending aorta (DAO), artery 1 (A1), and coronary artery  $f$ ) over a cardiac cycle.

and decreased blood flow through the coronary artery; the opposite was the case during diastole. Changes in the diameter of the CAA did not have a significant effect on coronary outlet flow.

**3.2. Wall Shear Stress.** The WSS is the force per unit area exerted by the wall on the fluid in a direction along the plane of the local tangent [28], calculated as follows:

$$\tau_w = \frac{4\mu Q}{\pi R^3}, \quad (4)$$

where  $\mu$  represents the blood viscosity,  $Q$  is mass-flow rate, and  $R$  is vessel radius. Previous studies have reported an association between thrombosis formation and low WSS [29]. The area average values of WSS in coronary artery aneurysm over a cardiac cycle in the four models

are listed in Table 2, and the values over a cycle and distribution contours are shown in Figures 5 and 6. The average WSS over a cycle in Model 0 (with no CAA) was 3.51 Pa. The averages for Models 2x, 3x, and 5x were 0.68, 0.26, and 0.08 Pa, respectively, substantially reduced in the CAA due to blood flow stagnation and recirculation, with the reduction increasing in CAAs of greater diameters. The distribution contours in Figure 6 confirm that the CAA results only in local hemodynamic disturbances without wider hemodynamic changes in the arteries. At some distance downstream in the coronary artery, the coronary diameter and WSS both return to normal levels.

**3.3. Oscillatory Shear Index.** OSI is a parameter that quantifies the magnitude of the WSS and directional changes [18], calculated as follows:

TABLE 2: Average values over a cardiac cycle for wall shear stress (WSS), the oscillatory shear index (OSI), and relative residence time (RRT) in the coronary artery aneurysm.

|                                      | Model 0 | Model 2x | Model 3x | Model 5x |
|--------------------------------------|---------|----------|----------|----------|
| Area average WSS (Pa)                | 3.51    | 0.68     | 0.26     | 0.08     |
| Area average OSI                     | 0.01    | 0.03     | 0.13     | 0.30     |
| Area average RRT (Pa <sup>-1</sup> ) | 0.38    | 2.88     | 23.12    | 51.59    |

FIGURE 5: Wall shear stress in the coronary artery aneurysm over a cardiac cycle for the four models.

$$\text{OSI} = 0.5 \times \left( 1 - \frac{\left| \int_0^T \tau_\omega dt \right|}{\int_0^T |\tau_\omega| dt} \right), \quad (5)$$

where  $T$  is the cardiac cycle. OSI has values in the range 0.0 to 0.5, with 0 representing undisturbed flow with no change in the direction of the shear stress and 0.5 representing disturbed flow with oscillating shear stress. Previous studies have reported an association between high OSI and the formation of intimal hyperplasia [30]. The average values of OSI in the aneurysm and OSI distribution contours are shown in Table 2 and Figure 7, respectively. The average value of OSI over the cardiac cycle in Model 0 was 0.01. The averages for Models 2x, 3x, and 5x were substantially higher, at 0.03, 0.13, and 0.30, respectively. Previous studies have pointed out that when OSI is greater than 0.2, it will cause endothelial cell damage [31]. As shown in Table 3, the ratio of high OSI area in the aneurysm to the area of aneurysm was 0%, 12.5%, 25.3%, and 66.2%, respectively. Model 0 has OSI close to zero throughout the cardiac cycle, and the flow in Model 0 is unidirectional without circulation. Normal coronary blood flow is unidirectional, usually without flow recirculation, so the OSI of the normal coronary artery (Model 0) was close to zero throughout the entire cardiac cycle. The high OSI values in the CAA models, which reached 30 times higher in model 5x, were due to the increased storage time resulting from the increased size of the cavity, which led to recirculation within the CAA lesion. The effect on OSI was locally confined; there

was little difference between the OSI in the distal coronary arteries in Models 2x, 3x, and 5x and those in Model 0.

**3.4. Relative Residence Time.** The RRT is an indicator that comprehensively characterizes the values and oscillation of WSS [32], as well as the time of local blood flow and vascular interaction [33]. It is calculated as follows:

$$\text{RRT} = \frac{1}{(1 - 2 \cdot \text{OSI}) \cdot \text{TAWSS}}, \quad (6)$$

where

$$\text{TAWSS} = \frac{\text{WSS}}{T}. \quad (7)$$

Here, TAWSS is WSS average over one cardiac cycle, and  $T$  is a cardiac cycle. Figure 8 shows the distribution contours for RRT in the four models, and Table 2 shows the area average values of RRT within the CAA lesion over the cardiac cycle. The average value of RRT in Model 0 was 0.38 Pa<sup>-1</sup>. The averages for Models 2x, 3x, and 5x were substantially higher, at 2.88, 23.12, and 51.59 Pa<sup>-1</sup>, respectively, showing a dramatic increase in RRT with increasing diameter of the CAA. Studies have reported a significantly increased risk of thrombosis when RRT is >10 Pa<sup>-1</sup> [12, 34]. As shown in Table 3, the ratio of high RRT area in the aneurysm to the area of aneurysm was 0%, 0.5%, 27.1%, and 78.6%, respectively. The increased diameter of the CAA makes it easier for blood to remain resident within it, hampering the blood flow to the distal coronary artery. The change in RRT was locally confined to the CAA; there was little difference between the RRT in the distal coronary arteries in Models 2x, 3x, and 5x and that in the distal coronary artery in Model 0.

## 4. Discussion

We have shown that the relationship between hemodynamic effects and different diameters of CAAs can be achieved by using CFD simulation method direct comparison with virtual control case based on the same patient. We found that changes in the diameter of CAA have a strong effect on local hemodynamics while they do not have a significant effect on global hemodynamics. The potential risk of thrombosis increases significantly with increasing CAA diameter indicated through decreasing WSS, increasing OSI and RRT. This research will allow us to estimate the thrombosis risk of CAAs from a hemodynamic perspective and provide more comprehensive support for doctors' decisions.

When making treatment decisions about CAAs, doctors typically depend on their own clinical experience [35]. This may be because of the lack of useful diagnostic tools. The current used tool is the method of imaging which can provide geometric information and almost no other information. The lack of other information cannot provide more help for the doctor's diagnosis. Therefore, it is necessary to find a way to provide more information to help the doctor. It has been shown that WSS over aneurysmal regions is

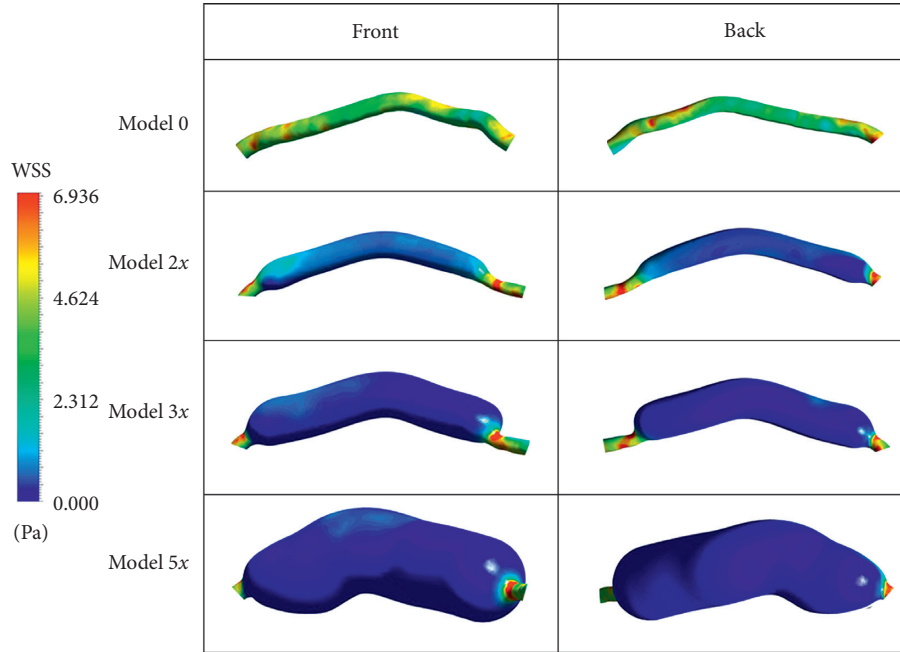

FIGURE 6: Wall shear stress (WSS) distribution in the coronary artery aneurysm at its peak ( $t=0.2$  s) for the four models.

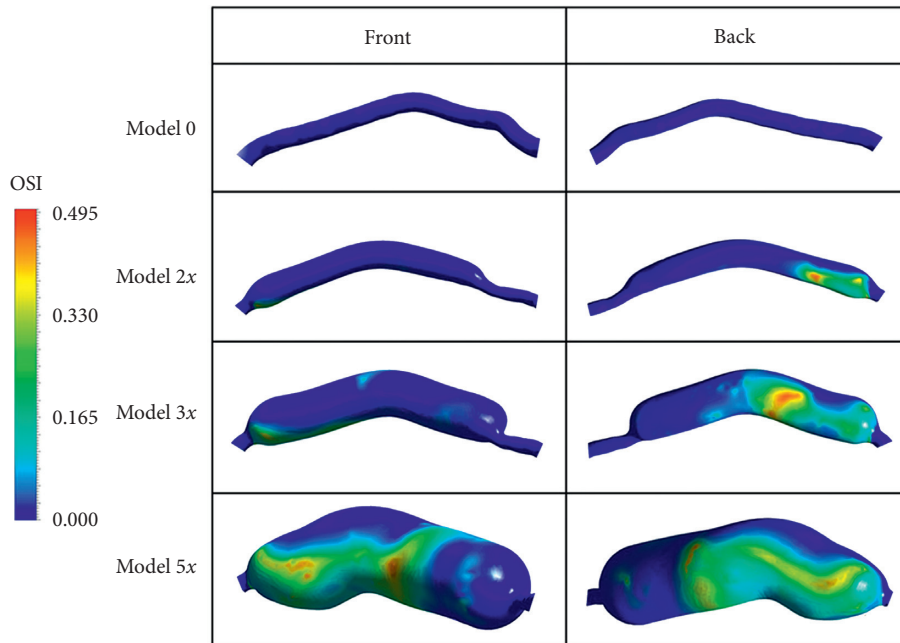

FIGURE 7: Oscillatory shear index (OSI) distribution in the coronary artery aneurysm for the four models.

associated with risk of thrombosis, and that is a more predictive factor of thrombosis than aneurysm diameter [36]. We confirmed that hemodynamic research is beneficial for aneurysm diagnosis and treatment [37]. Therefore, in

this study, we quantitatively calculated the hemodynamic parameters of CAA of different diameters in order to estimate the relationship between the risk level of thrombosis and the size of CAA. The results showed that CAAs only

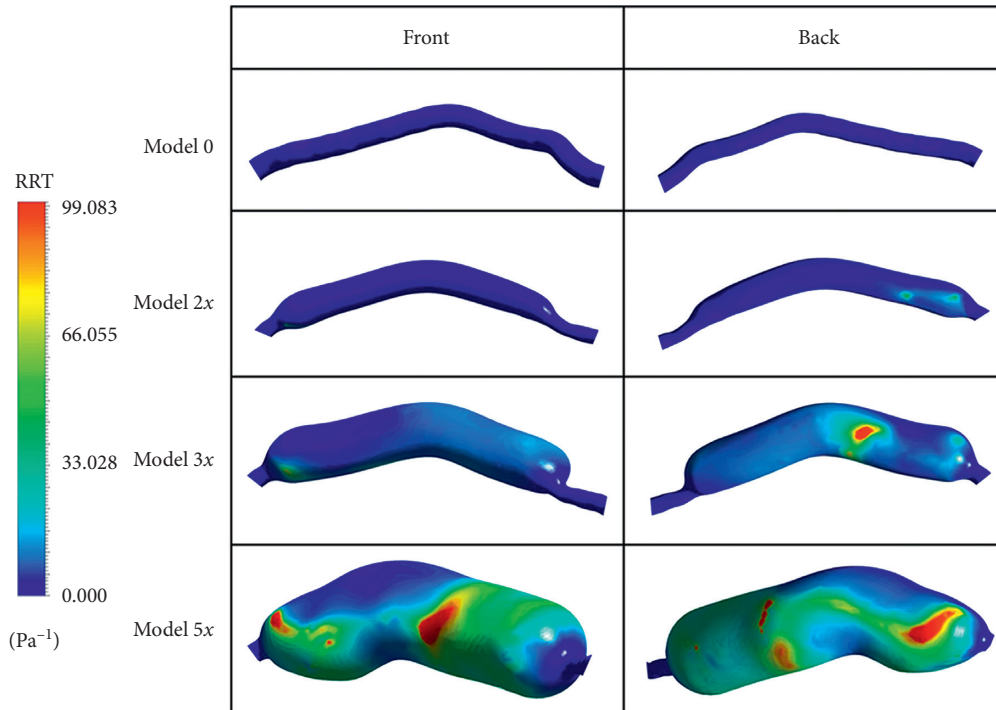

FIGURE 8: Relative residence time (RRT) distribution in the coronary artery aneurysm for the four models.

affect the blood flow and pressure within the region of the lesion itself, with little effect on global blood flow. However, there were substantial changes in local hemodynamic parameters related to thrombosis in the lesion location. Compared with the model without a lesion, all three CAA models showed low WSS, high OSI, and high RRT, with these changes exacerbated as the CAA diameter increased. These changes were the results of the sudden increase in the diameter of the lumen on entering the CAA. These results suggest there may be a high correlation between CAA diameter and the risk of thrombosis. CAA hemodynamic studies may therefore allow the development of a preliminary classification of the risk of thrombosis, helping to improve the effectiveness of anticoagulation therapy and facilitating better personalization of treatment according to a quantitative hemodynamic plan.

Simulation provides a powerful and effective method for estimating important hemodynamic parameters that are difficult to measure. As mentioned above, except mass-flow rate which can be easily detected by non-invasive ultrasound, other parameters, WSS, OSI, and RRT, cannot be directly measured which are usually obtained through in vitro experiments or indirect measurements. Simulation is a non-invasive way, providing a low cost way and avoiding the potential risk of some invasive ways to obtain hemodynamic parameters.

LPM boundary conditions can provide realistic physiologic flow conditions, as what has been confirmed in previous studies [38, 39]. In addition, the coronary microcirculation was introduced into the downstream boundary condition via the LPM. Resistance and pressure changes downstream of the coronary artery could be

accurately captured in this way, helping to ensure the accurate simulation of physiological conditions in the coronary artery. There was no difference between the models in the peripheral vascular structure, so the CFD models shared the same LPM, minimizing the impact of factors other than the diameter of the CAA. Thus, the differences in results between the models were due to the differences in CAA diameters.

As the diameter of the CAA increased, the WSS in the CAA lesion area progressively decreased, with the WSS in Model 5x observed to be >10 times lower than that of the normal coronary artery (Model 0). Parallel plate flow experiments have shown that a large number of platelets accumulate at locations with low WSS (<0.4 Pa) [40], and animal endothelial cell experiments have shown that thrombosis is associated with a decrease in WSS to within the range 0.0770.279 Pa [10]. In the present study, the area average values for WSS in Models 3x and 5x were within this range, suggesting that CAAs with diameters >3 times that of the normal artery are likely to carry a high risk of thrombosis. Although the area average WSS for Model 2x was much lower than that of the model without CAA, it was higher than 0.4 Pa, suggesting that CAAs with diameters double that of the normal artery may not be at high risk of thrombosis. Another important pathophysiological factor in vascular disease is endothelial dysfunction. Low WSS can locally inhibit the production of certain important substances such as NO [41]. An abnormal response to vasodilation agents, including the deactivation of NO by free radicals due to the impairment of acetylcholine or endothelial NO synthase, can lead to abnormal vasoconstriction, which can be associated with endothelial dysfunction [41]. In addition, platelets are prone to aggregation in areas of low WSS, which further

exacerbates the risk of thrombosis. WSS in the CAA lesion of Model 2x was lower than that in the normal model; however, further development is still to be studied just taking WSS as a reference. The risk for thrombosis in CAAs progresses with increasing diameter, so the risk associated with Model 2x would be lower than that for Models 3x and 5x. The development of CAAs needs further study. Although studies have investigated the association between WSS and thrombosis, the current understanding is not yet comprehensive. Therefore, the possibility of WSS and thrombosis in the corresponding *in vitro* experiments should be the focus of continued research.

The OSIs for the CAAs increased rapidly with increasing diameter of the lesion, with the OSI in Model 5x around 30 times greater than that of the normal coronary artery (which was close to zero throughout the CAA). Previous studies have pointed out that when OSI is greater than 0.2, it will cause endothelial cell damage [31]. The high OSI area (OSI > 0.2) ratio increased from 0.1% to 66.2% between Model 0 and Model 5x. *In vivo* experimental studies of porcine aortas have reported that disturbed flow (i.e., an increase in OSI) promoted the expression of proinflammatory cytokines in endothelial cells [11]. In addition, an *in vitro* study of bovine endothelial cells reported that the expression of monocyte chemoattractant protein-1 could be induced by applying a low-amplitude oscillating shear stress of 0.3 Pa at 1 Hz (equivalent to an OSI of 0.5), and this hemodynamic environment enhanced the binding of endothelial cells to monocytes [42]. These findings suggest that the elevated OSI values observed in the CAA models may be associated with conditions that can trigger thrombosis.

The RRT values for the CAAs increased dramatically with increasing diameters of the lesions, with the RRT for Model 5x > 100 times greater than that of the normal coronary artery. The high RRT area ratio increased from 0.1% to 78.6% between Model 0 and Model 5x. These findings indicate that the blood flow in the CAA recirculates when the diameter of the lumen increases, resulting in prolonged contact time between the CAA wall and the blood. Studies have reported a significantly increased risk of thrombosis when RRT is  $>10 \text{ Pa}^{-1}$  [12, 34]. The RRT values for Models 3x and 5x in the present study were both  $>10 \text{ Pa}^{-1}$ , suggesting a high risk of thrombosis when the diameter of a CAA exceeds three times that of the normal coronary artery. Conversely, the RRT for Model 2x was much lower than  $10 \text{ Pa}^{-1}$ , suggesting that the risk of thrombosis may be low when the diameter of the CAA is only double that of the normal artery. Although there have been various studies of the relationship between RRT and aneurysms [43], the current state of knowledge remains insufficient for patient classification; for example, there are no appropriate ranges of RRT values for distinguishing the risk level of thrombosis which needs further study.

In summary, the comparison of our modeling results with the findings of previous studies suggested that the low WSS, high OSI, and high RRT observed in the CAAs would significantly increase the risk of thrombosis. However, the risk varied considerably between the different diameters of CAA. The WSS, OSI, and RRT values for Models 3x and 5x all suggested a high risk of thrombosis, based on the previous study results. Thus, for CAAs with diameters >3 times that of

the normal coronary artery, the risk of uncertainty with conservative treatment may be higher than the risk associated with surgery, suggesting that the surgical operation should be considered. Conversely, although the WSS, OSI, and RRT values for Model 2x were unfavorable compared with those of the model of the normal coronary artery, implying an increased risk of thrombosis, the magnitude of these differences was insufficient to support a prediction of the future development of the CAA. For CAAs with a diameter up to two times that of the normal coronary artery, conservative drug treatment may be the better option, avoiding the risks associated with surgery.

The limitations of this study are as follows. First, this study has only one patient's data, and the conclusion may be accidental. We need to use more data for research. Secondly, an important assumption used in the CFD calculation is the rigid wall, where, in fact, elastic walls should be used. In particular, the coronary artery will deform greatly as the heart contracts which can be solved by two-way FSI in the future.

## 5. Conclusion

The evaluation of the relationship between hemodynamic effects and different diameters of CAAs was performed in this research through the CFD simulation method. The relationship between thrombosis risk and the size of the CAA diameter could be preliminarily evaluated from a hemodynamic perspective.

We found that as the diameter of the CAA increased, the risk of thrombosis increased substantially. The results suggested that when the diameter of a CAA is small (less than double that of the normal coronary artery), the risk of thrombosis may be relatively low, suggesting that medication may be a sufficient approach for the patient, avoiding the uncertain risks associated with surgery. If the diameter of CAA is large (>3 times that of the normal coronary artery), there may be a high risk of thrombosis, and surgical treatment could be considered. A similar approach could be taken in future studies to systematically assess the risk associated with different shapes, sizes, and locations of aneurysms. Such approaches may form the basis for more sophisticated hemodynamic-based risk stratification methods supporting clinical decision-making in assessment of CAA.

The supply chain optimization of e-commerce is the optimization of the integrated linear management model for e-commerce enterprises based on manufacturers, suppliers, warehouses, distribution centers, and channels. The application of Internet of Things (IoT) technology to the optimization of e-commerce supply chain can help e-commerce enterprises to monitor each product in real time and manage logistics system reasonably; thus, the circulation process of e-commerce product in the supply chain can be monitored and shared, and the product information at each stage of the supply chain can be analyzed and predicted, helping e-commerce companies to estimate the future trends or accident probability. On the analysis of summarizing and analyzing previous works, this article expounded the research status and significance of e-commerce supply chain optimization, elaborated the development background, current status, and future challenges of the IoT technology, introduced the methods and principles of the node distribution model and constraint parameter analysis of logistics supply chain, constructed the IoT-based e-commerce supply chain linear and nonlinear model including competition and risk-control modules, performed the design of IoT-based e-commerce supply chain optimization, and discussed the solutions to procurement robustness optimization and management process optimization. The final simulation analysis showed that the proposed optimization model can effectively predict e-commerce product information in each stage of the supply chain; the IoT-based e-commerce supply chain optimization can enable each node company in the supply chain to improve the quality of information transmission and reduce the risk of information asymmetry in the process of e-commerce exchanges and can quickly and easily respond to the sudden changes of market and environment, thereby promoting them to cooperate with each other for establishing a supply chain network structure with closer business relationships, smoother logistics transportation, more reasonable benefit sharing, and stronger market competitiveness.

## 1. Introduction

Internet of Things (IoT) is such an information-based and intelligent network that utilizes the communication technologies such as Internet to connect sensors, people, and things in a new way to form a connection. Through direct communication between things, the time taken for the entire transfer process is shortened, and the operation efficiency of the entire supply chain is improved so as to achieve the real-time tracking, monitoring, and management in a real sense [1]. The IoT is composed of three parts of sensor network, transmission network, and application network, including four key technologies of radio frequency identification, sensors, cloud computing, and network communication.

The rapid developments and industry applications of the IoT have brought huge opportunities to deepen the development of e-commerce [2]. The application of related technologies and methods in the field of e-commerce will help promote the rapid and healthy development of e-commerce. For example, in the aspect of product management, the use of IoT technology to establish a real-time tracking system for products can enable enterprises to monitor the status of products at any time and effectively manage the quality of the products [3]. The IoT provides an effective information technology support platform for the integration of information and resources in the e-commerce supply chain, tracking, and monitoring of the entire product life cycle. However, consumers still feel insecure about e-commerce

psychologically due to various shortcomings in e-commerce logistics, so it is necessary to study the optimization of the IoT-based e-commerce supply chain [4].

The application of IoT to the e-commerce supply chain optimization can help the e-commerce companies to monitor each product in real time and optimize the management of the logistics system, which can not only supervise and circulate products in the supply chain but also share related information [5]. The e-commerce supply chain information integration and sharing platform can achieve unified standards for internal and external information, interoperable, seamless docking, integration, analysis, and sharing so that each node company in the supply chain can perceive information in a short time. It can analyze and forecast the information of products at various stages of the supply chain, help e-commerce companies to estimate future trends or the probability of accidents, so as to take timely remedial measures or early warnings, greatly improve the ability of e-commerce companies to respond to the market, and improve business management capabilities traditional logistics is mostly confined within the enterprise [6]. With information flow as the control object and the main enterprise as the core, the entire logistics system is controlled from the supply source to the demand source [7]. The e-commerce supply chain is an optimization of integrated linear management models based on manufacturers, suppliers, warehouses, distribution centers, and channels, which includes the optimization of five main related links of production, distribution, and retailing in the context of increasingly sophisticated transportation and warehousing, global division of labor, and corporate transnational and cross-regional operations [8].

On the analysis of summarizing and analyzing previous works, this article expounded the research status and significance of e-commerce supply chain optimization, elaborated the development background, current status, and future challenges of the IoT technology, introduced the methods and principles of the node distribution model and constraint parameter analysis of logistics supply chain, constructed an IoT-based e-commerce supply chain linear and nonlinear model including competition and risk-control modules, performed the design of IoT-based e-commerce supply chain optimization, and discussed the solutions to procurement robustness optimization and management process optimization. The study results of this paper provide a certain reference for further research studies on the e-commerce supply chain optimization in the IoT environment. The detailed chapter arrangement is as follows. Section 2 introduces the methods and principles of the node distribution model and constraint parameter analysis of logistics supply chain; Section 3 establishes an IoT-based e-commerce supply chain model including competition and risk-control modules; Section 4 performs the optimization design of IoT-based e-commerce supply chain and discusses the optimization solutions to procurement robustness and management process; Section 5 performs a simulation experiment and its analysis; Section 6 provides conclusion.

## 2. Methods and Principles

*2.1. Node Distribution Model of Logistics Supply Chain.* The e-commerce supply chain is characterized by the complexity and dynamics of the supply chain itself, and the data and models used in supply chain optimization should also meet the dynamic characteristics [9]. Considering the disturbing effect of the dynamic environment on the supply chain node distribution, the optimized node distribution function is constructed as follows:

$$\frac{\partial \varphi(x)}{\partial x} = \frac{1}{k} \cdot \frac{\partial^2}{\partial x^2} [M(x) \cdot \varphi(x)] + \frac{1}{r} \cdot \frac{\partial}{\partial x} [M(x) \cdot \varphi(x)], \quad (1)$$

where  $M(x)$  is the average trend of measuring the optimization level of supply chain  $\varphi(t)$ ;  $k$  is the coefficient of supply chain risk-control ability;  $r$  is the coefficient of diffusion and convergence of supply chain optimization.

It is assumed that there is no shortage of e-commerce product supplies in the upstream and meets the above-mentioned optimization node distribution function, and then the maximum profit function that the upstream supplier may achieve is as follows:

$$M_x(p_x, q_x) = (p_x - k) \cdot q_x^2 - k \left( \frac{1}{\alpha} \cdot q_x - k \right) p_x^2, \quad (2)$$

where  $p_x$  is the cost bonus coefficient in the IoT environment;  $q_x$  is the output matching coefficient in the IoT environment;  $\alpha$  is the profit loss caused by information asymmetry in the entire e-commerce supply chain.

When the distribution of nodes such as manufacturers and retailers in the e-commerce supply chain shares real data, both parties can get a higher net income increase and at the same time bear the risk of data being leaked by each other, so the profit function of the two can be expressed as follows:

$$M_x[p_x, \varphi(x)] = w \cdot Q \cdot \varphi(x)^2 - c[\varphi(x) + P]p_x^2, \quad (3)$$

$$M_x[p(x), \varphi(x)] = \rho_R \cdot Q \cdot \varphi(x)^2 - E_M[\varphi(x) + P]p(x)^2, \quad (4)$$

where  $w$  is the order price;  $c$  is the unit cost,  $Q$  is the market demand,  $P$  is the market price of the product,  $E_M$  is the estimated value of the single-cycle shared data, and  $\rho_R$  is the probability of leaking shared data.

When the distribution of the nodes of the logistics supply chain does not affect each other, the standard deviation of the aggregate industry demand is less than the sum of the standard deviations ( $\sigma$ ) of the individual regional requirements, indicating that the aggregate effect can reduce the fluctuation of demand to achieve the purpose of reducing safety stocks. At this time, the aggregate demand is normally distributed:

$$\sigma = \sqrt{\varphi(x)^2 \cdot s_i^2 + \frac{1}{\rho} \cdot S_i \cdot \text{cov}(i, j) - R[\varphi(x) + P]p_x^2}, \quad (5)$$

where  $S_i$  is the company's expected value of the market demand in each period,  $\text{cov}(i, j)$  is the company's covariance of the market demand in each period, and  $R$  is the average level of the periodic service. Such enterprises do not participate in actual production and require less investment in infrastructure but have high requirements on management and planning.

**2.2. Constraint Parameter Analysis of Logistics Supply Chain.** The degree of information processing in the e-commerce supply chain can be obtained by using the ratio of the number of times the information is automatically processed in each circulation link of the supply chain to the total number of information processing times and then multiplying them by the importance of each supply chain link to obtain the following [10]:

$$E_i = \sum_{j=1}^n \left[ \frac{1}{\rho} \cdot \frac{X_i}{Y_i} + r_{ij} \cdot E_M[\varphi(x) + P]p(x)^2 \right]^2, \quad (6)$$

where  $X_i$  is the number of times that information is automatically processed on the  $i$ -th supply chain node;  $Y_i$  is the total number of times that information is processed on the  $i$ -th supply chain node;  $r_{ij}$  is a weighted value that is the importance of the information automation of the  $i$ -th node company to the entire supply chain.

It is supposed that there are  $n$  optimization processes in an e-commerce supply chain. Let  $X = (x_1, x_2, \dots, x_n)$  ( $i = 1, 2, \dots, n$ ), and each process is represented by  $m$  indicator sets. The optimization process  $x_i$  is measured by attributes, and its attribute value  $a_{ij}$  is obtained from the actual situation so as to form a decision matrix  $A = (a_{ij})_{n \times m}$ :

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nm} \end{bmatrix}, \quad (7)$$

where  $n$  is the number of rows in the optimization matrix,  $i$  is the number of optimizations for a particular process, and  $k$  is a criterion. If  $r_{ik}$  represents the optimization level of process  $i$  under criterion  $k$ , the ordinal value of the optimization number  $i$  can be given by

$$O_i = \sum_{k=1}^n \sum_{i=1}^n (n - r_{ik}). \quad (8)$$

It assumed that the revenue function of the upstream supplier is  $W_i(s_i, q_i)$ , where  $s_i$  is the sales price of the supplier and  $q_i$  is the sales volume of the supplier;  $Q_i$  is a single item. The cost of selling products and the indestructible constraint parameter function of the upstream supplier is given by

$$W_i(s_i, q_i) = (s_i - Q_i)q_i. \quad (9)$$

The core company's demand in each period follows a normal distribution with an average value of  $m$ ; each supply interval period is  $L$ , so the demand in the  $L$  period also

follows a normal distribution with an average value of  $Lm$  of target inventory holding  $N$  is as follows:

$$N = (LQ_i)^{1/2} \left( \frac{P-C}{P-H} \right) + Lm - W_i(s_i, q_i), \quad (10)$$

where  $P$  is the price provided by the supplier management enterprise to the core enterprise,  $C$  is the unit production cost, and  $H$  is the unit inventory holding cost. When the supplier management company cannot meet the inventory requirements due to some force majeure, the company can only go to resource pool for assistance.

### 3. IoT-Based E-Commerce Supply Chain Model

**3.1. Competition Model of E-Commerce Supply Chain.** In the traditional model, there are information barriers between logistics providers and they rely on information barriers to obtain competitiveness due to the immature information sharing mechanism and technology. But the IoT brings technical support for information sharing. In this context, the reasonable requirements for the disclosure of non-commercial confidential basic information such as distribution customers, channels, and partners of all logistics suppliers have been realized, and they have not obeyed the market because of the market's need for higher quality and lower cost logistics services. In the distribution and retail links in the linear and nonlinear supply chain optimization models, it is also convenient to monitor the inventory in real time, grasp the detailed information of the goods, improve the level of automation and mechanization of inventory and distribution, and realize a highly modernized logistics operation. Under the construction of the entire IoT architecture, this involves the specification of logistics information representation, the standardization of interfaces between different links, and the input and processing of output file formats from identification tags to label reading devices to transmission and processing [11]. This is beneficial to the information exchange infrastructure between different e-commerce supply chain member companies or different logistics subsystems and to build the largest information platform for information exchange between different individuals, of which the logistics industry is the biggest beneficiary.

The main risks faced by the e-commerce supply chain in the IoT environment are information security risks, reputation risks, and distribution risks in the linear and nonlinear supply chain optimization models. Due to the complexity and diversity of the e-commerce supply chain risk itself, it also requires higher risk assessment methods. Therefore, the selected risk assessment method must be able to deal with some unknown, large fluctuations and cause large losses, and it can give a more accurate assessment of the risks. The framework of the IoT-based e-commerce supply chain model is shown in Figure 1. For supply chain managers, it is necessary to determine the conditions under which the supply chain needs to be adjusted and optimized in order to reduce the maintenance cost of the supply chain while improving the value of the entire supply chain. A complete supply chain will always develop in two directions. First, the

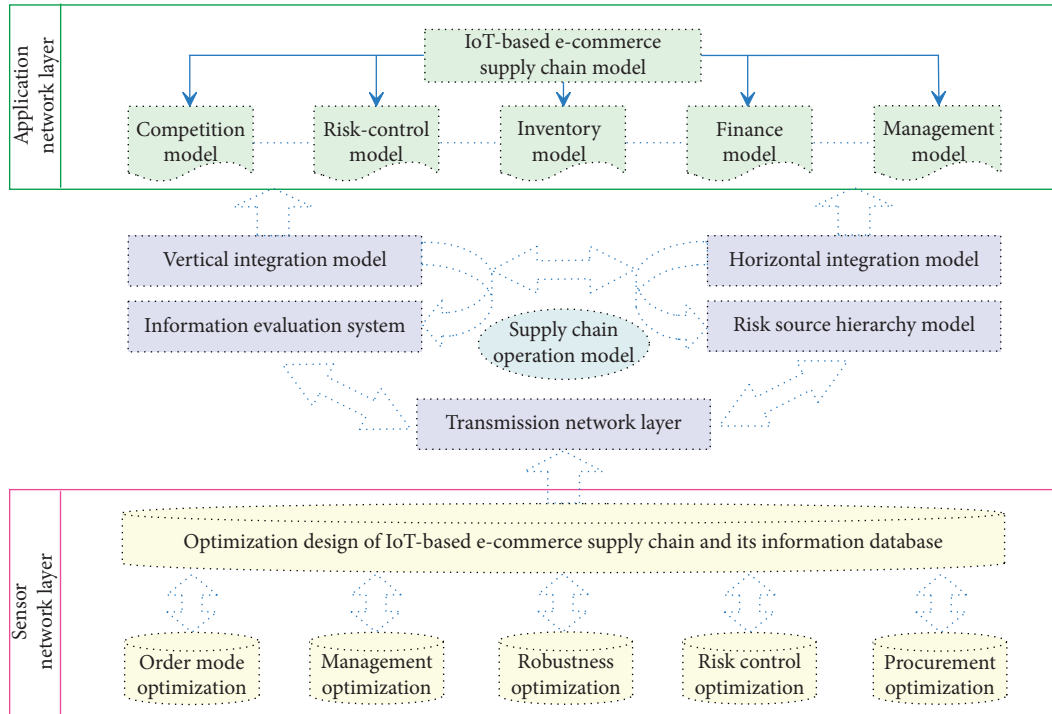

FIGURE 1: Framework of the IoT-based e-commerce supply chain model.

supply chain risks can converge well, and the influence of the supply chain risk factors on each other is reduced to the lowest level at a certain level of risk, and the supply chain maintains stable operation at a certain level of risk through effective management and control of the manager. Second, the supply chain manager's ability to manage supply chain risks is low, causing the supply chain risk level to exceed a critical value, and the supply chain risk cannot effectively converge. The mutual influence of factors is further strengthened, making the risks continue to spread, eventually leading to the collapse of the supply chain [12].

The closed-loop operation mode in the e-commerce supply chain includes the forward supply chain activities of new products from raw materials to consumers, the return of waste products from end users to producers, and the conversion of waste products into remanufactured products by producer activities, product redesign activities for reuse of waste products, environmental monitoring of raw materials, new products, waste products, and green logistics management. Ensuring the accuracy and timeliness of information is the key factor for the success of the closed-loop operation mode of the linear and nonlinear optimization models. The rise of the IoT has provided good development opportunities for its operation and management. Through the IoT platform, all companies in the closed-loop supply chain are connected to form an end-to-end intelligent supply chain logistics distribution service process, which can achieve accurate and effective collaborative distribution based on the real-time status of logistics distribution [13]. The IoT provides an effective information technology support platform for the integration of information and resources in the e-commerce supply chain, tracking and

monitoring of the entire product life cycle. The closed-loop supply chain operation system based on the IoT can implement real-time tracking and supervision of the production, distribution, retail, and recycling of products in the supply chain, enhance management transparency, and enable companies in the e-commerce supply chain to respond quickly to the market demand, improve service levels, and enhance corporate competitiveness.

### 3.2. Risk-Control Model of E-Commerce Supply Chain.

Because many small-volume orders in the traditional supply chain are difficult to access to the factory's mass production plan and subsequent shipment clearance is more troublesome, cross-border e-commerce has provided the possibility to solve these problems. Centralized processing of small orders enables exporters to place orders and produce uniformly, making it easy for factories to adjust product and profit structure. In recent years, as the minimum order quantity is not high, many customers have expressed difficulties in finding good suppliers. Some buyers prefer a supplier with poor quality but a low minimum order quantity, rather than a supplier with a high minimum order quantity but a high quality. Since consumers are not limited by time and space on the e-commerce platform and can browse the information of the products they are interested in, exporters need to pay more attention to the front end of the linear and nonlinear optimization models, actively develop and design products, and improve product quality to attract consumers' attention. The high-quality shops on the online platform will have a higher visibility than the products on the offline exhibition. Large exporters also need

to build brands, promote their brands on cross-border e-commerce platforms, expand product awareness and influence, and establish cross-border e-commerce operations teams to make every node on the line such as customs clearance and logistics. It gives full play to its own offline supply chain mature advantages, thereby forming an integrated advantage of online transactions. Figure 2 shows the relative optimization contribution rate of different optimization terms in the IoT-based e-commerce supply chain model.

The integration of intelligent sensing equipment and the Internet has optimized the basic links of e-commerce supply chain inventory management. The traditional method of manually recording financial data information has lagged behind and cannot match the current market development environment and technology level. For example, the quantitative assessment benchmark is established through corresponding index data. Before the related inventory management model is reformed, the product quality and service levels are difficult to quantify [14]. The integration of the IoT and Internet technologies can establish a sensor network, reduce costs to a certain extent, perform timely distribution, track real-time e-commerce products, reduce the risk of disputes between enterprises and consumers, and protect consumers' basic rights and interests. They improve the service level of the enterprise and increase customer satisfaction, and the e-commerce companies should use empirical data as the basic basis and make corresponding basic management decisions. For example, they should focus on capital investment, sort out changes in market demand, and provide customers with basic value-added services. As a method of supply chain inventory management reform, the use of quantification as an assessment standard is the basic sign of management progress for e-commerce enterprises, and it can be used as a reference for enterprise data demonstration and management reform.

Supply chain finance is a process of systematically optimizing the availability and cost of funds in a corporate ecosystem dominated by core companies. When the sensor of the IoT detects the risk of qualitative changes in the collateral, it timely sends a signal to the information management system and notifies the customer, which facilitates the bank to quickly determine the condition of the collateral and decide whether to recheck the price and compensate for the decline. If the total price drop exceeds the bank's minimum credit line and the borrower has not added pledges or provided new guarantees, immediately announce that the credits will expire prematurely. After communicating with customers, take measures such as auctions to sell pledges and repay loans. Through radio frequency identification technology, the e-commerce and banks can clearly understand and grasp every link of collateral from production and transportation to sales in the linear and nonlinear optimization models. The readers installed in factories, distribution centers, and logistics supervision warehouses can automatically record items throughout the supply of the flow of the chain. From the perspective of the entire integrated supply chain, the transparency of the supply chain and the accuracy of the

information will be maximized, which is exactly the problem of difficult supervision of banks. After the bank has reached a transaction with the on-chain enterprise, the bank delivers the collateral from the enterprise to the cooperative warehouse. The warehouse is responsible for keeping the collateral and regularly checks the value of the collateral with the bank [15].

## 4. Optimization Design of IoT-Based E-Commerce Supply Chain

*4.1. Procurement Robustness Optimization of E-Commerce Supply Chain.* With the support of IoT technology and the e-commerce procurement link, in order to achieve long-term mutual benefit and close cooperation of information sharing among members of the supply chain, it is necessary to continuously improve the management level of suppliers and support a series of supplier management activities. The perfect management system integrates powerful IoT technology, which can produce comprehensive data such as quantity, quality, price, cost, delivery efficiency, and service level and can provide the supplier's supply performance, supply capacity, supply reputation, and technical level. The management efficiency and other indicators better streamline and optimize suppliers and ensure the quality of supply chain procurement [16]. The e-commerce procurement logistics system includes many logistics activities, such as packaging, loading, unloading, transportation, warehousing, handling, and information management from suppliers to producers, and it is an important part of the robust optimization of supply chain procurement (Figure 3). The packaging and transportation links, storage inspection links, and material warehousing links of the e-commerce procurement logistics system need to be fully optimized in accordance with the new IoT environment. Through a comprehensive perception of raw materials, perfecting transportation plans, optimizing logistics routes, and improving procurement models, the scientific management of raw materials storage warehouses, delivery vehicles, and transportation routes is completed to realize flexible and agile procurement.

Delivery management under traditional supply chain management often becomes the last link that affects the overall efficiency of supply chain enterprises. Uncertain transportation information, poor timeliness, and high cargo damage rates are the direct causes of customer satisfaction decline. In e-commerce platforms, on the other hand, upstream companies in the supply chain can release logistics and transportation information in a timely manner to provide downstream companies and consumers with the convenience of querying and tracking. In addition, they can adjust delivery batches or delivery times in a timely manner when market sales conditions change, increasing the number of delivery companies and time flexibility and reducing the risk of corporate material reserves. The enterprise can reasonably arrange the production plan of the product according to the sales situation of the e-commerce platform and can adjust the production capacity and product structure in a timely manner based on the analysis of the data

FIGURE 2: Relative optimization contribution rate of different optimization terms in the IoT-based e-commerce supply chain model.

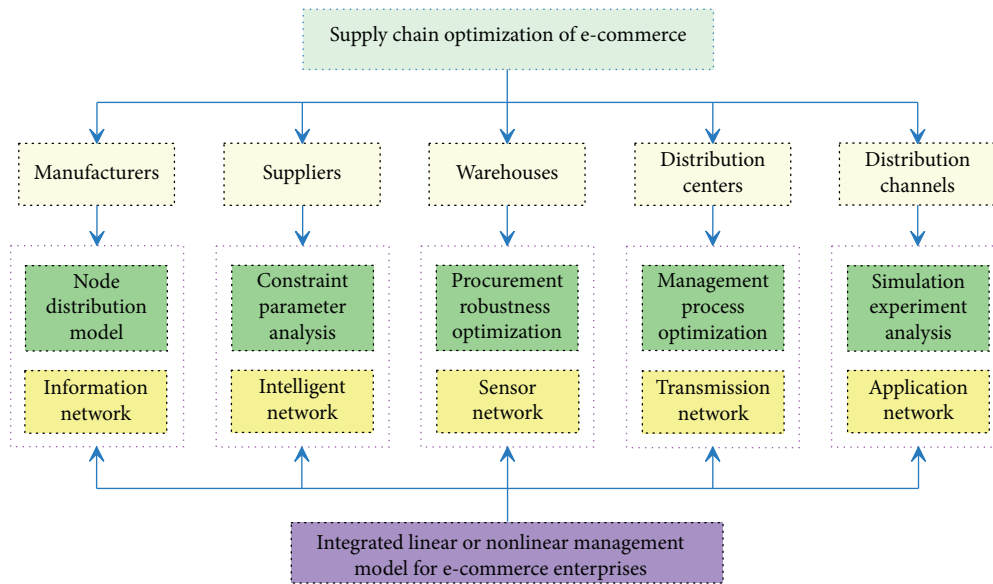

FIGURE 3: Optimization design for IoT-based e-commerce supply chain.

transmitted by the ordering system to further reduce the uncertain factors in production. Through the timely and rapid update of information and integrated processing, it can achieve collaborative management of production and sales, shorten the manufacturing cycle, reduce customer waiting time, and improve customer satisfaction. In terms of delivery and delivery time, real-time query of delivery information allows customers to reasonably arrange the delivery time and ensures the timely supply of goods in the linear and nonlinear optimization models. The customers can also log in to the enterprise's e-commerce platform to query product update information in real time in order to

carry out material procurement planning and inventory planning adjustment, and realize flexible procurement at any time.

Under the support of IoT technology, the connection between e-commerce companies has shown a networked and cross-shaped development. The network's corporate layout will provide a larger financial services industry including banks market space. In addition, the IoT will be used to achieve efficient resource allocation and information sharing, especially the IoT itself, in many areas of e-commerce product research and development and production processes, due to the cross and openness of the network.

With the further promotion and extension of the IoT in various fields such as social production, there will be applications of IoT technologies in everything from raw material production to product quality and logistics distribution. The services provided by this supply chain finance are no longer targeted at a specific customer but are based on the overall situation of the entire IoT system to formulate corresponding development strategies and countermeasures in the linear and nonlinear optimization models. Because the market is constantly changing and developing, only from a global perspective, we can avoid making wrong decisions due to unscientific analysis, which ultimately affect the vital interests of the financial services industry and its customers. Only constructing a three-dimensional and multidimensional IoT platform from the scope and degree will lay a solid technical foundation for the future development of e-commerce supply chain finance [17].

**4.2. Optimization of E-Commerce Supply Chain Management Process.** The supply chain management mode under the e-commerce environment information flow management, capital flow management, and logistics management constitutes the three major parts of supply chain management. The enterprises in the supply chain should consider the various business transactions within the enterprise and with the nodes in the supply chain as an overall functional process. By effectively and transparently coordinating the information flow, capital flow, and logistics in the supply chain, the internal supply chain of the enterprise integrated management with the supply chain outside the enterprise to form an integrated supply chain management system. Because the core enterprises of e-commerce and the upstream suppliers, downstream end customers, banks, and logistics centers can exchange information quickly through the Internet, at the same time, the nodes in the supply chain can also communicate with each other. The IoT-based node distribution of the logistics supply chain with horizontal and vertical integration modes is shown in Figure 4. They overthrow the traditional model and effectively connect the islands of each business node in the supply chain to achieve true business information integration and sharing through the application of e-commerce. At the transaction stage, the business needs to further improve the logistics management link, minimize the time required for logistics in the supply chain, and achieve unified and synchronized logistics management with information flow and capital flow management, thereby establishing a truly powerful and fast response of the supply chain management system.

The IoT technology enables tracking of items flowing in the e-commerce supply chain, and at the same time, it can transmit data to all participants in real time, reducing the phenomenon of information distortion. Fast information transmission speed can greatly reduce the cost of transmission time between roles such as enterprises, merchants, and users. With the development of globalization and the improvement of people's living standards, the demand for personalized customization is getting higher and higher, and

the e-commerce platform has turned to a user-oriented personalized design concept [18]. Each part of the e-commerce supply chain can be associated with users through the network to obtain a wider and more effective interaction and production scheme, so the platform more respects the individual needs of users. Intelligent management of e-commerce supply chain is an integrated management idea and method, which integrates the planning, organization, coordination and control of logistics, information flow, capital flow, value-added flow, business flow, and trading partnership in the linear and nonlinear optimization models. Through supply chain management, the enterprises can improve operational efficiency, improve asset utilization, shorten the total order cycle, reduce transaction costs, enhance customer service, improve response speed, penetrate new markets, obtain higher return on assets, and enhance their competitiveness.

With the widespread application of e-commerce, information and funds are transparently, quickly, and accurately transferred between member nodes of the supply chain through the Internet, which greatly improves the information flow management and capital flow management in supply chain management. Breakthrough to change the traditional scope of raw material procurement, production, sales, and services to meet the new requirements of high quality, high flexibility, and low cost imposed by the market on corporate production management in the new competitive environment is the inevitable requirement of the supply chain management model in the e-commerce environment. The realization of the e-commerce supply chain management process optimization is based on the integration and sharing of information. The efficient operation of the supply chain requires the enterprises of each node to give high-quality information data and fast information flow [19]. The e-commerce supply chain information integration and sharing platform can achieve unified standards for internal and external information, interoperable, seamless docking, integration, analysis, and sharing so that each node company in the supply chain can perceive information in a short time. At the same time, it is convenient for the enterprises of each node to grasp the production progress of the product and the operation of the supply chain in time. Based on the integration of internal and external mass information and the direction of the wind, it promotes the orderly interaction of internal and external management systems and the coordinated development of business.

## 5. Simulation Experiment Analysis

**5.1. Simulation Experiment Design.** According to the IoT-based e-commerce supply chain linear or nonlinear optimization model, the importance order of each influencing factor from least important to most important is circulation sociality, circulation convenience, circulation timeliness, surplus level, circulation quality, and circulation cost.

It is assumed that the selected e-commerce supply chain contains  $n$  optimization processes; the hierarchical single-order calculation of the above six influencing factors by the  $i$ -th process is as follows:

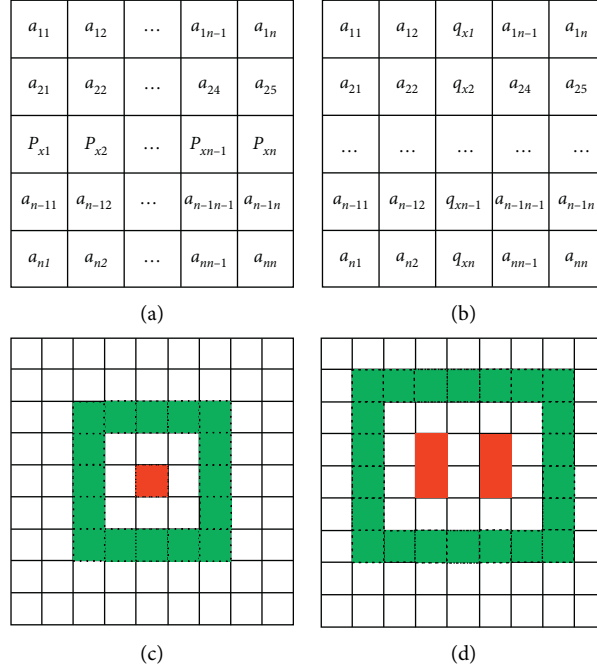

FIGURE 4: IoT-based node distribution of logistics supply chain with horizontal (a, c) and vertical integration modes (b, d).

$$M_{ij} = \sum A_{ij} (i, j = 1, 2, 3, 4, 5, 6). \quad (11)$$

According to the judgment matrix of the supply chain optimization process, it can be clearly obtained that the optimization coefficients ( $O_i$ ) are  $O_1 = 15.34$ ,  $O_2 = 13.66$ ,  $O_3 = 17.19$ ,  $O_4 = 14.03$ ,  $O_5 = 11.35$ , and  $O_6 = 12.89$ .

The optimization weighting factor  $s_i$  is calculated by  $s_i = \sum_{i,j=1}^6 (A_{ij} O_j / M_{ij})$ , and then the results are  $s_1 = 0.54$ ,  $s_2 = 0.23$ ,  $s_3 = 0.48$ ,  $s_4 = 0.56$ ,  $s_5 = 0.44$ , and  $s_6 = 0.29$ .

The optimization quality  $Q_i$  is calculated by  $Q_i = O_i / W_i$ , and then the values were calculated as  $Q_1 = 0.84$ ,  $Q_2 = 0.91$ ,  $Q_3 = 0.75$ ,  $Q_4 = 0.87$ ,  $Q_5 = 0.66$ , and  $Q_6 = 0.93$ .

According to the supply chain before and after the optimization, each level is sorted separately from the particularity of the second-order matrix, and the weight proportion ( $W_1$ ) and priority ( $W_2$ ) of each matrix are calculated as follows. In  $Q_1$ , the proportion of  $W_1$  is 0.31 and the proportion of  $W_2$  is 0.25. In  $Q_2$ , the proportion of  $W_1$  is 0.58 and  $W_2$  ratio is 0.42. In  $Q_3$ ,  $W_1$  ratio is 0.19 and  $W_2$  ratio is 0.85. In  $Q_4$ ,  $W_1$  ratio is 0.56 and  $W_2$  ratio is 0.63. In  $Q_5$ ,  $W_1$  ratio is 0.37 and  $W_2$  ratio is 0.94. In  $Q_6$ , the  $W_1$  ratio is 0.59 and  $W_2$  ratio is 0.66.

Finally, the consistency of the matrix is checked, and the supply chain optimization consistency parameter  $f_n = 0.0537$  under the condition of  $n = 6$ , and the value is less than 0.1, that is, it can pass the consistency check.

**5.2. Result Analysis.** To a certain extent, the structural level of the supply chain can reflect the cost and profit appreciation process of e-commerce products from demand forecasting, production, and processing to completion of sales. The more the layers in the supply chain structure, the more the number of different companies' value chains

linked, the greater the cost, and the worse the economic benefits of the entire value chain in the integrated linear or nonlinear management models (Figure 5). Therefore, reducing the structural level of the e-commerce product supply chain and establishing dynamic cooperation relationships are important ways for enterprises to reduce bad costs and improve operating results. The optimization efficiency varies from 0.96 to 0.50 when the weighting factor equals 0.30 in the linear model while it varies from 0.88 to 0.61 in the nonlinear model. The low entry cost of virtual markets, as well as the uneven distribution of market information reformed by information overload and dynamic information flow, makes the information asymmetry between economic entities continue to exist within a certain range. In most cases, this sedimentary value is mainly manifested as the cost of invalid logistics and continues to be a defect in the overall economic benefits of the e-commerce product supply chain. All members in the supply chain should be a unified and harmonious division of labor and cooperation, while the characteristics of the traditional supply chain structure are relatively complex, the members are relatively stable, and the interdependence is strong and harmony between members of the supply chain in the linear and nonlinear optimization models.

Different from the previous concept of the operation level of e-commerce supply chain, as an intermediary variable, the mechanism of IoT application affecting enterprise performance is studied. Supply chain integration is used as an intermediary variable to study the mechanism of IoT application affecting enterprise performance. The intermediary role of supplier integration and customer integration can affect business performance. The IoT applications can affect e-commerce business performance through the full mediation role of supplier integration but only through the

FIGURE 5: Relationship between optimization efficiency and coefficient with different weighting factors ( $s_i$ ) in the linear (a) and nonlinear (b) management model.

FIGURE 6: Relationship between optimization quality and the number of optimization progress with different optimization coefficients ( $O_i$ ) in the linear (a) and nonlinear management model (b).

partial mediation role of customer integration. The e-commerce can not only link the IoT with existing processes, products, or services but also the IoT with new processes, products, or services. In the process of IoT application, e-commerce companies should pay attention to the level of supply chain integration, especially supplier integration, because the two types of IoT applications can improve the performance of enterprises through the full mediation of supplier integration and the partial mediation of customer integration (Figure 6). The optimization quality changes from 0.87 to 0.84 when optimization coefficient

equals 11.00 in the linear model while it changes from 0.87 to 0.85 in the nonlinear model. Therefore, the enterprises should increase investment in supplier and customer relationships, establish mechanisms for sharing information with suppliers and customers, actively coordinate conflicts with suppliers and customers, and promote joint resolution of problems with suppliers and customers in the linear and nonlinear optimization models, thereby enhancing the company's relationship with the level of supplier and customer integration and then the performance impact of IoT applications [20].

FIGURE 7: Optimization weighting factors ( $s_i$ ) of influential factors in IoT-based e-commerce supply chain with horizontal (a) and vertical (b) integration modes.

Cost optimization is the main way for enterprises to win market competition. The implementation of e-commerce-based procurement supply chain management can effectively reduce the cost of global procurement for enterprises and make the procurement supply chain cost optimized. The optimization weighting factors of influential factors in IoT-based e-commerce supply chain with horizontal and vertical integration modes are shown in Figure 7. The procurement management system implements procurement management based on the supplier's credit points to support enterprises to realize the supply control process in the supply chain environment. Through the timely and rapid update of information and integrated processing, it can achieve collaborative management of production and sales, shorten the manufacturing cycle, reduce customer waiting time, and improve customer satisfaction. The inventory management system uses the supplier's joint inventory management strategy to share the e-commerce enterprise's inventory information with the supplier to achieve supply integrated optimization of chain inventory and service level [21]. The management efficiency of the supply chain depends on the coordination between enterprises through information sharing. The basis of information sharing is to establish an integrated management information system to increase the supply chain members to obtain information timeliness and visibility to improve demand forecast accuracy [22]. In the IoT environment, e-commerce can give full play to the synergies of products, processes, and information, reduce loops and cycles, effectively avoid problems caused by information asymmetry through system construction, improve technology, and make the entire system and management construction of the process cover all aspects of information sharing requirements, which further improves the effect of application integration and standardizes and collects information in the supply chain.

## 6. Conclusions

This article expounded the research status and significance of e-commerce supply chain optimization, elaborated the development background, current status, and future challenges of the IoT technology, introduced the methods and principles of the node distribution model and constraint parameter analysis of logistics supply chain, constructed an IoT-based e-commerce supply chain model including competition and risk-control modules, performed the design of IoT-based e-commerce supply chain optimization, and discussed the solutions to procurement robustness optimization and management process optimization. The optimization efficiency varies from 0.96 to 0.50 when the weighting factor equals 0.30 in the linear model while it varies from 0.88 to 0.61 in the nonlinear model. The optimization quality changes from 0.87 to 0.84 when the optimization coefficient equals 11.00 in the linear model while it changes from 0.87 to 0.85 in the nonlinear model. With the support of IoT technology, the e-commerce procurement link requires long-term mutual benefit and close cooperation of information sharing among members of the supply chain, which is necessary to continuously improve the management level of suppliers and support a series of supplier management activities. The final simulation analysis showed that the proposed optimization model can effectively predict e-commerce product information in each stage of the supply chain; the IoT-based e-commerce supply chain optimization can enable each node company in the supply chain to improve the quality of information transmission and reduce the risk of information asymmetry in the process of e-commerce exchanges and can quickly and easily respond to the sudden changes of market and environment, thereby promoting them to cooperate with each other for

establishing a supply chain network structure with closer business relationships, smoother logistics transportation, more reasonable benefit sharing, and stronger market competitiveness. The study results of this paper provide a certain reference for further research studies on the e-commerce supply chain optimization in the IoT environment.

Health assessment is an important part of PHM technology, which is crucial to product state monitoring and management. With the complexity of product structure and diversification of functions, the product health presents uncertainty under the complex influence of multiple factors. Nowadays, the general health assessment method is relatively simple and only considers the product function completeness, and the assessment effect accuracy still needs to be strengthened in the actual working environment. Most assessment parameters and assessment methods are selected ignoring the impact of environmental changes and operating time performance. Therefore, a new health measurement method for the avionic radio-frequency power source based on a three-dimensional complex measurement model is proposed. Firstly, the product health definition is proposed, and the health connotation is analyzed from three-dimensional aspects containing functional integrity, environmental adaptability, and temporal sustainability. According to the function and structure characteristics of radio-frequency power source, the health characterization parameters are then obtained and the health assessment parameter system is established. Finally, the three-dimensional complex measurement model is given, and the RF power source health assessment is carried out comprehensively from integrity, stability, and reliability aspects. The three-dimensional health assessment method provides a new way to solve the uncertainty of product health state under multiple factor effects, which is conducive to the targeted optimization management strategy.

## 1. Introduction

Prognostic and health management (PHM) technology refers to the use of advanced sensor integration, with the aid of various algorithms and intelligent models to diagnose, predict, and monitor the product health state and reasonably manage the product operation and maintenance so as to obtain the best product health state with the minimum investment. It has evolved from reliability analysis, testability design, fault analysis, and system health management [1]. With the economy development, people's living standards are constantly improving, and the safety awareness is also constantly improving. PHM technology is more and

more widely used, from the initial fighter field to the present civil aviation, aerospace vehicles, computer systems, large-scale mechanical equipment, nuclear power plants, complex product systems, and other fields.

Nowadays, the PHM technology system is developing towards a more intelligent, more precise, more comprehensive, and more convenient direction. Health management is an important part of PHM technology. Its purpose is to manage evaluation data, take proactive measures to monitor the complex product health state, and predict the performance change trend, failure time, and remaining useful life so as to take necessary measures to alleviate the complex product performance degradation [2]. As a state of

product, health has no clear definition, so the product health assessment method is different according to different people's understanding of health. According to the current research situation at home and abroad, health assessment methods are summarized into the following three categories: evaluation methods based on traditional methods, evaluation methods based on mathematical and physical models, and evaluation methods based on data.

Traditional health assessment methods include analytic hierarchy process (AHP), fuzzy theory and grey clustering theory, and so on. Wang et al. used the evaluation model combining fuzzy analytic hierarchy process, fuzzy preference programming, and order performance similarity ideal solution technology to evaluate the aeroengine health state [3]. Ren et al. combined grey clustering theory with rough set theory to form a fast and accurate fault classification decision-making method for numerical control machine tool health assessment [4]. Zhu and Song used cross fuzzy entropy to measure the similarity between test samples and normal samples and used similarity to evaluate the performance degradation state of bearings so as to complete the health state assessment of bearings [5]. Wang et al. combined the analytic hierarchy process (AHP) with variable weight processing to realize the comprehensive health assessment of diesel generator set operation state [6].

Health assessment methods based on mathematical and physical models include the application of Markov chain and so on. Allen et al. proposed a machine fault detection method using the hidden Markov model in process control, and the effectiveness of the method was illustrated by numerical calculation [7]. Bin et al. proposed a method combining Mahalanobis distance and histogram method to construct a complex system health assessment method for the comprehensive evaluation of system health state [8]. Liao et al. applied a new and flexible system or component prediction framework based on high-order hidden semi-Markov model (HOHSM) to assess the health state of NASA turbofan engine [9].

With the development of science and technology, artificial intelligence has become a hot spot of learning and is widely used in various fields; of course, the field of health assessment is no exception. For example, health assessment methods based on data are widely used. Samanta proposed the performance of artificial neural network and support vector machine in gear fault detection [10]. Xu et al. proposed a fault diagnosis method based on the fusion of neural network and D-S evidence theory to diagnose turbine fault [11]. Liu and Zio established a dynamic evaluation and fault prediction model of interconnected component system with noise monitoring data by using parallel Monte Carlo simulation and recursive Bayesian method [12]. Qin et al. developed a GIS equipment operation state analysis model based on machine learning algorithm and evaluated GIS equipment state according to the severity of PD [13]. Oluwasegun and Jung proposed a general framework based on discrete Bayesian network (BN), which is particularly suitable for decision fusion of heterogeneous prediction methods. BN parameters were calculated according to the fixed prognosis target. The validity of the proposed

prediction method based on decision fusion is proved by estimating the remaining useful life of turbofan engine [14]. Kexiong established a health assessment model of missile inertial navigation platform system by combining expert system with data driver according to the characteristics of a missile inertial navigation platform system [15]. Zhang et al. proposed a bearing health assessment method based on Hilbert transform envelope analysis and cluster analysis [16].

Most health assessment methods nowadays are based on the existing traditional assessment methods or modified by one or several methods. The assessment results are relatively simple, and the assessment effect accuracy still needs to be strengthened in the actual working environment. Most parameters are selected according to the product characteristics, ignoring the impact of environmental changes and operating time on product performance.

In this paper, a new multidimensional health assessment method is proposed to evaluate the health of a certain avionic radio-frequency (RF) power source. The model is built from three dimensions of functional integrity, environmental adaptability, and temporal sustainability. The health of the equipment is described comprehensively from three aspects of integrity, stability, and reliability so that the health level is no longer one plane point line, but a number of three-dimensional verticals. It provides a new idea to solve the uncertainty of product health state under the effects of multiple factors, which is conducive to the formulation of health optimization management strategy.

## 2. Health Connotation and Three-Dimensional Complex Measurement Model

Combined with the modern product characteristics, such as diversified functions, changeable use environment, and complex structure levels, product health is defined as the product ability degree/state to continuously respond to the environment and complete the specified tasks. When the product function is intact, only with good sustainability and stability can the product be in the best state. Otherwise, it may reduce or damage the function and cause failure. Therefore, a product in a healthy state should not only have good functions to ensure its ability to perform tasks but also maintain the stability of function, internal structure, and organization for a long time and have certain adaptability to environmental effects. Therefore, the meaning of health is diverse and extensive. The composition of product health should include functional integrity, temporal sustainability, and environmental adaptability.

In general, the changes of product health state are functional failure, sustainability, and the decline of adaptability to the external world. It has two interrelated characteristics: the increase of failure rate with time and the decline of adaptability to environmental changes. Therefore, focusing on three aspects of product health, a product health three-dimensional spatial measurement model is proposed, and the parametric modeling method is studied from the three dimensions of function, environment, and time. Among them, functional integrity is more focused on whether the function of the product can be realized,

temporal sustainability can be considered from the perspective of reliability and failure rate, and the essence of environmental adaptability is to investigate the stability of product performance in a certain environment. Therefore, the research of RF power source health measurement is to study whether the function of RF power source is complete, whether it has certain anti-interference stability, and how long it can work continuously without fault.

**2.1. Functional Integrity Dimension.** In these three aspects, the functional completeness and integrity is the basis of health. The most basic requirement of a healthy product is to be able to realize all its functions normally. The so-called function refers to the ability that a product should have when it runs normally. It is an abstract description of the tasks that a product can accomplish. It describes the inherent health capability of a product from a static state. The functional integrity of a product directly shows whether the product function can be fully realized. Therefore, the functional integrity  $C$  of the product is taken as the measurement index of its functional integrity, and the importance of each function is taken as the weight to measure the conformity between the functions and the complete functions of the product at the present stage, that is, the functional coverage rate, as shown in Figure 1. The value range of health degree is  $[0, 1]$ . When the research object meets all the design requirements (such as functional integrity, environmental adaptability, and temporal sustainability), the health degree is 1, which indicates a technical state that fully meets the design requirements. When the product fails to reach the required health level, the health degree is 0, and the product is in a complete failure state. The intermediate state is a subhealthy state with some defects. In practical application, we understand “the health degree state 1” as “the health design state value 1”.

Suppose that the product has  $m$  functions  $F_i$ , and the relationship between the functions is clear; let the importance weight of each function  $\omega_i \in [0, 1]$ ,  $i = 1, 2, \dots, m$ . Because the relationship between product functions directly affects the realization of the whole function, the expression of function integrity is different according to different functional relationships.

- (1) When the function relationship is in series, the functions are interrelated and indispensable. As long as one function fails, the realization of the function will be affected and the whole function cannot be realized. The product functional integrity is expressed as

$$C = \prod_{i=1}^m \|F_i\|, \quad (1)$$

$$\|F_i\| = \begin{cases} 1, & F_i \text{ function implementation,} \\ 0, & F_i \text{ function not implemented,} \end{cases} \quad i = 1, 2, \dots, m.$$

- (2) When the function relationship is in parallel, each function relationship is independent. As long as one function can be realized, it will not affect the realization of the whole function. However, the failure of multiple functions will directly lead to the decline of the product health state and reliability. It can be seen in product with reconfiguration and spare parts structure. The function integrity of the product is expressed as

$$C = \sum_{i=1}^m \omega_i \|F_i\|, \quad (2)$$

$$\|F_i\| = \begin{cases} 1, & F_i \text{ function implementation,} \\ 0, & F_i \text{ function not implemented,} \end{cases} \quad i = 1, 2, \dots, m.$$

In general, the functions of a product are not only in series or in parallel. In this case, according to the specific product function relationship or task reliability block diagram, the correlation of the functions should be analyzed, and the functional integrity expression can be obtained. However, when the product functional structure is more complex, especially for some complex electromechanical product, it is impossible to give a clear functional relationship. Then, the characterization parameters describing the product function can be used as variables to measure the conformity between the function and the functional integrity of the product at this stage, and the overall functional integrity of the product can be obtained.

Assuming that the characterization factor of product function is  $f$ , the expression form of product functional integrity  $C$  is

$$\forall C \in [0, 1], \quad \text{s. t. } X_F \vartheta C, \quad (3)$$

$$C = \vartheta[X_F - T], \quad (4)$$

where  $X_F$  is the parameter representing the functional state of the product;  $T$  is the standard parameter with full functionality corresponding to parameter  $X_F$  and  $\vartheta(\cdot)$  is the functional deviation function;  $\vartheta: X_F | R \rightarrow h_f | [0, 1]$  indicates that the mapping  $\vartheta$  projects the functional characterization parameter  $X_F$  into a real number of  $C \in [0, 1]$ .

The projection of  $X_F$  is a real number of  $C \in [0, 1]$ .

In some complex conditions, when the product monitoring data are difficult to obtain, it is impossible to measure the environmental adaptability or temporal sustainability, and the product health can also be simplified as functional integrity assessment.

**2.2. Environmental Adaptability Dimension.** Health is not just the synonym of good function. Healthy product can maintain the stability of function and structure for a long time and can realize all the predetermined functions, performance, or the ability not to be destroyed under the interference of external environment, that is, it has the ability

to adapt to the environment. Currently, healthy subjects with normal parameters are likely to have fatal problems once they are disturbed or changed due to lack of environmental adaptability.

Product environmental adaptability refers to the product ability to realize all its functions (properties) and not be damaged under the influence of various environments expected to be encountered in its life cycle, which is an important product quality characteristic [17]. It is inseparable from health. Environmental adaptability reflects the adaptability and stability of product function and performance to environmental changes, while functional integrity is to investigate whether the product can meet certain functional standards. In other words, the better the anti-interference and stability of the product under certain environmental conditions, the stronger the ability to maintain its structure and function and the stronger the environmental adaptability of the product. Therefore, product environmental adaptability is essentially to investigate the stability of the product health characterization parameters under the external environmental interference, that is, the noise cancelling ability.

The signal-to-noise ratio (SNR) of communication theory is introduced as a parameter index of product environmental adaptability. The signal-to-noise ratio (SNR) is the ratio of the effective part to the invalid part of the research object; it is commonly used in signal processing, speech recognition, image processing, and quality control [18–20]. Here, the output data of product health characterization parameters can be regarded as useful signal part, while the noise caused by environmental interference is useless signal part. The higher the SNR, the better the adaptability and anti-interference ability of the product to the external environment and the better the environmental adaptability of the product, and vice versa.

The signal-to-noise ratio (SNR), as a parameter to measure the ratio of useful signal to noise, originally came from the field of communication [18], which refers to the ratio of signal power/amplitude to total noise power/amplitude. The calculation formula is as follows:

$$\text{SNR} = \frac{P_S}{P_N} = \left( \frac{A_S}{A_N} \right)^2, \quad (5)$$

where  $P_S$  and  $A_S$  are signal power and amplitude and  $P_N$  and  $A_N$  are noise power and amplitude. In order to get the signal-to-noise ratio more intuitively, we need to convert the time-domain signal to the frequency domain, so we can calculate the signal-to-noise ratio  $S_N$  through Fourier transform, as shown in Figure 2.

$$S_N = \text{SNR} = \text{signal peak} - \text{noise floor} - 10 \lg N \text{ (dB)}, \quad (6)$$

where signal peak is the peak value of the signal; noise floor is the base of noise; and  $N$  is the number of samples.

**2.3. Temporal Sustainability Dimension.** The product health is closely related to its complete function, good stability, and sustainability, which is manifested in functional failure, increased failure rate with time, and decreased adaptability

FIGURE 1: Schematic diagram of functional integrity.

to environmental changes. Good temporal sustainability can greatly increase the reliable time between failure so as to maintain the stability of its function and structure. Therefore, the product temporal sustainability is studied from the perspective of reliability.

In the theory of reliability, time is the core of reliability. Generally speaking, the longer the normal work (time between failure) is, the higher the reliability is. The definition of basic reliability in GJB451-90 refers to the product non-failure duration or probability under required conditions [21]. We hope that the product can continue to have the required capability for a period of time. The reliability function  $R(t)$  precisely describes the possibility of the product to perform and maintain its function in a certain period of time  $[0, t]$ , as shown in Figure 3.

As shown in Figure 3, with the increase of operating or storage time, the reliability of the product decreases and the failure rate increases, which means that the continuous operation time of product reliability decreases and the temporal sustainability decreases. Therefore, from the perspective of time, reliability can fully reflect the continuous working ability. Therefore, this paper takes reliability as the measurement parameter index of temporal sustainability.

The higher the reliability  $R(t)$  of the product is, the smaller the failure rate is, and the higher the probability that the product can maintain the required function in time  $[0, t]$ , the longer the sustainable working time is, that is, the better the product temporal sustainability; otherwise, the lower the reliability is, the shorter the product sustainable working time is and the worse the temporal sustainability is.

Therefore, through the use of functional integrity, signal-to-noise ratio, and reliability, a three-dimensional spatial model of RF power health is established, which comprehensively describes the health of RF power source from three aspects of integrity, stability, and reliability.

As shown in Figure 4, the health expression of the three-dimensional space of the RF power source is recorded as

FIGURE 2: Schematic diagram of SNR calculation based on Fourier transform.

FIGURE 3: Reliability function and failure distribution function curve.

$$H_{\Delta} = (C, S_N, R), \quad (7)$$

where  $C$  is functional integrity;  $S_N$  is the signal-to-noise ratio; and  $R$  is the reliability.

$$H_i = \begin{cases} \{\text{unhealthy}\}, & \{[0, C_{\min}) \cup (-\infty, S_{\min}) \cup [0, R_{\min})\}, \\ \{\text{subhealthy}\}, & 1 - \{[0, C_{\min}) \cup (-\infty, S_{\min}) \cup [0, R_{\min})\} - \{[C_{\min}, +\infty) \cap [S_{\max}, +\infty) \cap [R_{\max}, +\infty)\}, \\ \{\text{healthy}\}, & \{[C_{\min}, +\infty) \cap [S_{\max}, +\infty) \cap [R_{\max}, +\infty)\}. \end{cases} \quad (9)$$

When the product can meet all the ability requirements of the three dimensions, the product belongs to the healthy state, that is, all of them reach or exceed the health threshold of the three dimensions  $[C_{\max}, +\infty) \cap [S_{\max}, +\infty) \cap [R_{\max}, +\infty)$ —green space area; when at least one of the three dimensions does not reach the health limit and these three dimensions are above the abnormal threshold, then the product health is in the subhealthy state—yellow space area. As long as a dimension drops below the threshold of the exception, i.e.,  $[0, C_{\min}) \cup (-\infty, S_{\min}) \cup [0, R_{\min})$ , the product is in a dangerous and unhealthy state—red space

FIGURE 4: Three-dimensional health measurement model.

If the threshold range of the three dimensions of health is determined, respectively, the three levels can be divided into normal, dangerous, and abnormal (or failure).

$$C = \begin{cases} [0, C_{\min}), & \{\text{abnormal}\}, \\ [C_{\min}, C_{\max}), & \{\text{dangerous}\}, \\ [C_{\max}, +\infty), & \{\text{normal}\}, \end{cases} \quad (8)$$

$$S_N = \begin{cases} (-\infty, S_{\min}), & \{\text{abnormal}\}, \\ [S_{\min}, S_{\max}), & \{\text{dangerous}\}, \\ [S_{\max}, +\infty), & \{\text{normal}\}, \end{cases}$$

$$R = \begin{cases} [0, R_{\min}), & \{\text{abnormal}\}, \\ [R_{\min}, R_{\max}), & \{\text{dangerous}\}, \\ [R_{\max}, +\infty), & \{\text{normal}\}. \end{cases}$$

Therefore, it can be divided into three-dimensional health level space, as shown in Figure 5. The health degree of the product can be obtained as follows:

area; until the three dimensions are reduced to zero, the product develops to the state of complete failure.

### 3. Construction of Index System for Health Characterization Parameters of RF Power Source

The typical power module of a certain equipment RF channel system is selected as the research object. It is known that the power module, antenna interface module, frequency

FIGURE 5: Three-dimensional spatial range of health degree.

FIGURE 6: A step-down power source product.

conversion channel module, digital interface, and processing module constitute the whole RF channel system. It is the total power source of each component module in the system. It completes the functions of signal receiving and sending, signal channel switching, signal frequency conversion processing, and signal preprocessing, commonly used in aerospace equipment such as aircraft.

The power module is a typical step-down power source product, as shown in Figure 6. It includes DC/DC converter and filter, which converts DC 270 V to DC 28 V and performs filtering output and provides overheating protection, overvoltage protection, and short-circuit protection.

**3.1. Construction of RF Power Health Characterization.** The key health characterization factors of RF power source were determined and screened step by step. The specific steps are as follows.

**3.1.1. Defining the Research Object.** The power source of RF system is taken as the research object. The indenture levels are as follows.

Initial indenture level: power module.

Minimum indenture level: constitutional unit:  
 $P = \{p_i\}$ ,  $i = 1, 2, \dots, 6$ , including input filter circuit, DC/DC converter 1, DC/DC converter 2, output filter circuit 1, output filter circuit 2, and output filter circuit 3.

**3.1.2. Dividing Product Levels.** The power source module is divided into levels according to its structure and functional characteristics, and the hierarchical division diagram is shown in Figure 7.

**3.1.3. Importance Analysis.** The power source converts 270 V DC to 28 V DC output and provides overheating protection for DC/DC and short-circuit protection for input filter. The power source adopts the redundant form of dual DC/DC converters output in parallel and isolated from each other. That is to say, when two DC/DC converters work normally, they will share current output; when one DC/DC converter is damaged, the other one will output full power (500 W), which reduces the impact on the normal operation of power module. At the same time, 28 V DC at the output end is divided into two separate output channels. Among them, the output end of output filter 2 is the normal output end of power supply, while output filter 3 only provides a short-term power transfer of about 30 seconds through short-term capacitor storage when the normal power source

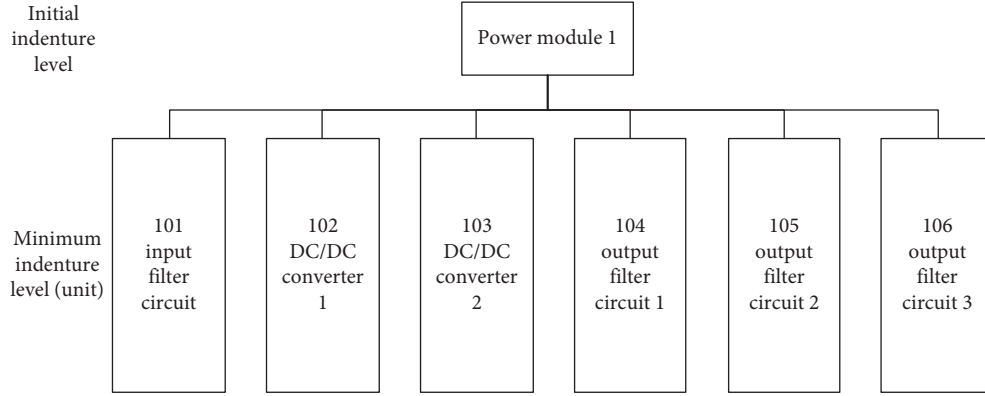

FIGURE 7: Schematic diagram of power module hierarchy.

terminal fails, which is not normally used. Its function diagram is shown in Figure 8.

The functional decomposition diagram of the power source product is shown in Figure 9.

According to the functional characteristics and engineering experience of step-down power source product, experts in the field scored each subfunction of the power module.

The difference in function importance of RF power source is not too big, and the number of subfunctions is not too much, so the 0–4 scoring method is used as the scoring standard [22]. The final scoring results are shown in Table 1.

Finally, the importance of each function of power module to the system is  $I_1 = 0.46$ ,  $I_2 = 0.29$ ,  $I_3 = 0.11$ , and  $I_4 = 0.14$ , as shown in Table 2.

The product function should be realized by the entity, and each subfunction is corresponding to its entity. As shown in the function decomposition in Figure 5, the function importance of the entity unit  $P = \{p_1, p_2, \dots, p_6\}$  is expressed as

$$\begin{aligned}
 I_f(p_1) &= I_2 + I_4 \\
 &= 0.43, \\
 I_f(p_2) &= I_1 + I_4 \\
 &= 0.6, \\
 I_f(p_3) &= I_1 + I_4 \\
 &= 0.6, \\
 I_f(p_4) &= I_2 \\
 &= 0.29, \\
 I_f(p_5) &= I_2 \\
 &= 0.29, \\
 I_f(p_6) &= I_3 \\
 &= 0.11.
 \end{aligned} \tag{10}$$

Therefore, the function importance weight of each unit power module is  $\delta_i(p_i) = I_f(p_i) / \sum_1^4 I_f(p_i)$ ,  $i = 1, 2, \dots, 6$ , i.e., input filter circuit, DC/DC conversion circuit 1, DC/DC conversion circuit 2, output filter circuit 1, output filter

circuit 2, and output filter circuit 3 are  $\delta_i(p_i) = \{0.19, 0.26, 0.26, 0.12, 0.12, 0.05\}$ .

According to the above importance analysis, all component objects  $P = \{p_k\}$ ,  $k = 1, 2, \dots, 6$  are sorted according to the importance of power module, and we get  $P^* = \{\text{input filter circuit, output filter circuit 2, DC/DC conversion circuit 1, DC/DC conversion circuit 2, output filter circuit 1, output filter circuit 3}\}$ . Output filter 3 only provides a short-term power transfer function for the power source when the normal output of the power source fails. Its state does not affect the normal operation of the power module, so the weight of the function importance is very small. Therefore, according to the requirements, we can focus on the key units of high importance for detailed characterization analysis.

**3.1.4. Characterization Factor Analysis.** In this paper, FMEA and failure rate statistical analysis are carried out for each key unit of power source module. Combined with engineering experience and expert opinions, the main failure modes, fault correlation, and monitoring parameters are determined. The simplified FMEA analysis table is shown in Figure 10.

Furthermore, according to the statistical failure rate distribution of historical fault case data, the frequency of DC/DC converter output failure accounts for the largest proportion of power system failure, and the failure modes of overheating protection, output short circuit, or output overvoltage caused by converter failure in DC/DC converter also occupy a large proportion. Therefore, power health characterization parameters mainly include DC/DC output voltage, ripple, insulation resistance, and module temperature.

Combined with domestic and foreign research, engineering experience, and expert opinions, six key functional units  $P^* = \{p_i\}$ ,  $i = 1, 2, \dots, 6$ . According to the importance analysis, the importance of output filter 3 to the system is very low, which basically does not affect the normal operation of the power supply. Therefore, without considering the transient transfer function, the set of key health characterization factors can be expressed as  $X_k = \{\text{power conversion efficiency } \eta, \text{ DC/DC1 temperature } T1, \text{ DC/DC2 temperature } T2, \text{ power output voltage } u, \text{ power output}$

| Comparison score<br>$k_i^j$ | Importance                      |                       |                        |                            |                                |
|-----------------------------|---------------------------------|-----------------------|------------------------|----------------------------|--------------------------------|
|                             | A is much more important than B | A is important than B | A is as important as B | A is not as important as B | A is far less important than B |
| $A(k_A^B)$                  | 4                               | 3                     | 2                      | 1                          | 0                              |
| $B(k_B^A)$                  | 0                               | 1                     | 2                      | 3                          | 4                              |

voltage ripple  $V$ }, which can cover or transform the above four factors greatly.

#### 4. Health State Assessment of RF Power Supply

Product health includes functional integrity, temporal sustainability, and environmental adaptability. Among them, the integrity of functions is the foundation and main basis

for measuring the product health. Therefore, the health of RF power source is directly related to the completeness of its functions. In addition, it should have the stability to deal with all kinds of disturbances and be able to work reliably for a long time so as to achieve the health in a broad sense.

By using functional integrity, signal-to-noise ratio, and reliability, we establish a three-dimensional spatial model of product health in terms of function, environment, and time

TABLE 2: Functional importance based on functional decomposition.

|       | F1 | F2 | F3 | F4 | Accumulated score | Correction score | Functional importance $I_i$ |
|-------|----|----|----|----|-------------------|------------------|-----------------------------|
| F1    | —  | 4  | 4  | 4  | 12                | 13               | 0.46                        |
| F2    | 1  | —  | 3  | 3  | 7                 | 8                | 0.29                        |
| F3    | 0  | 0  | —  | 2  | 2                 | 3                | 0.11                        |
| F4    | 0  | 1  | 2  | —  | 3                 | 4                | 0.14                        |
| Total |    |    |    |    | 24                | 28               | 1.00                        |

Note. In order to avoid zero score for the least important function, one point can be added to the cumulative score of each function as the correction score, and then the next step of calculation can be carried out.

Initial indenture level:

FIGURE 10: The screenshot of FMEA.

and comprehensively describe the health of RF power source from three aspects of integrity, stability, and reliability. First of all, a high temperature test was conducted on a certain type of RF power supply. The duration was 72 hours. A group of health characterization parameter data of power source was collected every 20 minutes. Each group contained 5 key characterization parameter data. A total of 200 groups of observation sequence samples were collected. Among them, the first 20 groups of observation data under the initial normal state are taken as the health reference state data, and the last 180 groups of data are taken as the observation data under different test conditions.

**4.1. Functional Integrity.** Suppose that the main function of the power source is  $F_i$ ,  $i \in R$ , including step-down, filtering, overheating, and short-circuit protection. To judge whether its function is in good condition, it can be obtained by detecting whether the voltage, ripple, and efficiency exceed the failure threshold. The functional integrity C is only divided into 0 and 1. However, when considering the short-term transfer function, it is also necessary to detect the voltage at the transfer terminal, so the basic characterization parameters of the power source are needed for the functional integrity. According to the previous function importance analysis, the function weights of step-down, filter, power

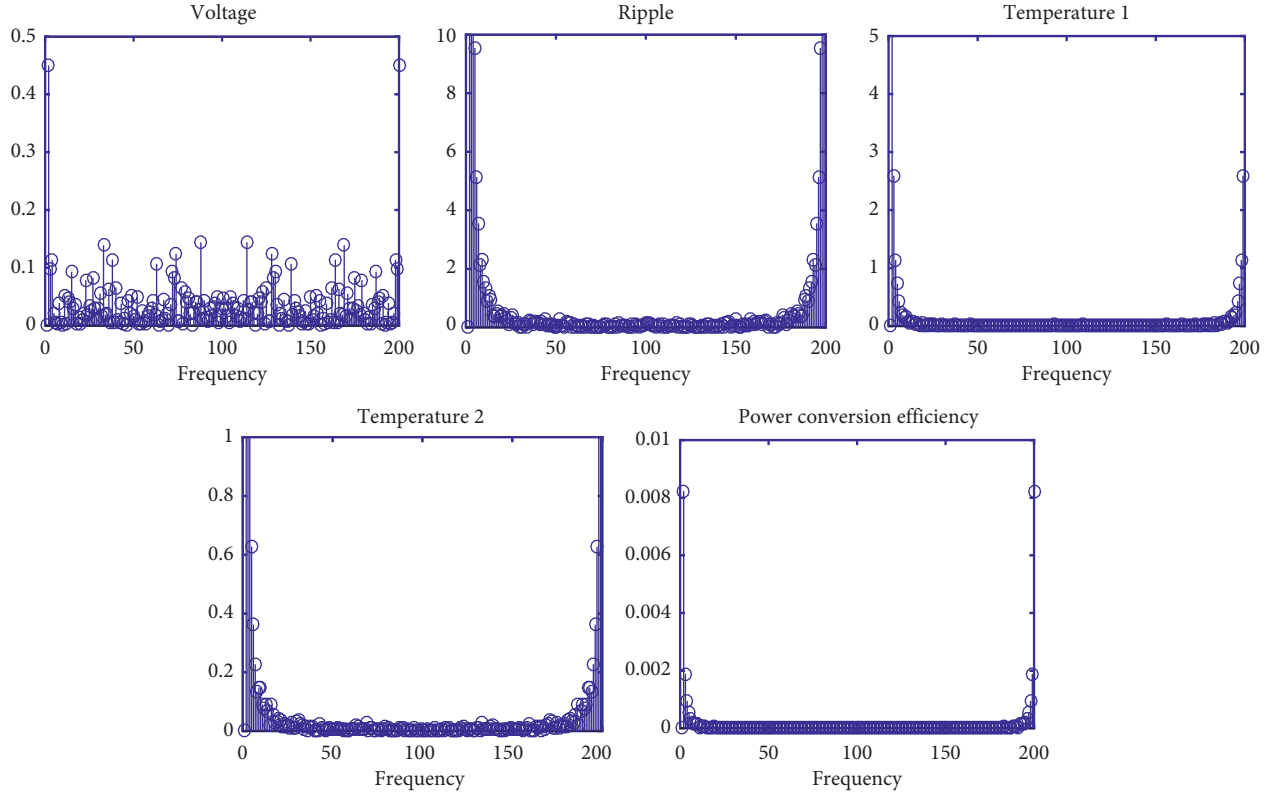

FIGURE 11: Power spectrum of power source key characteristic parameters based on fast Fourier transform.

transfer, and overheat protection are  $I_1 = 0.46$ ,  $I_2 = 0.29$ ,  $I_3 = 0.11$ , and  $I_4 = 0.14$ .

Therefore, the level threshold of functional integrity can be determined according to the importance of each function. When all functions can be executed normally, the functional integrity of the power source is 1; when the short-term power transfer function fails, the product function integrity can be determined by formula (2). By substituting the data into the above formula, it can be concluded that the power source functional integrity is 0.89. Obviously, the power

transfer failure does not affect the normal operation of the power supply, so 0.89 is taken as the threshold value of degradation stage; when the filtering function fails, the functional integrity decreases to 0.71, and the power source function is very incomplete, and the voltage output is unstable and close to the fault, which belongs to the upper limit of danger, and the step-down function fails. Therefore, it can be considered that when the functional integrity is 0.54, it has entered the area with the most incomplete function. The area is divided as follows:

$$\begin{aligned}
 C &= \sum_{i=1}^4 I_i \|F_i \\
 &= \begin{cases} \{0.89, 1\}, & \text{functionally intact,} \\ \{0.75, 0.86\}, & \text{functional decline,} \\ \{0.57, 0.60, 0.71\}, & \text{dangerous area,} \\ \{0, 0.11, 0.25, 0.40, 0.43, 0.46, 0.54\}, & \text{the lowest functional integrity.} \end{cases} \quad (11)
 \end{aligned}$$

According to the 200 sets of characteristic parameter data collected in 72 hours, it is found that none of them has actually reached the failure threshold (such as output voltage less than 25V, greater than 29V, and ripple peak  $\geq 120$  mV), and there is no functional failure. Therefore, from the perspective of whether the overall function of the power

source can be implemented, the functional integrity has always been  $\prod_{i=1}^4 \|F_i = 1$ .

4.2. *Environmental Adaptability.* Taking the key health characterization parameters of the product as the time-domain

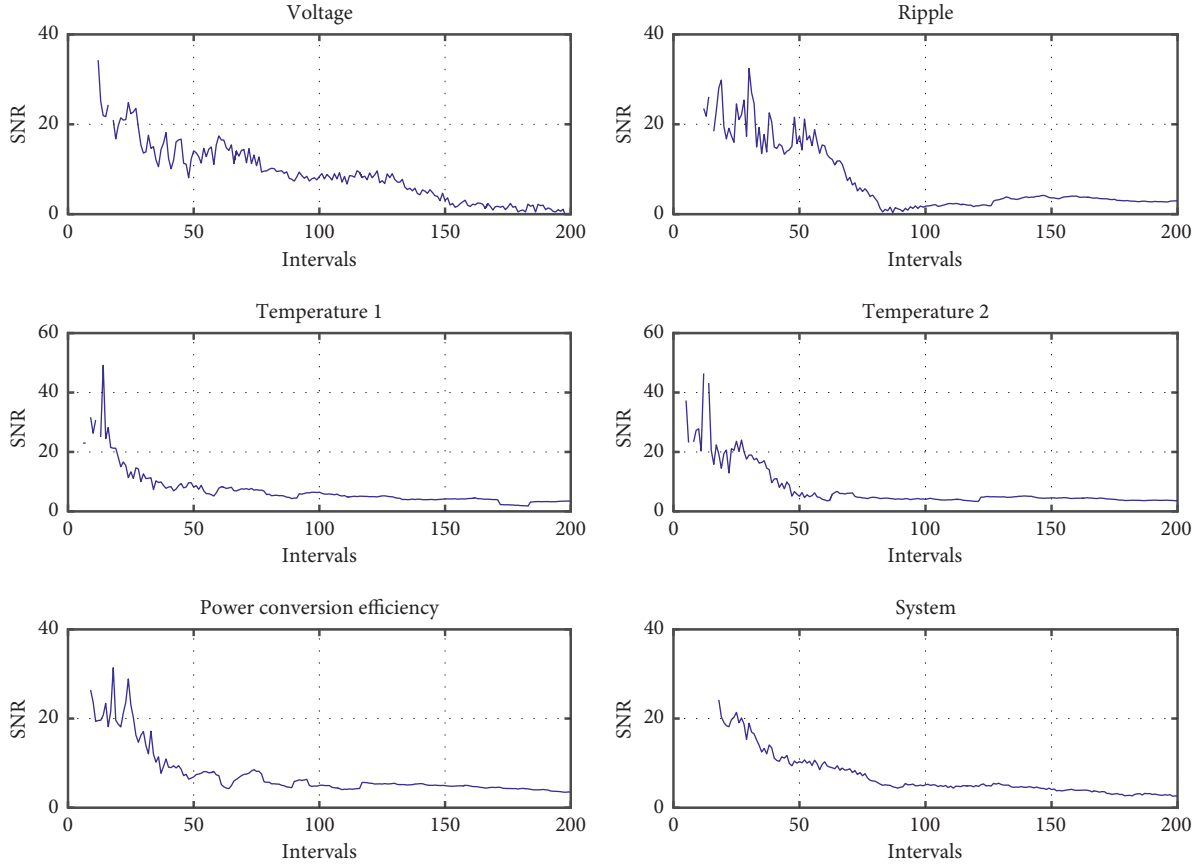

FIGURE 12: The power source key characteristic parameters and the system comprehensive signal-to-noise ratio curve.

signal, the health characterization parameters under the environment can be converted to the frequency domain through fast Fourier transform (FFT). The spectrum is shown in Figure 11.

According to formula (6), the SNR of each parameter is obtained, as shown in Figure 12.

The results show that when the power source is running at high temperature, the signal-to-noise ratio  $S_N$  shows a downward trend, indicating that the proportion of signal and noise of the product increases gradually, and the anti-interference and stability ability of the product to the environment gradually decreases, that is, the environmental adaptability decreases. It should be noted that from the beginning of sampling, the signal-to-noise ratio (SNR) presents a downward trend until it reaches the 40th sampling point. At this time, the signal-to-noise ratio (SNR) is about 14–16dB, and 15 dB is taken as the threshold value of SNR degradation stage; then, the downward trend gradually stabilizes until the sample points of 150–160th group decrease slowly, and the signal-to-noise ratio is about 3–6dB, so 5 dB is the signal-to-noise ratio with better environmental adaptability. According to the definition of SNR, when SNR is less than 0 dB, the signal is far less than noise, so 0 dB is taken as the worst threshold of environmental adaptability.

Thus, according to the signal-to-noise ratio, the level region of environmental adaptability can be determined. When the signal-to-noise ratio  $S_N > 15$ , the environmental adaptability is the best; when the signal-to-noise ratio

$5 < S_N \leq 15$ , the environmental adaptability decreases, but it is acceptable; when the signal-to-noise ratio  $0 < S_N \leq 5$ , the product has low environmental adaptability and is in the dangerous area; when the signal-to-noise ratio  $S_N \leq 0$ , the environmental adaptability of the product is the worst and extremely unstable.

**4.3. Temporal Sustainability.** Temperature is one of the important environmental factors affecting product reliability. Research [23] shows that the failure rate of electronic product increases monotonously with temperature according to exponential law when the temperature is higher than general indoor environment temperature (about 20°C–25°C). It is known that the MTBF of the power source module is 718.7041 hours when it operates at 100°C high temperature. Since the power source belongs to electronic product, its service life generally follows exponential distribution, so

$$\begin{aligned}
 \lambda(t) &= \lambda, \\
 \text{MTBF} &= \frac{1}{\lambda}, \\
 R(t) &= e^{-\lambda t} \\
 &= e^{-t/\text{MTBF}},
 \end{aligned} \tag{12}$$

FIGURE 13: Reliability curve of aging test stage.

FIGURE 14: Health grade and health curve in three-dimensional space.

where  $R(t)$  is the reliability and  $\lambda(t)$  is the failure rate.

When there is a power supply, the failure rate can be approximated as

$$\lambda = \frac{1}{\text{MTBF}} = 1.3914 \times 10^{-3}, \quad (13)$$

and the power reliability function is obtained as follows:

$$R(t) = e^{-\lambda t} = e^{-1.3914 \times 10^{-3} t}. \quad (14)$$

According to the above reliability function, the reliability value of the corresponding time in 72-hour experiment is obtained, as shown in Figure 13.

With time increasing, the reliability decreases continuously, which indicates that the reliable continuous operation time is decreasing, so the product temporal sustainability

decreases. According to the engineering experience and the characteristics of electronic devices, the health threshold of reliability is 0.98, while for electrical devices, the product failure rate with reliability of 0.90 is quite high, so only the risk threshold is set as 0.90.

#### 4.4. Three-Dimensional Complex Measurement Model.

Through the analysis of the above three dimensions, the health level area can be divided according to the parameter thresholds (functional integrity, signal-to-noise ratio, and reliability)—with three dimensions of functional integrity, environmental adaptability, and temporal sustainability. Therefore, the health level  $l$  can be divided into healthy state, subhealthy state, dangerous state, and fault state.

$$l = \begin{cases} \{1 \geq C > 0.89, S_N > 15, 1 \geq R > 0.98\}, & \text{healthy state,} \\ \{0.71 < C \leq 0.89, S_N > 5, 0.9 < R \leq 1\} \cup \\ \{0.71 < C \leq 1, 5 < S_N \leq 15, 0.9 < R \leq 1\} \cup & \text{subhealthy state,} \\ \{0.71 < C \leq 1, S_N > 5, 0.9 < R \leq 0.98\}, \\ \{0.54 < C \leq 0.71, S_N \geq 0, 0 \leq R \leq 1\} \cup & \text{dangerous state,} \\ \{0.54 < C \leq 1, 5 \geq S_N \geq 0, 0 \leq R \leq 1\}, \\ \{0 \leq C < 1, S_N < 0, 0 \leq R \leq 1\} \cup & \text{fault state.} \\ \{0 \leq C < 0.54, -\infty < S_N < +\infty, 0 \leq R \leq 1\}, \end{cases} \quad (15)$$

The RF power supply health level partition of the three-dimensional space is shown in Figure 14. At this time, the health level is no longer a plane point line, but a number of three-dimensional areas. The green area represents the healthy state, yellow represents the subhealthy state, blue represents the dangerous state, and red represents the fault state. According to the values of functional integrity  $C$ , signal-to-noise ratio  $S_N$ , and reliability  $R$ , a healthy three-dimensional spatial expression  $H_\Delta = (C, S_N, R)$  can be obtained, as shown in the black curve in the figure, and then the health degree of the power source at each time can be determined according to the health level.

As can be seen from the above figure, with the power supply aging, the health curve of the three-dimensional space gradually changes from the initial green area to the yellow area and then to the blue area, which represents the gradual evolution of the health of the power source to subhealth and then to the dangerous state.

## 5. Conclusion

In this paper, a new three-dimensional complex measurement model-based avionic radio-frequency power source health assessment method is proposed. The functional integrity, signal-to-noise ratio, and reliability are taken as the parameter indexes of functional integrity, environmental adaptability, and temporal sustainability. Taking a certain RF power source as an example, the three-dimensional complex health assessment model which can clearly reflect the three dimensions of RF power source is then built, respectively. The proposed method also provides a new approach to solve the product health state uncertainty under multiple factor effects and optimization management for decision makers. However, further research can be carried out to find an accurate solution for threshold division in the process of health measurement.

This paper is in view of the current algorithm to solve Multiple-Devices-Process integrated scheduling problems without considering parallel process between the parallel processing. Meanwhile, the influence of the first processing procedure on the second processing procedure is ignored, resulting in poor tightness between serial processes and poor parallelism between parallel processes, ultimately affecting the product scheduling results. We proposed Multiple-Devices-Process integrated scheduling algorithm with time-selective for process sequence. The proposed Multiple-Devices-Process sequencing strategy determines the process of scheduling order and improves the tightness between serial process. This paper presents a method to determine the quasischeduling time point of the multiequipment process, the time-selective strategy of Multiple-Devices-Process, and the time-selective adjustment strategy of Multiple-Devices-Process so that the first and the second processing processes cooperate with each other, and the purpose of improving the tightness of the serial process and the parallelism of the parallel processes is achieved, so as to shorten the product processing time.

## 1. Introduction

Scheduling, as a key factor affecting the production efficiency of enterprises, has always been a hot issue studied by scholars. Efficient scheduling optimization algorithm can maximize production efficiency and help enterprises achieve higher benefits [1]. At present, there are two main research directions in this field, namely, single processing (assembly) scheduling and integrated scheduling. Typical representatives of the former scheduling are job-shop and flow-shop scheduling [2]. This type of processing and assembly is common in mass production. The reason is the large quantity of the ordered products. The centralized production of disassembling them into work pieces will generate a large amount of inventory, and then the inventory will be assembled. In this way, synchronous processing and assembly can shorten the production cycle.

Currently, there are many research achievements in this direction, and more advanced methods include genetic

algorithm [3], tabu search [4], neural network [5], heuristic algorithm [6], particle swarm optimization [7], bionics algorithm [8], and various hybrid algorithms [9]. With the improvement of people's living standards, today's consumers increasingly pursue personalized products. Personalized product orders are often single small batch orders, which only produce a small amount of inventory or even zero inventories in the production process.

As a result, the above production methods will no longer be dominant but will separate the internal relationship between processing activities and assembly activities. The integrated scheduling problem makes up for this defect and provides practical solutions for single small batch production [10]. The main scheduling idea is that during the scheduling process, the assembly can be carried out as long as the work piece is finished and the assembly conditions are satisfied. The assembly activity is carried out synchronously with the ongoing processing activity, so as to effectively improve the production efficiency and reduce internal

consumption [11]. The most advanced research achievements in this field include the integrated scheduling algorithm for multiple-devices-process.

The content of this paper is the scheduling problem of Multiple-Devices-Process in the integrated scheduling problem. In the actual manufacturing process, some processes need to be processed by multiple equipment. This paper will study this problem. At present, the research on this problem is in its infancy, puts forward this problem, and gives solutions for the first time. In this method, the critical path method and priority scheduling the Multiple-Devices-Process method are adopted to determine the process scheduling sequence, and the first adaptive strategy is applied to determine the scheduling time of the process. The disadvantages are as follows: (1) Paying too much attention to the serial processing of the process, not considering the parallel processing between parallel processes. (2) The influence of the first processing step on the second processing step is ignored, resulting in poor tightness between serial processes and poor parallelism between parallel processes, which ultimately affects the product scheduling result.

In order to solve the above problems, a Multiple-Devices-Process Integrated Scheduling Algorithm with Selecting Time for Process Sequence is proposed (MDOI-SAWSTFPS). The Multiple-Devices-Process sequencing strategy is proposed. It can determine the scheduling sequence of the process and improve the tightness between serial processes. This paper presents a method to determine the quasischeduling time point of the Multiple-Devices-Process, the time-selective strategy of Multiple-Devices-Process, and the time-selective adjustment strategy of Multiple-Devices-Process so that the first and the second processing processes cooperate with each other, and the purpose of improving the tightness of the serial process and the parallelism of the parallel processes is achieved, so as to shorten the product processing time.

## 2. Problem Description and Analysis

The product processing technology of the multidevices scheduling problem is shown as a tree structure. The node in the tree represents the working procedure of the product, the directed edge represents the partial order relation of the working procedure processing order, the root node represents the last working procedure in the product, and the finished processing of the root node indicates the finished processing of the product. The following constraints must be met for the scheduling problem of Multiple-Devices-Process:

- (1) Each process must strictly comply with the agreed partial order relationship in the processing tree.
- (2) Each equipment can only process one process at any time, and the processing process can not be interrupted.
- (3) There are no devices with the same function in the device set.

- (4) There are multiequipment processes in the process set in which there are several related types of equipment working together. The multidevices process refers to the process that requires multiple equipment to cooperate with each other in a process. The processing time of multiple equipment is the same, and the processing start time and the processing end time are the same.
- (5) A process can only be processed if and only if all the preceding processes are in the finished state (or no prior process).
- (6) The difference between the end time of the latest processing step and the beginning time of the earliest processing step is the total processing time of the product.

## 3. Strategy Design

*3.1. Multiple-Devices-Process Sequencing Strategy.* The design of this strategy is similar to that of the common equipment process sequence sequencing strategy. The difference between the two strategies is that the multidevices process sequencing strategy contains multidevices processes and needs to be discussed separately. Since the start time, end time, and processing time of these processes are the same, they can be regarded as the same process, and they are arranged together in no particular order [12]. For example, the product process tree is shown in Figure 1, which contains 7 processes. First, the path length of 3 leaf nodes is calculated, and the results are A2:35, A6:70, and A7:80. Therefore, the process sequence 1 is A1, A3, A5, and A7. Remove the process in the first process sequence from the process tree, and the remaining leaf node is A2, A6. The path length is calculated, respectively, and the results are A2:20 and A6:35. Therefore, the second process sequence is A4, A6. Remove the process in the second process sequence from the process tree, and the remaining leaf node is A2. Since it is the last process sequence, there is no need to calculate its path length, and the upper process of the third process sequence is directly determined as A2.

A simplified version of the proposed algorithm can be described as follows:

Step 1:  $i = 0$ .

Step 2: calculate the path length of existing leaf nodes in the reverse process tree, respectively.

Step 3:  $i++$ .

Step 4: select the leaf node  $W$  with the longest path.

Step 5: if process  $W$  is not unique, select the process  $Q$  with the highest number of sequences on its path.

Step 6: if process  $Q$  is not unique, select the process  $O$  with the smallest difference between the number of layers of the process and the number of layers of the root node in the original processing tree.

Step 7: if process  $O$  is not unique, select the process  $P$  with the maximum total processing time of all preceding processes of each process on its path.

FIGURE 1: A product process tree with Multiple-Devices-Process.

Step 8: the sequence formed by all the processes on the path of process  $P$  is denoted as process sequence  $I$ .

Step 9: starting from process  $P$ , all the processes on process sequence  $I$  are successively pushed into  $S$ , followed by bomb stack  $S$ , and the resulting processes are successively stored in queue  $Qu$ .

Step 10: remove the process in queue  $Qu$  from the process tree.

Step 11: judge whether the current process tree is empty or not. Turn step 2 and turn step 12.

Step 12: exit.

**3.2. Determination of Quasischeduling Time Points of Multiple-Devices-Process.** Set the current scheduling process as process  $A$ , the finishing time of its pretightening process is  $T$ . Starting from point  $T$  on its processing equipment, the processing end time point of each scheduled process is found as the “quasischeduling time point” of process  $A$  and added to the “quasischeduling time point” set.

The determination of quasischeduling time point of Multiple-Devices-Process needs to consider the processing equipment of each parallel subprocess separately. The set of quasischeduled time points of a Multiple-Devices-Process is the union of all parallel subprocesses on its processing equipment. For example, there are two parallel subprocesses in processes  $A$ ,  $A1$ , and  $A2$ , which are processed on different processing equipment, respectively. The “quasischeduling time point” set of  $A1$  is  $Ta1 = \{T1, T2, T3\}$ . The “quasischeduling time points” set of  $A2$  is  $Ta2 = \{T4, T5\}$ . The set of “quasischeduling time points” of procedure  $A$  is  $tA = ta1 \cup ta2$ .

**3.3. Time-Selective Strategy of Multiple-Devices-Process.** The time-selective strategy of Multiple-Devices-Process schedules each parallel subprocess separately at each time point in the process’s “quasischeduled time points” set. In the scheduling process, it should be noted that the first quasischeduling time point is the end time of the pretight process in the processing process tree of this process. There are two situations at this time point, as illustrated below.

As shown in Figure 2,  $Wi$  is a Multiple-Devices-Process, which contains two parallel subprocesses  $Wi1$  and  $Wi2$ .

According to the partial order relationship in the process tree, the start time of process  $Wi1$  and  $Wi2$  should be consistent and greater than or equal to the end time  $T1$  of the process which tightening front of process  $A$  in the process tree. The processing equipment of process  $Wi1$  is  $M2$ , and the processing equipment of process  $Wi2$  is  $M1$ . At this time, there are the following two conditions on the processing equipment of each parallel subprocess  $Wi$  at time  $T1$ .

**Situation 1:**  $T1$  in Figure 2(a) is the end time of the scheduled process  $B$  or blank time. At this point,  $T1$  is taken as the first “quasischeduling time point” of process  $Wi$ , so that  $Wi1$  starts processing on  $M2$  at time  $T1$ , and  $Wi2$  starts processing on  $M1$  at time  $T1$ .

**Situation 2:**  $T1$  in Figure 2(b) is the processing time of the scheduled procedures  $B$  and  $C$ . In order to avoid conflict, there are two solutions. One is processes  $B$  and  $C$  do not move. Select  $T3$ , the maximum end time of steps  $B$  and  $C$ , as the first “quasischeduling time point” of step  $Wi$ . Second,  $T1$  is selected as the first “quasischeduling time point” of process  $Wi$ , and process  $B$  is adjusted to the back of process  $Wi1$ , and process  $C$  is adjusted to the back of process  $Wi2$ . As shown in Figure 3, it is obvious that  $Wi$  is scheduled according to the second processing mode, and the resulting Multiple-Devices-Process trial scheduling scheme set will contain the case of  $Wi$  scheduled according to the first processing mode. To enlarge the problem solution space, the second processing method is selected to schedule  $Wi$ .

A simplified version of the proposed time-selective strategy of the Multiple-Devices-Process algorithm can be described as follows:

Step 1: queue a process from queue  $Qu$  and set to process  $A$ .

Step 2: suppose the end time of the tight preprocess of procedure  $A$  is  $T$ .

Step 3: determine if the process is an ordinary process or a Multiple-Devices-Process. If the ordinary process, go to 4. If the Multiple-Devices-Process, go to 5.

Step 4: start from point  $T$  on the processing equipment of process  $A$ , find the finishing time point of each

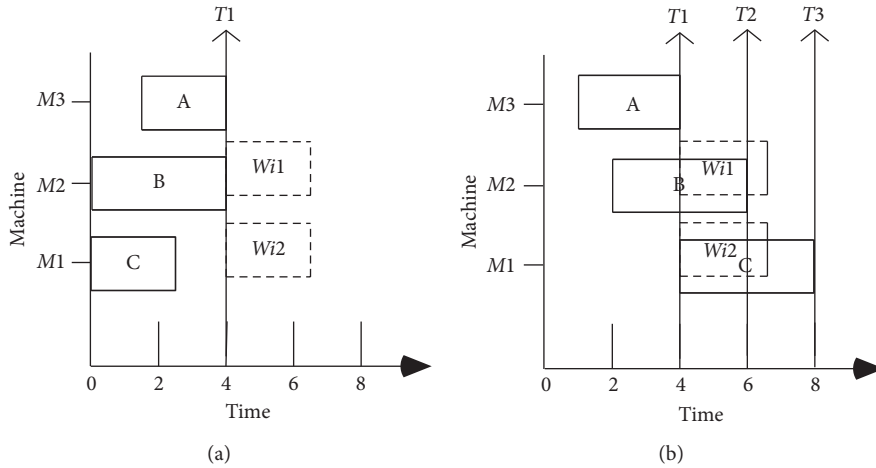

FIGURE 2: Scheduling analysis at the first quasischeduling time point.

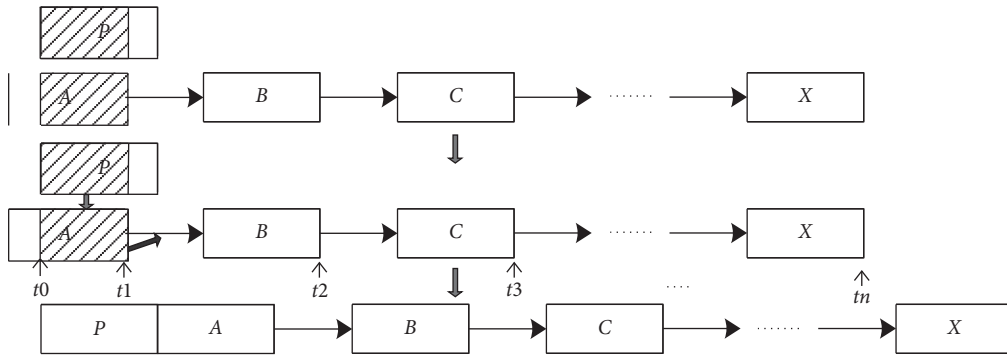

FIGURE 3: A schematic diagram of the backshift of the process affected by scheduling at the first “quasischeduling time point.”

scheduled process as the “quasischeduling time point” of process *A*, and add it into the “quasischeduling time point” set.

Step 5: starting from point *T* on several parallel processing equipment of process *A*, the processing end time point of each scheduled process on each parallel processing equipment is found to be the “quasischeduling time point” of process *A* and added to the “quasischeduling time point” set.

Step 6: judge whether the set of “quasischeduling time points” is empty, not for idling to 7, for idling to 15.

Step 7: take a time point *T* from the set of “quasischeduled time points,” and judge whether *T* point is the first “quasischeduled time point,” if it goes to 8, if not to 11.

Step 8: if process *A* is an ordinary process, go to 9. If process *A* is a Multiple-Devices-Process, go to 10.

Step 9: determine whether process *A* has affected the scheduled process on the current equipment. If the affected process is added to the list of scheduled processes of the equipment, the position is after process *A* and goes to 12.

Step 10: judge whether each parallel subprocess of Multiple-Devices-Process *A* has affected the scheduled process on the current device. If the affected procedure is added to the scheduled process chain list of each parallel subprocess equipment, the position is after process *A* and then goes to 13.

Step 11: if process *A* is an ordinary process, go to 12. If process *A* is a multiple-devices-process, go to 13.

Step 12: take *T* as the start time of process *A* to conduct trial scheduling of process *A* and adjust the processes affected by the scheduling of process *A*, so as to produce the trial scheduling scheme generated by the scheduling of process *A* at the “quasischeduling time point,” and add the trial scheduling scheme into the set of trial scheduling schemes of process *A* and turn it to 10.

Step 13: take *T* as the start time of each parallel subprocess in process *A*, and then conduct trial scheduling for each subprocess, and adjust the processes affected by each parallel subprocess of the scheduling process *A* (in accordance with section 3.4). The trial scheduling scheme of process *A* at the quasischeduling time point is generated; the trial scheduling scheme is added to the trial scheduling scheme set of Process *A*.

Step 14: delete this time point in the quasischeduling time point collection and go to 6.

Step 15: exit.

**3.4. Time-Selective Adjustment Strategy of Multiple-Devices-Process.** The selection of “quasischeduling time point” only considers the processing order between processes, without considering whether the scheduling of the process will affect the scheduled process on the equipment. Therefore, after the scheduling process, it is necessary to check the scheduled process that may be affected by it. When the processing completion time of the scheduling process is greater than the processing start time of the subsequent process on the same equipment or the processing start time of the process in the process tree, the time-selective adjustment strategy shall be started. For Multiple-Devices-Process, all parallel subprocesses need to be checked separately. Considering the situation of the first quasischeduling time point, as shown in Figure 4(a), when scheduling process  $W_{i1}$ , the processes affected are: Process  $B$ , Process  $D$ , Process  $E$ , and Process  $F$ . Wherein, when process  $B$  determines the first quasischeduling time point, its equipment is processing process, which has been processed in the design of time-selective scheduling strategy. The method is to arrange it in the chain list of processed processes of the equipment, and the position is after process  $W_{i1}$ . To adjust process  $B$  will affect the work process  $D$  on the device after tight; to adjust process  $D$  will affect the work process  $E$  on the device after tight, and work process  $F$  after tight in the process tree, by the same token, the scheduling process  $W_{i1}$  affected by the process are process  $C$ , working process,  $G/I$  and  $H$ . Consider the case that it is not the first quasischeduling time point, as shown in Figure 4(b), when scheduling process  $W_{i1}$ ; the processes affected are Process  $D$ , Process  $E$ , and Process  $F$ . When scheduling process  $W_{i1}$ , the processes affected are Process  $C$ , Process  $I$ , and Process  $H$ . To sum up, the time-selective adjustment strategy considers two situations when adjusting a process: one is the posttightening process on the processing equipment of the scheduling process. The other is the posttightening process on the equipment of the adjusted process and the middle-tightening process in the processing technology tree.

A simplified version of the proposed Multiple-Devices-Process timing adjustment strategy algorithm can be described as follows:

Step 1: queue all parallel subprocesses of the current Multiple-Devices-Process in sequence into  $Aqu$ .

Step 2: queue  $Aqu$  and store the results in  $W$ .

Step 3: judge whether  $W$  is empty, do not idle to 4, otherwise go to 10.

Step 4: suppose there are  $k$  post-tight processes in  $w$ 's process tree,  $n = 1$ .

Step 5: judge whether  $n > k$  is true. If it is true, go to 8. If not, go to 6.

Step 6: judge whether the processing completion time of  $W$  is greater than the processing start time of process  $wn$  after the tight process in the process tree (the starting time of the unscheduled process is  $+\infty$  by default), if to 7, otherwise to 8.

Step 7: take the machining end time of  $w$  as the start time of  $wn$ , and put  $wn$  into the team  $Aqu$ ,  $n++$ .

Step 8: determine whether  $w$  has tight postprocess  $WM$  on the chain list of scheduled processes of its processing equipment and the completion time of  $W$  is greater than the start time of  $WM$ . If it is 9, otherwise it is 2.

Step 9: take the end time of  $W$  as the start time of  $WM$ , enter  $WM$  into  $Aqu$ , and turn it to 2.

Step 10: after the adjustment, calculate the total processing time of the current scheme, exit.

A simplified version of the proposed multiple-devices-process integrated scheduling algorithm with time-selective for process sequence can be described as follows:

Step 1: invert the processing partial order relationship in the process tree.

Step 2: determine the process scheduling sequence in the process tree by using the Multiple- Devices-Process sequencing strategy.

Step 3: process sequence 1 is queued out of queue  $Qu$  and an initial scheduling scheme is formed.

Step 4: determine whether the process queue  $Qu$  is empty, not for idling to 5, for idling to 10.

Step 5: queue a process from process queue  $Qu$  and set to process  $A$ .

Step 6: judge that process  $A$  is an ordinary process and multiple-devices-process. If it is an ordinary process, switch to 7. If it is a multidevices process, switch to 8.

Step 7: apply time-selective strategy and the time-selective adjustment strategy to schedule process  $A$ , generate process  $A$  trial scheme set, and go to 9.

Step 8: apply the time-selective strategy of Multiple-Devices-Process and the time-selective adjustment strategy of Multiple-Devices-Process to schedule process  $A$ , generate process  $A$  trial scheme set.

Step 9: the scheduling scheme with the minimum processing time is found out from the trial scheduling scheme set of process  $A$ , which is taken as the scheduling scheme of process  $A$ , go to 4.

Step 10: process  $A$  scheduling scheme is the product scheduling scheme.

Step 11: exit.

## 4. Example Analysis

In order to facilitate to the reader to understand the algorithm, the following is an example analysis. Product  $A$  is shown in Figure 5, and its reverse process tree is shown in

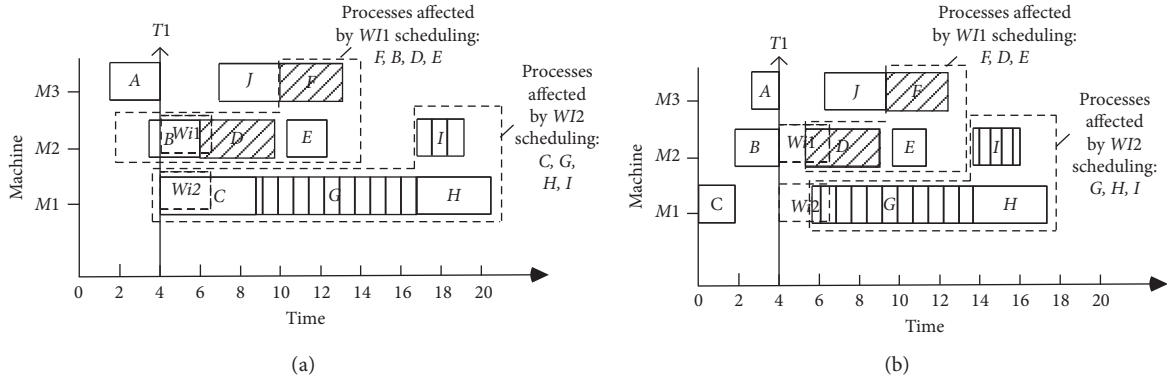

FIGURE 4: Scheduling analysis at the first quasischeduling time point.

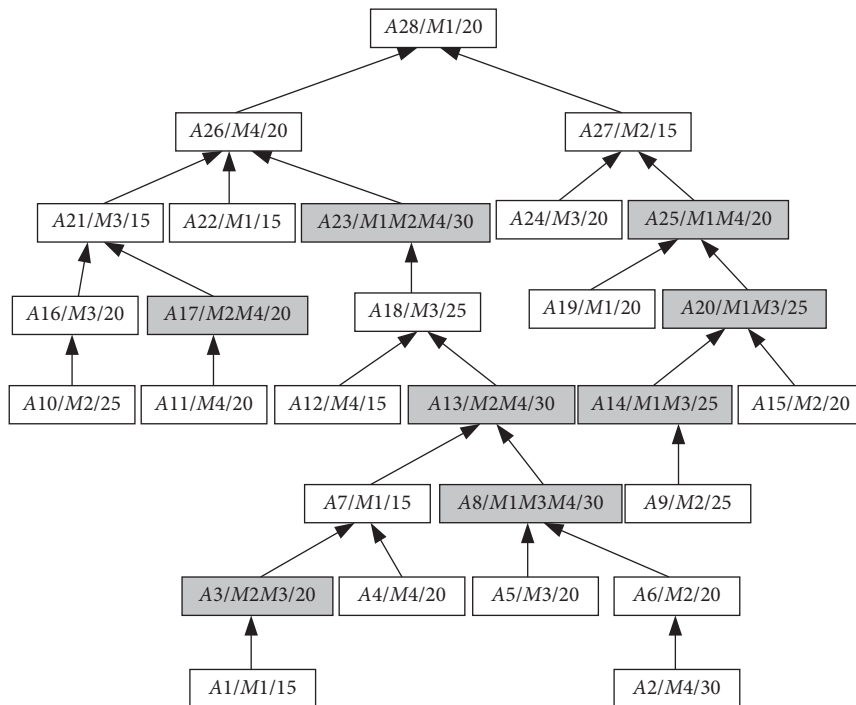

FIGURE 5: Product processing tree.

Figure 6 where each processing node represents  $A$  processing process, which is divided into ordinary processes and Multiple-Devices-Process. Such as  $A28/M1/20$ , which means that the process name is  $A28$ , and it is processed on equipment  $M1$ , which is an ordinary process and the processing time is 20.  $A17/M2M4/20$  means that the process name is  $A17$ , which needs to be processed on the equipment  $M2$  and  $M4$  at the same time, and it is a Multiple-Devices-Process. According to the algorithm proposed in this paper, the product processing process tree is shown in Figure 6. The scheduling process is shown in Table 1, and the total processing time of product  $A$  is 265. The result of scheduling product  $A$  is shown in Figures 7 and 8. Meanwhile, the total processing time of scheduling product  $A$  according to the algorithm proposed in [12] is 275, and the result of scheduling final product  $A$  is shown in Figure 9.

## 5. Experimental Results and Analysis

To verify the effectiveness of the proposed algorithm, four sets of data were randomly generated, with 50 products in each set. The parameters of the products were randomly generated. The software used on the experimental platform is Windows 10, 64 bit, GCC5.5, and the hardware of the experimental platform is an Intel Core I7-860 processor with 32 GB of memory. Five groups of experiments were designed as follows: Figure 10 is a comparison of the total elapsed processing time when the number of multidevices is 2 for the two algorithms, Figure 11 is a comparison of the total elapsed processing time when the number of multidevices is 3 for the two algorithms, Figure 12 is a comparison of the total elapsed processing time when the number of multidevices is 5 for the two

algorithms, Figure 13 is a comparison of the total elapsed processing time when the number of multidevices is 10 for the two algorithms, and Figure 14 is a comparison of the average elapsed processing time for the two algorithms.

## 6. Conclusion

On the basis of ensuring parallel processing, the Multiple-Devices-Process sequencing strategy improves the tightness between serial processes and shortens the product completion time. The time-selective strategy of Multiple-Devices-Process and the time-selective adjustment strategy of Multiple-Devices-Process to make the current scheduling process has to cooperate with each other, to make the current partial product processing always take the smallest scheduling scheme, further shortening the product completion time, and when the scheme of minimum total available not only chooses the plan of process over time are the first, to further improve the possibility of parallel processing in the sequence after work. The scheduling results are superior to the existing Multiple-Devices-Process integrated scheduling algorithms. The introduction of a backtracking strategy to improve the accuracy of the algorithm may be the next direction of work, and it is intended to solve the problem of the multidevices process in distributed manufacturing.

## Data Availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also form part of an ongoing study.

## Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this study.

In the traditional civil engineering industry, only abstract theoretical concepts are applied to express complex realistic contents, but this method of information transmission is sometimes very limited for engineering participants, because its expression is not comprehensive and specific and also makes the recipients have difficulty in understanding its information. The rise and development of virtual reality (VR) technology has become a good assistant to overcome this difficulty, providing an extremely effective means for displaying and simulating civil engineering project in real time. This paper introduced the methods and principles of VR platform system and structure dynamic analysis, conducted virtual scene design and three-dimensional modeling of civil engineering project, analyzed the synthetic debugging and simulation roaming of the virtual environment, proposed the engineering model of virtual construction process and planning structure calculation, discussed the realization method of virtual project management and visualization, and finally performed the simulation and its result analysis of panoramic display and planning of civil engineering project based on VR technology. The results show that the VR technology can simulate various environments and activities of civil engineering projects in advance, analyze the rationality of various schemes, and modify their different functional parameters, so it can achieve the simulation optimization of project planning, design, and construction.

## 1. Introduction

Virtual reality (VR) technology is an immersive interactive environment based on computable information, and it specifically uses modern high-tech with computer technology as the core to generate realistic visual, audio, and tactile integration in a specific range of virtual environments, through which the user interacts with the objects in the virtual environment in a natural way with the necessary equipment, so as to produce the feeling and experience of being in the real environment and realize the exchange of information between virtual and reality [1]. The VR is a more ideal form of human-computer interface between users and computers than traditional computer technology and users roam in a virtual environment and allow objects to be manipulated [2]. Applying the VR technology to the design, engineering control, and structural analysis of very large and complex structures will enhance the front-to-rear processing

capabilities of computing software. Compared with traditional computer technology, the VR technology has three important characteristics of immersion, interactivity, and imagination, and it has an extremely wide range of uses [3]. Because the VR technology can simulate various environments and activities beforehand, realize the function of analyzing the rationality of various schemes, and modify parameters of different schemes, it is possible to optimize planning, design, and construction [4, 5].

In the past, in the civil engineering industry, researchers could only express very rich content with very abstract theoretical concepts, such as graphic design drawings, section design drawings, elevation design drawings, and other flat design drawings to form some specific symbols, showing the three-dimensional building of three-dimensional images, and using abstract graphics and refined language as an auxiliary to describe the building to be built to convey information [6]. However, this method of

transmission will be restricted for the recipient of the information, because each recipient's work, level of knowledge, and ability to understand are different, so it will be difficult to communicate, and it will not be able to communicate what was originally intended [7]. The VR mobile terminals are applied to collect field data to achieve collaborative management of civil construction safety and quality and transfer potential safety hazards and quality defects on the site to the VR application in the form of data. The rise and development of VR technology has become a good assistant to overcome this difficulty, providing an extremely effective means [8]. This technology is a new high-end human-machine interface for the participants, and it is a three-dimensional environment generated by electronic computers, which not only enables users to feel the realistic existence of objects in the virtual world environment. As a structural entity, civil engineering is closely connected with the natural world and human environment, so the VR technology can be used to simulate the virtual environment [9].

Based on the summary and analysis of previous literature works, this paper expounded the research status and significance of VR technology, elaborated the development background, current situation, and future challenges of the panoramic display and planning simulation of civil engineering project, introduced the methods and principles of VR platform system and structure dynamic analysis, conducted virtual scene design and three-dimensional modeling of civil engineering project, analyzed the synthetic debugging and simulation roaming of the virtual environment, proposed the engineering model of virtual construction process and planning structure calculation, discussed the realization method of virtual project management and visualization, and finally performed the simulation and its result analysis of panoramic display and planning of civil engineering project based on VR technology. The detailed chapters are arranged as follows: Section 2 introduces the methods and principles of the VR platform system and structure dynamic analysis; Section 3 analyzes the panoramic display of civil engineering projects based on VR technology including the synthesis debugging and simulation roaming of virtual environment; Section 4 carries out the planning and simulation of civil engineering projects based on VR technology; Section 5 carries out civil engineering simulation and its result analysis; and Section 6 is the conclusion.

## 2. Methods and Principles

**2.1. VR Platform System.** The VR technology is based on the physiological and psychological characteristics of human vision and hearing and the computer generates realistic three-dimensional stereoscopic images. Users can put themselves in a virtual environment and become a member in the virtual environment by wearing interactive devices such as helmet displays and data gloves. The interaction between the user and various objects in the virtual environment is just like in the real world with all realistic feelings and there is a feeling of being on the scene. The human-

computer interaction in the VR system is a kind of nearly natural interaction. The user can not only use the computer keyboard and mouse to interact but also interact with sensor equipment such as special helmets and data gloves [10]. Users can investigate or operate objects in the virtual environment through their own natural skills such as language, body movement, or movement. Because the VR system is equipped with sensing and reaction devices for sight, hearing, and touch, users can obtain a variety of perceptions such as sight, hearing, and touch in the virtual environment, thereby achieving personal presence of feeling the environment. Due to the abovementioned advantages, the VR technology has been widely used in civil engineering and has broad application prospects.

The function realization of the simulation system is mainly at the model layer, the presentation layer realizes the interaction with the user, and the data layer realizes the recording and management of the simulation experiment data. According to the simulation teaching design, the main functions of user interaction are reflected in the movement of model components, rotation, and change of viewpoint and experiments of related animation display functions. Virtual reality modeling language is an object-oriented modeling language used to describe the data format of interactive objects and is also the standard of the VR technology. The modeling language can support network communication through the programming of its scripts, so that modeling language nodes can receive data through the network and can render scenes in real time. The language defines users' own objects by using prototypes, has object-oriented class characteristics, encapsulates corresponding data structures and methods, and is instantiated in applications, which has a certain degree of expansion. Through programming in routing and scripting languages, a visual scene can be constructed with a user interface, which not only facilitates user operations but also improves work efficiency. In the virtual simulation system, various common prototypes can be defined to realize the main simulation interactive functions, such as click, pan, rotate, select, and other functional modules.

Traditional geographic information systems have closed the characteristics from architecture to data format and different geographic information systems have different data storage formats. There are difficulties in data exchange between systems developed on different software, and data conversion standards can only partially solve the problem. Different application departments have different understandings of geographic phenomena and different data definitions of geographic information, which hinders the sharing of data between application systems. The digital city data have an infinitely seamless distributed data layer structure, including multisource, multiscale, multi-resolution, historical and current, vector format, and raster format data. In order to use these data for spatial analysis and decision-making, a spatial data warehouse must be established. The information sharing, data acquisition, and updating mechanisms and technologies have not been resolved, many necessary data standards and norms have not been established, and low-level repeated development has

occurred from time to time, resulting in a huge waste of human and material resources. Therefore, in order to achieve spatial information sharing, it depends on a special kind of metadata and data describing some attributes such as the format and precision of spatial data. The construction of the meta-database is very necessary; it is about the data of the database, through which you can understand the name, location, attributes and other information of the data, thereby greatly reducing the time for users to find data (Figure 1).

**2.2. Structural Dynamic Analysis Method.** The simulation model is composed of model components and the relationships between the components. The components are represented by multimedia objects, and the objects correspond to the entities in the real world; the interaction relationship between the components is realized by message events and the hierarchical relationship between them is described by combined multimedia simulation objects. The object is not only the basic conceptual unit of system analysis, but also the basic model unit of system design or basic programming unit of simulation programs. The object encapsulates all attribute definitions and operations about the object, and the state change of the object is triggered by internal or external events. Multimedia characteristics of sound that characterize the appearance of an entity, like quantitative parameters and state data that characterize the characteristics of an entity, are an integral part of real-world entity attributes. In real life, the external multimedia features of entities are an effective way for people to understand and understand nature; when people use models to describe the properties and state behavior of actual systems, they should not make the rich, colorful multimedia features of real objects. It is the most direct and simple way to lose sight of and disappear from the objective, so as to lose and understand the objective objects. The advanced modeling ideas and modeling methods of multimedia simulation are to ensure that this idea becomes a reality.

In the structural dynamic analysis method, the interface is firstly built and the first person and third person then are browsed through to allow users to get an immersive experience, getting a realistic effect brought by the VR technology and also getting a better understanding of every detail of the architectural plan. The flight mode is a bird-eye view of the underground buildings in the sky, which solves the problem that the overall style of the building cannot be observed in the building group and can judge whether it meets the aesthetic requirements and whether it can integrate with the surrounding buildings. Camera animation roaming is a roaming method that does not require manual operation and realizes browsing of multiple routes. This solves the problem of being unfamiliar with the overall architectural plan and easily disoriented and at the same time allows the user to relax. Finally, in the sound processing, the sound can deepen the sense of immersion and substitution, so that the entire operation process becomes more vivid, so that users get more operating experience. According to the above-mentioned functions to be realized, make buttons

corresponding to the functions, respectively. For the sound switch button, it is necessary to make an open button and a close button at the same position, monitor and replace each other, and execute the corresponding event [11].

The civil engineering works basically have the characteristics of large engineering volume and complex content, which is particularly noticeable in their construction plans. The framework and structure of virtual reality platform system is shown in Figure 2. The construction plan of the civil engineering project should take into account equipment management, material scheduling, capital operation, work type coordination, project schedule, quality control, cost control, information management, contract management, etc. Under such circumstances, the organization and management of construction plans are very difficult. Not only must they be able to collect, integrate, and use a large amount of engineering data, but also to balance contradictions and conflicts in various aspects. Therefore, the traditional organization and management of construction plans cost a lot of time and is difficult to ensure the quality and implement ability of the program. In civil engineering, a considerable part has the characteristics of a vast construction site and almost all civil engineering has three-dimensional features. In the traditional construction site organization and management, the floor plan is used to characterize and manage the construction site. Not only is it not intuitive but it also has to prepare a large number of plane drawings to fully display the three-dimensional characteristics of the site. The energy efficiency of organization and management is quite limited, and the organization and management of the construction site is a long-term and dynamic process, because during the construction process, the situation of the construction site will inevitably change with the progress of the project. The traditional site management uses paper drawings, which are difficult to modify and cannot reflect the dynamic changes of the site layout, and it is difficult to achieve the dynamic management requirements of the site.

### **3. Panoramic Display of Civil Engineering Projects Based on VR Technology**

**3.1. Virtual Scene Design and Three-Dimensional Modeling.** Panoramic technology is to stitch one or more groups of photos taken by the camera ring 360° into a panoramic image through seamless connection. The user applies special playback software to display it on the computer screen and can control the user's perspective through the mouse to achieve vertical or 360° horizontal scene viewing and supports arbitrary zoom-in and zoom-out, so that users can look around, look down, and look up as if they were in the field. After the design plan is determined, they perform virtual operations on the computer, and at this time, it can achieve the same situation as the actual construction and operation. After finding the problem, it can be quickly fed back to the planning and design to avoid the actual construction and operation process. If deficiencies and deficiencies are found, remedial measures will be taken, and some errors will cause great economic losses and the price of restricted use of

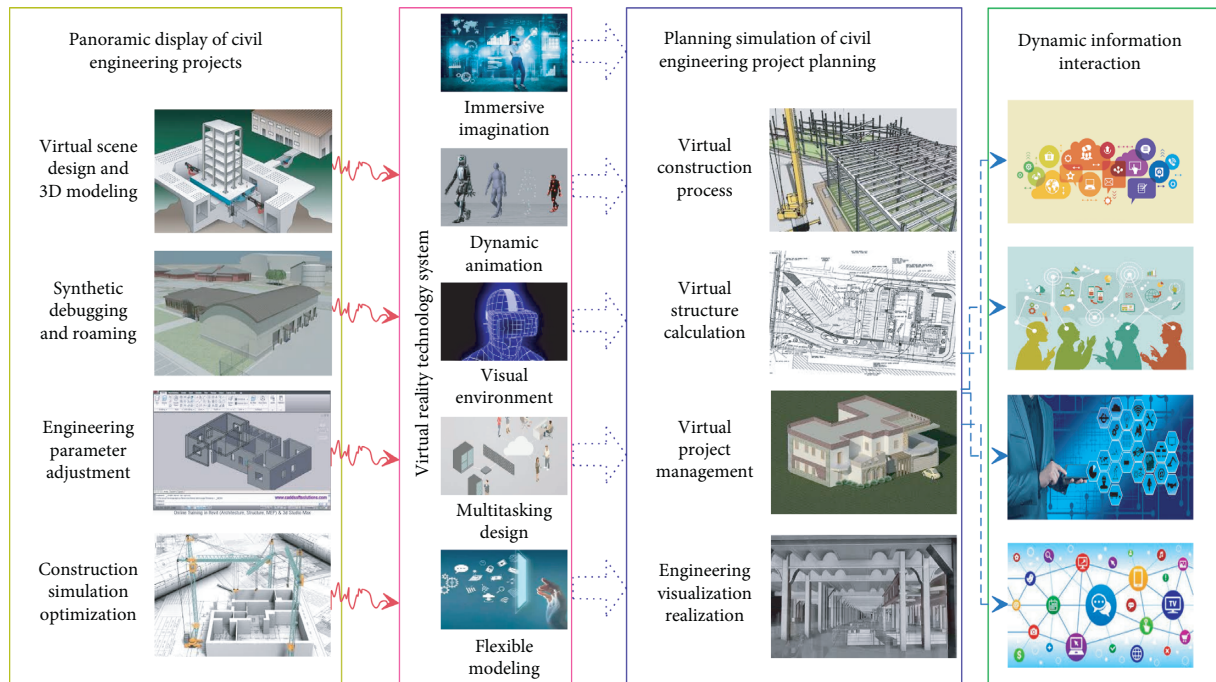

FIGURE 1: Virtual scene design and three-dimensional modeling of civil engineering project based on virtual reality technology.

functions. In the process of urban civil engineering design and implementation, the selection and optimization of construction schemes have a great impact on the construction quality and construction efficiency in the later stage. The effective application of the VR technology and the effective establishment of three-dimensional simulation models can to a certain extent effectively clarify the construction flow, construction procedures, etc., further optimize the selection of construction methods and construction machinery, and rationally arrange construction procedures.

In the construction process of civil engineering, the VR technology is mainly used for on-site construction management, to directly feedback the quality and safety issues on-site to construction management personnel, so as to be dealt with in time, improve construction quality, and to reduce the incidence of safety accidents (Figure 3). In practical applications, first log in to the VR application interface, then transfer the relevant photos of the construction site to the VR application, and in the corresponding options, including the project name, axis, and other specific parameters [12]. The VR mobile terminals are applied to collect field data to achieve collaborative management of civil construction safety and quality, transfer potential safety hazards and quality defects on the site to the VR application in the form of data, and then correlate these data to the VR model and the function of VR visualization to study on-site problems. In the construction of civil engineering construction, the use of VR technology can greatly improve the scientific and standardization of on-site construction and simplify the construction tasks. In addition, the use of BIM technology has also realized the supervision of the construction process, enhanced the use of information

technology, and reduced the interference of objective factors, which is conducive to comprehensive control of the project.

In the figure, different colored shapes represent different civil engineering construction entities; three red lines represent different perspective direction lines; different letters and numbers represent different virtual reality calibration points.

Traditional system simulation techniques rarely study the simulation of human perception models, and therefore cannot simulate human perception of the external environment. The introduction of the VR technology into the various stages of system simulation and simulation can make users immersed in it and have a clear understanding of the problems to be solved, instead of being limited to observing the simulation results from the screen, so that the establishment of the model and verification is more convenient. The VR technology is mainly reflected in the computer based on the established domain knowledge base and database and the use of artificial intelligence, pattern recognition, and other technologies, the main control agency for modeling, learning, planning, and calculation. Visual simulation in this field is carried out through three-dimensional animation production and display helmets, tactile simulation in this field is carried out through sensing mechanisms and gloves, sound simulation is carried out through sound production and sound effect cards, and dynamic simulation is carried out through mechanical control and transmission devices. Then, the human's response to these sensory stimuli is fed back to the main control mechanism, so as to generate a simulation of the new sensory model in real time. The civil engineering is closely related to people's lives, establishing a

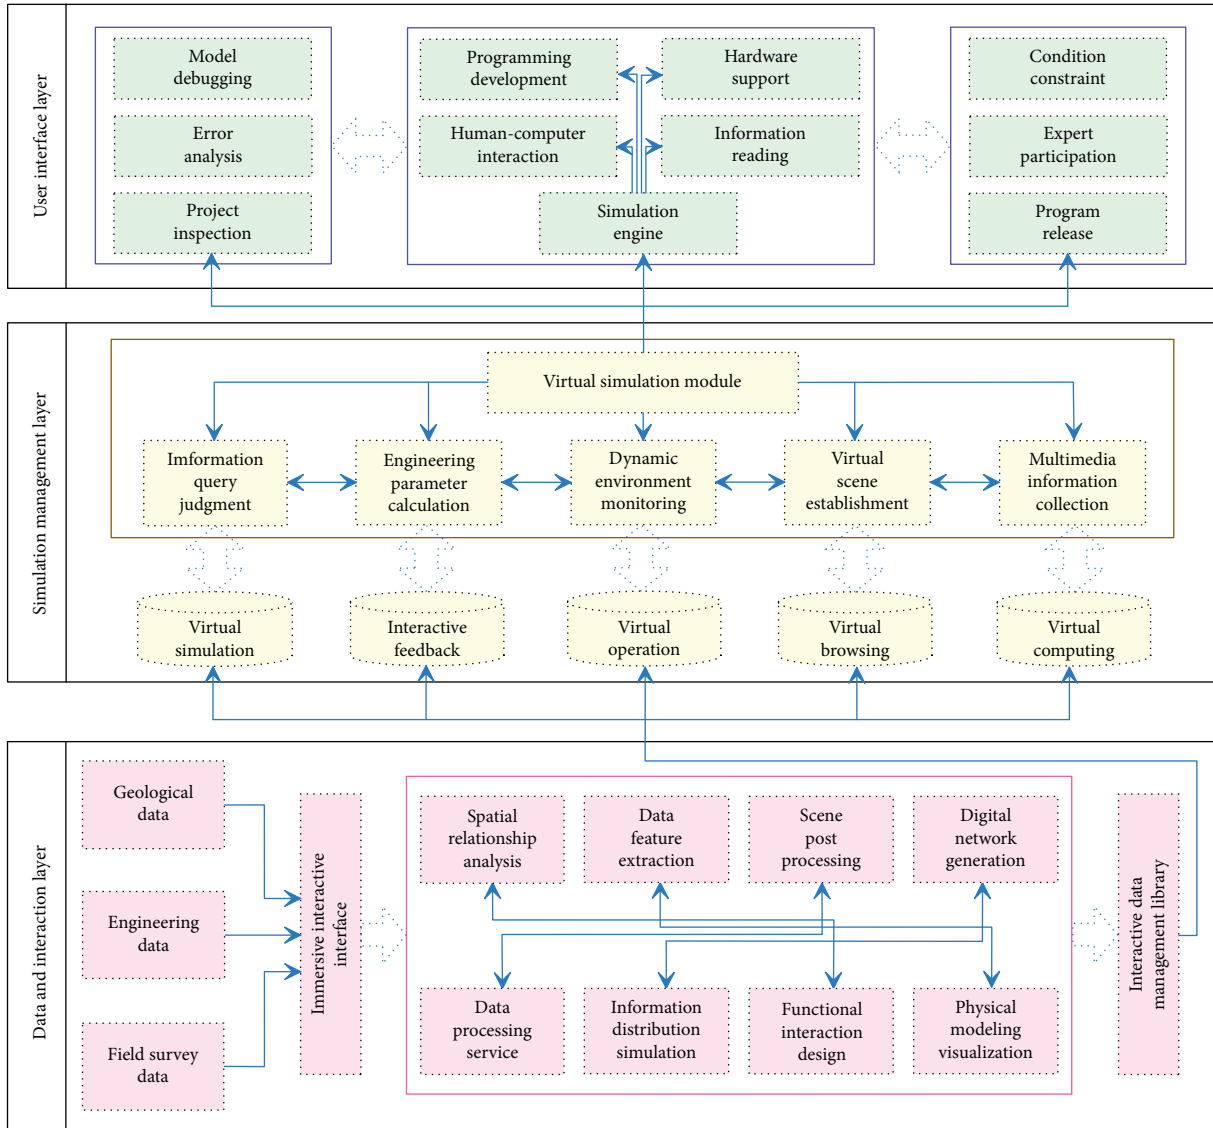

FIGURE 2: Framework and structure of virtual reality platform system.

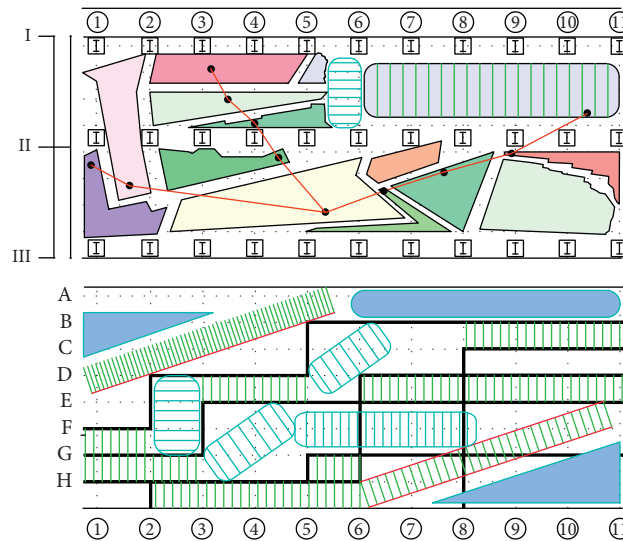

FIGURE 3: Planning display of civil engineering project based on virtual reality technology.

multidimensional information perception model and applying it to simulation systems is of great significance to the development of this industry [13].

**3.2. Synthetic Debugging and Roaming of Virtual Environment.** In the application process of the actual virtual simulation system, the display function can realize two-dimensional navigation, zoom-in, zoom-out, rotation, roaming, and corresponding animation functions; its query function can realize related query operations of attribute data, such as building name, area, weight Subordinate units, and completion time and can obtain corresponding target information from the database information. The simulation system actually records the city's topography, three-dimensional contours of buildings in key areas, and urban space, which can effectively help the relevant departments of urban planning, feel the construction status of the city more intuitively, and effectively evaluate it for comparison and optimization urban planning program. On the basis of effectively completing the modeling of virtual scenes, further synthesize and debug the virtual environment roaming system and this process requires the use of software to achieve the corresponding debugging effect (Figure 4). The debugging process is as follows: the hardware system and display device are firstly configured, and then project the screen, helmet, stereo glasses, etc. are installed, and set different operation modes, roaming paths, roaming viewing angles, running backgrounds, etc., to detect and debug collision effects and stereo effects. By clicking the mouse, users can effectively observe different angles in the virtual scene and adjust to watch the best effect.

Planning design is a very important link in the construction of civil engineering, and it is also an important foundation for civil engineering construction, which plays a decisive role in the successful completion of construction in the later stage of civil engineering and even affects the quality of the overall civil engineering. For civil engineering construction, the structure is very complex, and the construction environment has the characteristics of variability [14]. Designers usually spend a lot of energy and time to collect civil engineering construction data, and only after a comprehensive analysis of these data, we will be able to draw a complete civil engineering graphic design. The introduction of the VR technology can solve this problem well and designers can complete the mechanical performance model test through the computer, which avoids the influence of factors such as airflow and friction in the previous mechanical performance model test, which greatly improves the mechanical performance. The accuracy of the test and the test data can be comprehensively analyzed through the computer, and at the same time, it can help the designer to select the best civil engineering design plan. The VR system will also integrate the various links of civil engineering construction and clarify the relationship between the various construction links, so as to ensure that the civil engineering works are carried out step by step, and the construction is stopped because of the wrong connection of the construction links.

The application of the VR technology can also change the angle arbitrarily and observe from any point when performing visual calculation. At the same time, it can also use the human-computer interaction function provided by this technology to modify various calculation data in real time, so that make a detailed comparison of various schemes and results. Applying visual computing technology based on VR technology to the design, engineering control, and structural analysis of ultralarge and complex structures in civil engineering can effectively enhance the processing power of related visual computing software [15]. As far as the construction of civil engineering is concerned, the selection and optimization of engineering construction plans is an important task of engineering construction, and it is also an important guarantee to ensure the quality of engineering construction. In order to arrange the construction order, the application of this technology in the selection and optimization of construction plans can be used for the virtual construction and demonstration of the construction plans of various projects, and the construction plans can be compared through the virtual demonstration results, so as to effectively realize the selection and optimization of construction plans. When using the finite element method for structural analysis of the visual calculation of civil engineering, the application of the VR technology can mark the force of each point in the three-dimensional object with different shades of color, and use different colors to indicate Isobaric surface.

## **4. Planning Simulation of Civil Engineering Project Planning Based on VR Technology**

**4.1. Implementation of Virtual Construction Process and Structural Calculation.** The civil engineering planning needs to consider many factors, such as land use, economy, transportation, landscape, laws and regulations and other social and economic factors, meteorology, geology, terrain, hydrology, and other natural factors as well as water quality, noise, environmental pollution, greening and beautification, factors of living environment, etc. Planning information storage and query system, such as soil database system, regional information system, geographic information system, geographic information system, urban policy information system, and this type of system mostly uses the form of a database system. The shortcoming of the current database is the high degree of digitization and the low degree of visualization and these kinds of data are abstract and not easy to accept (Figure 5). For example, the geographic information system's representation of terrain and landforms is poorly readable if it is only represented by numbers. If it is represented in the form of a topographic map, it is relatively easy to accept, and the VR technology is used to input terrain; geomorphic data can be observed from different angles. Not only can the necessary data be obtained but also an intuitive experience can be obtained. Planning auxiliary performance integrated systems such as landscape performance system, and transportation planning system. At present, the representation method of landscape representation system is mainly two-dimensional pictures. If users

FIGURE 4: Planning display of civil engineering project from the perspective of O-I.

FIGURE 5: Planning display of civil engineering project from the perspective of O-II.

can feel a sense of immersion, landscape planning will be more scientific, reasonable, and comprehensive [16].

Construction plan design based on VR refers to the use of VR technology to establish a three-dimensional model of construction scenes, structural members, and mechanical equipment in a virtual environment to form a computer-based simulation system with certain functions and make the model in the system has dynamic performance and performs virtual construction on the model in the system. According to the result of virtual construction, it is verified whether it is correct. The construction plan is designed and modified in the visual environment of human-computer interaction to identify potential safety hazards and formulate safety precautions to get an optimized design plan. The identified hazards should be evaluated one by one by the construction company and the project manager. The major hazards identified can be combined with virtual environment research, detailed preventive measures, and feedback

to the hazard identification database. In the course of the project, the project manager department should adjust the identification of hazard sources, evaluate them, and formulate corresponding preventive measures at any time according to the safety conditions on-site, such as the implementation of safety plans, the accident conditions, and the generation of new hazard sources. The system then feeds back to the hazard source identification result database. After the hazard source identification results of the project are aggregated into the hazard source identification result database, the construction company can be used to continuously supplement and improve the standardized safety management system.

Improving the engineering measurement level can not only ensure the smooth progress of engineering construction and avoid construction changes during the construction process but also ensure that the quality of civil engineering construction meets the design requirements. In the

construction process of civil engineering, it usually involves three types of measurement work: angle measurement, distance measurement, and elevation measurement [17]. It is relatively tedious, and the measurement quality is easily affected by various factors and measurement errors. The application of VR technology in engineering survey work can build a virtual model by collecting environmental information, use computer technology to automatically measure based on the model, accurately analyze the measurement data, and issue a measurement report. As a result, multiple tasks such as measurement, data recording, data analysis, and drawing are combined in the same system to avoid investing too much manpower and material resources in the measurement work, while improving measurement accuracy and measurement efficiency. For example, in a high-rise residential building construction project, the surveyor needs to perform distance measurement, just input the engineering geographic environment data and residential building design data into the system, and build a three-dimensional model, and the system can accurately perform data measurement and analysis and intuitively present the measurement results on the three-dimensional model to facilitate the next work of the surveyor [18].

*4.2. Implementation of Virtual Project Management and Visualization.* As an emerging branch of civil engineering, engineering project management runs through the entire life cycle of construction projects. From project conception, planning, and design to project establishment, construction and other VR technologies provide more effective, more intuitive, and interactive engineering project management methods and approaches for engineering project management. The VR technology is a comprehensive high-tech information technology with a wide range of applications, which introduces its application in project feasibility studies and investment economic evaluation, real estate, bidding, construction management, property management, etc. and points out that this technology is used in civil construction with broad application prospects in project management (Figure 6). In actual engineering construction, the design of complex structure construction schemes and the calculation of construction structure are more difficult problems. The key to the former lies in the expression of the spatial relationship between the structural members and mechanical equipment on the construction site and the latter lies in the construction structure under construction. The deformation under state and load is greater than that after it is in place or after the structure is shaped. Especially modern large-scale engineering projects, long construction period, large quality, and even a series of enterprises produced by a project involve the coordination of various types of work, a lot of capital and material scheduling, construction machinery, and equipment management.

Visual processing or three-dimensional graphic display of the data obtained by scientific computing can be used to interactively change the parameters to observe the full picture of the calculation results and their changes and to achieve parameterized and visual calculations. When using

the finite element method for structural analysis, it can be used to give the force of each point in the three-dimensional object through the depth of the color; use different colors to represent different force surfaces. The users can also change the angle to observe by clicking on the interface and can also use the interactive performance of VR to modify various data in real time in order to compare various programs and results, which makes the engineer's thinking more visual and the concepts easier to understand [19]. Applying visual computing technology to the design, engineering control, and structural analysis of very large and complex structures will enhance the front-to-rear processing capabilities of computing software. More importantly, it can use graphics or images to re-analyze and dynamically control the structure in real time and obtain construction control data and at the same time can dynamically demonstrate and control the design and construction process in real time. The VR technology is constantly evolving and high-performance chips dedicated to computer graphics and multimedia information processing can increase the processing power by a hundredfold. Three-dimensional graphic algorithms and parametric modeling algorithms can make VR technology more mature.

Virtue reality has been tried to be applied in civil engineering construction and management. The use of its technology can simulate the construction site and construction activities, manage human and material resources in the construction organization, and identify hidden safety hazards. The traditional construction process management, organization, and safety plan are usually based on the provided design drawings. Since the drawings are two-dimensional ones provided by the designer, the understanding of these drawings requires a long translation process. Therefore, when planning, arranging, and managing construction, it is difficult to quickly form a global impression in the minds of engineering technicians and construction personnel. It is worth noting that the safety factors in construction often exist in the construction process, and it is impossible to find out from the drawings [20]. The use of VR technology can realize what users see is what you get and users can set the construction process parameters through interactive operation, analysis, and evaluation construction plan. In civil engineering, visual computing is an important trend in its future development and effectively integrating the VR technology can speed up the development of civil engineering visual computing technology to a large extent. The analysis of VR technology in urban planning and civil engineering should be analyzed, which is conducive to improving the overall transformation speed and construction quality of cities.

## 5. Simulation Experiment and Result Analysis

*5.1. Project Overview and Simulation Environment Design.* The V-Realm Builder visual editor provided by MATLAB greatly simplifies the modeling process, which is simple and easy to master, and the virtue reality modeling language is used to realize the dynamic visualization and interactive body of the virtual world. This modeling language is a scene

FIGURE 6: Planning display of civil engineering project from the perspective of O-III.

modeling language used to build real-world scene models or people's fictional three-dimensional worlds and is also platform-independent. It provides several degrees of freedom, can move in three directions, can rotate in three directions, and can also create hyperlinks in other spaces. The virtual world of the model created by the modeling language has all the static nodes of the three-dimensional world, including geometric relationships, backgrounds, textures, light, and viewpoints.

Two modeling methods are adopted for different objects: nonparametric modeling and parametric modeling. The nonparametric modeling method is only suitable for situations where there are a large number of identical shapes, and the size does not need to be changed. For relatively complex shapes and many dimensions, in order to install accurately, no deformation is allowed, and the size does not need to be changed, and then a nonparametric model is used. Parametric modeling is suitable for situations where the structure is more complex and there are more variant modeling constraints. The floor, staircase, tower crane, and other models are entered into the Envision module to form multiple institutions based on functional characteristics. In the Envision module, the mechanism is the smallest unit that can move independently. By positioning the organization, the entire organization model is assembled.

**5.2. Results Analysis.** The VR system can help planners organize and synthesize massive data in three-dimensional scenes. Based on the three-dimensional scene, the element information can be separately imported into the VR scene to form a database of all element space combinations, and planners can intuitively elaborate all element information. The VR technology is formed on the basis of true three-dimensional technology and can display all kinds of reality element information in VR scenes without additional text, symbols, and tables for annotation. After the application of VR technology to achieve results, the group evaluation and

modification phase is very convenient. When problems are found, all the modification work can be completed in real time in the VR environment. With the application of VR technology, during the review stage, the three-dimensional planning results can be displayed on the spot, so that the reviewers can feel the effects of the planning, experience the planning intention, and achieve the purpose of fully displaying the planning results (Figure 7). The results of VR can record the implementation of urban planning measures in real time. By modifying and recording the objects in the planned three-dimensional scene at any time, the current status documents of different periods are generated, and all the documents are stored as a database of the urban development process [21].

The reasonable choice of construction plan is the core of project organization design, which includes determining the construction flow direction and application procedures, selecting construction methods and construction machinery, and arranging construction sequence. For some projects with complex structure and large amount of engineering, it is difficult to choose the construction plan. However, through the VR system, the construction plan of each branch project can be virtually applied and demonstrated, which brings great convenience to the choices of construction plan [22]. As an emerging branch of civil engineering, engineering management runs through the entire life cycle of construction projects from project conception, planning, and design for project initiation and construction. In the entire project construction process, people have to use abstract concepts to express very rich content, such as plane drawings, section drawings, elevation drawings, and other plane graphics plus some prescribed symbols to represent three-dimensional buildings, using more abstract graphics and concise language to describe complex scenes to convey a lot of information. However, this kind of information processing and transmission method is affected by the occupation, knowledge structure, and understanding ability of the information receiver, so it is very inconvenient to

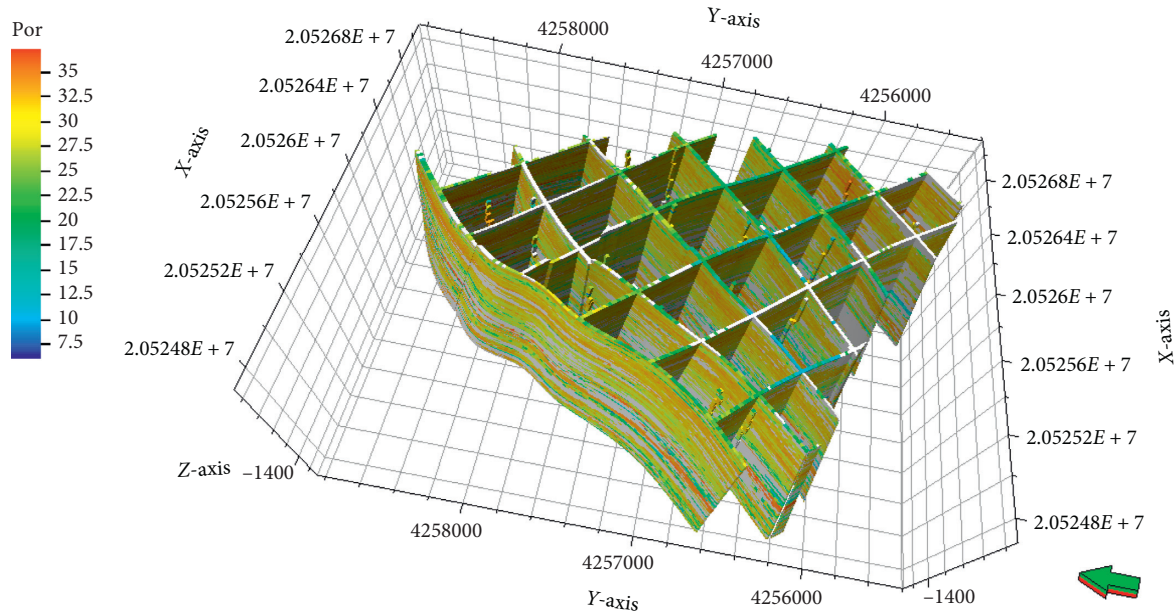

FIGURE 7: Panoramic display of civil engineering project based on virtual reality technology.

communicate. The development of the VR technology provides an extremely effective means to overcome this difficulty.

The computer simulation technology in the simulation technology realizes the constitutive relationship and mathematical modeling of civil engineering. For example, the constitutive relationship and failure criterion of concrete have many statements, and each failure criterion is only applicable under certain conditions within a certain range. In addition, the constitutive relation is based on the data obtained by the test, not derived from theory, and it is difficult to analyze its strength and tolerance in actual operation. The finite element method of computer simulation technology can be used to analyze and study concrete strength and other indicators. The simulation technology can also realize the full simulation of the design results, for example, building a simulation model of a bridge or other building through computer technology, then applying pressure or changing its structure through other means, and carrying out simulation force analysis under such changes [23]. Accurate results can be obtained, so that the mechanical characteristics of the building can be analyzed and studied. Through the application of computer technology, establish an information exchange platform within the civil engineering enterprise and improve the enterprise information sharing mechanism through the platform construction. Full communication and communication between the enterprise and employees can solve various problems in the construction of the project in a timely manner, promote the successful completion of civil engineering construction, and at the same time protect the two-way interests of the enterprise and employees.

## 6. Conclusions

This paper introduced the methods and principles of VR platform system and structure dynamic analysis, conducted virtual scene design and three-dimensional modeling of civil engineering project, analyzed the synthetic debugging and simulation roaming of the virtual environment, proposed the engineering model of virtual construction process and planning structure calculation, discussed the realization method of virtual project management and visualization, and finally performed the simulation and its result analysis of panoramic display and planning of civil engineering project based on VR technology. The application of the VR technology can simulate the construction site and construction activities, manage the human and material resources in the construction organization, and identify the construction safety hazards, which can also change the angle arbitrarily and observe from any point when performing visual calculation. From project conception, planning, and design to project establishment, construction and other VR technologies provide more effective, more intuitive and interactive engineering project management methods and approaches for engineering project management. Civil engineering project planning information storage and query system, such as soil database system, regional information system, geographic information system, geographic information system, and urban policy information system mostly use the form of the database system. The results show that the VR technology can simulate various environments and activities of civil engineering projects in advance, analyze the rationality of various schemes, and modify their different functional parameters, so it can achieve the simulation optimization of project planning, design, and construction. The VR technology can also use the three-dimensional

environment generated by electronic computers to make users feel the realistic existence of objects in virtual environment and also enable users to make accurate responses to movements and operations in the virtual world in a timely manner. The results of this study provides references for further researches on the panoramic display and planning simulation of civil engineering project based on VR technology.

With the rapid development of information technology, the information overload has become a very serious problem in web information environment. The personalized recommendation came into being. Current recommending algorithms, however, are facing a series of challenges. To solve the problem of the complex context, a new context recommendation algorithm based on the tripartite graph model is proposed for the three-dimensional model in complex systems. Improving the accuracy of the recommendation by the material diffusion, through the heat conduction to improve the diversity of the recommended objects, and balancing the accuracy and diversity through the integration of resources thus realize the personalized recommendation. The experimental results show that the proposed context recommendation algorithm based on the tripartite graph model is superior to other traditional recommendation algorithms in recommendation performance.

## 1. Introduction

With the rapid development of the Internet and the increasing popularity of smart phones, the information that people can access was increasing in complex systems. It became difficult to obtain information and easy to get lost in a huge amount of information. The data included information of major websites and mobile APPs. If the data had given a certain treatment, the information could have been more user-friendly and more efficient. Meanwhile, users would have been provided with a friendly experience, and the information provider could have had a higher revenue. So, the recommendation system came into being [1–4]. The introduction of complex context information brings more ideas to improve the efficiency of the recommendation algorithm. The main complex context information includes user context information, such as users' ages, occupation, and region; physical context information, such as location, weather, and time. There is much complex context information that could be considered by the recommendation algorithm. The context information can bring more accurate recommendations to the users of the recommendation system for complex real-world applications [5–9].

By applying recommendation technology, users are no longer passive recipients of services, but become active participants, directly affecting the way and content of services. With the rapid development and popularization of mobile information services and the continuous advancement of data collection technology, the dimension of the information we can collect has been continuously improved [10]. Traditionally, only the “user-item” two-dimensional recommendation model considers the amount of information collected. Relatively few data can be obtained with relatively low data dimensions, but in the context of mobile information services, relying only on the “user-item” two-dimensional recommendation model cannot generate a user for a given situational context effective personalized recommendations [11–14]. Therefore, it is very important and urgent to provide personalized recommendations for mobile users in specific situations.

There are three commonly used context-aware recommendation algorithms, and they are contextual prefiltering, contextual postfiltering, and contextual modeling. In this paper, a context recommendation algorithm based on the tripartite graph is proposed for the three-dimensional model. Improving the accuracy of the recommendation by

the material diffusion, through the heat conduction to improve the diversity of the recommended objects, and balancing the accuracy and diversity through the integration of resources thus realize the personalized recommendation of users. This algorithm focuses on projects with high popularity and improves the accuracy of recommendation. The experimental results show that the proposed recommendation algorithm on the accuracy and recall evaluation index has obvious improvement in performance than the traditional recommendation algorithm.

The remainder of this paper is organized as follows: Section 2 introduces the related work. Section 3 is the description and theory of the context recommendation algorithm based on the tripartite graph model. Section 4 presents the experimental process and results. The summary of the related work of our proposed model and algorithm and the conclusion of the paper are given in Section 5.

## 2. Related Work

The most important recommendation algorithms are the collaborative filtering algorithm and the content-based recommendation algorithm. However, there are certain problems that are hard to be solved in the two basic algorithms. Therefore, accuracy of the single recommendation algorithm is difficult to improve. Many scholars have shifted their goals from traditional recommendation algorithms, focusing on the research of context-based recommendation systems.

The research direction and application fields include shopping, tourism, catering, and other aspects, but they focused on proposing improved algorithms which are based on traditional algorithms. The contrast of advantages and disadvantages of various algorithms based on context perception is relatively rare. The fields and data types applicable to different context-aware algorithms are not studied. Kang et al. proposed not only paying attention to the explicit context information, but also implicit context information. And, they used the packet sniffing technique [15]. Ohbyung Kwona and Jihoon Kim proposed a way to discover the user's portrait by depicting the user's outline tree [16]. Since 2012, related research has exploded. Dao et al. combined user preferences and contextual interaction information and proposed a location-based advertising recommendation algorithm [17]. Sánchez-Pi et al. proposed the construction of a knowledge-based context-aware system [18]. Kasaki et al. proposed a localized adaptive modification model using a vector space model and saved time to obtain user-related information [19]. Unger et al. made a breakthrough in the acquisition of contexts, improving the accuracy of recommendations by extracting implicit context information from users' data [20].

The contrast of advantages and disadvantages of various algorithms based on context perception is relatively rare. Before 2016, there were not many research studies on context-aware recommendation algorithms. Most of them focused on the research of collaborative filtering algorithms. Such research is rare. There are three commonly used context-aware recommendation approaches, and they are

contextual prefiltering, contextual postfiltering, and contextual modeling [21]. Among them, Lee et al. proposed a novel TV system that combines gesture control, tag ranking, and context awareness, providing personalized recommendations [22]. Cai et al. used collaborative filtering to generate contextual concept ontology [23]. Ji et al. proposed an improved matrix approximate based on the clustering model [24]. Wang et al. proposed a hierarchical recommendation model based on the context tree structure, calculated situation transfer in the first layer, and recommended items in the second layer [25].

In research on the context recommendation algorithm, a lot of scholars have contributed to it. Among the above existing literature studies, some only use the two-dimensional model to calculate the recommendation list. Most of the papers on the research of 3D models focus on the label-based 3D model. The research aspect is relatively narrow and limited [26–30]. In this paper, the context recommendation algorithm based on the tripartite graph model is introduced. Research is more innovative and has improved accuracy in recommendations.

## 3. User-Item-Context Tripartite Graph Model

*3.1. Tripartite Graph Model.* The context incorporation task is the process of managing and interpreting the modeled context to be directly integrated in the recommendation system. This step consists of identifying the user and his/her preferences extracted from his/her implicit and explicit interactions with the system. These preferences are sensitive to the user's context and the change from a context to another. Then, the so-called contextual profile, the user's preferences in a given context, can be defined by the tuple (user, preferences, and context). These tuples can be saved in a database and have to be regularly updated to keep track of the evolution of the user's interests.

The application of context-aware algorithms is based on context acquisition. Current technology of shallow context acquisition can already be achieved. The user's latitude and longitude position, weather conditions, time information, etc., can be obtained through mobile devices. Age, gender, and other information, but deep-level information processing is currently relatively small, such as obtaining the user's location type, time type, and deep-level context information, have a greater effect on algorithm recommendation. The current research on this type of information is mainly obtained through user surveys and is provided voluntarily by users.

The context plays an important role in the user's selection of the item. The interest of the user will also migrate due to the context. If the context is not introduced, the interest changes in different contexts are not observed. In different contexts, users may feel different for the same item. For example, people will watch action movies with friends, but they may choose other types of movies when they are with family. The traditional algorithm ignores these interest migrations, and the recommendation is not personalized enough. The three-dimensional model formed in the context

introduced in this paper is more effective in improving the limitations of the recommendation algorithm.

Among the basic graph theory algorithm, the bipartite graph is commonly used in the related network model. In the bipartite graph, there are two sets of sets  $U$  and  $I$ :

$$U = \{u_1, u_2, u_3, \dots, u_i\}, \quad (1)$$

$$I = \{i_1, i_2, i_3, \dots, i_j\}. \quad (2)$$

The recommendation of the item is realized by the bipartite graph model. We should ensure that the intersection between the two sets is an empty set and is not affected by each other. Each element in the two sets is treated as a different point in the graph, representing a two-dimensional model of the user item. The elements between the same set are not connected by edges, and the edges between different sets are connected indicating that the user likes the project, forming a binary group  $\langle u_i, i_j \rangle$ . That constitutes an undirected bipartite graph model. The bipartite graph model is shown in Figure 1.

The tripartite graph model is an upgraded version of the bipartite graph model and can be viewed as a merged version of two bipartite graphs. It includes three sets  $U$ ,  $I$ , and  $C$ , where the set  $C = \{c_1, c_2, c_3, \dots, c_k\}$ . Each set ensures that the two-two intersections are empty sets, so that the points of the three sets in the figure can be obtained. Similar to the bipartite graph model, the collections are guaranteed to be bottomless. There are two sets of two-tuple relations in the figure. There are two sets of edges connected, which are  $\langle u_i, i_j \rangle$  and  $\langle i_j, c_k \rangle$ . The former indicates that the user likes the project, and the latter indicates that the project is in a certain context. We can realize the recommendation through the three-tuple relationship. The tripartite graph model is shown in Figure 2.

Through Figures 1 and 2, the concept of the model is intuitively felt. The item acts as a transfer station, communicates with the user's information, communicates with the context information, and finally the recommended list of items is a recommendation algorithm. It is more comprehensive compared with the traditional algorithm.

### 3.2. Tripartite Graph Model Based on Mass Diffusion.

When the bipartite graph is used to obtain the recommended result, the item is associated with the user to obtain the order of the item's preferences. The commonly used algorithms are the mass diffusion algorithm and the heat conduction algorithm. It can be understood from the existing literature that the mass diffusion algorithm is energy conservation while the heat conduction algorithm is not. The two algorithms play different roles in the field of recommendation algorithms. The mass diffusion algorithm is usually likened to a convex lens, which can focus on items with high heat. The heat conduction algorithm is like a concave lens, which can focus on the item which is more unpopular, thus increasing the diversity of recommendations.

FIGURE 1: Bipartite graph model.

FIGURE 2: Tripartite graph model.

Among the results obtained, the nearest neighbor of each user is found, assuming that the choice of these nearest neighbors is related to the user's own choice. After finding the score of the target user  $u$  for the item  $i$ , the score of the most neighboring user for the item  $i$  is also found. Then, the mean of the nearest neighbors' score is calculated. If the mean value is bigger than the predicted score and the absolute value differs by more than a threshold value, the result is the predicted score adding the quotient of mean and predicted values. If the mean is equal to the prediction result or the absolute value difference is less than a threshold, no operation is performed. If the mean is smaller than the predicted score, the result is the predicted score subtracting the quotient of mean and predicted values.

The energy of each item is shown in the following equation:

$$c_{i,j} = \begin{cases} 1, & \text{user likes it,} \\ 0, & \text{user does not like it.} \end{cases} \quad (3)$$

According to the historical behavior of the user, the user's preference for the item is obtained. One means that the user likes the item, and zero means dislike. The total number of items preferred by the user is the total energy in the algorithm.

The first step of diffusion is from the item to the user. The user obtains energy from the item, and the item spreads the energy to the user by equally distributing the energy of each item to each purchased user. The energy obtained by the user is shown in the following equation:

$$b_\alpha = \sum_{l=1}^n a_{\alpha l} \left( \frac{c_l}{k(O_l)} \right), \quad (4)$$

in which  $k(O_l) = \sum_{i=1}^m a_{il}$  represents the degree of the item and  $c_l$  represents the initial energy possessed by the item. The energy value owned by each user is obtained by one-step diffusion, and then the second step is performed.

The second step of diffusion is from the user to the item, which distributes the user's energy equally to the related items, and each item sums the collected energy to obtain the total energy, as shown in the following equation:

$$c'_j = \sum_{\alpha=1}^m a_{\alpha j} \left( \frac{b_\alpha}{k(U_\alpha)} \right), \quad (5)$$

in which  $k(U_\alpha) = \sum_{j=1}^n a_{\alpha j}$  represents the degree of the user and  $b_\alpha$  is the energy obtained by the user as described above. One of the recommended coefficients of the model is obtained by averaging the energy obtained in the first step by the second material diffusion.

In the bipartite graph, the elements in the figure have been replaced, but the idea of the bipartite method has not changed. Two-step diffusion is used to generate the recommended probability. The first step is to spread from the item to the context. The initial energy is related to whether the user likes the item. One means that the user likes the item, and zero means dislike. According to the relationship between the context and the item, the energy of the item is evenly distributed. For each occurrence of the context, the energy obtained by each context is the sum of the energy allocated to all related items.

$$d_\beta = \sum_{h=1}^p a_{\beta h} \left( \frac{c_h}{k(S_\beta)} \right), \quad (6)$$

in which  $k(S_\beta) = \sum_{k=1}^q a_{\beta k}$  represents the degree of the context,  $c_h$  represents the initial energy possessed by the item, and  $c_h$  and  $c_j$  correspond to each other. The equation represents the energy of each context. The energy value of the context is obtained by the diffusion of the first step, and then the second step is still required to spread.

The second step is from the context of the item. Like the first step, the energy obtained by the context is divided into all the items, and the energy of each item is accumulated and obtained:

$$c'_t = \sum_{\beta=1}^q a_{\beta t} \left( \frac{d_\beta}{k(F_t)} \right), \quad (7)$$

in which  $k(F_t) = \sum_{i=1}^p a_{\beta t}$  represents the degree of the item and  $d_\beta$  represents the energy value obtained by the context. In the second diffusion, the average value of the energy obtained from the previous diffusion is obtained.

It can be seen from Figure 3 that by processing of the tripartite graph model based on mass diffusion, the recommendation value of the items can be calculated and the recommendation sequence can be obtained. The recommendation sequence is  $\{i_3, i_2, i_5, i_1, i_4\}$ .

### 3.3. Tripartite Graph Model Based on Heat Reduction.

This section discusses the heat conduction method. As mentioned earlier, the heat conduction method is a divergent method that recommends unpopular items for users to increase the diversity of recommendations. Like the tripartite graph model based on mass diffusion, this model is divided into two bipartite graphs, and two heat conduction methods are used, respectively. Finally, the values of the two graphs are fused to obtain the coefficients recommended by the model.

The energy of each item is in the same way as mentioned above:

$$c_{i,j} = \begin{cases} 1, & \text{user likes it,} \\ 0, & \text{user does not like it.} \end{cases} \quad (8)$$

According to the user's historical behavior, the user's preference for the item is obtained. One means that the user likes the item, and zero means dislike. The total energy in the heat conduction method is not conserved.

Similarly, the first step of conduction is from the item to the user. The user obtains the temperature of the item, and the item transmits the temperature of the user. The method of transferring the temperature is to divide the sum of the temperature of the user's favorite item by the degree of the user, and the temperature obtained by the user is as the following equation:

$$b_\alpha = \sum_{l=1}^n \frac{a_{\alpha l} c_l}{k(U_\alpha)}, \quad (9)$$

in which  $k(U_\alpha) = \sum_{j=1}^n a_{\alpha j}$  represents the degree of the user and  $c_l$  represents the initial temperature possessed by the item. The temperature possessed by each user is obtained by the first step of conduction, followed by the second step of conduction.

The second step of conduction is from the user to the item. The temperature of each item is the sum of the temperatures of all users who like it divided by the degree of the item:

$$t'_j = \sum_{\alpha=1}^m \frac{a_{\alpha j} b_\alpha}{k(O_j)}, \quad (10)$$

in which  $k(O_j) = \sum_{i=1}^m a_{ij}$  represents the degree of the user and  $b_\alpha$  is the temperature obtained by the user as described above. Through the second step of heat conduction, the average temperature value is obtained; that is, the obtained

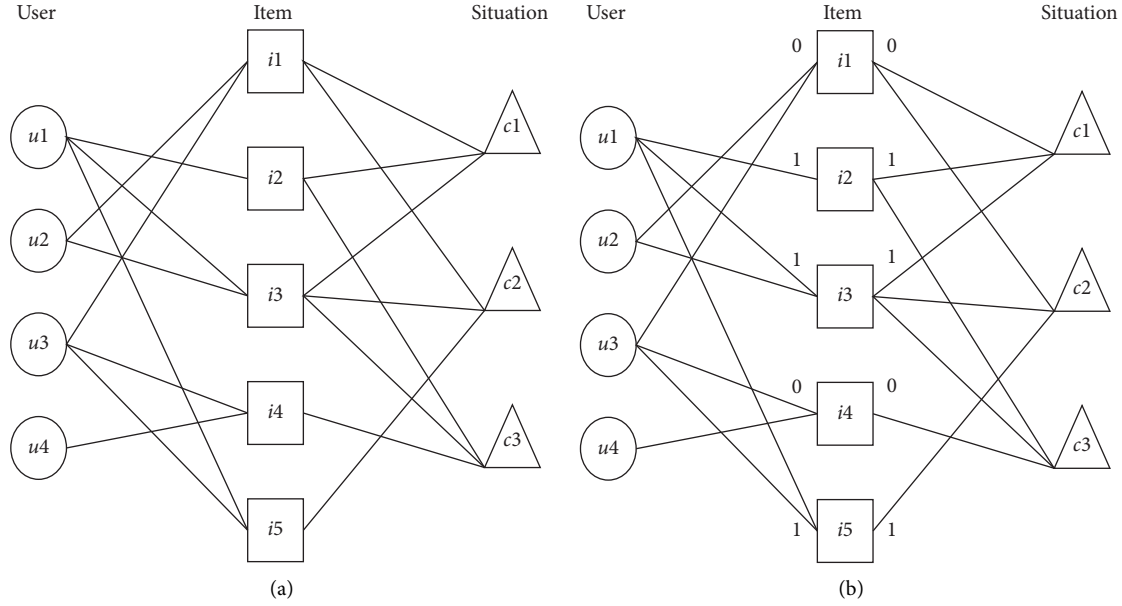

FIGURE 3: Processing of the tripartite graph model based on mass diffusion.

particle temperature value is one of the recommended coefficients of the heat conduction method.

The tripartite graph division method based on the heat conduction method is consistent with the material diffusion. For the item-context bipartite graph, the temperature of the calculated context is the sum of the associated item temperatures divided by the context:

$$d_{\beta} = \sum_{h=1}^p \frac{a_{\beta h} c_h}{k(F_t)}, \quad (11)$$

in which  $k(F_t) = \sum_{t=1}^p a_{\beta t}$  represents the degree of the context,  $c_h$  represents the initial temperature possessed by the item, and  $c_h$  and  $c_j$  correspond to each other. The equation represents the temperature of each context. The temperature of the context is obtained by the first step of conduction, and the second step is to conduct the temperature on the article.

The second step is to get the temperature of the item from the context of the item and divide the temperature of the context associated with the item with the degree of the item:

$$t'_k = \sum_{\beta=1}^q \frac{a_{\beta k} d_{\beta}}{k(S_{\beta})}, \quad (12)$$

in which  $k(S_{\beta}) = \sum_{k=1}^q a_{\beta k}$  represents the degree of the item and  $d_{\beta}$  represents the temperature obtained by the context. In the second conduction, the energy value obtained from the previous diffusion is averaged to obtain another recommendation coefficient.

Processing of the tripartite graph based on heat conduction is shown in Figure 4. Processing of the tripartite graph based on heat conduction is that nodes absorb resources from their adjacent nodes according to the number of adjacent nodes and the ratio of edge weight. After the

tripartite graph is divided into two bipartite graphs, the two recommended coefficients are obtained. In order to obtain the final recommendation coefficient, the average of the recommended coefficients obtained by the two is taken as the final recommendation coefficient:

$$E' = \frac{t'_j t'_k}{2}. \quad (13)$$

**3.4. Mixed Model.** The mass diffusion method and the heat conduction method are different in the recommendation system to improve the recommendation effect. The mass diffusion method focuses on improving the accuracy of the recommendation and the items with high popularity. The heat conduction method focuses on improving the diversity of recommendations. Therefore, the combination of the two methods is also a factor that is often considered, with the goal of ensuring accuracy and increasing the diversity of recommendations.

When mixing the two methods, it is usually a linear blending. We set the parameter  $\lambda$ , introducing parameters on the original three-part graph model, and construct a hybrid model:

$$e = \lambda E + (1 - \lambda) E'. \quad (14)$$

It is a common method in the hybrid model to change the value of the parameter  $\lambda$  to achieve the optimal effect of the model. In this paper, the influence of different parameter values on the model will also be explored.

## 4. Experiment Analysis

The hardware environment of this experiment is Intel Core i5 processor, 8G memory. The software environment is 64-bit Windows operating system, VMware Workstation Pro

FIGURE 4: Processing of the tripartite graph based on heat conduction.

Virtual Machine, CentOS7 operating system, Open JDK1.8, Python3.7, and Anaconda for Python3.7.

The data of this experiment are mainly from the questionnaire survey of college students' movie-watching context. A total of 107 users' data are collected. In order to ensure the accuracy of the data, they are not excessively sparse. Some invalid questionnaires are eliminated. The data of 96 users were retained, including 2145 data.

In this experiment, the original data set is about the user's rating of the item, and the score range is 1–10 points. User's rating reflects the user's satisfaction with the item. The recommendation algorithm should refer to this satisfaction.

As shown in Figure 5, user A and user B scored item 1, but the score is completely different. So, the similarity between users is very low. Therefore, when the tripartite graph model is established, only the items that the user likes are selected. The connection line between the user and the item indicates that the user prefers an item above a certain rating range.

The evaluation parameters used in this experiment are a standard for evaluating the quality of the recommended results. The precision of the recommended results and the recall rate are used. Precision measures the proportion of recommended items that result relevant to the users, that is, those recommended items that the user actually consumes. Recall measures the proportion of consumed items that were correctly recommended; that is, the fraction of items relevant to the user that was suggested by the system. Recall and precision are usually considered together as two facets of the quality of the recommendation. The recall and precision are given as follows:

$$\text{precision} = \frac{\text{hits}}{\text{items\_relevant}}, \quad (15)$$

$$\text{recall} = \frac{\text{hits}}{\text{items\_recommended}}, \quad (16)$$

where *hits* are the number of correct recommendations, *items\_relevant* is the number of all possible items that can be recommended for a given user, and *items\_recommended* is the number of items recommended to a user. The precision and the recall rate are between 0 and 1. The closer it is to 1, the better the effect of the recommendation algorithm is. Closer to 0 indicates that the recommended effect of the recommendation algorithm is very poor.

This article also uses novelty to judge the novelty of an item:

$$\text{novelty} = \frac{\sum_{i=1}^m p(i)}{l}, \quad (17)$$

in which  $p(i)$  represents the degree of the item in the recommendation list and  $l$  represents the length of the recommendation list. In this paper, the average popularity is used to represent the novelty, and the smaller the value, the more novel the item.

The original data of this experiment are about the user's score on the movie in some contexts. It is converted into the connection between the user and the item, the item and the context, and the connection between the user and the item. We establish the connection between the item and the context, and the form is shown in Table 1.

If the users give the item with rate greater than or equal to 8, we consider the users to be very fond of the items. Based on this rule to establish the connection between the users and the items, as well as the connection between items and context, the total number of filtered data is 1451. Some relevant predictions are made for these data. For this experiment, two control experiments were set up to determine the precision and recall rate under the collaborative filtering algorithm and the user-item bipartite graph algorithm and compare the results of the algorithm.

FIGURE 5: The score of items.

TABLE 1: The items that users prefer (part).

|    | User_id | Movie_id | S_id | Score |
|----|---------|----------|------|-------|
| 0  | 1101    | 2102     | 20.0 | 8.0   |
| 3  | 1101    | 2110     | 13.0 | 8.0   |
| 4  | 1101    | 2113     | 10.0 | 10.0  |
| 5  | 1101    | 2115     | 10.0 | 10.0  |
| 6  | 1101    | 2116     | 5.0  | 8.0   |
| 8  | 1101    | 2120     | 13.0 | 9.0   |
| 9  | 1101    | 2121     | 13.0 | 8.0   |
| 11 | 1101    | 2125     | 7.0  | 9.0   |
| 17 | 1101    | 2132     | 13.0 | 9.0   |
| 19 | 1101    | 2135     | 21.0 | 9.0   |
| 20 | 1101    | 2136     | 13.0 | 8.0   |
| 21 | 1101    | 2137     | 19.0 | 8.0   |

FIGURE 6: Continued.

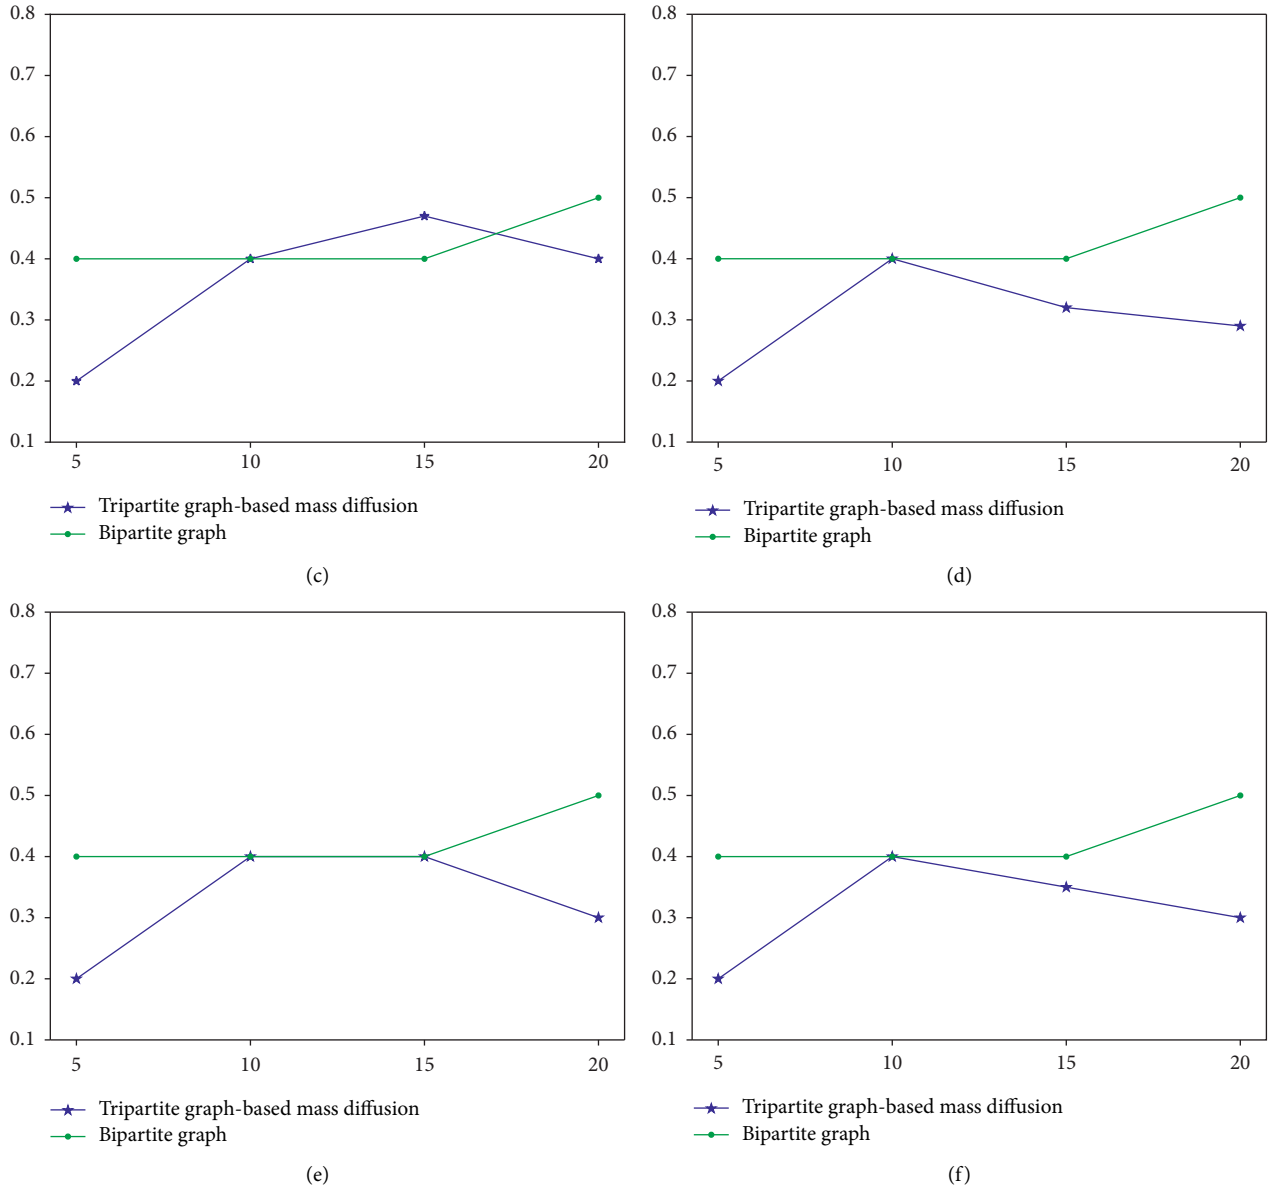

FIGURE 6: Precision of the hybrid model algorithm.

In the experiment, the user 1101 is taken as an example. The movie is recommended to be selected under the contexts 1, 5, 9, 13, 17, and 21, and 5, 10, 15, and 20 different movies are recommended, respectively. The comparison result of the accuracy rate and the recall rate is shown in Figures 6 and 7.

We calculate the novelty of the recommendation. The calculation base of the novelty is 20 when the recommended item is as shown in Table 2.

It can be seen from the comparison of the experimental results that in the experimental data set, the performance of the algorithm is not excellent enough. The precision rate is less reduced, and the recall rate is also somewhat reduced. When the recommended number of items is 10, the precision and recall rate of the algorithm are optimal.

Meanwhile, the novelty has also improved. Compared with the bipartite map recommendation algorithm, the items recommended by the three maps are more novel.

After the experiment, the precision and recall rate of the tripartite graph model based on heat conduction are almost zero, and the novelty is very high. Due to the divergence of the algorithm, the items focused on the unpopular, and the recommended results are not in line with actual needs, nor suitable for this data set.

In the hybrid algorithm, several of the mixed parameters are selected, which are 0.1, 0.3, 0.5, 0.7, and 0.9. We calculate the accuracy, recall, and novelty for each result as shown in Table 3.

The performance of the hybrid model algorithm has basically stabilized when the value of  $\lambda$  is greater than 0.5.

FIGURE 7: Recall of the hybrid model algorithm.

TABLE 2: Comparison of novelty.

|                  | 1     | 5     | 9    | 13    | 17    | 21    |
|------------------|-------|-------|------|-------|-------|-------|
| Bipartite graph  |       |       |      | 42.15 |       |       |
| Tripartite graph | 41.65 | 39.05 | 40.5 | 39.05 | 41.35 | 39.85 |

TABLE 3: Mixed model.

|           | 0.1    | 0.3    | 0.5   | 0.7   | 0.9   |
|-----------|--------|--------|-------|-------|-------|
| Precision | 0.1    | 0.2    | 0.3   | 0.3   | 0.3   |
| Recall    | 0.0714 | 0.1428 | 0.214 | 0.214 | 0.214 |
| Novelty   | 15.4   | 28.05  | 34.45 | 39.05 | 39.05 |

The change of parameters has little change on the algorithm result. The novelty shrinks as the parameter increases, and the accuracy increases as the parameter increases.

## 5. Conclusion

In this paper, to solve the problem of complex contexts, a new context recommendation algorithm based on the tripartite graph model is proposed for the three-dimensional model in complex systems. This algorithm focuses on projects with high popularity and improves the accuracy of recommendation. The range of recommended results is very narrow. Part of the reason is that the number of items in the data set is not large, and the recommendation results are not obvious. There is an urgent need to improve. And, the most popular items should be given some punishment mechanisms to enable more user interest. However, the novelty of the algorithm is slightly improved, and the performance of the algorithm tends to be stable after the model parameters reach a certain value [5–14, 26–30].

In this paper, the environmental control system of aircraft driven by a power turbine is further analyzed. Through the numerical simulation of the change of the bleed state under different flight conditions and the change of the flow field under different nozzle opening, the simulation results are verified by the experimental results, and the specific change rules of the power turbine output torque, power, and bleed flow are obtained. It is analyzed quantitatively that adjusting the adjustable nozzle ring can keep the output power stable, widen the flight envelope, and improve the stability of the environmental control system.

## 1. Introduction

The main purpose of the aircraft environmental control system is to provide comfortable environmental conditions for airborne personnel and electronic equipment. By controlling the pressure, humidity, and temperature in the cabin, the environmental control system makes the system environment in the comfortable range of the human body and ensures that the electronic equipment always works within the allowable temperature range. According to the research, the traditional environmental control system needs a lot of nonpropulsion energy from the engine, and the high-temperature and high-pressure gas produced by the engine compressor is used to drive the environmental control system. At present, in order to use energy more efficiently and economically, further system optimization of the environmental control system has become a research hotspot [1, 2]. At present, there are many methods proposed by researchers but mainly focus on the following two directions:

(1) Continue to drive the environmental control system by bleed air from the engine compressor. Improve the performance of components or use power turbine to replace the traditional air entrainment method, so as to reduce energy waste [3].

(2) By building multielectric or all-electric aircraft, use as much electricity as possible to drive equipment on the aircraft. According to the thermal load and pressure requirements of the cabin, the environmental control system adjusts the motor to control the compressor pressure ratio to obtain the appropriate air supply temperature and pressure. The environment control system with all-electric drive works more stably and the comfort of passengers is improved significantly. At the same time, the all-electric environmental control system does not need to draw air from the engine compressor, so it will not affect the engine performance [4].

In the flight energy-saving design, the overall system optimization is very important because the single subsystem optimization cannot get the optimal solution, so in 2008, the United States launched the integrated aircraft energy technology project [5]. In the INVENT program, the concept of F-35 adaptive power supply and thermal management system (APTMS) was proposed. APTMS improves emissions by using exhaust gas from power turbines and engine compressors. The gas from these engine compressors is directly discharged after expanding and working in the power turbine. The environmental control system driven by

the power turbine was first verified on the F-15 fighter [6, 7]. The original F-15 environmental control system was an open-air circulation refrigeration system, driven by the bleed air from the engine compressor. The main difference between the F-15 and F-35 environmental control systems is the treatment of the gas leaving the power turbine [8]. The gas discharged from the power turbine of F-15 needs to enter the engine room for refrigeration; because of the requirements of the cabin pressure system, the expansion ratio of the power turbine will be relatively small. The power turbine of F-35 directly releases the gas into the external atmosphere and obtains the maximum expansion ratio and power. When the engine compressor bleed parameters are identical, the power turbine of F-35 will output more work.

Adjustable nozzle ring turbines are currently mainly used in variable geometry turbochargers for automobiles. The variable geometry supercharger can continuously adjust the effective flow cross-sectional area of the turbine inlet according to the engine operating conditions, change the turbine inlet airflow parameters, and then change the supercharging pressure, so as to achieve a good match between the supercharger and the engine and also improve the engine transient responsiveness, reducing transient emissions. Compared with the operating characteristics of the variable geometry turbocharger and the traditional supercharger, the former is more efficient and economical in the entire flow range. Improving the adaptability of the turbine under variable operating conditions is a popular direction for the development of turbine technology. However, at present, there are few studies on power turbines using variable nozzle replacement used in aircraft environmental control systems [5]. This paper further studies the dynamic performance of the power turbine in the aircraft environmental control system after the variable nozzle ring is used and the change rule of the variable nozzle ring when the bleed air pressure and temperature change.

## 2. System Analysis

The environmental control system (Figure 1) in which the power turbine is located is an improved three-wheel high-pressure water removal system (Figure 2) [9]. The environmental control system directly introduces the engine bleed gas into the power turbine, which is directly discharged into the ambient atmosphere after the gas expansion work, and the power turbine directly outputs the shaft work to the turbine compressor assembly [10]. Fresh gas is pumped directly from the surrounding atmosphere by the compressor and supplied to the cabin.

In the traditional environmental control system, after the air is discharged from the engine, the absolute pressure regulator is needed to control the pressure, and the temperature of the future gas passing through the precooler is controlled within a certain range [11]. This process wastes a lot of energy. The environmental control system driven by the power turbine exhausts air directly from the engine, thus eliminating the need for precooler and absolute pressure regulator, which not only realizes the full utilization of energy but also reduces the weight of the system [12].

The bleed pressure and temperature of the engine will change with the flight state. When the bleed state changes, the performance of the power turbine can be controlled by adjusting the opening of the variable nozzle ring, so as to ensure that the output power and torque of the power turbine remain unchanged, so as to isolate the influence of the change of engine operating state on the environmental control system. More importantly, in low altitude or ground operation, because of the low bleed pressure, the system can be operated normally in a larger flight envelope by adjusting the nozzle to obtain a larger starting torque.

This paper calculates the torque, mass flow, and power of the power turbine in the flight curve based on the engine operating parameters of a certain type of flight. When the flight state changes, the torque, mass flow rate, and power change and the adjustment of nozzle opening are calculated. The flight profile used in the calculation is shown in Figure 3.

## 3. Calculation Model

The blades of the nozzle ring are usually modeled using aerodynamic blades, linear blades, and wing blades. Among them, the pneumatic blade has the largest flow range and the highest aerodynamic efficiency, but the manufacturing process is complex and the blade width is small, which is not conducive to the installation of the rotating shaft [13]. In this paper, NACA0065 symmetric airfoil blades are used in the nozzle ring of the power turbine. The basic parameter model of the power turbine is shown in Table 1, and the three-dimensional model of the turbine and nozzle ring is shown in Figures 4 and 5.

The power turbine uses gas expansion to output torque and power, which drives the load on the shaft to work together. When the turbine is started from a standstill, the torque generated by the gas impact and the friction torque of the bearing must satisfy the following relationship [14]:

$$M_t > M_l, \quad (1)$$

where  $M_t$  is the torque of the power turbine and  $M_l$  is the drag torque of the system to the turbine.

The rotation equation of the power turbine is

$$I_c \frac{d^2\theta}{dt^2} = \Sigma M_z, \quad (2)$$

where  $I_c$  is the total moment of inertia and  $\Sigma M_z$  is the total external torque received by the power turbine, including the gas generating torque and the external load and friction torque.

## 4. Simulation Parameters

*4.1. Simulation Model and Meshing.* This article uses ANSYS ICEM software to model and mesh the power turbine in three dimensions. As shown in Figure 6, the model is divided into three parts: a volute, a diffuser, and a blade, and the interface is used as an interface to connect the three models.

In FLUENT, the dynamic numerical simulation of the power turbine is carried out using the sliding grid method.

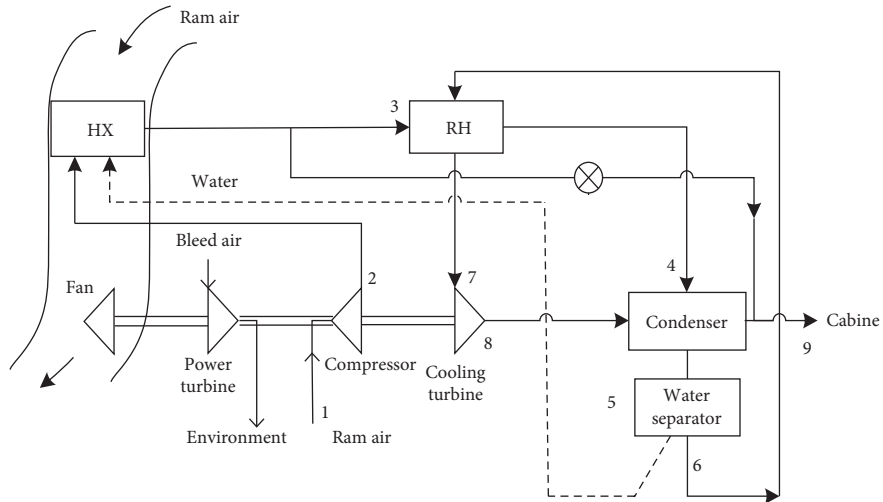

FIGURE 1: Environment control system driven by a power turbine.

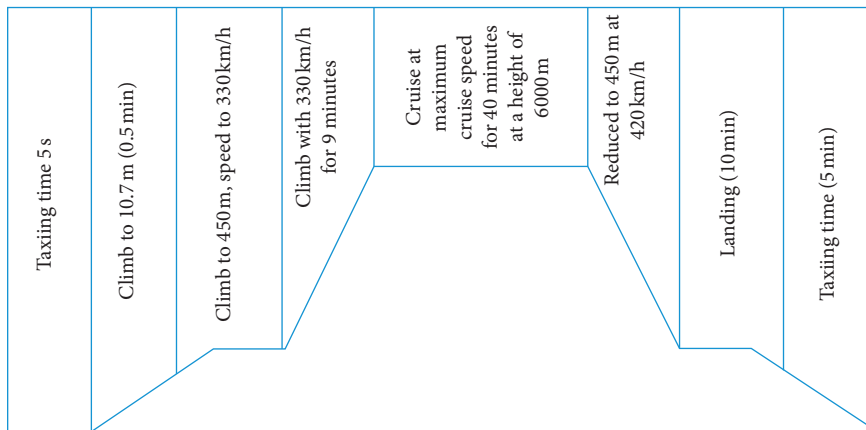

FIGURE 3: Typical mission profile.

TABLE 1: Basic parameters of the power turbine.

| Parameter                             | Value | Parameter                        | Value |
|---------------------------------------|-------|----------------------------------|-------|
| Impeller blade number $Z_i$           | 16    | Nozzle inner diameter $D_{1n}$   | 99    |
| Nozzle ring outlet blade height $I_n$ | 5.2   | Nozzle throat width $b_n$        | 4.5   |
| Impeller outlet hub diameter $D_{2h}$ | 24    | Impeller exit blade height $I_2$ | 14    |

FIGURE 4: Power turbine.

FIGURE 6: Power turbine.

FIGURE 5: Variable area nozzle.

FIGURE 7: Three-dimensional modeling.

In order to obtain better simulation results, the first-order steady-state method is used for calculation, and then it is converted to second-order dynamic calculation after convergence.

The number of power turbine model grids is large, and the convergence speed is slow when using parallel computing in FLUENT. In order to efficiently obtain the performance of the power turbine with different variable nozzle ring openings, the geometric model of the power turbine must be simplified. The common method is to ignore the influence of the intake volute and use the turbine single-flow model to mesh. In this paper, the optimization calculation model uses the 1/4 periodic flow channel model of the power turbine for calculation. 1/4 nozzle ring model and impeller model are selected, and the number of grids is about 700,000 for calculation. The number of corresponding nozzle ring blades in the 1/4 flow channel model is 4 and the number of impeller blades is 4, as shown in Figure 7. Figure 8 is the mesh file inside the runner after the nozzle ring grid and the impeller grid are stitched together. When setting the boundary conditions in FLUENT, the main difference between the 1/4-channel power turbine model and the complete machine model is that the former requires a closed geometric model by adding periodic boundaries in the flow area at the left and right boundaries of the channel. The

FIGURE 8: Grid model.

boundary attribute of the nozzle ring was changed to the pressure inlet, and the definition of the remaining boundary conditions was consistent with the fluent numerical simulation of the whole machine.

**4.2. Turbulence Model.** The SA model is complete, and the turbulence scale in the model is automatically defined, and no specific flow is required to adjust the closure constant. The effect is better in the prediction of far wake and mixed laminar flow, boundary layer flow, backward step flow and

airfoil flow with small separation. In general, the SA model is more suitable for engineering applications, especially in the airfoil and impeller applications. The SA model is used for calculation in this paper:

$$\begin{aligned} \frac{\partial \tilde{\nu}}{\partial t} &= C_{b1} [1 - f_{t2}] \tilde{S} \tilde{\nu} \\ &+ \frac{1}{\sigma} \left[ \nabla \cdot ((\nu + \tilde{\nu}) \nabla \tilde{\nu}) + C_{b2} (\nabla \tilde{\nu})^2 \right] \\ &- \left( C_{w1} f_w - \frac{C_{b1}}{k^2} f_{t2} \right) \left( \frac{\tilde{\nu}}{d} \right)^2 + f_{t1} \Delta U^2. \end{aligned} \quad (3)$$

The turbulent viscosity coefficient  $\mu_T$  is calculated by the following formula:

$$\mu_T = \rho \tilde{\nu} f_{v1}, \quad (4)$$

$$f_{v1} = \frac{\chi^3}{\chi^3 + C_{v1}^3}, \quad (5)$$

$$\chi = \frac{\tilde{\nu}}{\nu}. \quad (6)$$

$\nu$  is the viscosity coefficient of molecular motion and the generated term is

$$\tilde{S} = \Omega + \frac{\tilde{\nu} f_{v2}}{\kappa^2 d^2}, \quad (7)$$

$$f_{v2} = 1 - \frac{\chi}{1 + \chi f_{v1}}, \quad (8)$$

$$\Omega = \sqrt{\left( \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right)^2 + \left( \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right)^2 + \left( \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right)^2}, \quad (9)$$

where  $\Omega$  is the vorticity.

The function  $f_w$  is defined as

$$f_w \equiv g \left[ \frac{1 + C_{w3}^6}{g^6 + C_{w3}^6} \right]^{1/6}, \quad (10)$$

$$g = r + C_{w2} (r^6 - r), \quad (11)$$

$$r = \frac{\tilde{\nu}}{\kappa^2 d^2 \tilde{S}}. \quad (12)$$

The function  $f_{t1}$  is defined as

$$f_{t1} = C_{t1} g_t \exp \left[ -C_{t2} \frac{\omega_t^2}{\Delta U^2} (d^2 + g_t^2 d_t^2) \right], \quad (13)$$

$$g_t = \min \left( 0.1, \frac{\Delta U}{\omega_t \Delta x_i} \right), \quad (14)$$

where  $d$  is the shortest distance of the solid wall.

The function  $f_{t2}$  is defined as

$$f_{t2} = C_{t3} \exp(-C_{t4} \chi^2). \quad (15)$$

Constant values in model equations are

$$\kappa = 0.41,$$

$$C_{b1} = 0.1355,$$

$$C_{b2} = 0.622,$$

$$\sigma = \frac{2}{3},$$

$$C_{v1} = 7.1,$$

$$C_{w1} = 3.239,$$

$$C_{w2} = 0.3,$$

$$C_{w3} = 2,$$

$$C_{t1} = 1,$$

$$C_{t2} = 2,$$

$$C_{t3} = 1.1,$$

$$C_{t4} = 2. \quad (16)$$

**4.3. Parameter Settings.** Set the nozzle ring installation angle to  $12^\circ$  and the number of nozzle ring blades to 16. The change of the nozzle ring blade opening degree “+” means that the nozzle ring is closed and the flow rate decreases; the nozzle ring blade opening degree change “-” means that the nozzle ring is open and the flow rate increases. There are 7 calculation states of nozzle ring opening:  $+10^\circ + 6^\circ + 8^\circ + 3^\circ, 0^\circ, -3^\circ, -6^\circ$ , of which  $0^\circ$  is the design state, as shown in Figure 9.

The inlet pressure in FLUENT is set to 3 bar, 3.5 bar, 4 bar, 4.5 bar, and 5 bar and the outlet pressure is set to 1 bar. The starting torque received by the impeller is calculated by udf.

**4.4. Grid Independence Verification.** Table 2 can be drawn; when the number of grids is 3 million, the calculated value of the turbine efficiency is very different from the calculated value by the number of grids 4 million and 5 million. After the number of grids exceeds 4 million, the increase in the number of grids has little effect on the power turbine efficiency. It is considered that the 4 million grids have reached grid independence.

Using the same data, perform a numerical simulation on the 1/4-channel power turbine model and compare the calculation results with the numerical simulation results of the whole machine as shown in Table 3. It can be seen that the difference between the calculation results of the flow rate and efficiency between the two is very small. In the numerical simulation, the calculation result of the 1/4 flow channel can be approximately used as the numerical simulation result of the power turbine.

**4.5. Experimental Program.** Figure 10 is a traditional 3-wheel environmental control system, consisting of a turbo compressor, an electric compressor, and a radiator. The pressure

sensor and temperature sensor measure the temperature and pressure of the inlet and outlet of the turbine and compressor and calculate the efficiency of its various components. As shown in Figures 10–13, the high-temperature and high-pressure gas obtained by simulating the engine bleed air is simulated by an electric compressor, and the inlet and outlet temperatures and pressures of the power turbine are measured using pressure sensors and thermocouples, respectively, to calculate the efficiency of the power turbine. The experimental value is compared with the simulation value to verify the rationality of the simulation result [15, 16]. The accuracy of the absolute pressure sensor is 2%, the accuracy of the thermocouple is  $\pm 0.5^\circ\text{C}$ , the turbine inlet pressure is usually above 200 kPa, the temperature is  $30^\circ\text{C}$ – $200^\circ\text{C}$ , the outlet is directly connected to the atmosphere, the pressure is about

100 kPa, and the temperature drop is usually  $40^\circ\text{C}$  above. The accuracy of the experimental instrument is sufficient to meet the experimental requirements.

## 5. Results and Discussion

**5.1. Experimental Results.** It can be seen from Table 4 that the simulation value is slightly higher than the experimental value by about 5%, which may be because the simulation model does not consider the efficiency reduction caused by the heat conduction of the air introduction pipe and the shell itself. The simulation value and the experimental value are basically consistent, so the aerodynamic force should be basically consistent with the actual situation.

### 5.2. Simulation Results

**5.2.1. Flow Field Analysis.** Figures 14–17 are the static pressure distribution of the gas at the nozzle ring blade height of 50% when the nozzle ring blade openings are  $+3^\circ$ ,  $0^\circ$ ,  $-3^\circ$ , and  $-6^\circ$ , respectively. It can be seen from the figure that, in the case of the four middle openings, the low-pressure area obviously appears at the position of the maximum curvature of the suction surface of the blade, and the position of the maximum load of the blade does not change. During the change of the nozzle ring opening from  $-6^\circ$  to  $+3^\circ$ , the pressure value in the center of the low-pressure area is continuously decreasing, which also causes the nozzle ring blade outlet pressure value to continuously decrease, which is consistent with the calculated nozzle ring outlet static pressure data match.

The total pressure cloud at the nozzle ring blade height of 50% is shown in Figures 18–21. It can be seen from the figure that the total pressure loss at the nozzle ring outlet is significantly larger at  $+3^\circ$ , including  $0^\circ$ ,  $-3^\circ$ , and  $-6^\circ$ . In this case, the total pressure loss is not obvious, and the change of the airflow angle of the nozzle ring blade outlet causes the loss of turbine efficiency.

The Mach number at the nozzle ring blade height of 50% is shown in Figures 22–25. The nozzle ring flow channel is a convergent flow channel. At  $+3^\circ$ ,  $0^\circ$ , and  $-3^\circ$ , the suction surface curvature is at the maximum position at the nozzle ring blade height of 50% (low-pressure area). There is a local supersonic area, which is not present at  $-6^\circ$ . The presence of a local supersonic zone will affect the uniformity of the flow in the flow field and have a certain effect on turbine efficiency.

When the nozzle ring blade opening is  $+3^\circ$ ,  $0^\circ$ ,  $-3^\circ$ , and  $-6^\circ$ , the impeller blade efficiency distribution is 0.897, 0.900, 0.894, and 0.878, which is consistent with the change trend of turbine efficiency. The static pressure cloud diagram of the long blade of the impeller is shown in Figures 26–29. It can be seen from the figure that there is a significant reverse pressure gradient area at the outlet of the impeller flow channel. As the nozzle ring blades rotate from positive opening to negative opening, the reverse pressure gradient at the outlet of the impeller flow path becomes weaker, and the pressure distribution is more uniform. In the process of changing the opening of the nozzle ring, the decrease in the efficiency of the impeller is much greater than that of the nozzle ring. The main reason is that the opening angle of the nozzle ring blades causes the inlet angle of

TABLE 4: The adiabatic efficiency of the turbine in different states.

| Inlet static pressure (kPa) | Inlet static temperature (K) | Expansion ratio | Adiabatic efficiency |                  | Error (%) |

FIGURE 17: Opening  $-6^\circ$ .FIGURE 20: Opening  $-3^\circ$ .FIGURE 18: Opening  $+3^\circ$ .FIGURE 21: Opening  $-6^\circ$ .FIGURE 19: Opening  $0^\circ$ .FIGURE 22: Opening  $+3^\circ$ .

the airflow into the impeller to change significantly and because the nozzle ring blades can rotate, the gap between the nozzle ring and the impeller blades is slightly larger than that of the fixed nozzle ring turbine. The occurrence of divergence is also one of the important reasons for the decrease in the efficiency of the impeller.

**5.2.2. Torque.** As shown in Figures 30 and 31, when the inlet pressure of the power turbine is low, a larger starting torque can be obtained by opening the opening of the nozzle ring, thereby realizing the purpose of expanding

FIGURE 23: Opening  $0^\circ$ .

FIGURE 26: Opening  $+3^\circ$ .

FIGURE 24: Opening  $-3^\circ$ .

FIGURE 27: Opening  $0^\circ$ .

FIGURE 25: Opening  $-6^\circ$ .

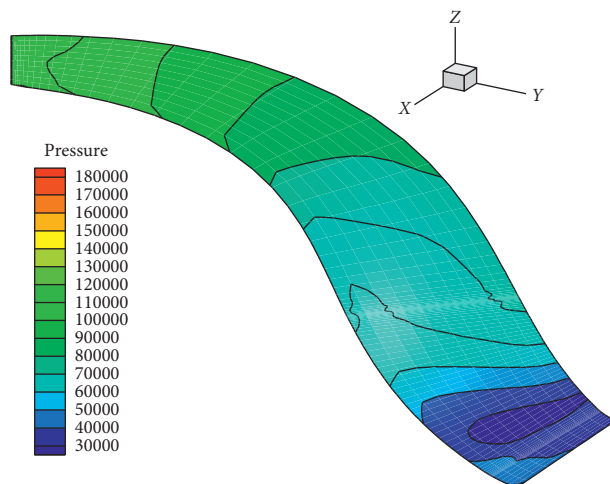

FIGURE 28: Opening  $-3^\circ$ .

the operating envelope of the system. Increasing the opening of the nozzle ring expands the system flow rate at the same inlet pressure, thereby obtaining more output torque. When the inlet pressure of the power turbine is too high, the opening of the nozzle ring can be reduced, and the system flow can be reduced, so that the torque

output by the power turbine is unchanged, and the smooth operation of the environmental control system is ensured.

FIGURE 29: Opening  $-6^\circ$ .

FIGURE 34: Relationship between opening and power.

FIGURE 35: Relationship between opening and torque.

FIGURE 37: Relationship between opening and power.

FIGURE 36: Relationship between opening and flow.

FIGURE 38: Relationship between opening and load.

5.2.3. *Constant Load and Inlet Pressure Change.* As shown in Figures 32–34, when the flight status of the aircraft changes, the bleed air pressure of the engine will change accordingly. If the opening of the nozzle ring is kept unchanged, the power and torque output by the power turbine will also change accordingly. In order to maintain the stable operation of the environmental control system, the output power and torque of the power turbine can be adjusted by increasing or decreasing the opening of the variable nozzle ring.

5.2.4. *Constant Load Change and the Inlet Temperature Changes.* As shown in Figures 35–37, when the inlet temperature of the power turbine changes, adjusting the opening of the variable nozzle can reduce the output power to match the load, thereby reducing the impact of the change in the engine bleed state on the environmental control system.

5.2.5. *Load Change and the Inlet Constant.* As shown in Figure 38, when the nozzle ring opening is changed from +0 to +6, the power can be increased by 25%, 21%, 18.1%, 15%, 12.4%, and 12.9%. When the nozzle ring opening is changed from +0 to -3, the power can be reduced by 16.5%, 15.7%, 15%, 13%, 12.1%, and 10.9%.

## 6. Conclusion

The power turbine with an adjustable nozzle ring structure can control the amount of engine bleed air according to the power required by the environmental control system. According to the flight profile, the calculated air intake of the

power turbine is significantly smaller than that of the existing aircraft environmental control system. In addition, the environmental control system can be started at a lower bleed pressure, which expands the operating envelope of the system. Therefore, a power turbine with an adjustable nozzle ring structure has the following characteristics. (1) The air circulation system driven by a power turbine with an adjustable nozzle ring structure can freely adjust the amount of bleed air according to the load, reduce fuel compensation, and realize the full use of energy. (2) The opening of the turbine nozzle can be increased or decreased to reduce the starting pressure of the power turbine and expand the range of use of the environmental control system. (3) And through the numerical simulation of the power turbine, it can be concluded that by adjusting the variable nozzle ring blades, the power turbine can provide sufficient work for the compressor throughout the flight. And when the temperature and pressure of the bleed air change, the opening can be adjusted to make the environmental control system run smoothly. In this way, the impact of changes in the engine bleed air parameters on the environmental control system is isolated.

In this paper, the gap between the nozzle ring blade and the turbine casing and the rotation axis of the nozzle ring blade are ignored in the calculation simulation. These gaps have a significant impact on turbine performance, are an important part of turbine energy loss, and also have an impact on torque. All should be considered. It is also possible to conduct research on the variable nozzle ring control actuator of the power turbine, as well as the control law of the variable nozzle ring and how to match the power turbine and the ring control system better and faster. In this paper, the research on the air circulation system driven by a power turbine with a variable nozzle ring is in its infancy, and there are still many problems to be studied in the future.

### Data Availability

The turbine's data used to support the findings of this study are included within the article. The environmental control system data used to support the findings of this study are available from the corresponding author upon request.

### Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

The joint capsule of the knee joint is attached to the edges of various articular surfaces and is thin and loose. Therefore, ligament reinforcement is needed to protect the knee joint and increase the stability of the joint. It plays a vital role in human activities. In this paper, a 3D-CT three-dimensional reconstruction method is used to reconstruct the ACL natural femoral imprint and double-bone tract. The relative positional relationship between the two center points is compared, and the law is summarized to guide the improvement of ACL anatomic double-beam reconstruction under arthroscopy. The 3D reconstruction results suggest that the bone layer in the anterior medial portion is the thickest, forming a peak, and the thickness of the bone layer in the posterior medial portion gradually decreases in a stepwise manner. The entire bone tissue in the anterior medial portion and posterior medial portion is integrated into one body. The tissues are connected as a whole, and the thickness is relatively uniform. The two parts of the bone tissues are not connected. The CF tissue was inserted into the bone tissue in a zigzag pattern. The changes of CF tissues in the anterior medial and posteromedial CF tissues were similar, and they were distributed stepwise from the inside to the outside. According to the bone and CF spatial structure and changing rules, ACL is divided into medial and lateral beams. According to this study, it can be summarized that (1) 3D reconstruction can clearly reconstruct the natural footprint of ACL femoral stops and postoperative osseous position and (2) 3D reconstruction can be used to evaluate the position of osseous postoperative ACL anatomic double-beam reconstruction. Arthroscopy double-beam reconstruction of ACL is instructive.

## 1. Introduction

With the increasing popularity of mass movements and the increasing incidence of traffic accidents, anterior cruciate ligament (ACL) injury is becoming more and more common, and research on it has received more and more attention from the academic community [1–3]. ACL is the core ligament that guides the movement of the knee joint. Its main function is to restrict the forward movement of the tibia, but it also plays a certain role in controlling the rotation of the knee joint, and the stress situation is complex [4]. The key part of its mechanical conduction, the tibia stop, has become the focus of biomechanical research of ligaments. Foreign scholars have reported that in animal experiments, the position of the ACL tibial plateau on the tibial plateau was moved forward and backward, and the tibial plateau and knee stability were significantly different,

suggesting the position of the tibial plateau and its restrictions [5]. The ability of the tibia to move forward and maintain the stability of the knee joint is closely related, but there is still no research report on the clear correspondence between the position of the ACL tibial stop and the ACL control force [6–9]. The connection point between the ligament and the bone is not a simple ligament bone connection, but a complex structure. The literature calls it a “stop point organ,” which can be divided into fibrocartilage stops (direct stops) and fiber stops (indirect stops). The ACL tibia stop is a typical fibrocartilage stop, including four regions, namely, fibrous tissue, uncalcified fibrocartilage (UF), calcified fibrocartilage (CF), and bone tissue. The structure mainly plays a role of stress buffering [10–12]. The domestic and foreign literature studies reporting the histological structure of ACL tibial junctions are mainly concentrated along the longitudinal axis of ACL. The purpose is

to observe the healing after surgical reconstruction. It is not a special continuous layer structure study.

The knee joint is the largest, most complex, and weight-bearing joint in the human body, and it is also the joint with the highest functional requirements of the human body. The joint capsule of the knee joint is attached to the edges of various articular surfaces and is thin and loose. Therefore, ligament reinforcement is needed to protect the knee joint and increase the stability of the joint. It plays a vital role in human activities. Ligaments are tough, band-shaped tissues connected between the femur and tibia. The knee ligaments mainly include anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), medial collateral ligament (MCL), and lateral collateral ligament (LCL). The anterior cruciate ligament is the most important stabilizing factor. The anterior cruciate ligament starts from the anterior angle of the meniscus and anterior to the tibial intercondylar eminence, and ends behind the medial side of the femoral condyle. Its main functions include the following: restricting the forward movement of the tibia, preventing overextension of the knee joint, and preventing internal and external rotation of the tibia [13–15]. When the external force applied to the knee joint exceeds the anterior cruciate ligament tolerance, anterior cruciate ligament injury occurs. Anterior cruciate ligament injury has been common in traffic accidents and professional athletes in the past, but with the improvement of social living standards, sports-loving, as the number of ordinary people increases, knee joint sports injuries also increase. Among them, sports injuries such as anterior cruciate ligament rupture are more and more common in the general people. In Europe and the United States, anterior cruciate ligament injury occurs mostly in fierce sports such as basketball and football. In domestic studies, anterior cruciate ligament sports injuries are most common in basketball, football, and jumping sports. The damage of anterior cruciate ligament between men and women is also different, which is related to their sports hobbies, sports technology, and sports popularity requirements. Imaging evaluation plays a key role in the diagnosis, treatment choice, and follow-up of kidney stones. Over the years, as the incidence of urinary tract stones has increased and the understanding of disease processes has increased, imaging techniques have continued to evolve. CT urography (CTU) developed on the basis of CT is a method of injecting a contrast agent into a vein, using the secretory function of the kidney and using CT to observe the degree of filling of the contrast agent over time in the renal calamus, renal pelvis, ureter, and bladder, as shown in Figure 1. Obtaining continuous tomographic data and then three-dimensional reconstruction of the original image using a computer to obtain a three-dimensional urinary system image has become a more common inspection method in urology [16, 17]. Preoperative imaging has a crucial influence on the choice of the surgical method. However, the CTU examination results uploaded to the doctor’s workstation by the radiology department currently only have 3D reconstructed images with several perspectives. The surgeon cannot perform more operations on the 3D reconstructed model and cannot meet the needs of the surgeon. In severe cases, the

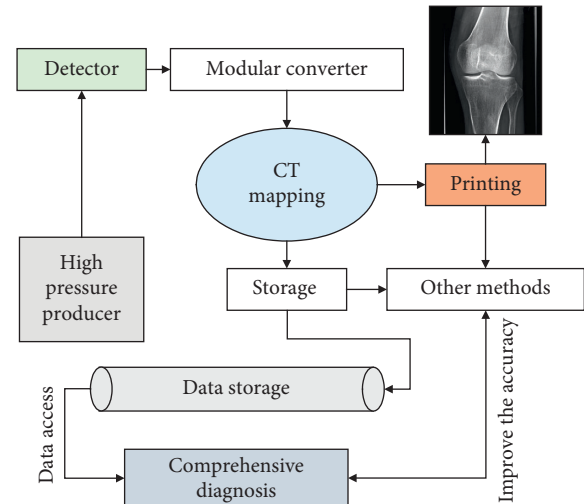

FIGURE 1: The schematic diagram of 3D-CT mapping used in the ACL detecting.

contrast agent cannot be well distributed in the pyloric renal pelvis, which may lead to poor CTU image quality, and some urinary tracts cannot be displayed. Doctors rely more on plain CT scans for preoperative planning, especially for complex situations. In more detailed preoperative planning, how to obtain better preoperative planning information is obviously the problem that the operator needs to solve first [18].

For medical images such as CT data reading and 3D reconstruction, part of the software comes from the CT machine of Siemens and other companies [19]. Usually, a machine corresponds to a software system, and individual users are generally unable to use it [20]. For external 3D reconstruction software, the current recognition is the Mimics software from the Materialise company [21]. The reconstructed model is highly consistent with the real situation. Through modular function settings, the operation is simple and easy to use, and it can directly interface with CAD, FEA, RP, and other data [22–24]. It is easy to process the model, and the software is constantly updated, and the algorithm is optimized to enhance the function. It has been widely used in orthopedics, stomatology, and other departments, mainly for individualized preoperative planning of implanted prostheses, etc., and can guide the operation in real time during the operation. 3D printing technology is an additive rapid prototyping technology. It was proposed by the Massachusetts Institute of Technology in the United States to form solids layer by layer according to a certain path [25]. With the development of materials, materials that can be used for 3D printing have also developed from traditional single solid powders such as metals and plastics to new hybrid materials such as liquids and gels. Different “inks” can be used to print different items. It has been applied in aerospace, medical, and other fields and has developed rapidly. In this paper, a 3D-CT three-dimensional reconstruction method is used to reconstruct the ACL natural femoral imprint and double-bone tract. The relative positional relationship between the two center points is

compared, and the law is summarized to guide the improvement of ACL anatomic double-beam reconstruction under arthroscopy. In addition, this study intends to perform a three-dimensional reconstruction based on the sequential tissue histological structure based on the clear tissue-stress correspondence reported in the literature, and then divide the functional bundle of the ACL, as well as the proposed positioning method for the inner center of the tibial tunnel in surgical reconstruction. It is a new method for the study of ACL function that is different from all previous reports in the literature and provides a new method and basis for future large sample research and animal experiment research.

In this paper, we firstly use the 3D-CT mapping methods to build an ideal ACL reconstruction scheme, and the innovation points can be listed as follows:

- (1) The 3D-CT three-dimensional reconstruction method is used to reconstruct the ACL natural femoral imprint and double-bone tract.
- (2) The relative positional relationship between the two center points is compared, and the law is summarized to guide the improvement of ACL anatomic double-beam reconstruction under arthroscopy.
- (3) The 3D reconstruction results suggest that the bone layer in the anterior medial portion is the thickest, forming a peak, and the thickness of the bone layer in the posterior medial portion gradually decreases in a stepwise manner. The entire bone tissue in the anterior medial portion and posterior medial portion is integrated into one body. The tissues are connected as a whole, and the thickness is relatively uniform. The two parts of the bone tissues are not connected. The CF tissue was inserted into the bone tissue in a zigzag pattern. The changes of CF tissues in the anterior medial and posteromedial CF tissues were similar, and they were distributed stepwise from the inside to the outside.
- (4) According to the bone and CF spatial structure and changing rules, ACL is divided into medial and lateral beams. According to this study, it can be summarized that (a) 3D reconstruction can clearly reconstruct the natural footprint of ACL femoral stops and postoperative osseous position and (b) 3D reconstruction can be used to evaluate the position of osseous postoperative ACL anatomic double-beam reconstruction. Arthroscopy double-beam reconstruction of ACL is instructive.

## 2. Materials and Methods

**2.1. General Information.** Among the patients undergoing three-dimensional reconstruction of the anterior cruciate ligament femoral junction treated in the affiliated hospital of Pingdingshan University from February 2018 to March 2020, 45 patients were selected, including 23 males and 22 females, aged 21 to 54 years, with an average of  $30.2 \pm 7.1$  years old (Table 1). All patients had no obvious history of

trauma to both knees, and those with knee joint swelling and pain were excluded. Patients with negative hyperextension test, lateral stress test, McMurray test, floater test, Lachman test, and knee drawer test were all negative. In addition, 45 subjects signed informed consent, and this study has been approved by the ethics committee of the hospital. In this study, a 64-row spiral CT scanner (240 mA, 120 kV) produced by GE of the United States was selected, the matrix size was  $512 \times 512$  pixels, the scan time was set to 5 s, the layer thickness was 5 mm, the window diameter was 360 mm, and the reconstruction interval layer thickness was 0.625 mm. The scan results were exported and stored in a workstation, and the 3D reconstruction software Mimics 10.01 produced by Materialise was used to construct the femur and ACL model and saved in format. Geomagic Studio12, the reverse engineering software manufactured by Geomagic, was used to analyze the SD data, implement image registration, and construct a three-dimensional solid model of cruciate ligament and attachment points of the knee joint through MRI and CT influence fusion methods. After the reconstruction of the model is completed, the femoral dead center is located according to the ACL three-dimensional model, and the ACL femoral dead center is identified and circled according to the morphological characteristics of the ACL attachment area. Geomagic software was used to record the area, long-axis angle, short distance, inner distance, back distance, short axis, and Changzhou of ACL femoral nodal points.

**2.2. Magnetic Resonance Scanning.** The magnetic resonance scanning was performed using a Siemens 3.0 T magnetic resonance instrument and an 8-channel knee joint coil. The subjects were supine with first entrance of their feet, and sagittal T1WI (repetition time (TR) 624 ms, echo time (TE) 17 ms), T2WI (TR 5069 ms, TE 113 ms), PDWI (TR 3155 ms, TE 33 ms), coronal T1WI (TR 614 ms, TE 16 ms), and PDWI (TR 3132 ms, TE 34 ms) sequence scanning were sequentially conducted. The T2-mapping imaging performed 5 echoes and 1 scanning through the SE sequence, and the sagittal scanning was conducted perpendicular to the tibial plateau. Scanning parameters were repetition time of 1500 ms, echo time of 12.4, 25.8, 39.1, 53.6, and 65.5 ms, number of layers of 24, layer spacing of 0.5 mm, field of view of  $16 \text{ cm} \times 16 \text{ cm}$ , matrix of  $368 \times 368$ , layer thickness of 5 mm, number of acquisitions of 1, flip angle of  $180^\circ$ , and acquisition time of 6.23 min. The scanning sequences were perpendicular to the sagittal plane, and the imaging data were transmitted to workstation for postprocessing to directly obtain T2-mapping pseudocolor image of the knee joint and the T2 value data measurement.

**2.3. Secondary Injury after Anterior Cruciate Ligament Rupture.** The anterior cruciate ligament of the knee joint is an important structure to maintain the stability of the knee joint's anterior and posterior rotation. If it breaks, it will seriously affect the function of the knee joint. If it is not treated in time, it will cause damage to the articular cartilage and meniscus, eventually leading to osteoarthritis happened.

TABLE 1: The general information of selected patients.

| Group  | Average age (years old) | Gender (male/female) | Disease duration (month) | Injury part |       | Patient's occupation |    |    |    |    |
|--------|-------------------------|----------------------|--------------------------|-------------|-------|----------------------|----|----|----|----|
|        |                         |                      |                          | Left        | Right | AL                   | SD | DC | FF | OO |
| ACL    | 30.2 ± 7.1              | 29/11                | 0.83 ± 0.12              | 18          | 22    | 13                   | 11 | 8  | 5  | 3  |
| Normal | 28.2 ± 2.1              | 29/11                | 0.76 ± 0.07              | 18          | 22    | 13                   | 9  | 10 | 6  | 2  |

Note: AL, athlete; SD, student; DC, dancer; FF, firefighter; OO, other occupation.

Studies have shown that the types of damage to the medial and lateral meniscus are more common after rupture of the anterior cruciate ligament, and the sites are mainly posterior horn injuries that can be sutured under the microscope. Most of the lesions need to be removed. The incidence of lateral meniscus tears is very stable and does not increase with the time after anterior cruciate ligament rupture. This suggests that anterior cruciate ligament injury may be accompanied by lateral meniscus injury. Incidence rate can rise to more than half within 1 month after anterior cruciate ligament rupture. Within 1 to 3 months after anterior cruciate ligament rupture, the patient is subjected to knee braking after trauma. Partial healing of the anterior cruciate ligament may cause the incidence of lateral meniscus tears was reduced to below 40%; the incidence of lateral meniscus tears increased to more than half within 3 months to 12 months after anterior cruciate ligament rupture. The incidence of fissures in the anterior cruciate ligament caused by lateral meniscus tears for more than 12 months remained at about 40%. There was no significant difference in each time period. The instability of the knee joint will cause damage to the medial meniscus [8]. The incidence of medial meniscus injuries within 3 months of anterior cruciate ligament rupture is about 30%; medial meniscus injuries lose 3 in the anterior cruciate ligament. The incidence rate is about 40% from a month to half a year; the incidence rate of medial meniscus injury in anterior cruciate ligament injury is more than half in half a year to one year, and the anterior medial meniscus injury occurs after cruciate ligament injury time exceeds one year. The rate can reach more than 60%, and the statistical analysis of each time period has statistical differences, as shown in Figure 2. It is suggested that the time after the cruciate ligament rupture is greater than half a year, and the probability of its medial meniscus injury will increase, indicating that after anterior cruciate ligament rupture, cruciate ligament reconstruction should be performed within 6 months to prevent secondary medial meniscus damage.

#### 2.4. Surgical Treatment of Anterior Cruciate Ligament Injury.

Anterior cruciate ligament reconstruction under knee arthroscopy is currently the preferred method for treating anterior cruciate ligament injury. Commonly used anterior cruciate ligament reconstruction includes single-beam reconstruction and double-beam reconstruction, anatomical reconstruction, and nonanatomical reconstruction [26–28]. Its current positioning method is anatomical reconstruction, including anatomical single-beam reconstruction and anatomical double-beam reconstruction. It also evolved from

the earliest nonanatomical reconstruction (nonanatomical single-beam reconstruction and nonanatomical double-beam reconstruction). The positioning of the bone canal is crucial in the process of anatomical reconstruction. First, see if you can see the broken end of anterior cruciate ligament injury to locate the femoral tract. If the broken end exists, you can use the method of central positioning of the broken end.

If the broken end does not exist, you can perform epiphyseal positioning. Resident Thallium and fasciatus are the main basis. The study found that about 80% of patients can only identify resident doctors, about 55% of patients can only identify fasciatus, and only about 50% of patients can identify both tadpoles at the same time. Anatomical studies of cadaver specimens vary. Therefore, not every patient can clearly identify the two in the knee joint. Chen Lianxu's experience is that he wants a better observation effect [29]. Arthroscopy can be accessed from the anterior internal approach and then use the hook to explore the stump of the anterior cruciate ligament to find the bulge and hard touch, as shown in Figure 3. Here, the AMB means the advanced material buffer used to improve the bone cross section. At present, most scholars insist on using single-beam reconstruction of anterior cruciate ligament. After long-term research and development, arthroscopic single-beam reconstruction of cruciate ligament has achieved satisfactory surgical results. However, due to the lack of single-beam reconstruction of anterior cruciate ligament in controlling the rotation stability of the knee joint, some scholars believe that double-beam reconstruction has obvious advantages in theory and advocate the use of double-beam reconstruction of anterior cruciate ligament [30]. However, whether the clinical efficacy of the double-beam reconstruction technique is better, the single-beam reconstruction technique has not been proved by large-scale clinical comparative trials. At present, there are mainly three kinds of grafts for anterior cruciate ligament reconstruction: allografts, autograft, and artificial ligaments. Discussion on the selection of anterior cruciate ligament grafts is mainly focused on the allograft and autograft. At present, for the selection of grafts, the comparison of the efficacy of autograft or allograft in anterior cruciate ligament reconstruction has no conclusion yet. Due to the relatively lack of reports on clinical research of synthetic grafts, and synthetic grafts have not been clinically validated due to factors such as their safety hazards and treatment effects, they are not currently the first choice by clinicians, so how to choose anterior cruciate ligament graft pair to the clinical treatment effect and clinical treatment plan has important influences [31–33]. For the graft, there are many choices for our doctors to consider,

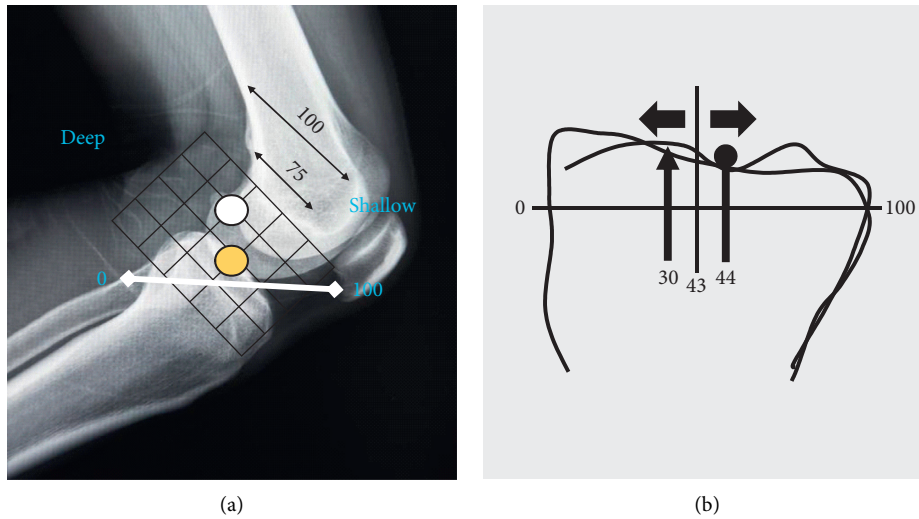

FIGURE 2: The ideal tibial bone tunnel positions for the secondary injury after anterior cruciate ligament rupture.

FIGURE 3: Mean length change patterns for the three ACL bundles during flexion, in internal (INT) and external (EXT) tibial rotation after surgical treatment of anterior cruciate ligament injury.

including the potential risk of infection, the hidden dangers of the need for a second surgery on the patient, and the mobility and stability of the knee joint after reconstruction. However, clinicians did not conduct too many screenings when selecting grafts due to various factors. At present, whether it is an allograft or an autograft ligament, its good clinical effect has been proven. However, the comparison of which type of graft to rebuild is preferred, which is inconclusive. For postoperative comparisons between autograft and allograft, the conclusions obtained in different studies are quite different. The main conclusions are divided into two types: one is that the choice of different grafts does not affect the function of the knee joint after patient

reconstruction, and the other is that patients who choose autograft reflect a better recovery of knee function, which may have potential infection risks and postoperative ligaments. Slow healing is the main problem for the choice of allografts, but it has been temporarily confirmed that the chance of rejection of allografts is not significantly different from that of autograft. Although autograft as a graft for reconstruction of knee ligament is still the first choice of most clinicians from the current research and clinical experience, it is important to note that the surgical effect of allograft and autograft is important. It is the surgical method chosen, how to treat the graft and the source of the graft, etc. These factors are also the main reasons affecting the effect of anterior cruciate ligament reconstruction. At the same time, allografts have a wide range of sources and are available in various sizes for clinical use. Selection, the operation during the operation is easy, and these advantages can shorten the operation time.

2.5. *Observation Indicators.* All data analysis was performed in the statistical software SPSS18.0. In this study, the count data were expressed as a percentage and tested. The measurement data were expressed as mean  $\pm$  standard deviation ( $\pm s$ ). Differences were considered statistically significant at  $P < 0.05$ .

### 3. Result Analysis

3.1. *Morphological Typing Results.* In this study, 45 patients with a total of 90 knees received 3D reconstruction analysis. The morphological classification showed that 44 knees were oval, 15 knees round, 16 knees crescent, 5 knees long, and 10 knees irregular. The oval shape is the most common, accounting for 48.89% of the total. Arthroscopy ACL reconstruction surgery is a common type of knee joint surgery. In the past, four-quadrant method, Takahashi method, and interpositional method were used to reconstruct the femoral tract, which cannot be applied in clinical promotion. With

the gradual popularization of the concept of anatomical reconstruction in recent years, due to the differences in the position, shape, and size of ACL femoral stops, it is very important to discuss how to implement effective 3D reconstruction of ACL femoral stop significance. Previous studies on ACL femoral nodal points were mostly performed on corpses. For example, Lorenz et al. used 12 corpses as samples for ACL anatomy analysis. Due to the limited number of samples and the age of the samples, the reliability of the ACL anatomy data obtained is low. The continuous development of clinical imaging technology has provided new ideas for the construction of ACL models. At present, a variety of knee joint models, such as anatomical models, mechanical models, and mathematical models, have appeared in clinical practice. Among them, the three-dimensional knee joint model based on MRI and CT technology has been widely promoted in clinic with its high degree of reduction, as shown in Figure 4. Relevant data show that the three-dimensional imaging of the knee joint can achieve multiplane and multiangle observation, thereby achieving good spatial positioning characteristics and providing reliable three-dimensional data for anatomical research. The angle is the same as the ACL femoral stop morphology plane suppression, which facilitates intraoperative osseous positioning.

In previous studies, knee functional braces were considered to be an integral part of exercise rehabilitation therapy, which can support the healing of ACL, improve the functional stability of joints, and restore normal kinematics. In different exercise rehabilitation stages, when performing exercise rehabilitation function exercises, the adjustable knee joint functional brace can adjust the knee joint activities in different ranges and has a supporting and protecting effect on the affected knee joint. In clinical exercise rehabilitation training after anterior cruciate ligament reconstruction, adjustable knee joint functional braces have been widely used. However, there are still different opinions on the effects of postoperative exercise rehabilitation training on whether or not a brace should be worn. A systematic review summarizes the related research of 28 braces. The research angle is to consider whether the braces can improve the kinematic function of the knee joint. The conclusion is that the literature does not currently recommend the use of knee function exercise rehabilitation after anterior cruciate ligament reconstruction braces, and it is believed that the use of knee functional exercise rehabilitation braces after anterior cruciate ligament reconstruction will not reduce postoperative pain and improve knee function. However, for patients after anterior cruciate ligament reconstruction, the main role of the knee functional exercise rehabilitation brace is first to support graft healing and maintain knee stability, and then to perform functional exercise rehabilitation training. In addition, some scholars believe that if the postoperative patients do not wear braces for protection, knee function cannot be recovered well during exercise rehabilitation. It is recommended that patients who undergo anterior cruciate ligament surgery need to wear braces within 1 to 3 months after surgery. In the early stage of exercise rehabilitation, the brace should be mainly

used to protect the knee joint. In the later stage of exercise rehabilitation, if there is a patient who needs to return to exercise, the choice of the brace should be mainly based on functional exercise.

CT technology covers the processes of projection data acquisition, data correction, and 3D image reconstruction, and finally obtains the 3D reconstruction image of the scanned object, and the input of 3D printing is based on the 3D volume data reconstructed by CT technology and represented by a triangular grid. As shown in the figure above, the entity is scanned by CT to obtain a multiangle projection data volume. After three-dimensional reconstruction, tomographic data are obtained. After format conversion, topography analysis and STL data export are performed; STL data are combined with 3D printing to print out samples. And we realize the structural information comparison between the original sample and the 3D printed sample.

### 3.2. Comparison of Left and Right ACL Femoral Stops.

There were no statistically significant differences in the measured data of ACL femoral dead points of the left and right knees of 45 subjects ( $P > 0.05$ ), as shown in Figure 5. Here, the bone section shows almost no difference on the left and right sides. The slight difference between 23.7% and 21.7% could be only the individual error. At present, CT imaging is used in the diagnosis of a large number of soft tissues, bone, and joint lesions. CT imaging is an ideal inspection method for bone and joint lesions. It can detect and reflect the small density differences of different tissues; MRI imaging has high spatial resolution rate, has significant advantages in imaging of small tissues or structures such as blood vessels, tendons, cartilage, and nerves, and has high diagnostic sensitivity and specific mockery for knee ligament rupture and meniscus injury. In this study, the knee joint MRI and CT data were collected, combined with the advantages of MRI imaging of soft tissue and CT for bone structure, and three-dimensional reconstruction of knee ACL and femur to obtain a three-dimensional model of knee joint, so as to fully reproduce knee ACL. Compared with the traditional ACL anatomy research method, the model constructed in this study can achieve accurate measurement of ACL anatomy data, and it is more accurate and reliable in confirming ACL femoral stops. Previous studies have shown that there is no significant difference in the morphological parameters of the left and right knees of knee specimens. For example, Dargel et al. performed ACL femoral measurement on the specimen. The length of the short axis was  $(10.31 \pm 1.45)$  mm, and the long axis was  $(17.01 \pm 1.83)$  mm. In this study, the measurement results of the knee ACL three-dimensional reconstruction model of 90 subjects showed that the left and right knees had no significant difference in parameters such as the long axis, short axis, area, and long-axis angle ( $P > 0.05$ ), which is basically consistent with the conclusions in related reports, indicating that the anatomical data obtained by 3D reconstruction of knee ACL given MRI and CT data have good reliability. Some studies have pointed out that the anatomical characteristics of ACL in knee joints are different between

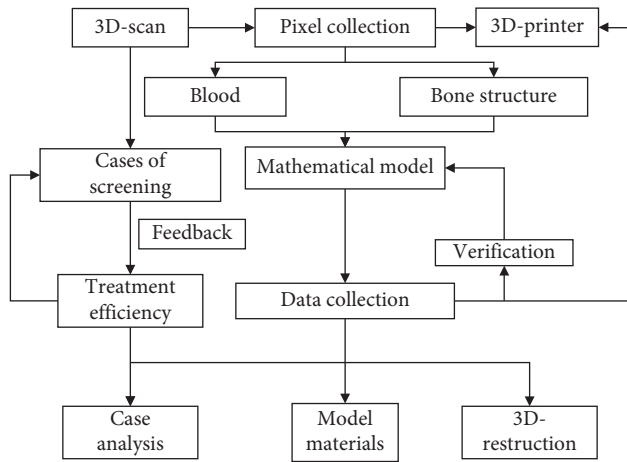

FIGURE 4: The schematic diagram for the process of 3D- reconstruction for bone tissues.

different races, genders, and ages. In this study, analysis of the ACL 3D reconstruction model data of subjects of different genders revealed that male ACL femoral stops were in terms of area, long-axis angle, distance, back distance, short axis, long axis, and other data. Both were significantly larger than females ( $P < 0.05$ ), suggesting that the impact of the patient's gender on the anatomy of the knee joint should be fully considered when formulating the knee joint reconstruction surgery under arthroscopy, so as to maximize the recovery of knee function of patients. In summary, there are anatomical characteristics of the knee joint anterior cruciate ligament femoral dead point, a certain individual difference. The combination of MRI and CI imaging data to achieve three-dimensional reconstruction can provide a reliable basis for the formulation of a surgical plan.

#### 4. Diagnosis and Exercise Rehabilitation of ACL Injuries

**4.1. Postoperative Recovery from Anterior Cruciate Ligament Injury.** Postoperative exercise rehabilitation is equally important in the treatment plan, and the specific process can be seen in Figure 6. Early scientific and reasonable exercise rehabilitation exercise treatment can promote graft healing and plastic reconstruction. At present, there is no consensus on the exercise rehabilitation treatment after anterior cruciate ligament reconstruction. It contains mainly conservative exercise rehabilitation treatment, intense exercise rehabilitation treatment, and individualized exercise rehabilitation treatment. Yasuda et al. advocate that the cycle of exercise rehabilitation is 1 year, and the patient starts the training of knee weight-bearing and activity in the second week after completing the anterior cruciate ligament reconstruction surgery. After training according to a conservative exercise rehabilitation treatment plan, the knee stability after reconstruction is good, but patients are prone to sequelae such as knee stiffness and poor joint mobility. Shellbourne et al. advocate that the treatment period for exercise rehabilitation is six months to nine months. Early in the postoperative period of anterior cruciate ligament

reconstruction, patients will begin training on knee weight bearing and mobility, which is a representative intense exercise rehabilitation treatment program. After exercise rehabilitation training, the patient can perform normal knee joint movements early after the operation; recovery of the knee joint activity is greater, and the incidence of knee complications can be reduced. However, some problems are prone to occur, such as loosened reconstructed grafts, even fractured grafts, and altered tunnels. The reason is that the degree of postoperative exercise rehabilitation activities is too strong, which may increase the relative activity of the graft in the bone canal. The Sharpey fibers formed early between the graft and the tunnel will be damaged, delaying the healing of the graft and the reconstruction stop, and even cause changes in the tunnel. The results of studies by foreign scholars show that patients with anterior cruciate ligament rupture reconstructed with autologous tendons (semiteudinosus and gracilis muscle) were divided into several groups of mutual control; one used a more intense exercise rehabilitation exercise treatment program, and for the other, a more conservative exercise rehabilitation exercise program was used for postoperative exercise rehabilitation, which is summarized in Table 2. On the plain radiograph of the knee joint 6 months after the operation, the changes in the tibial bone tract of the fierce exercise rehabilitation group were more obvious. The patients in the conservative exercise rehabilitation group had smaller changes in the tibial tunnel than the fierce exercise rehabilitation group. The intense exercise rehabilitation treatment will make the graft more active in the tunnel and, at the same time, will produce more severe cellular responses and inflammatory factors. With the development of sports medicine and exercise rehabilitation medicine, physicians have gradually realized that specific and effective exercise rehabilitation treatment programs must integrate all aspects of each patient to develop exercise rehabilitation training methods. In recent years, individualized exercise rehabilitation treatment programs have gradually started to rise, which requires professionals to be able to more accurately understand and master sports medicine and exercise rehabilitation medicine related knowledge. The patient first received a plain CT scan and then an MRI scan. The layer thickness was 2 mm, the layer spacing was 0.5 mm, the matrix size was set to  $512 \times 512$  pixels, and the number of excitations was taken twice. During the scan, the patient's knee joint was naturally straightened, and the external rotation was 10 to 15°. In order to enable the knee function to recover better and improve the shortcomings of conservative and intense exercise rehabilitation programs, exercise rehabilitation physicians need to formulate more individualized and targeted exercise rehabilitation treatment programs, which comprehensively analyze and consider all aspects of postoperative patients.

**4.2. The Role of Braces in Anterior Cruciate Ligament Injury.** In previous studies, knee functional braces were considered to be an integral part of exercise rehabilitation therapy, which can support the healing of ACL, improve the

FIGURE 5: The ideal tibial bone tunnel positions for the left and right ACL femoral stops.

TABLE 2: Assessing grade results of knee joint sports injuries of patients in the 3.0 T MRI group ( $n$  (%)).

| Knee sports injury        | Level I<br>( $n$ %) | Level II<br>( $n$ %) | Level III<br>( $n$ %) |
|---------------------------|---------------------|----------------------|-----------------------|
| Meniscus injury           | 3 (30.00)           | 5 (50.00)            | 2 (20.00)             |
| Ligament injury           | 4 (33.33)           | 6 (50.00)            | 2 (16.67)             |
| Bone contusion            | 1 (12.50)           | 4 (50.00)            | 3 (37.50)             |
| Articular cavity effusion | 0 (0.00)            | 2 (66.67)            | 1 (33.33)             |

functional stability of joints, and restore normal kinematics. In different exercise rehabilitation stages, when performing exercise rehabilitation function exercises, the adjustable knee joint functional brace can adjust the knee joint activities in different ranges and has a supporting and protecting effect on the affected knee joint. In clinical exercise rehabilitation training after anterior cruciate ligament reconstruction, adjustable knee joint functional braces have been widely used. Here, the research angle could influence the growth rate of the bone section, so it could be easy to understand that it could also influence the kinematic function of the knee joint. However, there are still different opinions on the effects of postoperative exercise rehabilitation training on whether or not a brace should be worn. A systematic review summarizes the related research of 28 braces. The research angle is to consider whether the braces can improve the kinematic function of the knee joint. The

conclusion is that the literature does not currently recommend the use of knee function exercise rehabilitation after anterior cruciate ligament reconstruction braces, and it is believed that the use of knee functional exercise rehabilitation braces after anterior cruciate ligament reconstruction will not reduce postoperative pain and improve knee function. However, for patients after anterior cruciate ligament reconstruction, the main role of the knee functional exercise rehabilitation brace is first to support graft healing and maintain knee stability and then to perform functional exercise rehabilitation training. In addition, some scholars believe that if the postoperative patients do not wear braces for protection, knee function cannot be recovered well during exercise rehabilitation. It is recommended that patients who undergo anterior cruciate ligament surgery need to wear braces within 1 to 3 months after surgery. And the specific recovery comparison among different groups can be seen in Figure 7, and the details are summarized in Table 3. In the early stage of exercise rehabilitation, the brace should be mainly used to protect the knee joint. In the later stage of exercise rehabilitation, if there is a patient who needs to return to exercise, the choice of the brace should be mainly based on functional exercise.

Wearing a functional exercise rehabilitation brace after surgery can maintain knee stability, reduce postoperative pain, and protect the graft from injury without affecting the recovery of the patient's lower extremity strength. Although there is literature found that after the patient wears a brace

FIGURE 7: Compatibility and recovery rate at different recovery stages for different methods.

| MRI      | 0     | 0 (0.00)   | 3 (7.50)   | 8 (20.00)  | 14 (35.00) |
|          | I     | 11 (27.50) | 17 (42.50) | 16 (40.00) | 13 (32.50) |
|          | II    | 14 (35.00) | 11 (27.50) | 10 (25.00) | 9 (22.50)  |
|          | III   | 11 (27.50) | 9 (22.50)  | 6 (15.00)  | 4 (10.00)  |
| $\chi^2$ |       | 8.26       | 13.18      | 17.25      | 7.69       |
| $P$      |       | <0.05      | <0.05      | <0.05      | <0.05      |

after surgery, in terms of exercise and stress, the affected side has an inconsistency with the unoperated healthy side. In addition, there are reports in the literature that patients wearing braces may affect the sense of postoperative pain. This may increase the difficulty of gait training or motor skills for patients in the late stage of exercise rehabilitation. Moreover, there are no cases in the literature that report that wearing protective functional braces early after surgery will lead to changes in the reconstruction of the patient's tunnel. There are still different opinions on the use of braces, but no literature has found any reports of anterior cruciate ligament surgery. Patients wearing the brace will aggravate pain, and the recovery of knee joint mobility and graft healing and plastic reconstruction of ligaments after surgery are not affected. Although there are many types of functional exercise rehabilitation braces in the market and the quality and price are quite different, we have found that the general knee functional braces have knee motion trajectories that are

simply hinge flexion and extension. The normal knee joint is a series of complex three-dimensional movements accompanied by rolling and sliding of femoral condyles and axial internal rotation of tibia. Therefore, these knee joint braces currently used in China do not conform to the physiological structure of our human knee joints. According to reports in the literature, after anterior cruciate ligament injury, the tibia advances to the femur, and the severity of the injury varies, and the relative displacement of the tibia varies. The anterior cruciate ligament injury of the knee joint resulted in the tibia advancing to the femur.

## 5. Discussion

*5.1. Comparison of 3D-CT and MRI Mapping in Assessing ACL Cases.* There are many research methods about the ACL-related injuries of ACL femoral stops, mainly divided into several groups by different scan methods (Table 4). Through the comparison of the data in Figure 8, it is found that different methods can obtain different distortion reconstruction for bone tissues, even the same method, and the results obtained are different. The author believes that there are two reasons: (1) the positioning of Blumensaat lines by different authors is not very accurate; (2) there may be differences between different groups, populations, and individuals, leading to different positions of ACL femoral centers in this control group. For the selection of subjects, patients with high incidence of ACL injury were selected.

Compared with previous studies, it has the following advantages: (1) this study can do a large sample study, excluding the shortcomings of the limited number of studies on corpses, older age; (2) there may be individual differences in ACL anatomic location. Different races and populations may have different anatomical positions of ACL. This study

TABLE 4: Comparison of assessment results of different imaging methods on the exercise rehabilitation therapies of the three groups of patients.

| Reconstruction methods    | CT group |    |       | 1.5 T MRI group |    |       | 3.0 T MRI group |    |       |

FIGURE 8: Distortion level for different reconstruction methods in at different recovery stages.

selected patients in the age group with high incidence of ACL injury in China, making the measured relative position of the center point more representative. The high-resolution DSC thin-layer scan used by the author can clearly show the natural imprint of the ACL femoral dead point and the position of the double-bone tract after surgery, making it possible to reproduce the anatomical position of the ACL dead point before surgery. Intraoperative and surgical positioning and postoperative evaluation of the position of the bone canal help to improve the surgical operation, and truly achieve the purpose of restoring the anatomy as much as possible. The volume reconstruction technology used can reconstruct the points and surfaces in any direction that the author is interested in, so that the imprint and bone can be visualized in front of the eyes, and overcome the lateral femoral condyle of interest that the author could not observe on the conventional X-ray plain film. However, the relative position of the bony structure was measured on the three-dimensional model, and the soft tissue of the ACL attachment point at the femoral end was not reconstructed. Due to the irregular imprint of the ACL stop, the group was drawn on the imprint circle and the center point. It is inevitable that there are individual subjective differences, as shown in Figure 9. In this study, the most commonly used quadrant method is used to compare the relative positions of the center points of the experimental group and the control group. The advantage is that the results of this study can be compared with the results of related reports in the past. However, the Blumensaat line is not visible on the 3D model

FIGURE 9: Coincidence rate for different reconstruction methods at different recovery stages.

of the image, and it is not a definite bone mark, as shown in Figure 10. Therefore, it is difficult to determine the Blumensaat line on the three-dimensional model. Different people inevitably have subjective individual differences when determining the position of the Blumensaat line.

**5.2. Biocompatibility of 3D-CT Modeling to Evaluate ACL and Related Cases.** The 3D-CT is a minimally invasive diagnostic method with high soft tissue resolution, which can clearly display bone lesions, and the characteristics of the images obtained by different sequences are different and can better identify and diagnose the type of injury. Using 3D-CT to diagnose knee joint sports injuries can obtain accurate diagnostic results and accurate classification, providing an accurate basis for forensic identification, as shown in Figure 11. Because the anatomical structure of the knee joint is more complex, the injury is wider, and the location of the injury is different, the impact on the function of the knee joint is also different. Therefore, in the process of identifying knee injuries, clinical forensics should analyze the patient's trauma history, injury mechanism, clinical characteristics, and imaging characteristics. In order to improve the accuracy of diagnosis, some injuries may cause complications because the knee joint is a weight-bearing joint and affected by factors such as improper function recovery training.

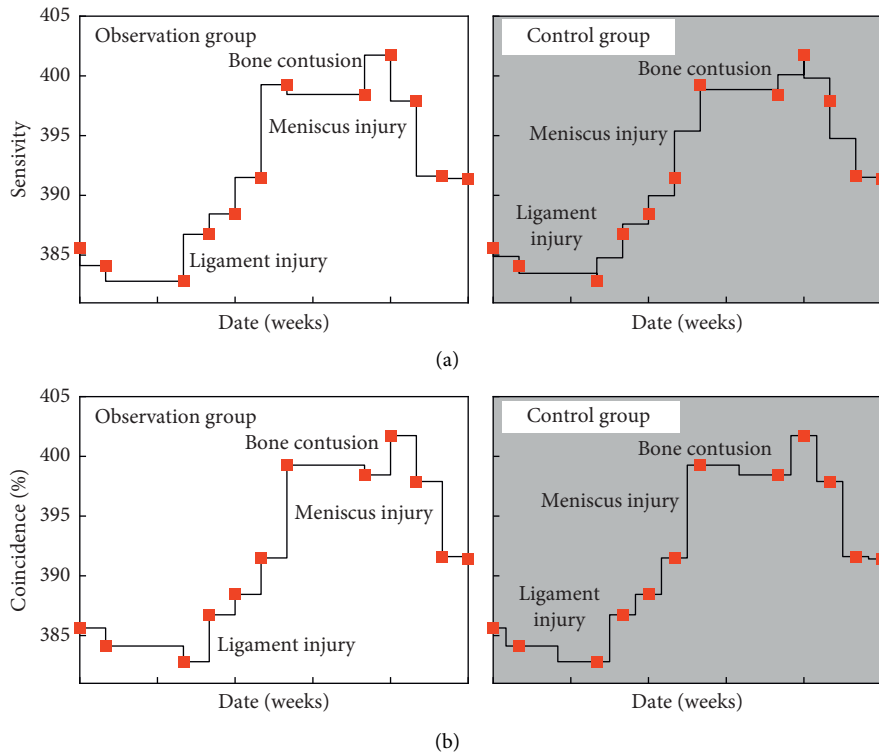

FIGURE 10: Sensitivity for different reconstruction methods at different recovery stages.

FIGURE 11: Biocompatibility of 3D-CT modeling to evaluate ACL and related cases in bone and blood tissues.

Therefore, when identifying them, they should be performed again after the patient's condition is stable and it is necessary to accurately grasp the best time for assessment, thereby ensuring the accuracy, objectivity, and impartiality of the conclusion of the assessment. In this study, all patients with anterior cruciate ligament injury were required to have the affected knee joint in an upright position and then take

X-rays from the side. Among them, the degree of advancement of the tibia relative to the femur was significantly different among different patients, and the tibia of some patients was significantly advanced relative to the femur. Later, it was reported in the literature that by scanning magnetic resonance imaging (MRI) of the knee joint, it was found that the degree of advancement of the lateral tibial

plateau to the lateral femoral condyle of patients with anterior cruciate ligament reconstruction failure was significantly increased. The results of this study further suggest that the clinical efficacy of anterior cruciate ligament reconstruction may be affected by the degree of advancement of the tibia relative to the femur after anterior cruciate ligament injury. Recently, a document reported by foreign scholars reported the role of soft tissues in maintaining the relationship between the normal position of the tibia and the femur, although the document confirmed the degree of forward displacement of the lateral tibia platform of the knee relative to the lateral femoral condyle in patients. When the anterior cruciate ligament is injured and the posterior horn of the lateral knee joint is damaged, it will increase significantly. However, there are no reports about the effect of bony structure on maintaining the relative position of tibia and femur after anterior cruciate ligament injury. At present, related literature has reported that one of the risk factors leading to anterior cruciate ligament injury is an increase in PTSA. Some literature studies have reported that through biomechanical studies, when the anterior cruciate ligament of the knee joint is injured, the displacement of the tibia relative to the femur will increase by about 6 mm forward with each increase of the tibial inclination of the tibia. Through the biomechanical model constructed by it, different foreign scholars have obtained similar experimental conclusions. However, at present, no scholars have proposed whether the relative position of the tibia relative to the femur will have different degrees of forward displacement after the anterior cruciate ligament injury in different patients.

## 6. Conclusion

In this paper, the 3D-CT three-dimensional reconstruction method is used to reconstruct the ACL natural femoral imprint and double-bone tract. The relative positional relationship between the two center points is compared, and the law is summarized to guide the improvement of ACL anatomic double-beam reconstruction under arthroscopy. The 3D reconstruction results suggest that the UF layer in the anterior medial portion is the thickest, forming a peak, and the thickness of the UF layer in the posterior medial portion gradually decreases in a stepwise manner. The entire UF tissue in the anterior medial portion and posterior medial portion is integrated into one body. The tissues are connected as a whole, and the thickness is relatively uniform. The two parts of the UF tissues are not connected. The CF tissue was inserted into the bone tissue in a zigzag pattern. The changes of CF tissues in the anterior medial and posteromedial CF tissues were similar, and they were distributed stepwise from the inside to the outside. According to the UF and CF spatial structure and changing rules, ACL is divided into medial and lateral beams. According to this study, it can be summarized that (1) 3D reconstruction can clearly reconstruct the natural footprint of ACL femoral stops and postoperative osseous position and (2) 3D reconstruction can be used to evaluate the position of osseous postoperative ACL anatomic double-beam reconstruction. In summary, the debate on how to reconstruct ACL will

continue, and the focus of everyone's debate is mainly on bone positioning and postoperative efficacy. Therefore, ACL surgery requires continuous improvement of surgical methods and surgical concepts.

## Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

## Conflicts of Interest

The author declares that there are no conflicts of interest.

With the continuous development of big data technology, the data of online lending platform witness explosive development. How to give full play to the advantages of data, establish a credit risk assessment model, and realize the effective control of platform credit risk have become the focus of online lending platform. In view of the fact that the network loan data are mainly unbalanced data, the smote algorithm is helpful to optimize the model and improve the evaluation performance of the model. Relevant research shows that stochastic forest model has higher applicability in credit risk assessment, and cart, ANN, C4.5, and other algorithms are also widely used. In the influencing factors of credit evaluation, the weight of the applicant's enterprise scale, working years, historical records, credit score, and other indicators is relatively high, while the index weight of marriage and housing/car production (loan) is relatively low.

## 1. Introduction

In recent years, with the rapid development of Internet finance, P2P platform develops rapidly in this context and gradually forms a new financial platform with great influence. P2P platform relies on cloud computing, social networking, and other channels to collect, organize, and record data, which greatly enhances the ability of financial risk prevention and control based on data mining technology. Through comparative analysis of user information, combining with specific historical data, it can effectively improve the information flow efficiency of both sides of capital supply and demand and provide necessary support for both sides to establish the relationship between supply and demand, and based on this, the financial risk caused by information asymmetry is kept at the lowest level [1]. However, the domestic P2P platform research time is relatively short, has not yet established a sound credit system, coupled with the relevant legal system is not perfect, and is easy to induce credit risk, which is a serious threat to the safety of users'

funds. In addition, with the advent of the era of big data, the data of online lending platform are constantly increasing, the data types are diverse, and the data are updated quickly [2]. How to give full play to the data advantages, obtain the required information, and enhance the platform's ability to monitor capital risk factors become the key to the development of the platform. In this case, the platform needs to rely on big data, combined with data mining technology, to build a scientific and reasonable credit risk assessment model to provide necessary basis for platform risk supervision and user investment. Therefore, this study is of great significance on the practical level.

Relatively speaking, the development time of foreign P2P platform is relatively long, and the level of related research results is high, which has more reference value in the aspects of concept discussion and risk assessment [3]. In the aspect of loan success rate, the relationship between personal information and loan success rate has been studied, and then the borrowing strategies are comprehensively discussed with the help of quantitative analysis tools. In terms of credit risk,

domestic scholars use empirical analysis and specific cases to analyze the influencing factors of credit risk and summarize the influencing factors related to default behavior [4]. Based on this, a classification method with random forest as the core is constructed, which greatly improves the effectiveness of credit risk assessment [5]. Affected by the Internet, computer, information technology, etc., building a smart city has become a key task of socialist construction work [6]. The empirical analysis shows that compared with FICO or LC, the evaluation method based on random forest has more advantages in identifying high reputation borrowers [7]. The research results in recent years show that the role of social network cannot be ignored in the development of online lending. The higher the richness of social resources, the lower the cost of obtaining loans [8]. There is a significant negative correlation between the two [9]. Empirical analysis shows that through the analysis of applicants' social networks, we can deeply understand the soft information related to credit risk so as to evaluate the applicants' credit risk more comprehensively. In the dual-channel supply chain system, channel optimization is influenced by channel attitude toward risk, in which risk is classified as general risk and interruption risk [10]. For individuals, P2P platform provides convenience for its financing or capital problems but also produces a series of risk problems, such as imperfect credit system, high moral hazard, and serious adverse selection [11]. At present, credit risk is the key content of risk research, and the research direction includes default characteristics analysis and platform reputation [12]. As the number of selected lines increases, the current same price for all passengers in different riding paths could make the bus industry development a step further [13]. In terms of default probability of applicants, incomplete market-oriented interest rate has more significant prediction effect, but the use of personal public information can also reflect the default risk to a certain extent [14]. Taking Renrendai as an example, its credit certification mechanism has certain advantages in reflecting credit risk, but the index system has certain limitations, so it is necessary to supplement and improve its evaluation index system.

Overall, the depth of research on P2P network lending needs to be further expanded. Compared with western developed countries, China's P2P platform development time is relatively short and mainly concentrated after the rise of Internet finance in 2012. The empirical research data are insufficient, mainly referring to the data provided by foreign platforms. However, both the research methods and the research conclusions are difficult to fully meet the domestic research demand. In view of this situation, this paper introduces R language and python to write web crawler program in data crawling of online credit platform, introduces smote algorithm in unbalanced data processing, and constructs credit risk assessment model combined with six data mining algorithms, which is more consistent with the development of domestic P2P platform. It is a kind of research on network credit risk based on big data background, and the new ideas play a positive role in improving the level of theoretical research in China.

## 2. Model Description

### 2.1. Commonly Used Data Mining Classification Model.

In the field of classification technology, decision tree presents the classification process in the form of directed acyclic tree, which is intuitive and simple, so it has a high application rate [15]. For classified data, the greedy algorithm is used as the core of decision tree to determine the nodes, and then the local optimal decision strategy is used to construct the decision tree. In the dual-channel supply chain system, channel optimization is influenced by channel attitude toward risk, in which risk is classified as general risk and interruption risk [16]. There are significant differences in decision tree types with different classification criteria. For example, taking information theory as the standard, it can be divided into ID3, C4.5, and cart, and SLIQ and sprint can be obtained from Gini index. Among the above methods, only ID3 can be used for discrete variables. On the basis of comprehensive analysis, cart and C4.5 algorithms are selected in this paper.

AdaBoost algorithm is a kind of lifting algorithm which can adjust the distribution of training samples by itself. It has high adaptive ability to ensure that the base classifier fits the samples with higher difficulty in classification. Through the AdaBoost algorithm, the weights of training samples can be combined, the parameters can be updated, and then the corresponding weighting can be completed:

$$\omega_i^{(j+1)} = \frac{\omega_i^{(j)}}{Z_j} \times \begin{cases} e^{-\alpha_j}, C_j(X_i) = y_i, \\ e^{\alpha_j}, C_j(X_i) \neq y_i, \end{cases} \quad (1)$$

where  $\omega_i^{(j)}$  refers to the weight of the sample  $(X_i, y_i)$  in the round of  $j$  iteration. Using this weight can enhance the weight of the wrong classification samples to a certain extent, which is not conducive to highlighting the weight of the correct classification samples [17]. Therefore, for unbalanced data sets, this algorithm can improve the accuracy of minority prediction to the greatest extent, and its defect is that the fitting problem is more prominent.

Support vector machine (SVM) is a realization method based on statistical learning theory. This method relies on the Mercer theorem and combines with nonlinear mapping method to realize the effective mapping of feature space in the Hilbert space and realize the accurate division of samples according to the linear decision boundary [18]. The application fields of this method include nonlinear regression model, high-level data analysis, and sample classification.

Artificial neural network (ANN) is a method to analyze the law of things by imitating the organizational structure of biological neural network. It is based on a large number of nodes with connection relationship, which can realize continuous iteration by connecting different nodes. The online-to-offline (O2O) business model is the new online shopping model in which consumers purchase products or services online and get the products or services in offline physical stores [19]. In this process, we need to determine the weight of the previous iteration, then calculate the weight of the node, and update the weight with the error value. Through the repetition of the above process, the error is reduced to the allowable range. Practice

shows that neural network is suitable for sample classification and variable regression and has good application effect. However, due to the high sensitivity of this method to noise, it is prone to local minimum problem, which has a certain negative impact on the accuracy of the final results.

**2.2. Random Forests.** Random forest is a combined classifier algorithm with decision tree as its core. In this method, the cart algorithm is used to construct the decision tree, the decision tree is used as the metaclassifier of sample classification, and the corresponding training set is obtained. In the construction of a single decision tree, the corresponding variables can be determined randomly, and node splitting can be completed based on the vector. According to the characteristics of this method, random forest has high robustness to noise, but low sensitivity to multiple reproducibility, so it can be relatively robust to deal with nonequilibrium data and get reasonable results.

The core of random forest is tree classifier, which is composed of various types of classifiers  $\{h(x, \theta_k), k = 1, 2, \dots, n\}$ . Among them, the nonconstructed classification decision tree obtained by using the cart algorithm is the metaclassifier. According to the simple arithmetic average of single decision tree and majority voting output results, the accurate result data can be achieved, and the steps are as follows.

Firstly, the training sample set is constructed. In general, self-help resampling technology can be used to generate independent sample sets; that is, based on  $n$  sample sets,  $k$  new organizational sample sets are obtained by random return, and then the corresponding decision tree is formed, while the unselected samples constitute out-of-bag data, namely, OOB.

Secondly, the decision tree node is split. According to the overall situation of decision tree characteristic variables, assume  $m$  and then randomly determine  $m$  characteristic variables from them to split the corresponding nodes. Among them, the number of characteristic variables randomly obtained by each node is less than the number of assumed characteristic variables, and the corresponding splitting is carried out according to the principle of node impure minimization. It should be emphasized that all decision trees have no pruning operation.

Thirdly, the decision tree completes the corresponding combination. Based on the decision trees obtained in the above steps, the output results are determined by averaging all decision trees by majority voting, and then the error analysis stage is entered.

For the data of nontraining set, the possibility of error classification by a specific classifier is the generalization error. Theoretical research shows that if the number of decision trees reaches a certain degree, the upper bound of random forest generalization error will converge according to the law of large numbers. Under the premise of the given sample, the interval function provided by using the random forest is as follows:

$$mr(x, y) = P_{\Theta}(h(x, \theta_k) = y) - \max_{j \neq y} P_{\Theta}(h(x, \theta_k) = j). \quad (2)$$

The strength of classifier set  $\{h(x, \theta)\}$  can be expressed as follows:

$$s = E_{X,Y}mr(x, y). \quad (3)$$

According to the above expression, there is a positive correlation between the strength of the classifier set and the value of the interval function, that is, the strength of the classifier set increases with the increase of the value of the interval function, and the prediction accuracy will also be improved accordingly:

$$PE^* \leq \frac{\bar{\rho}(1 - s^2)}{s^2}. \quad (4)$$

According to the above expression, the upper bound of generalization error is negatively correlated with the strength of the combined classifier, but positively correlated with the decision tree. Therefore, by weakening the correlation or enhancing the strength of a single decision tree, the generalization error performance can be improved.

The first is the OOB estimation. The bagging method can be used in self-service sampling. If the data are selected in the future, it will be used to predict the classification accuracy, that is, the OOB estimation of classification error rate. After averaging, the random forest generalization error estimation can be obtained.

The second is the characteristic importance value. The application of the random forest method can determine the specific degree of the importance of a single eigenvalue. At the same time, the performance of each decision tree can be evaluated by using the data outside the bag, that is, the accuracy rate of OOB. By combining with the noise interference test, the performance of the decision tree can be tested more accurately, that is, the new OOB accuracy rate. The important value of feature  $V$  in the decision tree can be expressed as the difference between the accuracy of new and old OOB, and its important value is determined after averaging. If there are more features in the basic samples, the best model can be determined by sorting the important values. Figure 1 shows the parameter selection of the random forest algorithm.

### 3. Data Collection and Processing

**3.1. Data Sources.** According to the relevant data, there are more than 1700 domestic P2P platforms, which complete the lending process with the help of third-party platforms. At present, Renrendai is the largest and longest established P2P platform in China. Therefore, this paper selects Renrendai loan as the research object, combines R language and python to write a web crawler program, obtains its relevant data, and gets about 50 variables, including amount and interest rate.

#### 3.2. Data Preprocessing

*Step 1.* Eliminate the variables that do not meet the conditions. Specifically, it includes the variables with the same values, the variables with repeated specific contents, the variables not related to the research topic, and the variables with serious missing data.

FIGURE 1: Parameter selection of the random forest algorithm. (a) ntree. (b) mtry.

*Step 2. Missing value processing.* It is found that the variables of some loan items are incomplete, such as the lack of industry, enterprise scale, and position. According to the specific situation, its industry can be defined as e-commerce; the enterprise scale is expressed as 0; and the position is expressed as individual shopkeeper.

*Step 3. Data normalization processing.* The output variable selects the number of overdue times, in which if it exceeds 0, it is marked as 0; otherwise, it is marked as 1; 0 and 1 are used to represent binary variable values; integers are used to represent education level, subject type, etc.; working hours are represented by the median value; and the amount of loan can be expressed as  $x' = (X - \min(X)) / (\max(X) - \min(X)) \times 10$ . The basic information of data after preprocessing is shown in Table 1.

#### 4. Credit Risk Assessment Model Based on Data Mining Algorithm

*4.1. Unbalanced Data Processing.* In the data sample obtained in this paper, there are 30 default items, accounting for 2.935%, and the rest are nondefault items, namely, unbalanced data set. Traditional data mining algorithms have some limitations in dealing with unbalanced distribution classes, and it is difficult to effectively focus on a few classes. Therefore, its classification performance is difficult to meet the requirements.

The data sampling method can be selected, that is, up or down sampling; on the contrary, data mining algorithms can be optimized and improved, such as cost sensitive learning. Through comparative analysis, it can be found that the possibility of incomplete data in down sampling is high.

Therefore, the application of upward sampling is more extensive. The basic up sampling method achieves the balance of data sets by randomly copying a few samples, but it is difficult to avoid the fitting problem.

The smote algorithm uses a small number of samples to construct artificial samples, thus achieving the balance of data sets, which is conducive to avoid the over fitting phenomenon. In this algorithm, the artificial samples are inserted into the adjacent samples in the feature space to increase the number of samples. For  $X_i \in S_{\min}$ ,  $k$  nearest neighbor points are searched, and the nearest neighbor points are selected by combining the parameters such as correlation coefficient or Euclidean distance. After determining the nearest neighbor points, the corresponding sample points  $Y_j$  are determined. On the basis of determining the difference between  $X_i$  and  $Y_j$  with the corresponding eigenvector, the random number  $\delta$  is determined, and then the artificial samples  $X_{\text{new}}$  are determined as follows:

$$X_{\text{new}} = X_i + (X_i - Y_j) \times \delta, \quad (5)$$

where  $j$  is the number of sample points  $j = 1, 2, \dots, n$ . Repeat the above steps, and stop after all minority samples are processed.

The smote algorithm uses the smote function to complete the confirmation of majority class sample  $m$  and minority class  $n$ . On the basis of determining the up and down sampling rates, the final majority class sample and minority class sample number  $N + nN$  and  $nNm$  are obtained.

The first is sample classification, which is divided into the test set sample and training set sample by random sampling; the second training set data balance is that minority class

TABLE 1: Basic information of data.

| No. | Variables   | Actual meaning            | Data processing   |
|-----|-------------|---------------------------|---|
| 1   | ID          | User ID                   |   |

$N = 15$ , majority class  $M = 496$ , taking  $n = 500\%$ ,  $m = 200\%$ ,  $k = 5$ , and keeping the proportion of 3 : 5, so as to improve the model performance. Table 2 shows the data composition.

**4.2. Model Empirical Analysis.** In this paper, the classification variable is repayment, and then the scientific selection of model parameters is performed, in order to obtain the analysis results of different data mining models, to lay the foundation for the subsequent empirical analysis. Table 3 lists the results of parameter selection and important variables of each model.

- (1) Determine the model parameters and output the corresponding results. In this paper, the random forest algorithm is selected to determine the number of decision trees and the number of variables of node branches (mtry). Then the model is built according to the new training set. If the number of decision trees is less than 40, the error rate fluctuation is not more

than 0.05; if the number of decision trees is more than 40, the prediction error rate is reduced to 0; determine the selected variables of 3–13 nodes to achieve the maximum AUC and accuracy under stable state. To sum up, ntree = 800 and mtry = 3 can be selected to complete the model construction, and each category can be accurately predicted. Figure 2 shows the Friedman average ranking.

On the whole, the variables with higher importance were paid, succeeded, application, score, field, etc., while the variables with lower importance were house and marriage. The importance of some variables is 0. Therefore, in the process of credit risk assessment, personal work information, credit rating, and historical records are the main variables. Relatively speaking, the importance of personal life information is lower than the above variables. Taking Renrendai as an example, the platform is based on the credit rating mechanism, combined with the

FIGURE 2: Friedman average ranking.

materials provided by the applicant, and serves as a reference for investors. In the main variables of credit risk evaluation, historical loan information can reflect the use of customer loans, while personal work information can reflect the stability of applicants' work, which is an important reference for evaluating their repayment ability. For the platform, we must further strengthen the collection, collation, and storage of data, provide more powerful information support for credit risk assessment and qualification review, and help investors obtain more income on

the premise of ensuring the safety of investors' funds to the greatest extent. Table 4 shows classification results summary of each model.

- (2) Comparative analysis of model performance is done before and after data balance processing. In the aspect of classifier performance evaluation, the accuracy index is usually selected; however, for the classification of unbalanced data, it is not appropriate to select the accuracy only. Therefore, the original model can be optimized by combining the

|          | Mean value              |    |    |    |     | 0911               | 0977               | 0972          | 0935 |

specific index and sensitivity index. We can compare the ROC curve of each model in Figure 3.

The first is accuracy. The model built by the new training set can basically achieve the accuracy rate of 0.963–0.982, among which ANN, RF, and C4.5 rank in the top three. Even though the accuracy of cart, AdaBoost, SVM, RF has declined, it can more accurately predict a few items. Among them, C4.5 and ANN models have greatly improved the prediction accuracy based on the original training set model.

The second is ROC curve and AUC. The closer to the upper left corner, the higher the accuracy of the model prediction. Comparatively speaking, the ROC

curve of the model constructed based on the new training set is more concentrated in the upper left corner, which indicates that the classifier has better performance. In particular, after the original sample is balanced by using the smote algorithm, the model constructed based on this has significantly higher AUC, which is more than 0.85. RF, cart, and C4.5 rank in the top three, and RF, cart, and C4.5 rank the best. The AUC of random forest method is very close to 1, reaching 0.987. Compared with other models, its advantages are very significant.

Generally speaking, in the related research of credit risk evaluation, it is of great significance to

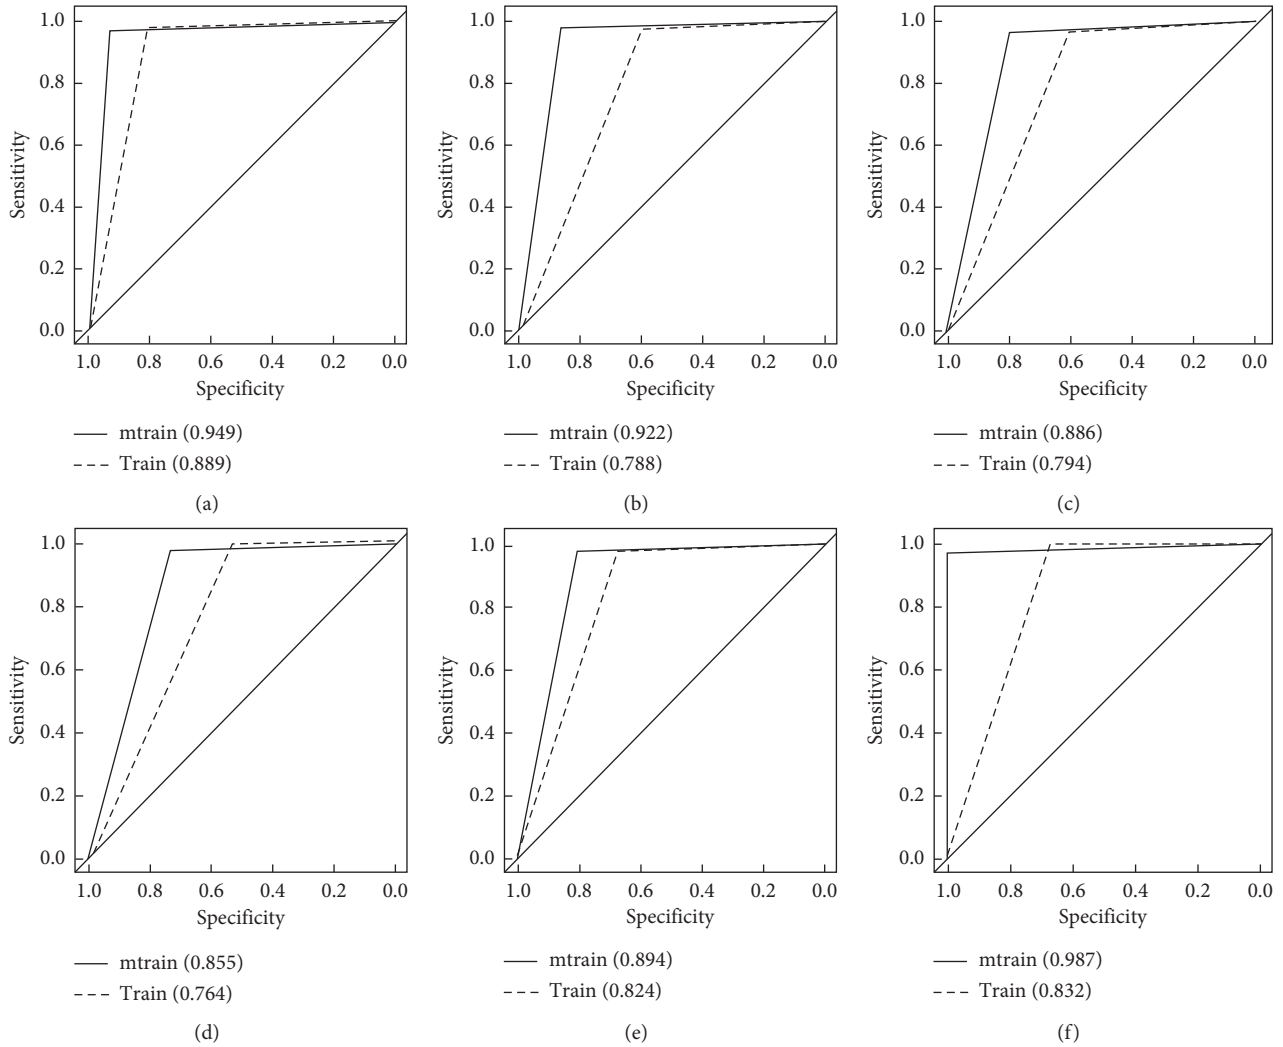

FIGURE 3: ROC curve of each model. (a) CART. (b) C45. (c) AdaBoost. (d) SVM. (e) RF. (f) ANN.

strengthen the research on the prediction of a small number of samples, which can provide more information support for relevant investors, help investors choose investment projects more scientifically, so as to minimize the credit risk, and improve the security of funds, which has good practical value. In this case, according to the characteristics of the original training set, this paper introduces the smote algorithm to deal with it, which greatly improves the performance of credit risk assessment model, and improves the accuracy of default project prediction.

- (3) The prediction performance of different models was compared and analyzed. Through the analysis of Table 4, it can be found that the true rate of the random forest model in the model built based on the new training set is about 1, and its AUC is as high as 0.987, which has relatively high accuracy and has good identification ability for relevant default samples. In summary, this paper preliminarily

determines that the random forest model has higher prediction accuracy and the best performance.

In order to verify the conclusion of this paper and determine the best model, this paper selects a 3-fold cross validation method. According to the standard of this paper, dependent variables include default variables and nondefault variables. In order to balance the two categories in the original data, we can divide them into three parts randomly, that is, three data sets including default variables and nondefault variables, and run them as test sets. The data sets are processed by using the smote algorithm, and then the corresponding models are established and their classification performance is evaluated to carry out the targeted test. It can be seen from Table 5 that the mean values of true positive rate are larger, the difference is larger.

Among them, the models with more than 0.85 include RF, cart, and ANN, which are in the forefront. Therefore, the above three models have high recognition ability for default items; the true negative rate of RF, AdaBoost, and C4.5 is in the top three, and the accuracy rate of RF, C4.5, and

AdaBoost is in the top three. Considering that the accuracy rate is difficult to distinguish the minority class from the majority class, the accuracy can only be used as a reference to determine the best model, rather than the main factor. The AUC of RF, cart, and ANN ranked in the top three. To sum up, the best performance is the random forest model, which has broad application prospects in the evaluation of network lending credit.

## 5. Conclusion

This paper comprehensively and systematically studies the credit risk factors in P2P network lending and constructs a data mining model in risk assessment, which lays the foundation for the follow-up research. The smote algorithm is used to process the unbalanced data, and then the corresponding model is established, which can reduce the volatility of prediction accuracy and improve the risk identification ability of AUC index and default items. The future research focuses on the following: first, strengthen the analysis of user behavior; second, judge the correlation between user behavior and credit risk; and third, build a user credit risk assessment system to provide real-time search function for the platform.

## Data Availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also forms part of an ongoing study.

## Conflicts of Interest

The authors declare that they have no conflicts of interest.

## Acknowledgments

The findings were sponsored by the National Social Science Fund of China (Grant no. 18CGL015).

In the recent years, along with the development of artificial intelligence (AI) and man-machine interaction technology, speech recognition and production have been asked to adapt to the rapid development of AI and man-machine technology, which need to improve recognition accuracy through adding novel features, fusing the feature, and improving recognition methods. Aiming at developing novel recognition feature and application to speech recognition, this paper presents a new method for articulatory-to-acoustic conversion. In the study, we have converted articulatory features (i.e., velocities of tongue and motion of lips) into acoustic features (i.e., the second formant and Mel-Cepstra). By considering the graphical representation of the articulators' motion, this study combined Bidirectional Long Short-Term Memory (BiLSTM) with convolution neural network (CNN) and adopted the idea of word attention in Mandarin to extract semantic features. In this paper, we used the electromagnetic articulography (EMA) database designed by Taiyuan University of Technology, which contains ten speakers' 299 disyllables and sentences of Mandarin, and extracted 8-dimensional articulatory features and 1-dimensional semantic feature relying on the word-attention layer; we then trained 200 samples and tested 99 samples for the articulatory-to-acoustic conversion. Finally, Root Mean Square Error (RMSE), Mean Mel-Cepstral Distortion (MMCD), and correlation coefficient have been used to evaluate the conversion effect and for comparison with Gaussian Mixture Model (GMM) and BiLSTM of recurrent neural network (BiLSTM-RNN). The results illustrated that the MMCD of Mel-Frequency Cepstrum Coefficient (MFCC) was 1.467 dB, and the RMSE of F2 was 22.10 Hz. The research results of this study can be used in the features fusion and speech recognition to improve the accuracy of recognition.

## 1. Introduction

Along with the popularity of artificial intelligence, man-machine interaction technology has put forward higher requirements for speech processing technology, and it is hoped that intelligent products, such as computers and mobile phones, will have the ability to communicate harmoniously with human beings and the ability to express emotions. The existing technology of emotional speech processing inevitably took advantage of the human pronunciation mechanism, and then human speech is pronounced successfully by the systematic movements through the muscle's contraction of the vocal organs, such as the tongue, lips, and jaw. This relationship between articulatory and acoustic data has been formed through the accumulation of a great deal of articulatory experience.

Although people have adopted a variety of technologies to collect the motion information of articulators, such as X-ray [1], real-time Magnetic Resonance Imaging (rMRI) [2], Ultrasound [3], EPG [4], and EMA [5], most data acquisition environments were not perfect, and the collected data were of poor natural degree or were easily disturbed by external noise [6]. Among them, due to the EMA technology using sensors placed on the pronunciation organs such as the surface of the lip, contact area is only 3 mm<sup>2</sup>; at the same time, the sensors' working theory is simple and with stable performance, which has been widely used in pronunciation organs' trajectory tracking and data collection.

For more than a decade, researchers have been studying the acoustic-to-articulatory inversion. Ouni and Laprie [7] first proposed the codebook method in 2005, which used vector quantization to encode the acoustic vectors of speech

and calculate the minimal Euclidean distance between the acoustic vectors and the articulatory vectors, so as to construct the inversion system. The drawback of this method is that it requires a large amount of data to achieve the accurate conversion effect.

King and Wrench [8] implemented a dynamic system to train EMA data using Kalman filter in 1999. They defined the acoustic and articulatory features of speech as linear relationship based on the physical model of speech production. However, there was no strict linear relationship between the acoustic and articulatory features.

Furthermore, in 2000, Dusan and Deng [9] used an extended Kalman filter to train the acoustic-articulatory data to establish a more realistic inversion relationship. By combining this model with Kalman smoothing filter, the movement trajectory of the articulator would be simulated, and the RMSE between the simulated trajectory and the original trajectory was realized to be 2 mm.

Korin Richmond and Yamagishi [10] used neural network to realize the acoustic-to-articulatory inversion firstly in 2002. They used the data of two subjects in MOCHA-TIMIT and achieved the inversion result with a RMSE as low as 1.40 mm. At the same time, Toda et al. [11] proposed a feature inversion method based on Gaussian Mixture Model (GMM), which used maximum likelihood estimation method to analyze the parallel acoustic data stream and the EMA data stream, and established the joint probability density function. Different quantities of Gaussian mixture elements had been used to achieve higher inversion accuracy.

Hiroya and Honda [12], Lin et al. [13], and Ling et al. [14] successively used and improved HMM and finally achieved the integrated RMS of 1.076 mm, which is also the highest inversion accuracy achieved by using HMM model so far.

In recent years, deep learning has attracted great attention for its ability to model nonlinear mapping relations and has been applied to the inversion of articulatory and acoustic features. Leonardo Badino et al. [15, 16] realized acoustic-to-articulatory inversion using Deep Belief Network (DBN) and Hidden Markov Model (HMM) and applied it to speech recognition, resulting in a 16.6% reduction in the recognition relative bit error rate. At the early stage, convolutional neural network (CNN) [17] has been widely used in the field of image signal processing, which had obvious advantages in the analysis of local features; meanwhile the articulatory features could be seen as the visual features of speech. Sun et al. [18] from Yunnan University showed that CNN could be applied to the emotion classification of speech and achieved good results. They were the first to introduce word-attention mechanism to emotion classification and reveal the influence of semantics on classification effect.

However, most researchers only focus on the acoustic-to-articulatory inversion, and the research on the articulatory-to-acoustic conversion is less and started relatively late. Yet the articulatory-to-acoustic conversion is helpful to the study of pronunciation mechanism and the development of speaker recognition and emotion recognition. Liu et al. [19, 20] of the University of Science and Technology of

China used Cascade Resonance Network and BiLSTM-RNN to convert articulatory features into spectral energy and fundamental frequency features in 2016 and 2018, respectively, and achieved a good conversion effect.

At present, the conversion focuses on the frame or phoneme level, with emphasis on the pronunciation rules and acoustic characteristics of phonemes. However, in the tonal languages like Mandarin, the interaction between syllables must hide certain acoustic-pronunciation information. Meanwhile, word-attention mechanism has been widely applied in the field of text processing and emotion classification. Wang and Chen [21] proposed an LSTM emotion classification method based on attention mechanism and realized emotion classification through feature screening of short- and long-text features combined with attention mechanism. Wang et al. [22] proposed a word-attention convolution model with the combination of CNN and attention mechanism, aiming at word feature extraction.

Relying on deep learning with nonlinear and attention mechanism, BiLSTM-CNN method and word-attention mechanisms were used to realize the articulatory-to-acoustic conversion in this paper. The paper is organized as follows. First, we review related work on articulatory-to-acoustic conversion, as well as CNN and word-attention mechanism in Section 2. Next, the detailed method we proposed is described in Section 3, and Section 4 reports our experiments and their results. Section 5 provides the discussion and conclusion of the work.

## 2. Related Work

To explore the articulatory-to-acoustic conversion and improve the conversion effect, lots of researches have been carried out in the past decades, and several methods have been proposed to model the conversion, including Gaussian Mixture Model (GMM), recurrent neural network (RNN), Long Short-Term Memory (LSTM), BiLSTM, and CNN. We will give a brief introduction in this section.

*2.1. GMM-Based Articulatory-to-Acoustic Conversion.* GMM is a classical feature conversion method [23], which used the joint probability density function of acoustic-articulatory features to realize the conversion. The description of the transformation model is

$$y_i = \sum_{i=1}^M p(\lambda_i | t_i) p(y_i | x_i, \lambda_i), \quad (1)$$

Here,  $M$  is used to represent the number of Gaussian mixture elements,  $p(\lambda_i | x_i)$  denotes the probability of acoustic feature vector  $x_i$ , and  $p(y_i | x_i, \lambda_i)$  represents full covariance matrix of conditional Gaussian distribution.

$x = (x_1, x_2, \dots, x_M)$  and  $y = (y_1, y_2, \dots, y_M)$  have been defined as articulatory and acoustic features, respectively, where,  $M$  is the number of frames. Considering that the articulatory features of frame  $i$  are known, the first-order dynamic features are as follows:

$$\Delta x_i = -0.5x_{i-1} + 0.5x_{i+1}. \quad (2)$$

The articulatory features and the first-order dynamic features are spliced as the input feature vector  $X_i = [x_i^M, \Delta x_i^M]^M$ , and then output vector  $Y_i = [y_i^M, \Delta y_i^M]^M$  can be obtained. Thus, the joint probability distribution of input and output vectors can be described as follows:

$$P(Z_i | \vartheta) = P(X_i, Y_i | \Theta) = \prod_{j=1}^N \partial_j \mathbb{N} \left( Z_i, \mu_j^Z, \sum_j^Z \right), \quad (3)$$

$$Z_i = \begin{bmatrix} X_i \\ Y_i \end{bmatrix},$$

$$\mu_j^Z = \begin{bmatrix} \mu_j^X \\ \mu_j^Y \end{bmatrix},$$

$$\sum_j^Z = \begin{bmatrix} \sum_j^{XX} & \sum_j^{XY} \\ \sum_j^{YX} & \sum_j^{YY} \end{bmatrix},$$

where  $Z_i = [X_i^M, Y_i^M]$  is the joint vector of articulatory and acoustic features,  $N$  is the number of Gaussian elements,  $\theta = \alpha_j, \mu_j^Z, \sum_j^Z | j = 1, 2, \dots, N$ , denotes the model parameters of GMM, and  $\alpha_j, \mu_j^Z$ , and  $\sum_j^Z$  are weight, mean, and covariance of Gaussian element  $j$ , respectively. Among them, model parameter  $\Theta$  will be estimated by Maximum Likelihood Estimation Algorithm (MLEA) [24]. When the dimension between articulatory and acoustic features is different, the covariance matrix  $\sum_j^Z$  is full-rank matrix.

During the conversion, input articulatory features are supposed to be  $X = [x_1, x_2, \dots, x_M]$ , and output acoustic features are supposed to be  $Y = [y_1, y_2, \dots, y_M]$ ;  $y^*$  can be calculated relying on the MLE as follows:

$$y^* = \arg \max_y p(Y | X, \Theta), \quad \text{s.t. } Y = W y, \quad (4)$$

Here,  $W$  is dynamic window coefficient matrix. In formula (4), conditional probability distribution can be rewritten as follows:

$$p(Y | X, \Theta) = \sum_{j=1}^N p(j | X, \Theta) p(Y | j, Y, \Theta). \quad (5)$$

If we only refer to a Gaussian element, it can be calculated by Maximum Posterior Probability, which is shown as follows:

$$j^* = \arg \max p(j | X, \Theta). \quad (6)$$

If the frames are independent of each other, for input of frame  $i$ ,  $X_i$  exist as Formula (7); meanwhile, the output of frame  $i$ ,  $Y_i$  exist as Formula (8):

$$p(j | X_i, \Theta) = \frac{p(j | \Theta) p(X_i | j, \Theta)}{p(X_i | \Theta)} = \frac{\alpha_j \mathbb{N}(X_i | \mu_j^X, \sum_j^{XX})}{\sum_n \alpha_n \mathbb{N}(X_i | \mu_n^X, \sum_n^{XX})}, \quad (7)$$

$$p(Y_i | j^*, X_i, \Theta) = \mathbb{N}(Y_i | \mu_{j^*}^{y|x}, \sum_{j^*}^{y|x}). \quad (8)$$

Here,  $\mu_{j^*}^{y|x}$  and  $\sum_{j^*}^{y|x}$  are mean and covariance matrix, respectively, which are calculated using the following two formulas:

$$\mu_{j^*}^{y|x} = \mu_{j^*}^Y + \sum_{j^*}^{YX} \sum_{j^*}^{YX^{-1}} (X_i - \mu_{j^*}^X), \quad (9)$$

$$\sum_{j^*}^{y|x} = \sum_{j^*}^{YY} - \sum_{j^*}^{YX} \sum_{j^*}^{XX} \sum_{j^*}^{XY}. \quad (10)$$

On this basis, we can obtain the output sequence using maximum likelihood criterion, as shown in formula (11), where  $\Sigma^y$  is square matrix and  $\mu^y$  can be calculated through  $\mu_{j^*,t}^{y|x}$  connecting nose to tail:

$$y^* = \left( W^T \sum_{j^*}^{y-1} W \right)^{-1} W^T \sum_{j^*}^{y-1} \mu^y. \quad (11)$$

**2.2. LSTM of RNN.** Recurrent neural network (RNN) is a kind of neural network that takes sequence data as input data and recurses along the time domain direction of the sequence [20]. All nodes in this network are connected in a chain. RNN has the advantages of memorability, parameter sharing, and Turing completeness and is obviously superior to GMM in learning nonlinear features. The network has been widely used in speech recognition, speech modeling, feature conversion, and other fields.

The core of RNN is the directed graph, and the loop unit is fully connected. Input sequence is given as  $X = \{X_1, X_2, \dots, X_M\}$ , and spread length is given as  $\tau$ . For time-step  $t$ , the recurrent unit should be taken as

$$h^{(t)} = f(s^{(t-1)}, X^{(t)}, \theta), \quad (12)$$

where  $h$  denotes systematic state of RNN,  $s$  denotes inner state calculated by  $s = s(h, X, y)$ , and  $f$  represents activation function, such as logistic and hyperbolic tangent function, or represents a kind of feedforward neural network. The excitation function corresponds to the simple recurrent network, and the feedforward neural network corresponds to some depth algorithms.  $\theta$  is weight coefficient in the recurrent unit.

We take the example of an RNN containing a hidden layer; the hidden layer vector sequence  $H = \{h_1, h_2, \dots, h_M\}$  can be obtained by

$$h^{(t)} = f(W_{hh} h^{(t-1)} + W_{xh} X^{(t)} + \theta_h). \quad (13)$$

Then, output sequence  $Y = \{Y_1, Y_2, \dots, Y_M\}$  can be shown as follows:

$$Y^{(t)} = W_{hy} h^{(t)} + \theta_y. \quad (14)$$

Initially, inverse error transfer algorithm on the time axis has been adopted to update the parameters, which would produce some inverse transfer error. So gradient erasing and explosion would occur, which seriously affected the training effect of RNN. In order to reduce the above problems, Li et al. [25] put forward Long Short-Term Memory (LSTM), including nonlinear transform and gate-structure affection function. Through the development of LSTM, the structure brought forward by Aviles and Kouki [26] is consisting of

input gate, output gate and forgetting gate. Among them, input gate is used to control the conversion processing from accepted information to memory sequence, which is shown as follows:

$$i^{(t)} = \sigma(W_{ix}X^{(t)} + W_{ih}h^{(t-1)} + W_{ic}c^{(t)} + \theta_i), \quad (15)$$

Here,  $\sigma$  is sigmoid function and  $c$  is memory sequence. Forgetting gate is used to control how much of the current memory information should be discarded, the implementation method of which is

$$f^{(t)} = \sigma(W_{fx}X^{(t)} + W_{fh}h^{(t-1)} + W_{fc}c^{(t)} + \theta_f). \quad (16)$$

The memory sequence can be updated as follows relying on input and output gates:

$$c^{(t)} = i_t * \tan h(W_{cx}X^{(t)} + W_{ch}h^{(t-1)} + \theta_c) + f^{(t)} * c^{(t-1)}. \quad (17)$$

The output gate can be used to scale output sequence, and the detailed method is as follows:

$$o^{(t)} = \sigma(W_{ox}X^{(t)} + W_{oh}h^{(t-1)} + W_{oc}c^{(t)} + \theta_o). \quad (18)$$

Finally, we can obtain

$$h^{(t)} = o^{(t)} * \tan h(c^{(t)}), \quad (19)$$

and the result can be transferred into RNN.

**2.3. BiLSTM.** Bidirectional Long Short-Term Memory (BiLSTM) [18] is a variant of traditional neural network and combination of forward LSTM and backward LSTM. Output of the model can be represented as

$$\begin{aligned} \vec{h}^{(t)} &= \overline{\text{LSTM}}(h^{(t-1)}, X^t, c^{(t-1)}), \\ \overleftarrow{h}^{(t)} &= \overline{\text{LSTM}}(h^{(t+1)}, X^t, c^{(t+1)}), \\ h^{(t)} &= \left[ \vec{h}^{(t)}, \overleftarrow{h}^{(t)} \right]. \end{aligned} \quad (20)$$

Let us take the mean of  $h^{(t)}$  as the output; that is to say, the output is mean( $h^{(t)}$ ). Until the long-short sequence has arrived at BiLSTM layer, gate structure began to carry adoption and releasing of the information through sigmoid, and the output is between 0 and 1 (1 means complete adoption, and 0 means complete discarding). The ideal structure of BiLSTM is shown in Figure 1.

**2.4. CNN.** Convolutional neural network (CNN) [18] is a feedforward neural network containing convolution operation, and its model structure generally includes input layer, convolution layer, pooling layer, full-connection layer, and output layer. The convolution layer, pooling layer, and full-connection layer can all be seen as hidden layers. Among them, the role of the convolution layer is to carry out feature extraction, and the feature extraction of input layer data can be realized by using the set filter. The specific method is shown as follows:

FIGURE 1: Structure of BiLSTM.

$$J_i = f(\omega * X_{i:i+g-1} + \theta). \quad (21)$$

Here,  $\omega$  denotes convolution kernel,  $g$  denotes the size of convolution kernel,  $X_{i:i+g-1}$  denotes articulatory feature vector from frame  $i$  to frame  $i+g-1$ , and  $\theta$  denotes bias value. Thus, we can obtain the feature matrix  $J = [c_1, c_2, \dots, c_{n-g+1}]$  through the convolution layer calculation.

Using max pooling technology, pooling layer can downsample the feature matrix and achieve optimal solution of the local value. Full-connection layer is located in the last layer of the hidden layer and can expand the feature diagram with topological structure to activate function. Output layer uses logical function or Softmax function to output classified label and predicted value.

### 3. Methods

**3.1. Speaker Normalization Based on Prussian Transformation.** Because speakers' articulatory characteristics are easily influenced by the speakers themselves, including their vocal tract characteristics, height, and sitting position; these factors are inherent differences between speakers. In order to eliminate these inherent differences and better quantify the kinematic characteristics of speech, we used the Prussian Transformation to normalize the articulatory characteristics of different speakers. The specific processing is shown in Figure 2.

The algorithm realized the linear geometric transformation from the original multipoint object to the target multipoint object, including scale transformation, translation transformation, and rotation transformation. It is supposed that the raw articulatory data was  $D_1$ ; then the normalization of  $D_1$  was  $D_3$ , and the target speaker's articulatory data was  $D_2$ . Using hybrid transform consisting of scale transform and rotation transform, we can take the relation between  $D_1$  and  $D_3$  as follows:

$$D_3 = HD_1a + b, \quad (22)$$

where the normalizing parameter  $\{H, a, b\}$  can be optimized relying on minimized Root Mean Square Error between target data  $D_2$  and the normalized data of raw speaker's articulatory  $D_3$ .

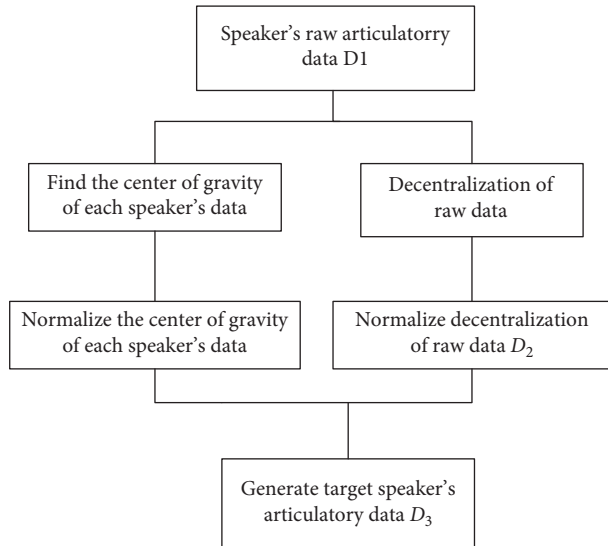

FIGURE 2: Diagram of speaker normalization algorithm based on Prussian Transformation.

To be specific, rotation matrix can be calculated using singular value decomposition, which is shown as follows:

$$(D_1)^T D_2 = U \Sigma V^T, \quad (23)$$

Here,  $\Sigma$  is the diagonal matrix,  $U$  and  $V$  are separate orthogonal matrices, and  $A$  is the diagonal matrix in which the absolute value of the diagonal elements is 1.

**3.2. BiLSTM-CNN-Based Articulatory-to-Acoustic Conversion.** According to Sections 2.2 and 2.3, CNN has a good ability to extract local features, and BiLSTM network has a good performance on the coherence of previous frames and semantic features based on word-attention mechanism [27]. This paper combined CNN and BiLSTM and used the theory of word attention to achieve articulatory-to-acoustic conversion, where BiLSTM used context information to analyze the articulatory features and train continuous frames, and word-attention layer used word-attention mechanism to extract semantic features and send them to the BiLSTM for training. In the later stage, the CNN was mainly composed of convolutional layer, pooling layer, and full-connection layer. Finally, acoustic features are output by regression layer. The specific model structure is shown in Figure 3.

As illustrated in Figure 3, the LSTM cells at each layer in the BiLSTM-CNN were divided into two parts to capture the forward and backward dependency, respectively. In this case, the forward and backward articulation feature sequences were both 10 frames and the feature vector of each frame was 8 dimensions, and the semantic feature was 1 dimension. Thus, the input feature dimension of the feature fusion layer was 169 dimensions. In the CNN part, we used 4 full-connection layers, the convolution layer with size of 128 dimensions, and the regression layer.

## 4. Experiments and Results

### 4.1. Materials

**4.1.1. Participants.** In the study, ten participants (5 males and 5 females) were recruited; all of them were aged between 25 and 40 years (average of ages is 27.1, and the STD is 1.94) with no professional language training and no orofacial surgery history [28]. Before collecting the data, all subjects were told the processes for collecting data and signed informed consent. The study was approved by the Health Sciences Research Ethics Board at Institute of Psychology of the Chinese Academy of Sciences (No. H16012).

**4.1.2. Textual Material.** Disyllable words and sentences of neural affect were chosen as textual material. Sentences of neural textual material were chosen as the spoken material, including “Xia4 yu3 le1.” (It is raining.), “Jin1 tian1 shi4 xing1 qi1 yi1.” (Today is Monday.), “Wo3 xiang3 gei3 ta1 yi2 ge4 jing1 xi3.” (I want to give him a surprise.), “Ni3 yuan2 lai2 zai4 zhe4 li3” (So you here.), “Wo3 cuo4 le1.” (I am wrong.), “Ni3 xue2 de1 zhen1 kuai4.” (You learn fast.), and “Wo3 men2 shi4 lao3 tong2 xue2.” (We are old classmates.).

Disyllable words were chosen as the spoken material, including “Mama” (Mum), “Zaijian” (Good-bye), “Tiantian” (Everyday), “Daqi” (Encourage), and “Nihao” (Hello).

**4.1.3. Data Collection.** All articulatory data and acoustic data were collected using the AG501 [29] EMA device of Carstens [29] (Lengler, Germany) as shown in Figure 4, which has 24 articulatory channels and one audio channel with 250 Hz and 48 kHz sampling rate. AG501 is widely used in electromagnetic articulography, which allows the collecting in 3D of the movements of the articulators with high precision.

We have glued 6 sensors (2 mm \* 3 mm) with thin wires to the left and right mastoids, nose bridge, and the bite plane to carry head collection and 9 sensors to the upper and lower lips, left and right lip corners, upper and lower incisors, and tongue tip, tongue mid, and tongue root (as shown in Figure 5). All subjects engaged in conversation for approximately 5 minutes after sensors were attached to provide subjects the opportunity to familiarize themselves with the presence of the sensors in the oral cavity.

The collection experiment has been carried out in the quiet environment with a maximum background noise of 50 dB. Acoustic data was collected by a match condenser microphone EM9600, and articulatory data was collected in synchronization with the acoustic data.

**4.1.4. Data Processing and Feature Extraction.** The collected data were loaded into the VisArtico, a visualization tool for filtering using a low-pass filter (cut-off is 20 Hz). Meanwhile, the articulatory data were corrected for head movement using Cs5normpos tool, which is a kind of tool in the EMA control system of AG501.

The VisArtico program can visualize kinematic data while also allowing for calculation of tongue kinematic

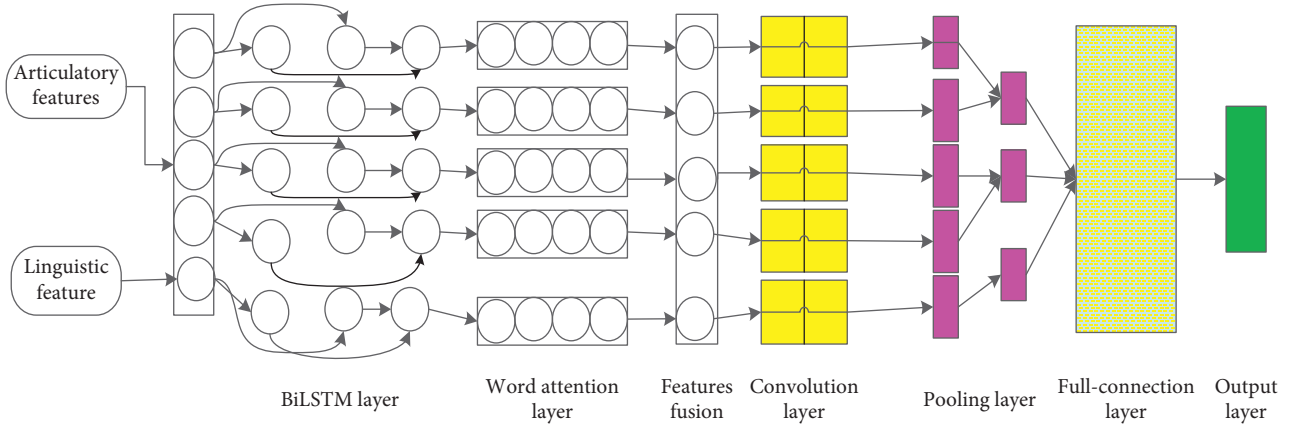

FIGURE 3: Integration model of BiLSTM-CNN.

FIGURE 4: Sensor placements on occlusal bite plane.

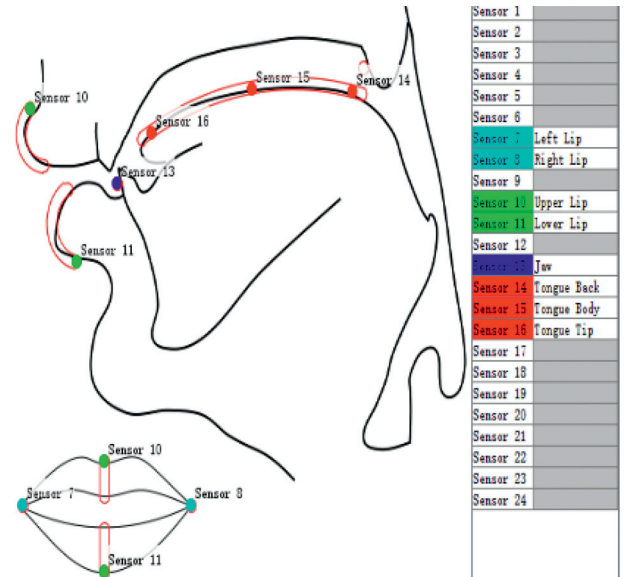

FIGURE 5: Sensor placements on the articulator.

parameters. In this paper, we extracted 8-dimensional articulatory features as shown in Table 1.

In this paper, we have chosen 299 samples of disyllables and sentences and then took 200 samples as the training data and 99 samples as the test data, respectively.

**4.2. Model Comparison of EMA-to-F2 Conversion.** In the EMA-to-F2 experiment, we compared the performances of the GMM-based, RNN-based, and BiLSTM-CNN-based methods. The Root Mean Square Error (RMSE) in Hz between the true and the predicted F2 was adopted as the evaluation measure parameter.

As a classical prediction model, GMM can approximate any function as long as the number of mixing elements is sufficient. In this study, we selected GMM with 500 Gaussian elements to accurately describe the joint probability density function of the articulatory features and acoustic features.

According to the maximum likelihood criterion, the conditional probability of acoustic features has been obtained by approximate calculation of the joint probability density function of acoustic features and articulatory features, and the closed solution of the best acoustic features has been obtained. The result is shown in Figure 6 (the figure takes 80 frames of data as the example).

For the EMA-to-F2 conversion based on BiLSTM-RNN, the 21-frame input window (10 frames forward and 10 frames backward) has been used to train the network. We have trained 50 iterations for BiLSTM-RNN with 5 hidden layers and 100 hidden units per hidden layer. The training results are shown in Figure 7, which illustrated the RMSE and loss of training data. Along with increasing the iterations number, the RMSE between the true and predicted data and loss function values decreased. The optimal model occurred at the 48th epoch, and the loss function value and RMSE reached their minimum, respectively.

The BiLSTM-CNN we proposed consisted of BiLSTM, word-attention layer, and the CNN (convolutional layer,

TABLE 1: Articulatory features.

| Abbreviation for features | Description of features                                      |
|---------------------------|--|
| Tongue root-X             | The normalized back-forward velocity of the tongue root      |
| Tongue root -Z            | The normalized up-down velocity of the tongue root           |
| Tongue body-X             | The normalized back-forward velocity of the tongue mid       |
| Tongue body-Z             | The normalized up-down velocity of the tongue mid            |
| Tongue tip-X              | The normalized back-forward velocity of the tongue tip       |
| Tongue tip-Z              | The normalized up-down velocity of the tongue tip            |
| Tongue constriction       | The kinematics range of tongue tip at back-forward direction |
| Lip aperture              | The open degree of lips at up-down direction                 |

FIGURE 6: Comparison between true and conversed values of GMM-based F2.

pooling layer, full-connection layer, and regression layer). About the CNN part, we have chosen the convolutional layer with size of  $169 * 169$ , 4 full-connection layers, and the 1-dimensional regression layer. About the BiLSTM part, we took 5 hidden layers with 100 hidden units per hidden layer and adopted 21 frames (10 frames forward, 1 current frame, and 10 frames backward) as the input feature; meanwhile, the semantic feature needs input to the BiLSTM for feature fusion and training. In the training process, we initially set the learning rate to 0.005 and fixed the momentum at 0.8, with maximum epochs of 50. Then, we can find that BiLSTM-CNN is much better than the BiLSTM-RNN and GMM conversion model, and the comparisons of F2 between true value and the predicted values, using the GMM, BiLSTM-RNN, and BiLSTM-CNN based on word attention, all are shown in Figure 8.

From the figure, we can find that the predicted F2 using BiLSTM-CNN is most similar to the true value, and the predicted F2 using BiLSTM-RNN is less similar to BiLSTM-CNN. Furthermore, we used test data on GMM, BiLSTM-RNN, and BiLSTM-CNN based on word attention; the RMSE and correlation coefficient  $r$  of F2 can be obtained and shown in Table 2.

The correlation coefficient  $r$  has been used to analyze the correlation between the predicted features and the true features using Pearson product moment correlation method, which is a method to analyze the linear relationship between two variables. Here, it is supposed that there are two databases: articulatory feature input ( $x = \{x_1, x_2, \dots, x_n\}$ ) and

acoustic features output ( $y = \{y_1, y_2, \dots, y_n\}$ ), and the size of the database is  $n$ . Thus, Pearson correlation coefficient can be defined as

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}, \quad (24)$$

where  $\bar{x}$  and  $\bar{y}$  represent the means of sample features  $x$  and  $y$  and  $x_i$  and  $y_i$  show  $i$ th values of  $\bar{x}$  and  $\bar{y}$ , respectively. Correlation coefficient  $r$  can reflect the strength information of the linear relationship between variable sets  $x$  and  $y$ , ranging from  $-1$  to  $1$ . If  $x_i$  and  $y_i$  are multidimensional vector, the dimensionality of the vector should be reduced first, and then the correlation analysis should be carried out.

In the study, we can find that there are strong positive correlations between the predicted and true features on all three models, which is shown in Table 1. In detail, the correlation was, in turn, BiLSTM-CNN > BiLSTM-RNN > GMM.

**4.3. Model Comparison of EMA-to-MFCC Conversion.** In the EMA-to-MFCC experiment, we adopted MMCD as the parameter to evaluate the results of articulatory-to-MFCC conversion, which can be defined as the mean value of Euclidean distance between the predicted value and true value. Here, we used 12-dimensional MFCC as the acoustic feature and compared the performances of the GMM-based, RNN-based, and BiLSTM-CNN-based methods.

In the experiment, we selected GMM with 500 Gaussian elements to accurately describe the joint probability density function of the articulatory features and acoustic features. For the BiLSTM-CNN, we set the convolutional layer with size of  $169 * 169$ , 4 full-connection layers, the 1-dimensional regression layer, and 5 hidden layers with 100 hidden units per hidden layer and adopted 21 frames (10 frames forward, 1 current frame, and 10 frames backward) as the input feature.

In the training process, we initially set the learning rate to 0.005 and fixed the momentum at 0.9, with the maximum epochs of 60. Then, we can find that BiLSTM-CNN is much better than the BiLSTM-RNN and GMM conversion model, and the comparison results are shown in Table 3.

From the table, the MMCD of BiLSTM-CNN is the minimum among three models, and BiLSTM-RNN is better than GMM but not better than BiLSTM-CNN. Meanwhile, we can find that there are strong positive correlations

FIGURE 7: The RMSE and loss function values on the training database of BiLSTM-RNN.

FIGURE 8: Kinematics comparison of F2 based on different network.

TABLE 2: The RMSE (Hz) and  $r$  on the test set when using GMM, BiLSTM-RNN, and BiLSTM-CNN for EMA-to-F2 conversion.

|      | GMM   | BiLSTM-RNN | BiLSTM-CNN |
|------|-------|------------|------------|
| RMSE | 37.13 | 26.42      | 22.10      |
| $r$  | 0.565 | 0.625      | 0.738      |

TABLE 3: The MMCD (dB) and  $r$  on the test set when using GMM, BiLSTM-RNN, and BiLSTM-CNN for EMA-to-MFCC conversion.

|      | GMM   | BiLSTM-RNN | BiLSTM-CNN |
|------|-------|------------|------------|
| MMCD | 2.384 | 1.824      | 1.467      |
| $r$  | 0.576 | 0.725      | 0.753      |

between the predicted and true features on all three models; in detail, the correlations are, in turn, BiLSTM-CNN > BiLSTM-RNN > GMM.

## 5. Discussion and Conclusion

This study provided a novel conversion method combining BiLSTM, CNN, and word-attention theory. In the current study, features of the tongue and the lip in 3D coordinates of AG501 have been extracted for the conversion and recognition research and acoustic features (i.e., F2 and MFCC).

From the conversion research, we found that the kinematics of tongue and lips can construct a simple graph, which are found from the application of CNN, because CNN has been used to graph signal processing widely. Meanwhile, because the database we used is Mandarin, as a kind of tone language, semantic feature plays an important role in the speech processing, especially in articulatory-to-acoustic conversion and speech recognition. So, we adopted word-attention theory in this study and achieved ideal effect, which proves that the semantic feature is helpful to the conversion study especially in Mandarin.

The current study broke the limitation of focusing on the vowel only and fused the semantic features and articulatory features. Due to the limitation of numbers of samples, we choose 299 disyllables only in this paper; the sample size was a little bit small, which will be considered in future efforts. The study in this paper should be the basement of the research of speech recognition and speech production. It can promote the fusion of artificial intelligence and Smart Campus in the future.

## Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

## Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

## Acknowledgments

Thanks are due to all the subjects in current experiment, to Guicheng Shao for technical assistance, to Jianmei Fu for

modal design, and to Jianzheng and Dong Li for assistance in data collection. With the rapid development of market economy, the task scheduling model has become the core problem in the field of corporate management. In order to solve the problem that the stability of the model will decline due to the interference of human factors in the process of multitask scheduling in the traditional algorithm, a reasonable scheduling model based on the priority principle is proposed in this paper. This paper expounds the principle of multitask scheduling in company management, constructs a multitask scheduling network model based on priority, performs virtual scheduling on the model, searches the optimal solution in the solution space of the scheduling problem, and obtains the reasonable multitask scheduling method in the company management. Through the analysis of relevant simulation experiments, it can be concluded that the task scheduling algorithm proposed in this paper can not only allocate the corresponding resources for high-priority tasks effectively, but also can save the cost, so as to show better execution efficiency.

## 1. Introduction

With the rapid development of market economy, the competition between enterprises is becoming more and more fierce. As a more important factor affecting the competitiveness of enterprises, the method of task scheduling in company management has been paid more and more attention by company managers [1, 2]. Therefore, the method of task scheduling in company management has become a hot topic in the field of enterprise, which has been paid attention by many experts. At present, the main task scheduling models in company management mainly include the task scheduling method based on the fuzzy clustering algorithm, the task scheduling method based on the optimization genetic algorithm, and the task scheduling method based on the ant colony algorithm [3, 4]. Because of the wide development space of the task scheduling method, it has become the focus of many experts.

Task scheduling model has become the core problem in the field of company management. In the management of the company, the pipeline work task management mode is

adopted, and the multithread and multitask mode is adopted for the work task under this management [5]. In the process of multitask scheduling, the correlation between tasks is very complex, which is greatly affected by the scheduling order. The traditional task scheduling model is based on single linear order optimization [6, 7]. Once there are too many tasks, the contradiction between different task scheduling will increase, the stability of the model will decline, and the efficiency of scheduling will be low. However, it is difficult to assign a schedulable priority to each task in the design model due to the limitation of multiple times. At the same time, it is difficult to avoid the undesirable priority inversion. Therefore, the design model cannot be used to analyze the fixed priority scheduling theory.

Aiming at the defects of the traditional algorithm, a reasonable scheduling method based on the multiconstraint scheduling model is proposed. In this paper, the principle of multitask scheduling in company management is described in detail [8, 9]. A multitask scheduling network model based on priority is constructed by using this principle. Virtual scheduling is carried out for the network model, and the

optimal solution is searched in the solution space, and the reasonable multitask scheduling method in company management is obtained [10]. The experimental results show that the improved algorithm can improve the resource utilization rate and scheduling efficiency and avoid the defect of reduced stability of the scheduling model caused by multiwork doping.

## 2. Principle of Multitask Scheduling in Company Management

*2.1. Analysis of Task Scheduling Model.* Task scheduling is simply a problem of allocating resources according to time to complete tasks. The accuracy and rationality of scheduling is directly related to the economic effect of the whole production activity. The goal of task scheduling software is to use advanced computer technology to achieve efficient control of production scheduling [11]. The objectives of the task scheduling software are as follows:

- (1) *Convenient Interaction.* The software should have a friendly man-machine interface, which is convenient, intuitive, and easy to learn. The user can easily realize the man-machine dialogue.
- (2) *Network Management.* As a part of the enterprise internal management system, the task scheduling software should have a good information interface to realize the information interaction with other sub-systems. Through the interface, it can realize the functions of task allocation, release, and processing.
- (3) *Controllability of Scheduling Process.* It has the monitoring function for the whole process of task scheduling and timely reflects the problems to the system administrator.
- (4) *Security.* Most of the internal resources involved in software are confidential, so security is very important. The software should have the ability of user identification and authority control.

According to the requirement analysis of task scheduling software, the task scheduling is divided into six functions: plan preprocessing, task scheduling, basic information management, material resource management, job management, and work process tracking. Thus, the domain model of task scheduling is obtained, as shown in Figure 1. The task scheduling model is mainly composed of two modules: task request scheduling and optimal task selection. The classifier classifies tasks into several classes according to their priority and sends them to the corresponding queue buffer and gives each queue a weight. The difference between virtual scheduling and actual scheduling is that the virtual scheduling task allocates a set of resources, while the actual scheduling task allocates a specific resource. Virtual scheduling is developed based on relaxation theory, so virtual scheduling is an intermediate process to solve the scheduling scheme.

After the plan preprocessing function searches the plans, it classifies the plans according to the retrieved results and compiles the dispatch list, which is used to

drive the task scheduling [12]. After receiving the dispatch list issued by the plan, the task scheduling first calls the residual production capacity information in the basic information management, the process information of the product, and the task decomposition, assignment, and sorting based on the example-based contract net scheduling method. Then, the raw materials and semifinished products in the resource management are called to schedule and process the tasks [13, 14]. After the scheduling is completed, the production, man hour quota, and cost are statistically managed. The whole scheduling process is accompanied by work process tracking. Work process tracking tracks the execution status of the plan before the execution of the task scheduling, tracks the logistics and cost information generated in the scheduling process, and tracks the output and quality in the operation management after the scheduling is completed.

*2.2. Design of Task Scheduling Architecture.* Class model is the core of object-oriented modeling and an important part of UML. Its main function is to define the classes in the system and the relations between them. Class structure in the class model is formed by abstracting meaningful concepts from domain requirements and then encapsulating certain behaviors with them [15, 16]. The initial class model is a concept-based class model, which focuses on the expression of the relationship between classes, while ignoring the expression of the attributes and behaviors in the internal structure of the class. According to the domain requirements and basic framework of the system, the initial class model is constructed abstractly. The following is an analysis and summary of the abstract modeling methods of the initial class model [17, 18]:

- (1) The initial class is extracted from the underlying use case, activity diagram, and information carrier analysis, and the initial class framework is established
- (2) From the use case diagram and the activity diagram to the relationship between information flow and data flow abstract classes in the class diagram
- (3) The mapping from the use case diagram and the activity diagram to workflow in the class diagram is used to reflect business processing logic
- (4) Accurate identification of association types (association, aggregation, composition, and generalization)
- (5) An interface definition or description that expresses the services (operations) provided to the user using the interface
- (6) Proxy object is used to refine association and provide access control; action object is used to provide preprocessing to simplify interaction

The initial class architecture of task scheduling software is shown in Figure 2. The initial class framework of task scheduling is developed according to the business main line of domain application, which embodies the functional abstraction and data processing flow of IPO control.

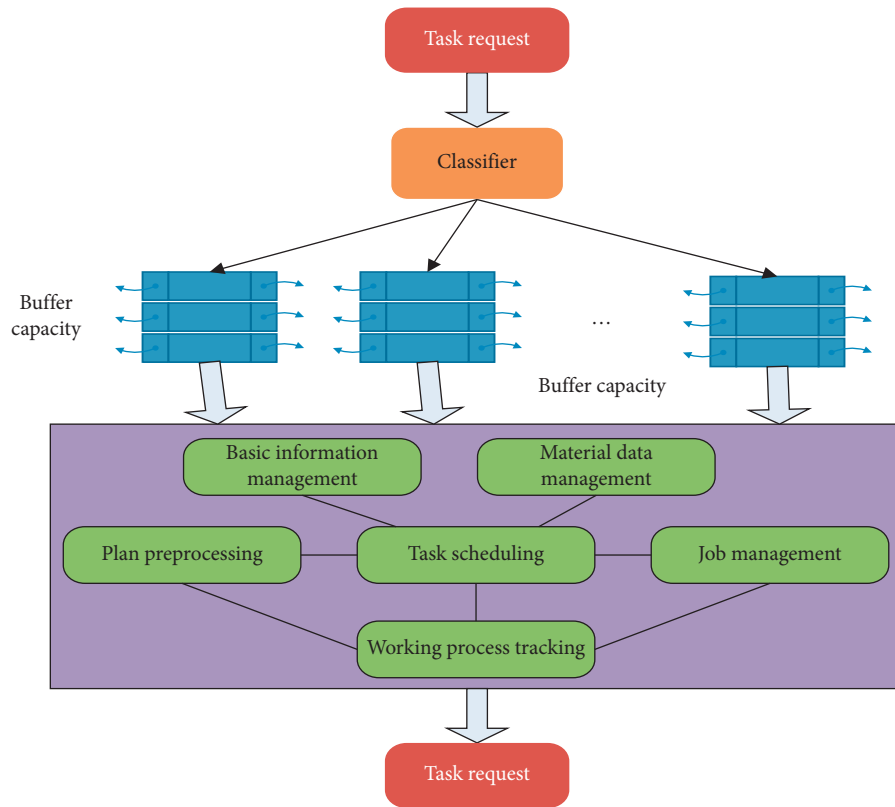

FIGURE 1: Domain model of production task scheduling.

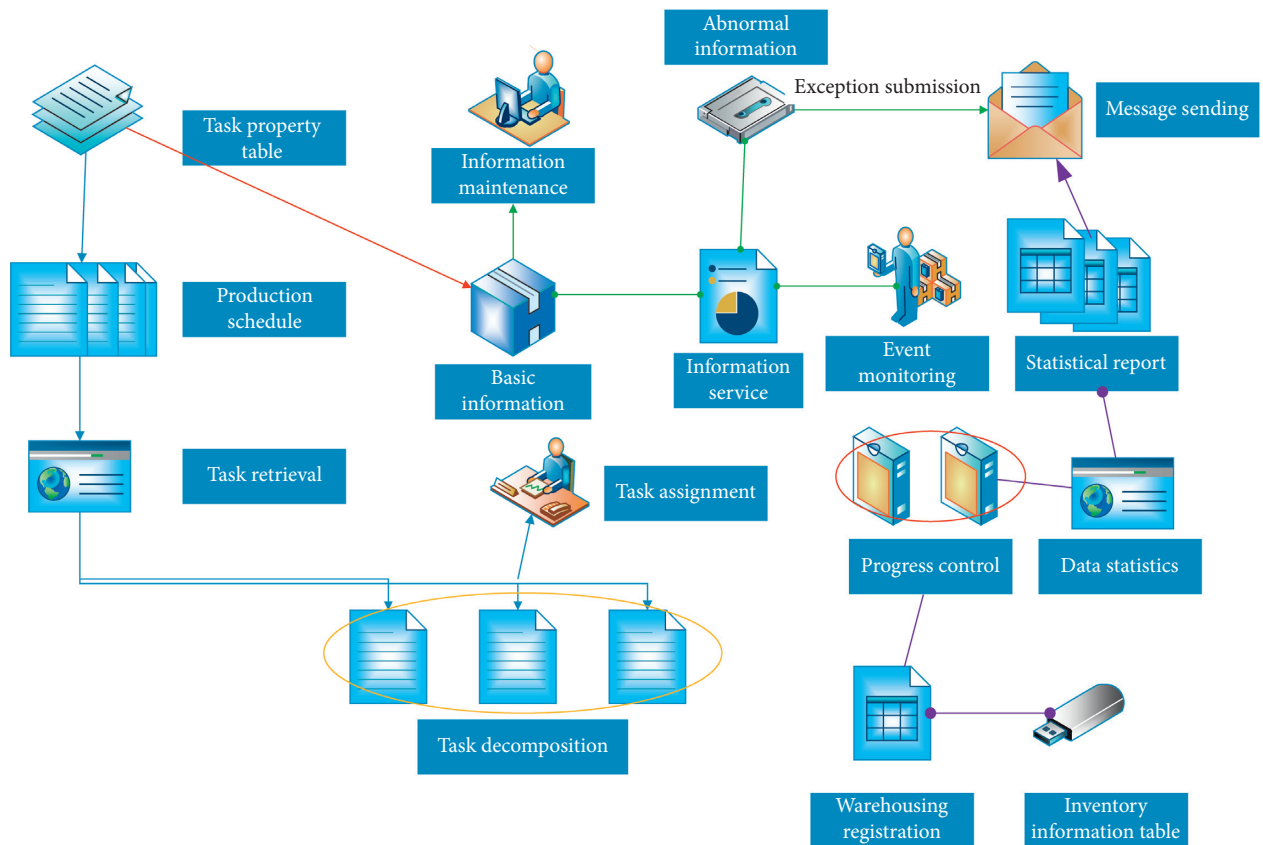

FIGURE 2: Initial class architecture of production task scheduling.

In addition, the initial architecture of the system only describes the status of this class in the system and the relationship between this class and other classes in the system, but fails to describe its detailed design and optimization. Therefore, it is necessary to further analyze and design the middle classification of the initial class framework according to the situation. The optimization method is used to optimize the structure [19–21]. Task assignment class is the core process of collaborative task scheduling. According to the domain analysis, the task assignment class is further analyzed and designed. The structure of the task assignment class is shown in Figure 3.

*2.3. Description of Multitask Scheduling Principle.* According to the above method, we can solve the utilization ratio of scheduling resources in multitasks. In the process of scheduling tasks, the demand for nonrenewable resources is determined. Therefore, the task scheduling cannot be ignored. Therefore, when solving the multitask scheduling problem, we first simplify the problem [22, 23]:

- (1) Nonupdatable resources are ignored during the operation
- (2) The duration of task completion is only related to the working capacity of the selected renewable resources

The solution of the scheduling problem with multiple tasks is  $(W, R, S)$ .  $W$  is used to describe the total number of tasks, and  $\omega_i$  is used to describe  $i$ .  $R$  is used to describe the resource allocation vector of all tasks, and  $r_i$  is used to describe the allocation of resources to task  $i$ .  $S$  is used to describe the start time of work task, and  $S_i$  is used to describe the start time of work task  $i$ .  $S$  is obtained by calculating  $W$  and  $R$ . Therefore, the process of solving the scheduling problem is to solve the  $W$  and  $R$  values. The process of solving the multitask scheduling problem can be described as follows: (1) constructing the priority network of the problem to be scheduled; (2) through virtual scheduling, the solution space is continuously compressed until the end condition is met, and the problem solving process is exited; (3) the solution result (no solution or optimal solution) of the scheduling problem is obtained.

In the management of the company, the pipeline work task management mode is adopted, and the multithread and multitask mode is adopted for the work task under this management. In the process of multitask scheduling, the correlation between tasks is very complex, which is greatly affected by the scheduling order. In the company management, reasonable distribution of work tasks is conducive to improving task efficiency. The principle of scheduling is as follows.

Set  $t = \{T_i\} (1 \leq i \leq l)$  as the multitask set in company management, which can be described by the following matrix:

$$t = \begin{bmatrix} T_1^{\text{Type}} & T_1^L & T_1^{\text{In}} & T_1^{\text{Out}} & T_1^E \\ T_2^{\text{Type}} & T_2^L & T_2^{\text{In}} & T_2^{\text{Out}} & T_2^E \\ & & \dots & & \\ T_l^{\text{Type}} & T_l^L & T_l^{\text{In}} & T_l^{\text{Out}} & T_l^E \end{bmatrix}. \quad (1)$$

The row vector of the matrix can be used to describe the attribute set of the corresponding task. Among them,  $T_i^{\text{Type}}$  is used to describe the types of work tasks;  $T_1^L$  is the total length of work tasks;  $T_i^{\text{In}}$  is the input size of work tasks;  $T_i^{\text{Out}}$  is the output size of work tasks;  $T_i^E$  is the expected value of work tasks by company management. QoS can also be divided into different tasks according to the type of QoS. For example, completion time, labor quantity, and cost.

Set  $d = \{D_i\} (1 \leq i \leq m)$  to describe the resource set of a work task in the company management, which can be described by the following matrix:

$$d = \begin{bmatrix} D_1^{\text{rg}} & D_1^{\text{time}} & D_1^{\text{sm}} & D_1^{\text{cb}} & D_1^{\text{jq}} \\ D_2^{\text{rg}} & D_2^{\text{time}} & D_2^{\text{sm}} & D_2^{\text{cb}} & D_2^{\text{jq}} \\ & & \dots & & \\ D_m^{\text{rg}} & D_m^{\text{time}} & D_m^{\text{sm}} & D_m^{\text{cb}} & D_m^{\text{jq}} \end{bmatrix}. \quad (2)$$

The row vector of the matrix is used to describe the attributes of various resources in the corresponding task. Among them,  $D_i^{\text{rg}}$  is used to describe the working ability of workers;  $D_i^{\text{time}}$  is used to describe the completion time of tasks;  $D_i^{\text{sm}}$  is used to describe the number of workers required to complete tasks;  $D_i^{\text{cb}}$  is used to describe the use cost of a single worker;  $D_i^{\text{jq}}$  is used to describe the use cost of machines. In order to comprehensively consider the performance of various resources in multitask scheduling, it is necessary to normalize the performance attribute values of resources.

$$V = \begin{cases} \frac{V_i^{\text{rg}} - \min(\text{rg})}{\max(\text{rg}) - \min(\text{rg})}, & \max(\text{rg}) \neq \min(\text{rg}), \quad 1 \leq i \leq m, \\ 1, & \max(\text{rg}) = \min(\text{rg}), \end{cases} \quad (3)$$

where  $V_i^{\text{rg}}$  is the working ability attribute value of the  $i$ th worker,  $\min(\text{rg})$  is the minimum value of the working ability performance attribute value of  $m$  workers in the scheduling resource set, and  $\max(\text{rg})$  is the maximum value of the working ability attribute value of  $m$  workers. Obviously, formula (1) normalizes the attribute value of workers' working ability to the interval of  $[0, 1]$ .

The utilization rate of scheduling the resource set under multitasks can be described by a vector, where  $D_{i,\text{uti}} (1 \leq i \leq m)$  is used to describe the corresponding scheduling resource utilization. For example, for labor-intensive tasks, the utilization rate of scheduling resources is mainly reflected by worker resources, and its calculation formula can be described as follows:

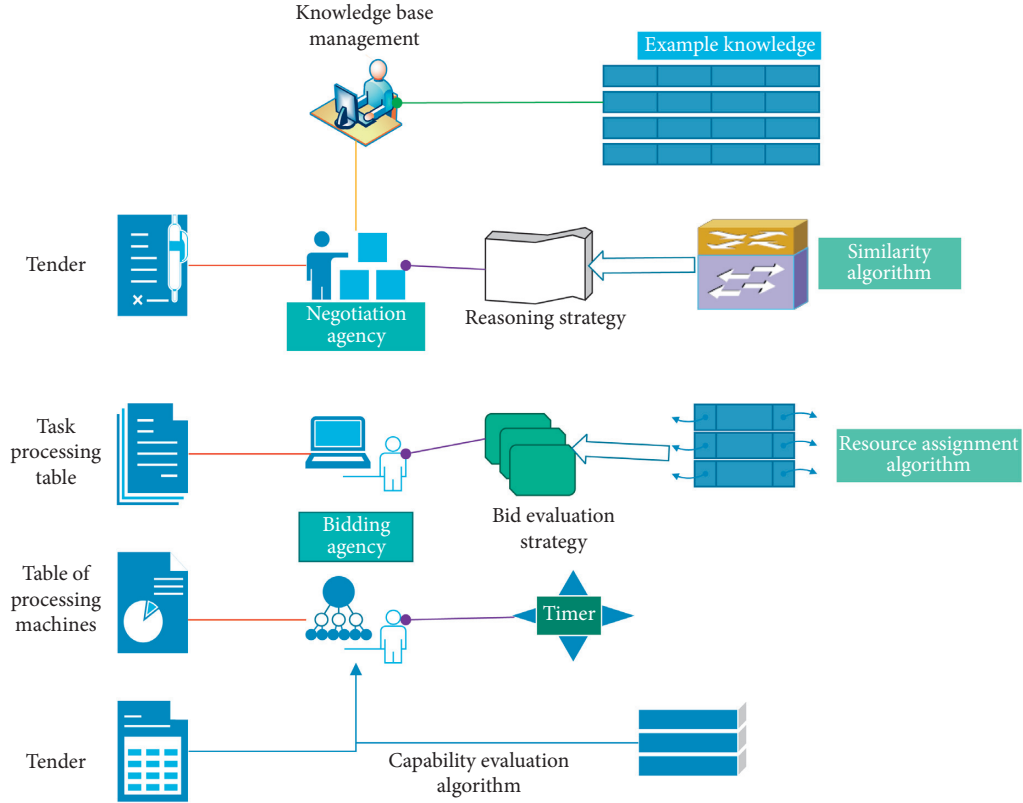

FIGURE 3: Task assignment class architecture.

$$D_{i,uti} = \frac{\sum_{j=1}^l (T_{j,etime} - T_{j,stime}) \times \Delta_{ij}}{T_{time}}, \quad 1 \leq i \leq m, \quad (4)$$

where  $T_{j,etime}$  and  $T_{j,stime}$  are used to describe the end time and the start time of the corresponding task;  $\Delta_{ij} = 1$  is used to describe that task  $J$  is allocated on schedule  $I$ , otherwise  $\Delta_{ij} = 0$ .

The overall load balance  $V_m$  of scheduling resources under multiple tasks can be described by the standard value of variance. The specific calculation formula is as follows:

$$\begin{cases} V_m = \sqrt{\frac{1}{m} \sum_{i=1}^m (V_{i,uti} - \bar{V})^2}, \\ \bar{V} = \frac{1}{m} \sum_{i=1}^m V_{i,uti}. \end{cases} \quad (5)$$

The optimization goal of scheduling is to achieve the minimum task scheduling span  $T_{j,etime}$  and the minimum system resource overall load  $V_m$  through the reasonable scheduling of task set  $t$  on the scheduling resource set  $v$ . In the management of the company, the pipeline work task management mode is adopted, and the multithread and multitask mode is adopted for the work task under this management. In the process of multitask scheduling, the correlation between tasks is very complex, which is greatly affected by the scheduling order. The traditional task

scheduling model is based on single linear order optimization. Once there are too many tasks, the contradiction between different task scheduling will increase, the stability of the model will decline, and the efficiency of scheduling will be low.

In addition, due to the need to maintain the stack of each task, there is also a lot of memory overhead. In order to reduce the space-time cost of real-time multitasking, it is common to map multiple tasks to the same thread, so that the thread will receive and process the requests of each task in the queue in turn. However, it is difficult to assign a schedulable priority to each task in the design model due to the limitation of multiple times. At the same time, it is difficult to avoid the undesirable priority inversion. Therefore, the design model cannot be used to analyze the fixed priority scheduling theory. The other method is to assign an implementation thread for each task; that is, the number of tasks is equal to the number of threads, which will have the disadvantage of high space-time cost.

### 3. Research on Multitask Scheduling Algorithm Based on Priority

**3.1. Priority Workflow Scheduling Prototype.** The level of a workflow can be determined by the level of user payment, as shown in Figure 4. For example, if a cloud service provider divides users into free users, VIP, the priority value can be 0, 1, and 2. If there are multiple workflows applying for one cloud resource at the same time, the higher the level of

workflow, the easier it is to obtain the cloud computing resources needed. If a workflow does not get the cloud computing resources it needs for a long time due to its low level, we can set a value for the workflow. Counting from 0 and adding one after each scheduling. If the value exceeds the set value after multiple rounds of scheduling, the workflow can obtain the cloud computing resources it needs regardless of its priority level in the next round of scheduling. The set value can be calculated according to the following steps.

Firstly, suppose that there are  $M$  workflows applying for the required cloud computing resources and the cloud resource provider divides the user level of cloud computing resources into  $N$  levels, then the value can be set as  $M/N$ . For the workflow being executed, its priority may be lower than that of the workflow that is applying for cloud computing resources. We prefer to let the workflow continue to execute, rather than stop its execution forcibly, because this will waste the consumed resources and make the total consumption more.

**3.2. Scheduling Algorithm Based on Workflow Priority (PISA).** PISA algorithm is based on the access control model; that is, the workflow task can enter the scheduling sequence and calculate the priority factor only after it has been authenticated by the access control model. Therefore, in PISA, this paper first introduces the access policy audit step. This is based on access control model authentication. When a workflow applies for cloud computing resources, the cloud computing resource provider first queries the access policy library and then queries the corresponding access policy according to the application information of the workflow. If the access policy is accessible, the workflow can enter the second step, that is, entering the workflow scaling sequence. First of all, the workflow task of computing resource application is authenticated. Only the task that meets the rules can enter the second step. In order to facilitate the experiment, we call the access policy of the workflow task as WAPC. The definition of WAPC is as follows:

$$\text{WAPC}[\text{work, task, } (T_s, T_c, P)], \quad (6)$$

where  $T_s$  is the start time of task  $T_i$ ,  $T_c$  is the end time of task  $T_i$ , and  $P$  is a periodic expression. The value priority defines the corresponding level of cloud computing resources that the workflow task can obtain. If the level of resource requested by the workflow task matches the value of priority, the request of the workflow will be passed. If the level of the workflow does not meet the corresponding requirements or the time quota is insufficient, the application is rejected. We define the time quota  $T_q$ , which indicates the maximum execution time quota of the task. Work defines the set priority value of the workflow to which the workflow task belongs. The authorization rules for the policy are as follows.

Suppose that user  $U$  applies to the cloud computing service provider for a workflow instance  $W$ , and the task ID contained in the request obtains the required cloud computing resources at time  $T$ . In the workflow task, the priority

value of the corresponding level resources required is priority. If  $T_s < t < T_c$ , the access application is passed, otherwise the application is rejected.

For a workflow with multiple tasks, the completion of one task may depend on the completion degree of other tasks, so their running time is related. In order to facilitate the statistics of the possible time completion rate of a task, we define the time parameter  $T_q$ , which takes the time parameters of each task into account:

$$\text{time} = \frac{\text{Min}(t_i) + \text{WS}(t_i)(t_e - t_s)}{\sum_{i=1}^m t_i}, \quad (7)$$

where  $\text{Min}(t_i)$  is the minimum execution time of task  $t_i$ ,  $\text{WS}(t_i)$  is the time parameter required for the task to use all available cloud computing resources, and  $t_q$  cannot be greater than  $t_e - t_s$ , otherwise its request will not be passed.

For a workflow  $W_i$ , it may contain multiple tasks. Similarly, users can specify the hierarchical weights of these tasks. Suppose that there are  $n$  tasks whose rank weights are  $T_1, T_2, \dots, T_n$  and  $W_i$  are the priority weights of the workflow to which these tasks belong, then the average rank weight bps of the tasks is

$$\text{bps} = \sum_{i=1}^m \frac{t_i}{N}. \quad (8)$$

Figure 5 only shows the work scheduling process, so there is no numerical value in the graph. It is only a reference for the process, and there may be other types. Figure 5 illustrates the scheduling process of workflow tasks.

For task scheduling, we also have the following considerations:

- (1) The amount of cloud computing resources that a cloud computing service provider can provide is limited.
- (2) Tasks belonging to high-level workflow should be executed first, which means that the first-level impact factor  $A$  is more important than the second-level impact factor  $B$ . In some cases, some tasks of low-level workflow may be higher in the scheduling queue after being calculated by the above formula, so we need to add the above conditions.

The second step is to bind the tasks that have been prioritized to the virtual machine and establish the mapping relationship between tasks and virtual machines. This involves the concept of quality of service. In cloud computing, service quality is used to measure the user satisfaction with cloud computing services. Different users have different standards for QoS, some may need to ensure real-time performance, while others want low cost. According to the importance of the user's task, the priority factor of the related task is calculated, and all the tasks participating in the scheduling are prioritized. Then the virtual machine resources are sorted. The higher the level of the task, the more abundant the resources can be obtained.

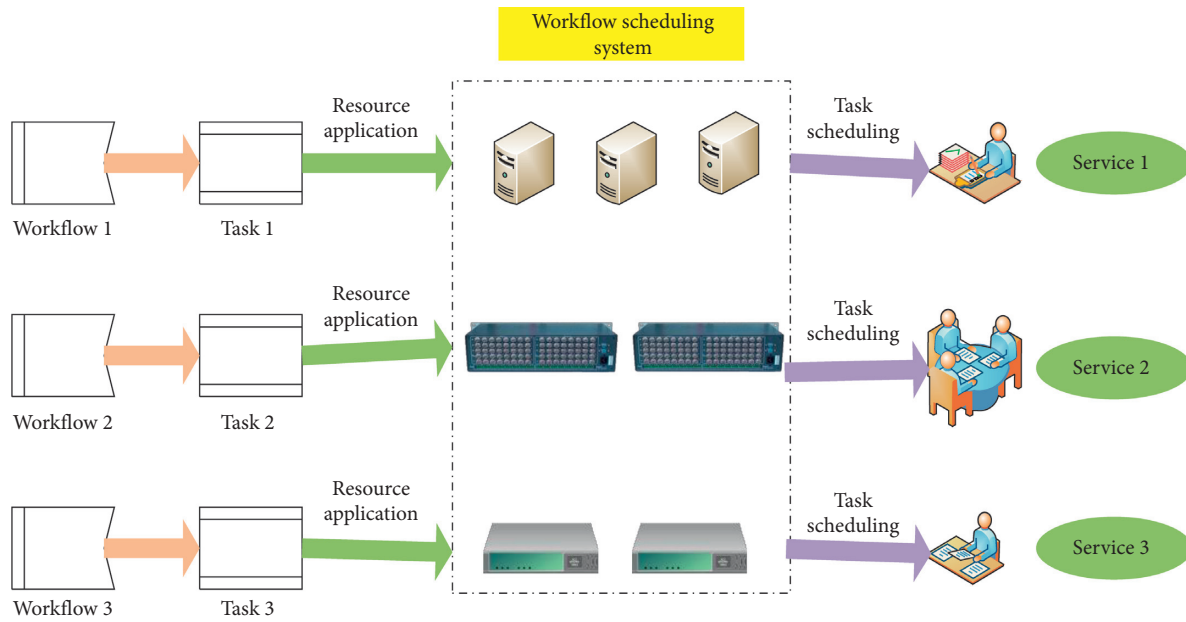

FIGURE 4: Workflow scheduling system.

FIGURE 5: Task scheduling block diagram.

### 4. Simulation Experiment and Analysis

4.1. *GABP Optimized RO*. The cloud simulation environment used in this paper includes 10 virtual machines, each of which performs a task. We set up five users to apply to cloud computing service providers. Each user proposes a workflow, and each workflow package contains two tasks. Based on the convenience of experiments, this paper assumes that all tasks for priority factor calculation have passed the authentication of the access control model, and we only consider the priority of tasks without considering the order of task execution. In order to verify the rationality of the multitask scheduling method based on the multiconstraint scheduling algorithm, an experiment is needed. In the process of the experiment, the resource utilization, personnel utilization, and scheduling efficiency are used to

measure the performance of the multitask scheduling method. The relationship among enterprise personnel, resources, and work tasks is described in Figure 6.

The data related to the relationship among personnel, resources, and work tasks are described in Table 1.

The traditional algorithm and the improved algorithm are, respectively, used for multitask scheduling in company management. In the process of the above experiment, the personnel utilization rate of different algorithms is shown in Figure 7.

The traditional algorithm and the improved algorithm are used to schedule multitasks in company management, respectively. The scheduling efficiency of different algorithms is shown in Figure 8.

According to Table 1, it can be seen that using the improved algorithm for reasonable scheduling under

FIGURE 6: Relationship among personnel, resources, and tasks in enterprises.

| 4                     | 45                  | 8                   | 70       |
| 5                     | 55                  | 10                  | 80       |
| 6                     | 65                  | 12                  | 120      |
| 7                     | 75                  | 14                  | 150      |
| 8                     | 85                  | 16                  | 180      |
| 9                     | 95                  | 18                  | 210      |
| 10                    | 105                 | 20                  | 220      |

FIGURE 7: Comparison of personnel utilization of different algorithms.

FIGURE 8: Comparison of scheduling efficiency of different algorithms.

FIGURE 9: Comparison chart of execution time experiment results.

multiple tasks in company management can improve resource utilization and personnel utilization and effectively improve scheduling efficiency. The experimental data are compared and analyzed, as shown in Figures 9 and 10. Generally speaking, the task scheduling algorithm based on PISA has higher execution efficiency for high-priority tasks than those based on FIFO and fixed-priority FPSA.

FIGURE 10: Execution cost comparison chart.

In terms of execution time, taking MS as the unit and 135 ms as the boundary, we can see in Figure 9 that in the PISA test, 5 tasks were completed within 135 ms, including 3 tasks with high priority. In the FIFO test, 5 tasks were completed in time, but only 1 was of high priority. Obviously, the task scheduling strategy based on the PISA algorithm is more suitable for the resource allocation of high-priority tasks. Compared with FPSA fixed priority, both of them can provide better services for high-priority tasks. Therefore, the efficiency difference is relatively small, and the efficiency of FPSA is higher than that of PISA because FPSA takes the maximum satisfaction of high-priority tasks as the optimization condition, and optimization is more extreme.

From the perspective of the execution cost, we can see from Figure 10 that although the fixed priority can meet the user's execution requirements for important priorities to a certain extent, its priority is fixed. Only the priority level of the workflow is considered, and the priority value of each task included in the workflow is not considered. Therefore, the implementation cost of FPSA is not as reasonable as that of PISA. PISA has more advantages in controlling the overall execution cost of workflow tasks. Because of its randomness, FIFO has no corresponding optimization in the execution cost, so its cost-effectiveness ratio is very low.

## 5. Conclusion

In order to solve the problem that the stability of the model will decline due to the interference of human factors in the process of multitask scheduling in the traditional algorithm, a reasonable scheduling method based on the priority principle in company management based on the multi-constraint scheduling model is proposed. This paper expounds the principle of multitask scheduling in company management, constructs a priority-based multitask scheduling network model based on the above principles,

conducts virtual scheduling on the model, searches the optimal solution in the solution space of the scheduling problem, and obtains the reasonable multitask scheduling method in the company management. The experimental results show that the improved algorithm can improve the resource utilization rate and scheduling efficiency and avoid the defect that the stability of the scheduling model is reduced in the case of multiwork doping, and the satisfactory effect is achieved. The use environment of the model is more complex, and the role mapping and permission inheritance between multiple domains are taken into account, so that it can be applied to a wider range of fields. The various types of the cloud computing simulation platform are continued to be studied and strived to expand them to better simulate task scheduling.

RGBD camera-based VSLAM (Visual Simultaneous Localization and Mapping) algorithm is usually applied to assist robots with real-time mapping. However, due to the limited measuring principle, accuracy, and distance of the equipped camera, this algorithm has typical disadvantages in the large and dynamic scenes with complex lightings, such as poor mapping accuracy, easy loss of robot position, and much cost on computing resources. Regarding these issues, this paper proposes a new method of 3D interior construction, which combines laser radar and an RGBD camera. Meanwhile, it is developed based on the Cartographer laser SLAM algorithm. The proposed method mainly takes two steps. The first step is to do the 3D reconstruction using the Cartographer algorithm and RGBD camera. It firstly applies the Cartographer algorithm to calculate the pose of the RGBD camera and to generate a submap. Then, a real-time 3D point cloud generated by using the RGBD camera is inserted into the submap, and the real-time interior construction is finished. The second step is to improve Cartographer loop-closure quality by the visual loop-closure for the sake of correcting the generated map. Compared with traditional methods in large-scale indoor scenes, the proposed algorithm in this paper shows higher precision, faster speed, and stronger robustness in such contexts, especially with complex light and dynamic objects, respectively.

## 1. Introduction

In order to build intelligent applications for mobile robots in a large scene, autonomous and efficient navigation plays an increasingly important role. VSLAM, a technique with high-precision positioning and obstacle avoidance information, has been popular in the field of robot navigation. At present, VSLAM is usually applied on monocular camera, binocular camera, and depth camera RGBD. Among these three, the RGBD-based VSLAM algorithm has obvious advantages in terms of real-time accuracy. This is mainly because of the fact that the depth camera can input the depth image with accurate scale information to the computer directly. It not only overcomes the problem that the binocular camera needs to consume extra computer resources to obtain the depth image, but also solves the problem that the monocular

camera cannot do dense construction during mapping, or has no scale information and poor drawing quality in mapping. Despite of advantages, some popular RGBD-based VSLAM algorithms, such as RGBD SLAM V2 algorithm [1], RTAB algorithm [2, 3], and DVO algorithm [4], still have typical limitations in large-scale indoor scenes, which mainly reflect in that dynamic objects will introduce additional errors to VSLAM or even cause to operation failure. However, this would be impossible in real-time large scene reconstruction. For example, some inevitable changes, lights, people moving, and object moving can cause the loss of position and posture of mobile robots [5] and, in turn, lead to inaccurate mapping. In order to deal with some dynamic objects that may exist in large scenes, the current algorithm usually eliminates dynamic objects by adding object detection or image segmentation algorithm based on

deep learning in the system, such as Dynamic SLAM [6], Cluster VO [7], and Cluster SLAM [8] algorithm [9]. However, this will inevitably lead to a large consumption of computing resources, and some microdynamic objects are usually distributed near the camera. After removing these feature points, the accuracy of the camera odometer will also be affected. In addition, since the effective measuring distance of the RGBD depth camera (i.e., Kinect V2) is only 4.5 meters [5], it may result in a large cumulative error in the large scenes. Therefore, it is challenging to obtain a high-precision environmental map. Nevertheless, this weakness can be compensated by using a 2D laser range finder. For example, the commonly used SICK TIM 561 laser range finder has 270 degree field of view angle with 12 meter effective measuring distance. Cartographer [10], a laser SLAM algorithm based on graph optimization proposed by Google in 2016, is specifically used on such kind of a 2D laser range finder. It applies SPA [10, 11] (Sparse Pose Adjustment), as well as the branch and bound method [10, 12], to adjust the constructed map and reduces the accumulated error effectively. Hence, it is more suitable for large-scale scene mapping. However, this method still has some shortcomings. A typical weakness lies in its limitation of data that is obtained only from a certain level of the space. This limitation may lead to the loss of large amount of environmental information during the performance of mobile robots and can hamper their behaviors and control in turn.

According to the analysis mentioned above, based on the existing Cartographer algorithm, this paper proposes a new method for 3D mapping in large scene contexts, which integrates a laser range finder and RGBD depth camera. Its working principles mainly include three steps. Firstly, it inserts the 3D point cloud generated in real-time into the submap generated by the Cartographer algorithm for 3D reconstruction. Then, visual loopback is introduced to check the accuracy of laser loopback. It needs to run a visual loopback test on the back end of the computer (not in real-time), which will check the loopback results established by the Cartographer algorithm. If the two loopback results are significantly different, it will replace the laser loopback with the results obtained by the visual loopback. Finally, after the algorithm detects the loop-closure, it adjusts the pose of the point cloud in real-time, modifies the map, and inserts the 3D point cloud bound to the submap into the appropriate space position. Comparative experiment results show that the proposed algorithm is more accurate, real-time, and robust than the simple vision SLAM and laser SLAM algorithms.

The main contributions of this paper can be summarized into three aspects:

- (i) The approach proposed in this paper about reconstruction in large dynamic scene implements the fusion of RGBD camera and laser range finder based on the Cartographer algorithm. Cartographer provides more robust odometer data for algorithm reconstruction, and an RGBD camera provides rich environment data for the algorithm to eliminate the point clouds and laser points of dynamic objects, so

as to optimize the odometer calculation of Cartographer.

- (ii) A novel approach to calculate the ground true value in large scene, which does not need extra instruments but simply laying the Apriltag on the ground instead. With the time and cost required in the experiment being greatly reduced.
- (iii) Experimental results show that the proposed approach has achieved the robust state-of-the-art performance on the real large public scene.

The remainder of this paper is organized as follows: Section 2 presents the related work in the past few years about 3D reconstruction in dynamic scene and the Cartographer algorithm presented in this paper. Section 3 describes the sensor calibration method in our proposed approach. Section 4 introduces the new approach in detail. The experimental results in the real scene are given in Section 5. Conclusions are drawn in Section 6.

## 2. Related Work

This section focuses on the review of previous works in terms of the 3D reconstruction method of dynamic scale and the introduction of Cartographer algorithm, upon which our new method is developed.

*2.1. 3D Reconstruction in Large Dynamic Scenes.* To avoid generating errors while reconstructing, existing works addressing this problem are of three types.

The first category is based on dynamic object detection. In [9, 13], algorithms reduce the introduced error by removing the feature points in the image where the dynamic object is located and, then, uses the points in the remaining static objects to calculate the camera odometer data of the two frames.

The second category is based on the random consistency of established maps. In [14], the random consistency algorithm was proposed to evaluate the established map, which, in turn, removes the dynamic objects mistakenly inserted into the map.

The third category is based online and surface features. References [15, 16] proposed methods to calculate the pose change of the camera between two frames by line and surface features instead of point features.

Although these algorithms can solve the interference of moving objects in the scene, they will increase extra burden on computing and bring about disadvantageous effects on the accuracy and the real-time performance. Especially when the proportion of external interference data exceeds a certain threshold [17], no algorithm to remove noise or interference could help.

*2.2. Cartographer Algorithm.* The Cartographer algorithm [10], a cross-platform and multisensor fusion -based laser

SLAM algorithm proposed by Google, consists of local SLAM and global SLAM algorithms.

In the local SLAM algorithm, Cartographer calculates odometer information by fitting scan points and IMU data from newly inserted scan points. Calculating the position of the newly inserted scan point in the submap is the least square problem [10] which aims to maximize the probability of matching the scan point with the submap.

The submap generated by local SLAM is a part of the global map, which is presented in the form of probability grid. Each grid has a fixed odds value, which indicates the blocked probability of the grid. After the new scan points are inserted into the submap, a set of odds are recalculated, and the probability values  $p_{\text{hits}}$  or  $p_{\text{miss}}$  of the grid points represented by odds set is updated using probability formula (1), Reference [10], and the score of each point of the probability grid is calculated by formula (2). After sufficient scans have been inserted, the current submap will be updated and output.

$$\text{odd}(p) = \frac{p}{1-p}, \quad (1)$$

$$M_{\text{new}}(x) = \text{clamp}(\text{odd}^{-1}(\text{odds}(M_{\text{old}}(x)) \cdot \text{odds}(p_{\text{hits/misses}}))). \quad (2)$$

In the global SLAM algorithm, Cartographer recorded each submap generated by the local SLAM algorithm and the scans data and their locations for loop-closure detection. During the movement of the robot, the branch and bound method [12] was used to establish loop-closure constraints, using SPA (Sparse Pose Adjustment) algorithm [11] to optimize the locations of all submaps.

With the assistance of global SLAM and local SLAM, the Cartographer algorithm has much better robustness, real-time performance, and accuracy in the real scene than the compared methods.

### 3. Sensor Calibration

In this paper, the large scene reconstruction algorithm integrates an RGBD depth camera and laser range finder. Due to the need to superimpose the point cloud data of the RGBD camera according to the laser range finder, odometer sensor calibration is the first and the necessary step to do. The proposed algorithm has two key components: (i) point cloud generation and (ii) registration of point cloud to the laser range finder coordinate system.

**3.1. Point Cloud Generation.** The RGBD camera to be used in this paper is Kinect  $v_2$ , and its depth camera and RGB camera are located in different positions of Kinect  $v_2$ . In order to obtain accurate environmental point cloud, it is necessary to calibrate the depth camera first.

Firstly, we can get the RGB camera's internal parameter matrix  $C_c$ , depth camera's internal parameter matrix  $C_d$ , and the external parameter matrix  $M$  of these two cameras by Zhang's calibration method [18], respectively.

Then, we assume that the points in the space are at the same distance from the center of the two cameras and substitute matrix  $C_c$ ,  $C_d$ , and  $M$  in the derived equation as follows:

$$\begin{bmatrix} Dx_c \\ Dy_c \\ 1 \\ \frac{1}{d} \end{bmatrix} = C_c \cdot M \cdot C_d^{-1} \begin{bmatrix} Dx_d \\ Dy_d \\ 1 \\ \frac{1}{d} \end{bmatrix}, \quad (3)$$

where  $d$  is the pixel value at the depth coordinate  $(Dx_d, Dy_d)$  and denotes the depth of this point. By equation (3), point  $(Dx_d, Dy_d)$  on the depth image can be transformed to the RGB image coordinate system and recorded as  $(Dx_c, Dy_c)$ .

Finally, this method is used to transform each point on the depth image to the RGB image coordinate. By superposing to display the depth image with the color image, as can be seen in Figure 1, the color image and the depth image are well coincided.

After calibration, the depth  $d$  of each point  $P_{\text{img}} = (x_{\text{img}}, y_{\text{img}})$  of the RGB image can be obtained by using the corresponding pixel value in the calibrated depth image transformed, then the coordinate  $P_{\text{img}}$  and depth  $d$  are plugged into equations (4)–(6) [19, 20], and the position of this point  $P_{\text{cam}} = [P_x, P_y, P_z]$  is figured out in space.

$$P_z = d, \quad (4)$$

$$P_x = \frac{P_z}{f_x} (x_{\text{img}} - c_x), \quad (5)$$

$$P_y = \frac{P_z}{f_y} (y_{\text{img}} - c_y). \quad (6)$$

In the abovementioned equations,  $(f_x, f_y, c_x, c_y)$  expresses the parameter in the camera's internal parameter matrix focal length of the depth camera. The parameter represents the optical center coordinate and the product of the camera zoom factor and focal length, respectively.

**3.2. Registration of Point Cloud to the Laser Range Finder Coordinate System.** After obtaining the point cloud, in order to accurately insert the point cloud data into the grid map generated by Cartographer, the camera point cloud and laser range finder scanning points need to be calibrated. The position of the calibration plate relative to the robot is shown in Figure 2.

The point cloud in world coordinate  $P_{\text{world}}$  and its corresponding points in the RGBD camera coordinate  $P_{\text{cam}}$  system can be expressed by the following equation:

$$P_{\text{cam}} = R P_{\text{world}} + t. \quad (7)$$

The  $3 \times 3$  rotation matrix  $R$  and 3-vector translation  $t$  represent the orientation and the position of the camera,

FIGURE 1: Calibration results between RGB and depth of Kinect. (a) Camera data cannot be aligned before calibration. (b) After calibration, the depth image can be well-aligned with the color image.

FIGURE 2: Calibration is performed using a calibration plate affixed to a prominent raised surface.

respectively. Similarly, it can be deduced that each scanning point  $P_{\text{laser}}$  measured by the laser range finder in the laser coordinate system has a corresponding point  $P_{\text{cam}}$  in the camera coordinate system, and the transformation relationship between them can be expressed by the following equation:

$$P_{\text{laser}} = \Phi P_{\text{cam}} + \Delta. \quad (8)$$

In equation (8),  $\Phi$  is a  $3 \times 3$  orthogonal matrix, representing the rotation relationship between the reference system of laser range finder and the world reference system.  $\Delta$  is a translation 3-vector representing the relative displacement between the two reference systems.

In order to calibrate the laser range finder and RGBD camera, there are two steps to do. Firstly, assuming the calibration board is located in the plane of  $Z=0$  in the world coordinate system, the surface of the calibration plate identified in the camera image is transformed into a 3-vector matrix  $N$  [20]. The norm of the matrix is adopted to show the Euclidean distance from the camera phase center to the calibration board. According to the transformation relationship between the camera coordinate system and real coordinate system as expressed in equation (7), the vector matrix can be deduced by the following equation:

$$N = -R_3(R_3^T \times t). \quad (9)$$

Secondly, assuming that the plane detected by the 2D laser range finder is located at  $Y=0$  in the world coordinate, the scanning points recorded by the laser rangefinder on the chessboard are represented by the following equation:

$$\hat{P}_{\text{laser}} = [X, Z, 1]^T. \quad (10)$$

Substituted  $\hat{P}_s$  into equation (8), the corresponding points of the scanning point in the camera reference can be obtained. When  $\hat{P}_{\text{laser}} = [X, Z, 1]^T$  is located in the calibration plane represented by the parameter  $N$ ,

$$\|N\|^2 = N \cdot P. \quad (11)$$

Furthermore, equation (11) can be deduced as equation (12):

$$\|N\|^2 = N \cdot H\hat{P}_s, \quad (12)$$

$$H = \Phi^{-1} \begin{bmatrix} 1 & 0 & -\Delta_1 \\ 0 & 0 & -\Delta_2 \\ 0 & 1 & -\Delta_3 \end{bmatrix}, \quad (13)$$

$$\Delta = [\Delta_1, \Delta_2, \Delta_3]^T. \quad (14)$$

After solving linear equation (12), the external parameter matrix from the RGBD camera to the laser range finder can be calculated. Then, we substitute  $\Phi$  and  $\Delta$  into equation (8) and transfer each laser scanning point. The calibration between the  $s$  scanning point and the point cloud can be calibrated. The calibration effect is shown in Figure 3.

## 4. System Overview

Figure 4 is the overall architecture of the proposed algorithm in this paper, which is divided into two major parts: the Cartographer algorithm and 3D reconstruction.

The Cartographer algorithm consists of local SLAM and global SLAM algorithms and provides odometer information and submap information for 3D reconstruction. The local SLAM is used to fit the acceleration and angle data of the newly inserted laser scanning point and IMU (inertial measurement unit) compare with the laser scanning points of the previous frame in order to calculate the acceleration, angle data, and odometer information. Also, the pose of the generated submap representing the new area is continuously adjusted, to which the robot reaches. The global SLAM algorithm, or global optimization algorithm, applies the branch and bound method to perform closed-loop matching on the newly generated submap with all previous submaps and point set data.

FIGURE 3: Calibration results between Kinect and the laser range finder.

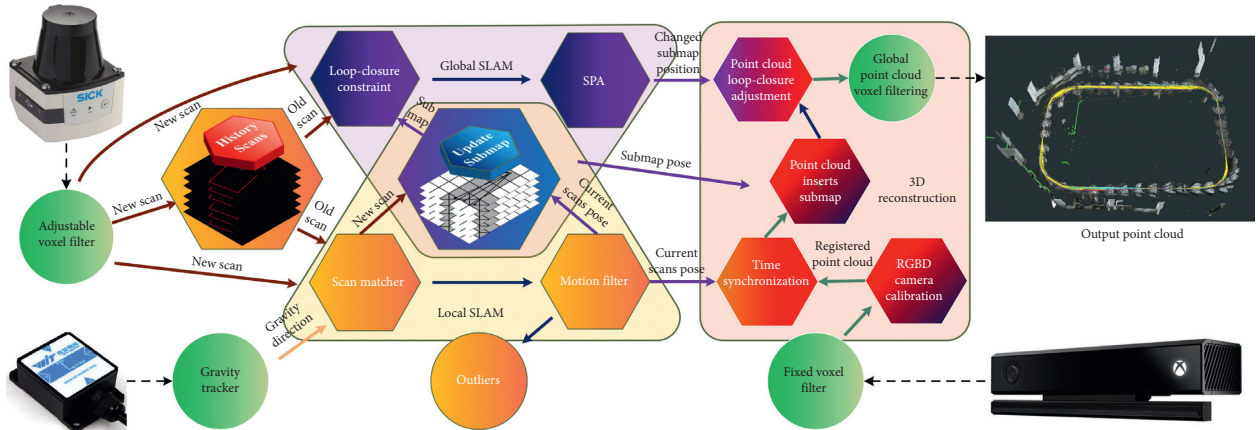

FIGURE 4: Overview of the 3d scenario construction system.

It uses SPA (Sparse Pose Adjustment) to adjust all previously generated submaps and scan point sets. After the match completes, the construction of 2D map is performed.

In the part of 3D reconstruction, after receiving the data of the depth camera, firstly, the corresponding point cloud information is calculated, and the position and pose are transformed and bound to the corresponding submap space. Along with the adjustment of the submap pose by Cartographer, the point cloud data bound to the submap is adjusted in real-time simultaneously. When superposition submap generates a 2D map, superposition point cloud generates a 3D map and publishes point cloud information to the robot in real-time.

In more detail, the proposed algorithm is introduced from three major functional parts which are described as follows.

**4.1. Filling Space Point Cloud into the Submap.** The proposed algorithm builds the map by filling the space point cloud into the submap. In order to accurately superimpose the 3D point cloud information that is inserted into each submap, the point cloud information needs to be bound with each submap. Then, a method with less resource consumption needs to be found to update the adjusted point cloud. Along with robot moving forward and continuous insertion of laser scanning points, the Cartographer algorithm will estimate the robot's mobile posture among scanning points and output the robot pose at the frequency of 70 Hz as shown in the following equation:

$$\delta = [\delta_x, \delta_y, \delta_z, \delta_{roll}, \delta_{pitch}, \delta_{yaw}]^T. \quad (15)$$

When the robot reaches a new area, the algorithm will generate a submap and publish all the previously established submaps' information at the frequency of 5 Hz, and the pose of submap can be expressed by the following equation:

$$\phi = [\phi_x, \phi_y, \phi_z, \phi_{roll}, \phi_{pitch}, \phi_{yaw}]^T. \quad (16)$$

At the same time, the Kinect depth camera on the robot publishes depth images and RGB images at a frequency of 25 Hz, and the IMU publishes robot pose information at a frequency of 200 Hz.

In ROS, computer uses time stamp to record time information when data are published. The time stamps of the robot pose, submap, RGBD camera image, and IMU are represented by  $T_\delta$ ,  $T_\phi$ ,  $T_{RGBD}$ , and  $T_{IMU}$ , respectively.

In order to ensure the normal operation of the algorithm, different sensors need to be synchronized to ensure the sensor data input to the system is of synchronization. Time synchronization includes hardware synchronization and software synchronization. Hardware synchronization is achieved using the BIOS time to screen multiple sensors' data, but cannot be achieved among different devices. Software synchronization caters for this need. This type of synchronization uses software to select data closest to the base time from the sensor data that are input to the same host and completes the time binding of sensor data. Main steps are taken as follows:

The first step is to synchronize the pose of the RGBD camera and the pose of robot, which is to find the pose data closest to  $T_{\text{RGBD}}$  in the prestored 2000 pose data of the robot, as the process shown in Algorithm 1.

Similarly, such synchronization can be achieved for the RGBD camera and the submap, by which the point cloud data closest to  $T_{\phi}$  can be selected.

In the process of binding RGBD image data, robot pose information, and IMU data, the maximum theoretical time difference is 7 ms while the average time difference in actual tests is less than 1 ms. If the robot runs at the speed of 2 m/s, the distance error generated is of the millimeter level. In the process of synchronizing submap and RGBD point cloud, the time difference in theory is 20 ms if the release frequency of the RGBD image is at 25 Hz. In real running, the measured time difference is about 100 ms due to the time consumption on point cloud generation. When the robot is running at 2 m/s, the center of the submap and the point cloud at a distance deviation of 20 cm will be generated if the point cloud is directly inserted into the submap. The abovementioned error data generated in time synchronization are shown in Table 1.

In order to eliminate the abovementioned spatial dislocation, it is necessary to transfer the point cloud to the reference frame of its corresponding submap before the point cloud is filled into the submap space. To achieve this, it is, firstly, needed to calculate the spatial position difference between the robot pose and the submap pose while generating the point cloud and, then, make use of equation (22) to transform the change of the rotation angle between two reference systems into rotation matrix  $R$ [21], which can be calculated by equations (17)–(21).

$$\tau = [\delta_x - \phi_x, \delta_y - \phi_y, \delta_z - \phi_z], \quad (17)$$

$$\gamma = [\delta_{\text{roll}} - \phi_{\text{roll}}, \delta_{\text{pitch}} - \phi_{\text{pitch}}, \delta_{\text{yaw}} - \phi_{\text{yaw}}], \quad (18)$$

$$R_x = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \gamma_{\text{roll}} & -\sin \gamma_{\text{roll}} \\ 0 & \sin \gamma_{\text{roll}} & \cos \gamma_{\text{roll}} \end{bmatrix}, \quad (19)$$

$$R_y = \begin{bmatrix} \cos \gamma_{\text{pitch}} & 0 & \sin \gamma_{\text{pitch}} \\ 0 & 1 & 0 \\ -\sin \gamma_{\text{pitch}} & 0 & \cos \gamma_{\text{pitch}} \end{bmatrix}, \quad (20)$$

$$R_z = \begin{bmatrix} \cos \gamma_{\text{yaw}} & -\sin \gamma_{\text{yaw}} & 0 \\ \sin \gamma_{\text{yaw}} & \cos \gamma_{\text{yaw}} & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (21)$$

$$R = R_z R_y R_x, \quad (22)$$

$$\text{Trans} = \begin{bmatrix} R & \tau \\ 0^T & 1 \end{bmatrix}. \quad (23)$$

After obtaining the rotation matrix and translation matrix,  $R$  and  $\tau$  will be taken into equation (23). According

```

Procedure Time synchronized
 $T_{\text{base}} \leftarrow T_{\text{RGBD}}$ 
 $\text{data}[2000] \leftarrow \text{Sensor\_data}(\text{aim\_sensor})$ 
 $\text{mini\_time} \leftarrow \text{max\_timeinterval}()$ 
for  $i$  in 2000, do
   $T_{\text{aim}} \leftarrow \text{data}[i]$ 
  if  $\text{abs}(-T_{\text{aim}}) < \text{threshold}$ , then
     $\text{minitime} \leftarrow \text{abs}(-)$ 
     $\text{mini\_I} \leftarrow i$ 
  end if
end for
 $\text{aimsensordata} \leftarrow \text{data}[i]$ 
return  $\text{aimsensordata}$ 

```

ALGORITHM 1: Time synchronized.

TABLE 1: Errors occurred in time synchronization.

| Objects that synchronize with RGBD | IMU  | Submap |
|------------------------------------|------|--------|
| Theoretical time error (ms)        | 7    | 20     |
| Theoretical distance error (cm)    | 1.4  | 4      |
| Actual time error (ms)             | <1   | >100   |
| Actual distance error (cm)         | <0.2 | >20    |

to equation (24), all points in the original point cloud, denoted by  $P$ , can be inserted into the submap, denoted by  $P_{\text{submap}}$ .

$$P_{\text{submap}} = P \cdot \text{Trans}. \quad (24)$$

**4.2. Point Cloud Superposition.** The pose of the submap needs to be adjusted continuously in the process of loop optimization. To facilitate the adjustment, on top of the transformation mentioned in part A, it still needs to transfer the pose of the point cloud to its corresponding spatial position. This requires a translation of the point cloud using equation (25) based on the submap's location information.

$$\tau_{\text{submap}} = [\phi_x \ \phi_y \ \phi_z]^T. \quad (25)$$

After that, the translated point cloud will be superimposed on the total point cloud. The Cartographer algorithm constantly generates submaps when running.

With the superposition of submaps, the bound point clouds are also superposed. In the process of generating the 2D map, the joint of 3D point cloud can be completed. Figure 5 gives an example. Along with the robot moving forward, the Cartographer algorithm generates submap14 and submap15. When the two submaps are superposed, the corresponding point clouds of these two submaps are also superposed.

**4.3. Dynamic Object Removal.** In the process of 3D reconstruction, there are usually a large number of dynamic objects in the scene, and it will not only affect the accuracy of odometer but also introduce dynamic noise points into map.

FIGURE 5: Binding of point cloud data to the submap.

The proposed algorithm based on the odometer calculated by the Cartographer algorithm has higher accuracy than VSLAM, in the dynamic scene.

However, the more accurate odometer can ensure the accuracy of the map, but it cannot avoid the residual dynamic point cloud being inserted into the map in the process of reconstruction. Therefore, in order to solve this problem, this section proposes a method to eliminate the residual dynamic point cloud with the least computing resources in the reconstruction.

In this algorithm, we calculate the relative pose of two submaps and their corresponding point clouds relative to submap (16) and (17). Then, the view intersection area of two cloud points is calculated based on this pose.

When the algorithm inserts a new point cloud into the total point cloud using formula (26), it first opens a window around each point of the new point cloud, runs, “AND” operates with the points in the total point cloud so that the points that exist in both point clouds are preserved.

In this way, the residual point cloud in the map can be eliminated, as shown in Figure 6.

**4.4. Adjustment of Point Cloud Sloop-Closure.** Along with the continuous insertion of new scanning points, the global SLAM algorithm will open a window around the scanning points for detection with the help of the branch and bound method.

However, the laser range finder can only obtains the data of a certain plane in space, which is limited for the Cartographer algorithm to calculate loop-closure precisely or establish a loop-closure in the position where laser features are scarce.

We designed to use the ORB feature points to extract point cloud feature in every submap. When a new submap is generated by local SLAM, our algorithm will detect the loop-closure between the current submap’s point cloud and the previous submap’ point cloud. When the visual loop and the laser loop are established at the same time, we use the loop information calculated by the visual loop to replace the laser loop information. When visual loop-closure was established without laser loop-closure established, visual loop-closure will force the Cartographer algorithm to establish loop-closure between submaps.

During the course of loop-closure detection, no matter whether the algorithm detects a loop-closure or not, SPA will be performed to adjust the pose of the submap, in which the

FIGURE 6: Dynamic object removal. (a) Before removal, the foot of the woman in red is detected, leaving a gray occupying grid and point cloud in the generated submap. (b) After removal, the woman in red walked through the machine and not appeared on the point cloud again. The Cartographer algorithm used formula (2) to update the occupied grid of basket position in (a) to the non-occupied state, and the proposed algorithm in section C removes the point cloud of the woman in red.

loop-closure occurs, from  $\phi_{old}$  to  $\phi_{new}$ . Through calculating the position difference of the old and the new submap, we can obtain the following equations:

$$\tau_{loop} = [\phi_{newx} - \phi_{oldx}, \phi_{newy} - \phi_{oldy}, \phi_{newz} - \phi_{oldz}], \quad (26)$$

$$\gamma_{loop} = [f_{newroll} - f_{oldroll}, \delta_{newpitch} - f_{oldpitch}, \delta_{newyaw} - f_{oldyaw}]. \quad (27)$$

Taking equations (26) and (27) into equations (22) and (23), the Euclidean transformation matrix between the new and the old submaps can be calculated, which is recorded as  $Trans_{loop}$ . Then, the loop-closure adjustment of the point cloud can be made by multiplying the  $Trans_{loop}$  and the point cloud bound by the submap that the pose has changed based on formula (24) and, then, translating and superposing the new generated point cloud according to formulas (25) and (26). Whenever a new submap is inserted, SPA will optimize and adjust the pose  $\phi$  of all generated submaps. Due to this reason, it is easy to jam the program and affect the display effect by resuperimposition of the point cloud. Moreover, after the superimposed point cloud is filtered by the voxel, the point cloud bound by the submap that the pose has been changed cannot be directly subtracted from the superimposed point cloud.

To solve the abovementioned problem, our algorithm divides the point cloud into several regions based on a certain threshold, and only the point clouds in the regions, where the submaps adjust their pose is located, are superimposed. The above algorithms are shown as (Algorithm 2)

## 5. Experiment

```

ALGORITHM 2: Regional point cloud stack.

depth camera, SICK TIM561 laser range finder, and IMU is chosen as the experiment platform, as shown in Figure 7, to perform various tests and comparative experiments in large indoor scenes.

In the experiment, we choose a relatively accurate range between 0.2 m and 5.5 m of Kinect depth data for calculation and down sample the point cloud using a 0.03 m grid-size voxel filter. After the calculation, the point cloud is sent to RVIZ for display. Also, we define the starting point of the mapping work as the origin of the world coordinate system, that is, the position of No. 0 submap.

In addition, in order to verify the robustness and accuracy of the algorithm based on its real-time performance, we select RTAB algorithm for comparison because of its better accuracy and robustness than other popular algorithms, such as DVO SLAM algorithm and RGB-D SLAM V2 algorithm.

**5.2. Comparison of Algorithm Robustness.** In order to verify the robustness of the proposed algorithm, we select the outer of the corridor hall (an area of 27 m  $\times$  16 m) on the 2nd floor of the main building at our campus as the experimental scene, as shown in Figure 8(a). In the course of mapping, the robot moves around the selected area at a speed of 2 m/s for one and a half laps.

As shown in Figure 8(b), due to a glass wall at the entrance of the hall, there is serious ambient light interference. Under this circumstance, the RGBD camera will lose most of its depth information, and such lost can exert a

FIGURE 7: Experiment platform: the Meconium-wheel mobile robot.

great impact on RTAB algorithm's performance due to its sensitivity on visual information.

In many mapping experiments, RTAB algorithm is unable to complete the 3D mapping. The failures are all caused by the loss of location at the entrance. Despite that only a few mappings are successful, ghosting dislocation and distortion appear in many places, as shown in Figure 9(a).

Since RGBD's RTAB algorithm can lead to large error, our algorithm introduces a Cartographer algorithm, which reduces this error and improves the robustness, as shown in Figure 9(b).

**5.3. Comparison of Mapping Accuracy.** The lobby on the 1st floor of the selected building, which has sunlight interference

FIGURE 8: Second floor cloister of the main building. (a) Corridor hall on the 2nd floor. In the scene (b) with sunlight interference, depth camera (c) cannot obtain depth information.

FIGURE 9: Comparison of mapping results on the second floor. (a) RTAB algorithm result. (b) Our result.

at night, sufficient indoor light source, and rich environmental characteristics, is selected as the experimental scene.

Its outer dimension is also  $27\text{ m} \times 16\text{ m}$ . The richer layout of the lobby, including several self-service recharge machines on both sides of the hall, many tables, and chairs, is the ideal place for comparative experiments, as shown in Figure 10. In addition, the scene has ideal conditions because there is no strong outdoor infrared interference.

The robot moves around the selected area of the first floor at the speed of  $2\text{ m/s}$  for one and a half laps, and the constructed 3D maps by our algorithm and RTAB algorithm are shown in Figures 11(a) and 11(b), respectively. It can be seen that both algorithms can complete the mapping in an ideal environment, without serious loss or damage to important environmental information.

Figures 11(c) and 11(d) are enlarged views of the 3D map constructed by our algorithm and RTAB algorithm, respectively. It can be seen that the map constructed by RTAB in Figure 11(d) has an obvious dislocation, while the mapping effect by our algorithm shown in Figure 11(c) is more accurate without significant dislocation.

A basic criterion of 3D mapping is no obvious error in point cloud superposition. For this reason, we measured

and compared the errors of the constructed 3D maps by both algorithms. Firstly, we use the laser range finder and meter ruler to measure the six specific locations in the field to obtain the actual size of the map, as shown in Figure 12.

In that, six numbers marked on the given map are used to represent the features of the selected six positions, which are (1) the length of self-service machine of campus card, (2) the horizontal distance between two bearing pillars of the main building hall, (3) the distance between the two walls at the entrance of the main building hall elevator, (4) the vertical distance between the main building hall's bearing columns, (5) the longest vertical distance of the main building hall, and (6) the longest horizontal distance of the main building hall.

Then, RVIZ is used to measure the length of the map constructed by two algorithms, and the absolute error and relative error of them are calculated, respectively, compared with the real value of the map. The comparison results are shown in Table 2.

As seen from Table 2, in terms of the relative errors, all relative errors of the maps constructed by our algorithm are less than 1%, which is much lower than that of the RTAB algorithm. In addition, the distribution of relative errors in

TABLE 2: Measurement results of 3D mapping reconstruction.

| No. | Algorithm | GT (m) | Measurement (m) | Absolute error (m) | Relative error (%) |
|-----|-----------|--------|-----------------|--------------------|--------------------|
| 1   | OURS      | 5.51   | 5.53            | 0.02               | 0.363              |
|     | RTAB      |        | 5.41            | 0.10               | 1.815              |
| 2   | OURS      | 4.03   | 4.01            | 0.02               | 0.496              |
|     | RTAB      |        | 3.94            | 0.09               | 2.234              |
| 3   | OURS      | 6.52   | 6.50            | 0.02               | 0.307              |
|     | RTAB      |        | 6.36            | 0.16               | 2.454              |
| 4   | OURS      | 7.90   | 7.89            | 0.01               | 0.127              |
|     | RTAB      |        | 7.03            | 0.87               | 11.013             |
| 5   | OURS      | 16.05  | 15.98           | 0.07               | 0.436              |
|     | RTAB      |        | 15.56           | 0.49               | 3.053              |
| 6   | OURS      | 27.04  | 27.08           | 0.04               | 0.148              |
|     | RTAB      |        | 26.04           | 1.00               | 3.698              |

our algorithm is more even and is not affected by the sparse sensor feature points. However, the relative errors of RTAB algorithm are smaller in vertical scenes such as the position No. 3, No. 4, and No. 5 due to rich features, but larger in the case of No. 6 scene due to fewer feature points.

In terms of the absolute error, the results of our method are of relative balance, while the accuracy of RTAB algorithm increases along with the increase of map size and, in particular, reaches to 1 m in scene 6.

Based on the abovementioned comparisons, our algorithm is of significant advantages in a large scene.

#### 5.4. Comparison Experiment on Track and Loop Accuracy

##### 5.4.1. Calculating the Ground True Value of Robot Motion.

Experiments on the comparison of the track and the loop-closure precision require comparing the error between the ground truth value of robot motion and the errors of odometers in our method and the RTAB algorithm.

In the experiment, the ground truth value of robot motion is calculated by the position of Apriltag code on the floor tiles (60 cm × 60 cm per floor tile), as shown in Figure 13.

Firstly, the location of Apriltag code in the field is prestored in the industrial personal computer equipped by the robot using the following equation:

$$L_n = (x, y), \quad n = 1, 2, 3, \dots \quad (28)$$

Then, by identifying the Apriltag code laid on the ground, the position of the robot relative to Apriltag code is obtained, captured by the following equation:

$$L_A = (x, y). \quad (29)$$

Next, the position of the robot in the test site can be obtained by the following equation:

$$L_R = L_A + L_n. \quad (30)$$

According to the experiment of Wang and Olson [22], the robot's recognition accuracy of the Apriltag code can be up to 100% within 6 meters. Therefore, the ground true value

FIGURE 13: Apriltag on the ground.

of the robot's track can be calculated by the Apriltag algorithm.

##### 5.4.2. Contrast Experiments on Track and Loop-Closure Accuracy.

In order to compare the odometer accuracy and the loop-closure ability of two algorithms (our method and RTAB algorithm), we designed the following experiment. The remote-control robot first runs one lap along a rectangular track in the hall on the 1st floor, and continues running a certain distance after the robot passes the starting point in order to allow the algorithm to run loop-closure sufficiently. Finally, the robot returns to the starting point again.

Figures 14(a) and 14(b) show the comparison of the odometer. Here, the red asterisk and green asterisk in (a) represent the end point and the start point of the robot running, respectively, and (b) gives an enlarged figure showing that the proposed algorithm has much higher odometer accuracy in large-scale indoor scenes than that of RTAB algorithm.

To be more specific, as can be seen from Figure 14(b), the distance difference value between the start point and the end point of our method is 15.1 cm, while the data of RTAB is 65.307 cm.

Figures 14(c) and 14(d) show the comparison between the two algorithms after full loop-closure, and the result is that the loop-closure accuracy of our method is better than that of RTAB algorithm. As can be seen in (d) that shows more detailed information about the results, after loop-closure, most accumulated errors can be eliminated. In this case, the distance error in our algorithm is only 0.6 cm, while the result of RTAB algorithm is 1 cm.

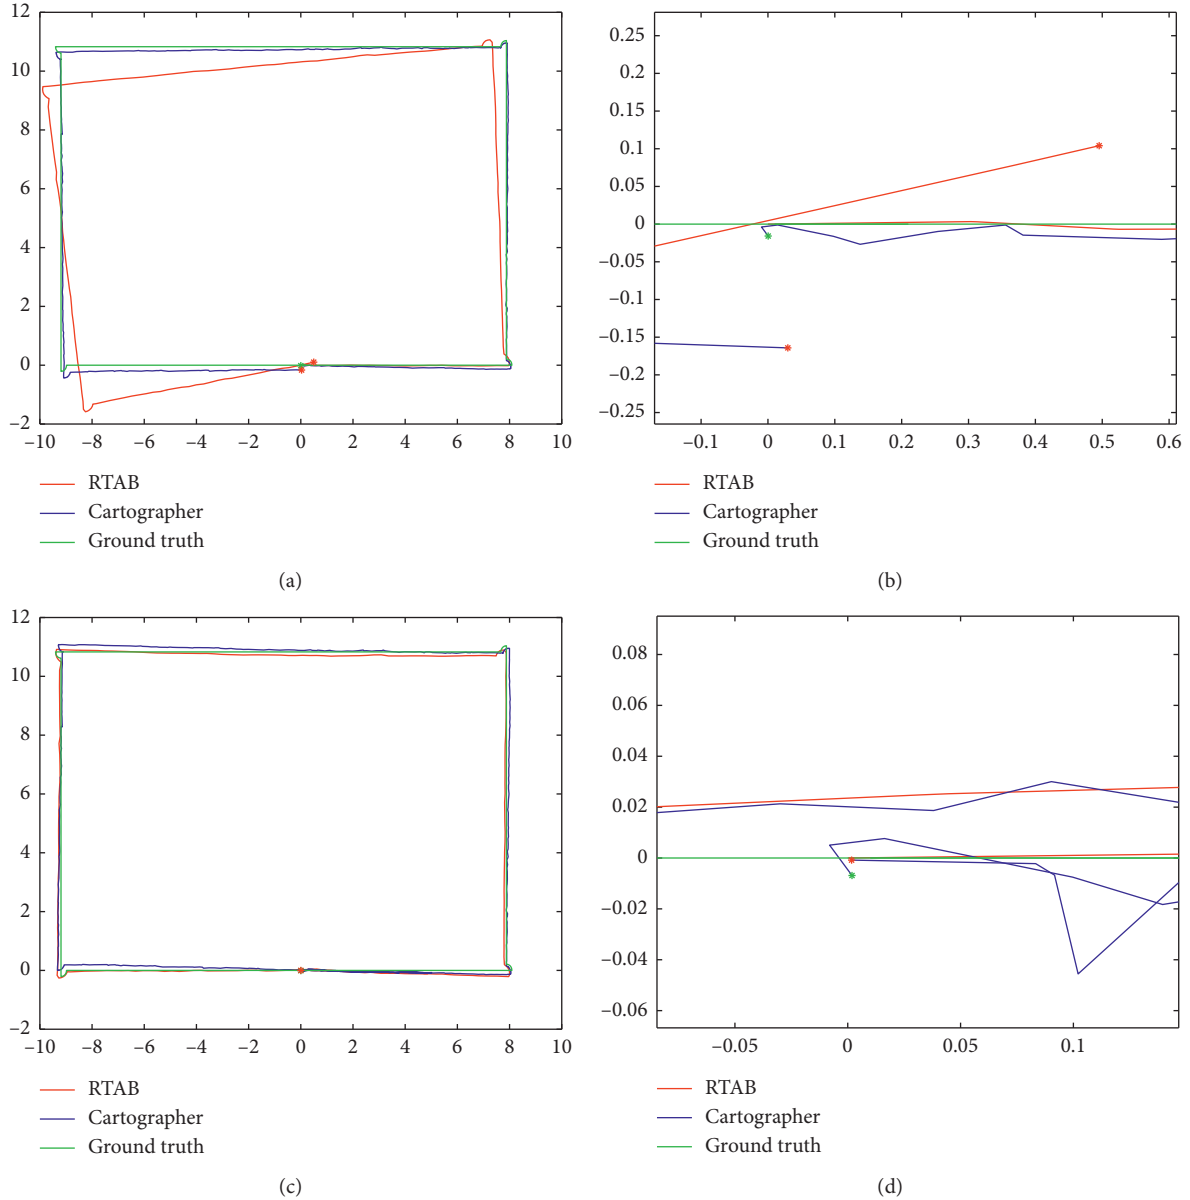

FIGURE 14: Trajectory accuracy contrast. (a) Accuracy comparison of the odometer. (b) Comparison of odometer accuracy after robot returns to origin. (c) Accuracy comparison of loop-closure. (d) Comparison of loop-closure accuracy after robot returns to origin. Unit: meter.

**5.5. Algorithm Contrast Experiment in Real-Time.** In order to ensure the integrity of the established map, in principle, our algorithm and RTAB algorithm are designed to process the current frame after all previously stored frames are processed. However, this design may not guarantee the real-time of map construction in reality.

In order to compare the real-time of two algorithms, in this paper, the environment information recorded by the robot in the real scene is packaged as rosbag function in ROS (robot operating system). During the verification phase, it is ensured that the sensor data received by the two algorithms are consistent through data packet playback in ROS.

Since the data types of the two algorithms are different, it is very troublesome and error-prone to record

and process each frame of the data produced by each algorithm. Instead, in the comparative experiment, we use the total time spent on mapping to compare the real-time performance of them. The experimental results are shown in Table 3.

It can be seen that the real-time of this algorithm is much higher than that of RTAB algorithm.

The computer configuration and environment used in this algorithm experiment are as follows:

CPU: I5-5200U 2.2GHZ

Ubuntu: 16.04

ROS: Kinetic

TABLE 3: The comparison of total time spent by the algorithms.

| Experiment site         | 1 <sup>st</sup> floor (s) | 2 <sup>nd</sup> floor (s) |
|-------------------------|---------------------------|---------------------------|
| Total rosbag duration   | 241                       | 213                       |
| Time for our algorithm  | 241                       | 213                       |
| Time for RTAB algorithm | 506                       | 421                       |

## 6. Conclusions

In the 3D reconstruction of a large scene, although the interference of moving objects and uneven sunlight can be eliminated, it needs to consume a huge amount of extra computing resources and, more importantly, is not conducive to the improvement of the real-time and accuracy of the algorithm. In this paper, a new algorithm is presented for 3D reconstruction in large scenes, which integrates the 3D point cloud generated by the Kinect camera and odometer information output by the Cartographer algorithm. Also, it is of high robustness and high accuracy. In addition, we also propose a new method applying Apriltag code to calculate the ground truth value of robot motion in large scenes. This method effectively solves the problem of the insufficient measurement range of the optical tracker in large scenes. The results of the real tests conducted in two selected actual scenes show that the newly proposed algorithm has higher real-time, robustness, and accuracy than the traditional RGBD camera-based 3D reconstruction algorithms.

Foam aluminum is an energy-absorbing material with excellent performance. The interlayer composed of multiple layers of foam aluminum and steel plate has good antiexplosion ability. In order to explore the antiexplosion performance of double-layer foam aluminum under different porosity rankings and to reveal its microscopic deformation law and failure mechanism, three kinds of aluminum foams with a porosity of 80%, 85%, and 90% were selected to form six different structures. Based on the Voronoi algorithm, a three-dimensional foam aluminum generation algorithm with random pore size and random wall thickness was written by using the Python language and Fortran language. The three-dimensional mesoscopic model of double-layer closed-cell aluminum foam sandwich panel is established by using LS-DYNA and ABAQUS software. The explosion process was simulated, and the flow field movement of explosion shock wave of aluminum foam under different porosity rankings was analyzed. Two groups of aluminum foam were randomly selected for the explosion test and compared for the strain and compression. The test results are consistent with the simulation results, which verifies the correctness of the three-dimensional meso-model. The results show that when the porosity of the upper layer of aluminum foam is greater than that of the lower layer of aluminum foam, the sandwich structure of double-layer aluminum foam has a large compression and the bottom plate has a small displacement; it is not that the greater the compression amount of aluminum foam is, the better the antiexplosion and wave absorption ability is. When the aluminum foam reaches the ultimate load-bearing capacity, the aluminum foam transfers the load due to compaction, resulting in stress enhancement phenomena. Through the analysis of the compression amount, floor deformation, wave dissipation capacity, and energy ratio of aluminum foam, it is concluded that the antiexplosion wave absorption effect of the sandwich structure of aluminum foam with 80%/85% group is the best; the changes of porosity and cell wall are important factors affecting the energy absorption capacity of aluminum foam.

## 1. Introduction

In recent years, various explosions have occurred frequently. Explosion containment vessels (ECVs) are widely used to completely contain the effects of explosions. Foamed aluminum (ALF) is a kind of solid material based on aluminum or aluminum alloy with three-dimensional polyhedral holes randomly distributed inside [1–4]. Because of its special porous properties, aluminum foam can have a very long and almost unchanged platform compression section during compression. While the strain increases gradually, the stress in the compression zone of the platform basically remains

unchanged and can absorb a lot of energy, so aluminum foam is an excellent energy-absorbing material [5–7], which has a good effect on reducing stress waves [8]. It has been widely used in all aspects of explosion shock protection [9–12].

The sandwich type structures, comprising the aluminum foams in the core and the thin steel cover plates, have been used to withstand higher impulse under intense dynamic events. By attaching the sandwich structure containing aluminum foam in the middle to the protective engineering or the outer surface of the building, under the impact load, the upper panel directly

acted by the external load produces a shock wave and then compresses the internal aluminum foam material; it leads to the deformation and buckling of aluminum foam, which absorbs energy, protects the bunker target, and resists the impact effect and explosion damage caused by strong dynamic load [8, 13–16]. Many scholars have studied the dynamic response and energy absorption capacity of metal foam sandwich structure, especially under explosive loading [17–21]. The results show that the dynamic properties of metal foams are affected by many factors, such as meso-structure (density, core gradation, cell wall strength, etc.), plate thickness, and loading strain rate. Functionally graded materials optimize their properties by controlling the performance gradient [22], and this method can be extended to metal foams with gradient relative density. Mortensen et al. [23, 24] made sandwich multilayer aluminum foam with core relative density  $\rho/\rho_s = 150.45\%$  and found that density classification does provide weight reduction in some strength-limited applications. The study [25] shows that the equal density foam shows the conventional behavior of metal foam. Under the condition of high strain, the foam expands to a nearly flat platform area, and then densification occurs, while the density gradient sample shows an obvious positive slope in the plateau region. As we all know, aluminum foam is a highly complex porous material. Its inherent multiscale characteristics and heterogeneity come from randomly distributed cells [26]. The meso-reaction is of great significance to the mechanical behavior of aluminum foam and the energy absorption capacity under impact loading. Li et al. [27] studied the response of gradient honeycomb sandwich structure under explosive loading by means of experiment and numerical simulation. It was found that, under the same conditions, graded sandwich plate had better antiexplosion ability than ungraded Sandwich plate. When the sandwich plate is arranged in the order of decreasing relative density, the energy absorption capacity of the sandwich plate and the attenuation effect of the contact stress on the back plate are the best. Zhou et al. [28] established a high-speed compression model of aluminum foam based on impact theory and rigid ideal plastic locking model of aluminum foam. Combined with numerical simulation, the energy absorption of gradient aluminum foam under explosive loading was studied. The results show that the larger the density gradient of aluminum foam sandwich is, the smaller the total energy input to aluminum foam is and the smaller the final deformation of aluminum foam is. Dou et al. [29] have studied the strain rate of aluminum foam sandwich panels by means of numerical simulation and think that the strain rate effect of aluminum foam becomes more and more obvious with the increase of relative density. However, the proposed meso-model of aluminum foam also has some shortcomings. Based on the three-dimensional Voronoi algorithm technology, many scholars [30–32] have established a three-dimensional meso-model of aluminum foam, which can well simulate the random distribution of aluminum foam pores and greatly

promote the study of three-dimensional meso-mechanical properties of aluminum foam. However, for the meso-model of aluminum foam established by three-dimensional Voronoi algorithm, most of the hole walls are shell elements, and their thickness is the same at any position, which obviously does not accord with the experimental results. In order to simulate the deformation and failure process of aluminum foam more truly under external load, it is very necessary to establish a wall thickness model.

## 2. Three-Dimensional Mesoscopic Modeling of Double-Layer Aluminum Foam Sandwich Panel

In this chapter, we consider the cells in the foam and give the generation algorithm of the three-dimensional model of double-layer closed-cell aluminum foam. The algorithm consists of three steps. Firstly, the random polyhedron is modeled and the geometric features are extracted; then, a three-dimensional random aluminum foam generation algorithm is developed to control the random wall thickness of the pore wall, and the aluminum foam mesh model is established by reading it into the TrueGrid software. Finally, the three-dimensional mesoscopic model of aluminum foam is imported into the LS-DYNA software to establish the explosion model of double-layer aluminum foam sandwich panel.

*2.1. Modeling Method of Three-Dimensional Meso-Model of Aluminum Foam.* In this paper, based on the three-dimensional Voronoi algorithm technology, the discrete data points are connected reasonably, the Delaunay triangulation is constructed, and the vertical bisector of the two adjacent points is connected to form the Tyson polygon [33]. The pores of the aluminum foam are regarded as the interior of the Tyson polygon, and the outline of the polygon is regarded as the cell wall of the aluminum foam. Because the wall thickness of aluminum foam is random and uneven, the random polyhedron is modeled by ABAQUS software, and the geometric features of the model are extracted. Then, based on the Voronoi algorithm, a three-dimensional foam aluminum generation algorithm with random pore size and random wall thickness was written using Python language and Fortran language. The geometric boundary parameters were read, and the random wall thickness was set to better simulate the foam aluminum under real conditions. The model uses TrueGrid's excellent grid filling technology to build a meso-grid model of aluminum foam. The finite element model of aluminum foam is obtained, as shown in Figure 1.

*2.2. Material Model and Parameters.* The bottom plate, sleeve, bracket, and end cover of the system are made of Q235 steel. The above materials and aluminum foam are numerically simulated by PLASTIC KINEMATIC material model. The model can well describe the mechanical

FIGURE 1: Three-dimensional microscopic view of double-layer foam aluminum.

TABLE 1: Metal material parameters.

| Metallic material | $q$ (kg/m <sup>3</sup> ) | $E$ (GPa) | $\mu$ | SIGY (MPa) | ETAN (GPa) |
|-------------------|--------------------------|-----------|-------|------------|------------|
| Q235 steel        | 7830                     | 210       | 0.274 | 235        | 6.1        |
| Aluminum foam     | 2730                     | 70        | 0.34  | 185        | 4.62       |

properties of metal materials and is widely used in numerical calculation. The calculated parameters of the metal are shown in Table 1.

The air uses the \* MAT\_NULL material model, and the equation of state is described using \* EOS\_LINEAR\_POLYNOMIAL. The expression of the equation of state is as follows:

$$p = C_0 + C_1\mu + C_2\mu^2 + C_3\mu^3 + (C_4 + C_5\mu + C_6\mu^2)E, \quad (1)$$

$$\mu = \left(\frac{1}{V}\right) - 1 = \left(\frac{\rho}{\rho_0}\right) - 1,$$

$$C_4 = C_5 = \gamma - 1.$$

Considering air as the gas in an ideal state, the coefficients of the polynomial equation are  $C_0 = C_1 = C_2 = C_3 = C_6 = 0$ . The variable coefficient  $\gamma$  is often set to 1.4, so  $C_4 = C_5 = 0.4$ .  $E_0$ ,  $\rho_0$ , and  $V_0$  are the initial energy density, the initial density, and the initial relative volume parameter values which are 1.29 g·cm<sup>-3</sup>, 0.25 MPa, and 1.0. The parameters are shown in Table 2.

The high-energy combustion explosives use \* MAT\_HIGH\_EXPLOSIVE\_BURN material model, and the equation of state uses \* EOS\_JWL to represent the pressure of the explosive product. The expression of the equation of state is shown in the following formula [18]:

TABLE 2: Material model and EOS parameters of air [20, 34, 35].

| $C_0$ (MPa) | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ | $\rho$ (kg/m <sup>3</sup> ) |

$$p = A \left(1 - \left(\frac{\omega}{R_1 V}\right)\right) e^{-R_1 V} + B \left(1 - \left(\frac{\omega}{R_2 V}\right)\right) e^{-R_2 V} + \left(\frac{\omega E}{V}\right), \quad (2)$$

where  $E$  and  $V$  are energy density and relative volume, respectively. When the initial calculation is performed, they should be given initial values  $E_0$  and  $V_0$ ;  $A$ ,  $B$ , and  $E_0$  are pressure units;  $R_1$ ,  $R_2$ , OMEG, and  $V_0$  are dimensionless. The specific material parameters are shown in Table 3.

The outer boundary of the air adopts a nonreflective boundary, the bottom of the bottom plate is set as a fixed boundary, and the contact setting is set: the cover plate is bound to connect with the bottom plate, \* CONTACT\_TIED\_SURFACE\_TO\_SURFACE, cover plate is connected with aluminum foam, and the aluminum foam is automatically contacted with the bottom plate by automatic surface contact \* CONTACT\_AUTOMATIC\_SURFACE\_TO\_SURFACE.

**2.3. Modeling of Double-Layer Aluminum Foam Sandwich Panel.** The energy absorption effect and explosion resistance of aluminum foam are closely related to the density, and the

|-----------------------------|-----------|-----------|-------|-------|-----------|-------------------------|-----------|-------|----------|
| 1500                        | 347.6     | 3.39      | 4.15  | 0.95  | 17.92     | 6.34e9                  | 6957.2    | 1.0   | 0.28     |

difference of porosity will inevitably lead to the change of the density of aluminum foam. The arrangement of different porosity of multilayer aluminum foam will also have a significant impact on the dynamic response of aluminum foam sandwich panels. Six groups of different structures were obtained by permutation and combination of aluminum foam with three densities, namely, 80%, 80%, 85%, 85%, 90%, 90%, 90%, 90%, 80%, and 90%, respectively. The numerical model is shown in Figure 2. In the model, the mass of the charge is fixed as 520 g, the density is 1.601 g, the radius is 0.086 m, and the spherical charge and the height of the charge are fixed as 25 cm. The thickness of cover plate is fixed at 10 mm, the total height of aluminum foam sandwich is fixed at 78 mm, and the height of single layer is 39 mm. As shown in Figure 2, the bottom plate support of the model is set as a fixed constraint, and a downward prestressed load is applied on the upper surface to clamp the aluminum foam. The pore sizes  $R_{\min}$  and  $R_{\max}$  in the model are 1 mm and 3 mm, respectively, and the average pore size is 2 mm. In order to ensure the calculation accuracy of the flow field in the container, the element size in the finite element model is 0.2 mm.

**2.4. Layout of Measuring Points.** After the explosion of the explosive, the explosion products and shock waves of high temperature and high pressure will be produced, which will have a strong destructive effect on the surrounding structures. A measuring point is set up in the sandwich structure bearing the explosion shock wave to test the strength of the stress wave. The location of the measuring points is shown in Figure 3, and three groups of stress measuring points are set. The stress wave intensities of the cover plate were transmitted to the first layer of aluminum foam, the first layer of aluminum foam to the second layer of aluminum foam and the second layer of aluminum foam to the bottom plate are measured, respectively, and the test results are recorded as  $\sigma_1$ ,  $\sigma_2$ , and  $\sigma_3$ , respectively.  $\sigma_1$  is the mean stress of the uppermost element of the first layer of aluminum foam,  $\sigma_2$  is the average stress of the lowest element of the first layer and the uppermost element stress of the second layer, and  $\sigma_3$  is the mean stress of the uppermost element of the bottom plate.

### 3. Validation

**3.1. Experiment Setup.** In this paper, the explosion test device shown in Figure 4 is designed to study the anti-explosion performance of double-layer aluminum foam sandwich structure. The shock wave produced by the explosion of the spherical TNT charge causes the cover plate to move and deform and compress the aluminum foam under the explosion load. In the experiment, the blasting height of the charge is fixed at 25 cm, the thickness of the upper panel

is fixed at 10 mm, the height of each layer of aluminum foam is 39 mm, and the total thickness of the aluminum foam sandwich is fixed as 78 mm.

In order to evaluate the explosion resistance of different aluminum foam sandwich structures, a cylindrical pressure sensor is installed on the upper surface of the base plate. According to the fixed mode of the whole device, strain gauges are set at the positions of S1, S2, and S3 on the lower surface of the base plate, which mainly test the dynamic response of the bottom plate under the explosion impact load. As shown in Figure 5, the load and deformation of the bottom plate are monitored, respectively. The pressure sensor is in the center of the upper surface of the base plate. The strain gauge S1 is in the center of the lower surface of the base plate.

**3.2. Comparative Analysis with the Test.** In order to verify the correctness of the model, the strain test values of 80%/90% group and 80%/85% group of aluminum foam were randomly selected and compared. Figure 6 is the comparison diagram of the strain time history curve of 80%/90% foam aluminum test value and simulation value of each measuring point. S1 (2, 3)-e represents the experimental value, and S1 (2, 3) represents the simulation value. As can be seen from the chart, the strain peak value of each measuring point has little difference, and the trend of the strain curve waveform is the same, which tends to be smooth with the increase of time. The test simulation results verify the test results. Figure 7 shows the test height and simulation height of 80% ram 85% aluminum foam after compression. The initial height of double-layer aluminum foam is 78 mm. After the test, the height of double-layer aluminum foam becomes 46.55 mm, and the compression amount is 31.45 mm. The compression amount of the numerical simulation is 32.8 mm, and the difference between the experimental value and the simulation value is small, which can verify the correctness of the model.

## 4. Analysis of Energy Absorption Mechanism of Aluminum Foam

**4.1. Analysis of the Movement Process of Double-Layer Foam Aluminum.** This section explores the motion process of 85%/90% foam aluminum sandwich panels under explosive loading.

In the first stage, the explosive center detonates until the shock wave reaches the cover plate and begins to compress the aluminum foam. As shown in the figure, during 0 ms, the explosive initiates at a single point center, and the shock wave front begins to expand outward with the sphere as the center, reaching the cover plate at a certain time between 0.07 ms and 0.08 ms, and the cover plate obtains a certain speed to compress the aluminum foam downward, as shown

FIGURE 2: Double-layer aluminum foam sandwich (AFS) structure.

FIGURE 3: Stress measuring point arrangement.

in the pressure cloud diagram of aluminum foam on the right side of Figure 8.

In the second stage, the cover plate begins to compress aluminum foam to fully compress double-layer aluminum foam. As shown in Figure 9, contact compression occurs at the delamination interface at 0.08 ms, and the stress wave

begins to travel from the top foam to the bottom foam, resulting in reflected and transmitted waves. Because the wave impedance of 90% porosity aluminum foam is less than 80% porosity aluminum foam, and 90% porosity is high, so 90% porosity aluminum foam absorbs most of the energy and produces great deformation. The stress wave is

FIGURE 4: Sandwich plate antiexplosion test device.

FIGURE 5: Sensor settings.

transmitted to the bottom plate at 0.24 ms and begins to act to the bottom plate, so that the floor begins to compress and deform. During the explosion process to 1.0 ms, we can see that 90% aluminum foam is completely compressed almost at some time between 1.0 ms and 1.24 ms, while, after 1.0 ms, 80% aluminum foam is compressed as the main energy-absorbing material. This is very helpful for us to study the energy absorption mechanism of layered aluminum foam.

From the summary of the previous research background, we can see that the stress-strain performance of aluminum foam is different under the sorting condition of different aluminum foam density, but the simulation analysis of the

FIGURE 6: 80%/90% foam aluminum strain diagram.

FIGURE 7: 80%/85% aluminum foam compression.

ordering of density gradient is still less. In order to further analyze the effect of density gradient on the mechanical properties of closed-cell aluminum foam, this section is based on a three-dimensional meso-model to study the explosion resistance of aluminum foam specimens under different density order and the energy absorption characteristics of aluminum foam with different density gradient under explosive impact loading.

*4.2. Analysis of Delamination Characteristics of Double-Layer Aluminum Foam.* You can see significant compression when the time reaches 0.48 ms. When compressed to 1.24 ms, the compression of aluminum foam is completed. Figure 10 shows the deformation distribution of aluminum foam under explosive loading under six groups of porosity combinations during 1.24 ms. It can be seen from the figure that the deformation of aluminum foam in 90%/80% group is the largest, with a deformation amount of 34.23 mm. The deformation of the pore wall of aluminum foam is mainly concentrated in the area with large porosity. Through the

FIGURE 8: Compressed foam aluminum cover.

FIGURE 9: Compressed foam aluminum cover.

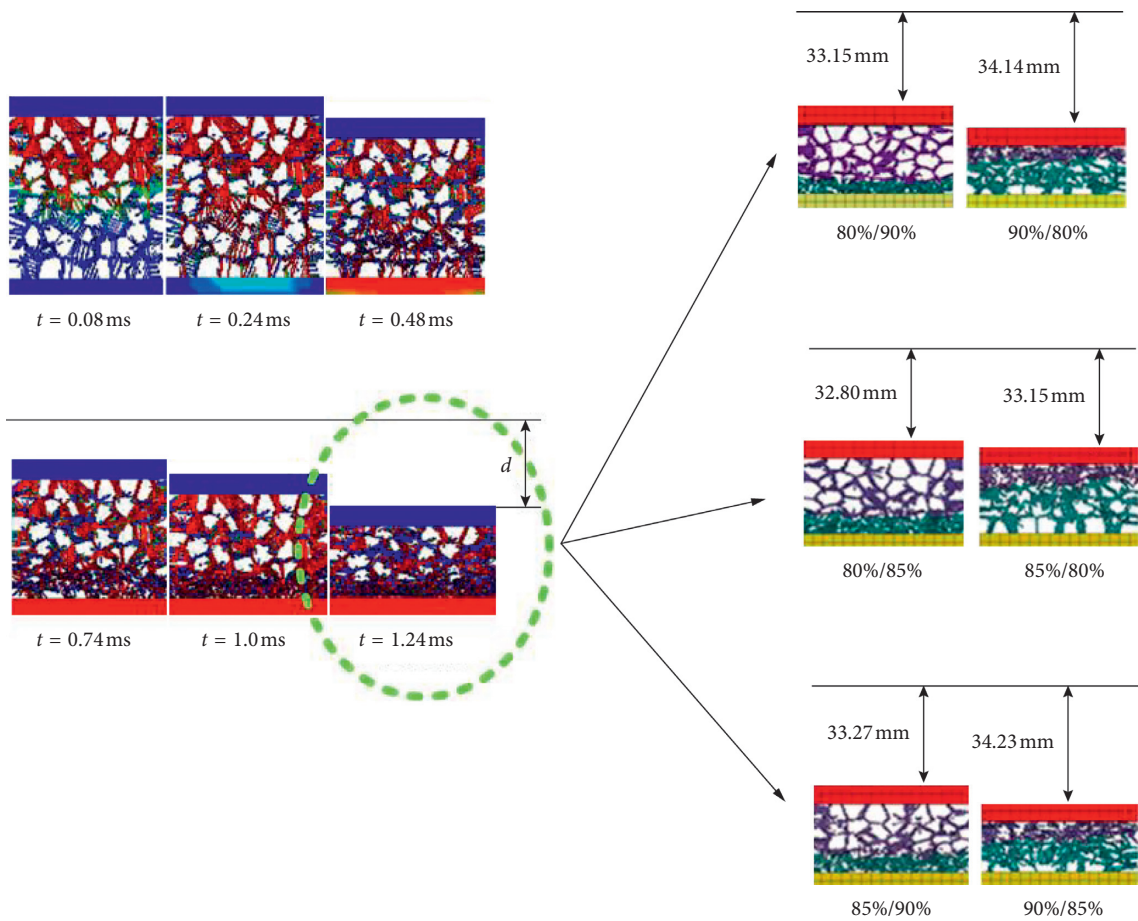

FIGURE 10: Deformation analysis of six groups of structures.

comparison of the structures of each group, it is found that if the porosity of the upper layer aluminum foam is higher than the lower layer aluminum foam, the compression amount of the double-layer aluminum foam sandwich structure is larger, such as group 90%/80% and group 90%/85%. When the porosity of the upper layer aluminum foam is small, the two layers of aluminum foam begin to deform at the same time, but when the porosity of the upper layer aluminum foam is larger, it will not begin to deform at the same time. Before the upper layer of aluminum foam is compressed to a certain extent, the contact stress between the two layers of aluminum foam is greater than the yield stress of the lower layer of aluminum foam, and the lower layer of aluminum foam begins to deform.

As can be seen from Table 4, the maximum peak displacement of the 90%/80% group is the largest among the six groups, followed by the 90%/85% group displacement. The order of the bottom plate displacement under each combination is as follows: 80%/90% < 85%/90% < 80%/80% < 90%/85% < 90%/85% < 90%/80%. Under the only combination of the two groups of porosity, the large upper porosity will increase the compression of the sandwich structure of double-layer aluminum foam and reduce the displacement of the bottom plate. With the increase of time, the elastic deformation of the bottom plate ends and enters the plastic deformation stage, and the deformation of the bottom plate tends to be stable. After reaching stability, the minimum displacement of the bottom plate is 80%/90% group, followed by 85%/90% group. The order of displacement is as follows: 80%/85% < 85%/90% < 80%/80% < 90%/80% < 90%/85% < 90%/80%. Since the bottom plate displacement of the aluminum foam in the 80%/85% group is the smallest after the stress balance, it is considered that the reorganization is the total optimal group of the six groups. It can be found that, under the positive sequence of porosity, the displacement of the bottom plate is smaller. By comparing the compression amount of aluminum foam, it can be found that the compression amount of aluminum foam in the group of 90%/85% is the largest, but the deformation of the bottom plate is not the smallest, but very large. This also shows that it is not that the greater the compression amount of aluminum foam is, the better the antiexplosion and wave-absorbing ability is and the better the protective effect on the substructure is. The analysis shows that after the aluminum foam reaches the ultimate bearing capacity, the aluminum foam produces stress enhancement due to compaction, so the compression amount of aluminum foam is the largest, but its wave absorption capacity is not the best.

In order to quantitatively describe compressive quantities of double-layer aluminum foams and compare compressive quantities of single-layer aluminum foams, we draw a curve of displacement time history of different porosity combinations in Figure 11. It can be seen from graphs that foam aluminum reaches maximum displacement rapidly during elastic stage and then decreases and eventually tends to be smooth. Results show that compressive strength of double-layer foamed aluminum bottom plate is smaller than that of single-layer aluminum foam plate. Design of double-layer aluminum foam can improve antiexplosion property of

TABLE 4: Displacement of double-layer foamed aluminum under each combination.

aluminum foam effectively, eliminate partial explosion shock wave effectively, and play positive role in protecting lower structure.

**4.3. Energy Analysis.** Tables 5–7 provide energy for upper and lower aluminum foams and bottom plates, respectively. According to the tables, the total energy of lower aluminum foam is higher than that of upper aluminum foam, which is consistent with wave dissipation rule of aluminum foam at upper and lower level. The fluctuation dissipation rate of low aluminum foam is obviously higher than that of aluminum foam. As shown in Table 5, the difference between total energy and internal energy is smaller than that of upper foam aluminum, and the kinetic energy of 80%/90% group is maximum, which is consistent with minimum law of peak displacement of bottom plate of upper foam aluminum group, followed by group 80%/85%. As shown in Table 6, the gap between total energy and internal energy is larger during lower aluminum foams. The maximum kinetic energy is in group 80%/85%, and the minimum kinetic energy is in group 80%/90%. As shown in Table 7, total energy, internal energy, and kinetic energy are minimal in group 80%/85%. The results show that porosity has great influence on energy absorption characteristics of samples; when the total energy of aluminum foam increases, the energy of bottom plate decreases. There are mainly two types of aluminum foam to improve porosity; one case is pore quantity that increases; another case is pore wall thickness that decreases. Therefore, more cell walls produce larger deformation plastic strain absorbing more energy under the same strain condition. However, due to low porosity, the overall antiblast performance of this device is better but critical point of complete compression and incomplete compression can be found which ensures that load can be absorbed completely without destroying floor.

Figure 12 shows the ratio of internal energy to kinetic energy of the floor arranged at all levels of density. It can be seen from the diagram that the energy ratio of the floor fluctuates with the increase of time, indicating that the kinetic energy ratio of the floor continues to decrease and the kinetic energy is converted into internal energy and finally tends to be stable. The soleplate of 80%/85% group showed the maximum peak of energy ratio during 4.496 ms, and obvious secondary damage occurred at the interface, resulting in secondary work done by aluminum foam, so it consumes a lot of energy. Since the displacement of the bottom plate of the 80%/85% group is the smallest, it can be concluded that this group is the best group in density order.

FIGURE 12: Energy ratio of aluminum foam.

## 5. Investigation on Three-Dimensional Meso-Mechanical Properties of Double-Layer Aluminum Foam Sandwich Panels

In order to analyze the relationship between meso-parameters and mechanical properties of materials under explosive loading, we study the energy absorption characteristics of aluminum foam materials and the effects of meso-failure mechanism of aluminum foam cell wall on its antiexplosion performance and energy absorption. In this section, the dynamic mechanical properties of aluminum foam specimens are studied by simulating the double-layer aluminum foam sandwich panel under explosive load.

The literature research [36] shows that the stress wave propagates from one medium to another; if the wave impedance of the two media is different, then the stress wave will be reflected and transmitted at the interface of the two media, and its intensity satisfies the following relationship:

$$\left(\frac{\sigma_R}{\sigma_I}\right) = \frac{(\rho_2 C_2 - \rho_1 C_1)}{(\rho_2 C_2 + \rho_1 C_1)}, \quad (3)$$

$$\left(\frac{\sigma_T}{\sigma_I}\right) = \frac{(2\rho_2 C_2)}{(\rho_2 C_2 + \rho_1 C_1)}. \quad (4)$$

Among them,  $\sigma_I$ ,  $\sigma_R$ , and  $\sigma_T$  represent the incident wave, reflected wave, and transmitted wave intensity of the shock wave at the interface, respectively;  $\rho_1 C_1$  represents the wave impedance of the first layer medium, and  $\rho_2 C_2$  represents the wave impedance of the second layer medium. It can be seen from formulas (3) and (4) that when the aluminum foam sandwich is delaminated in density, due to the difference of medium wave impedance on both sides of the interface, the shock wave that continues to propagate along the foam

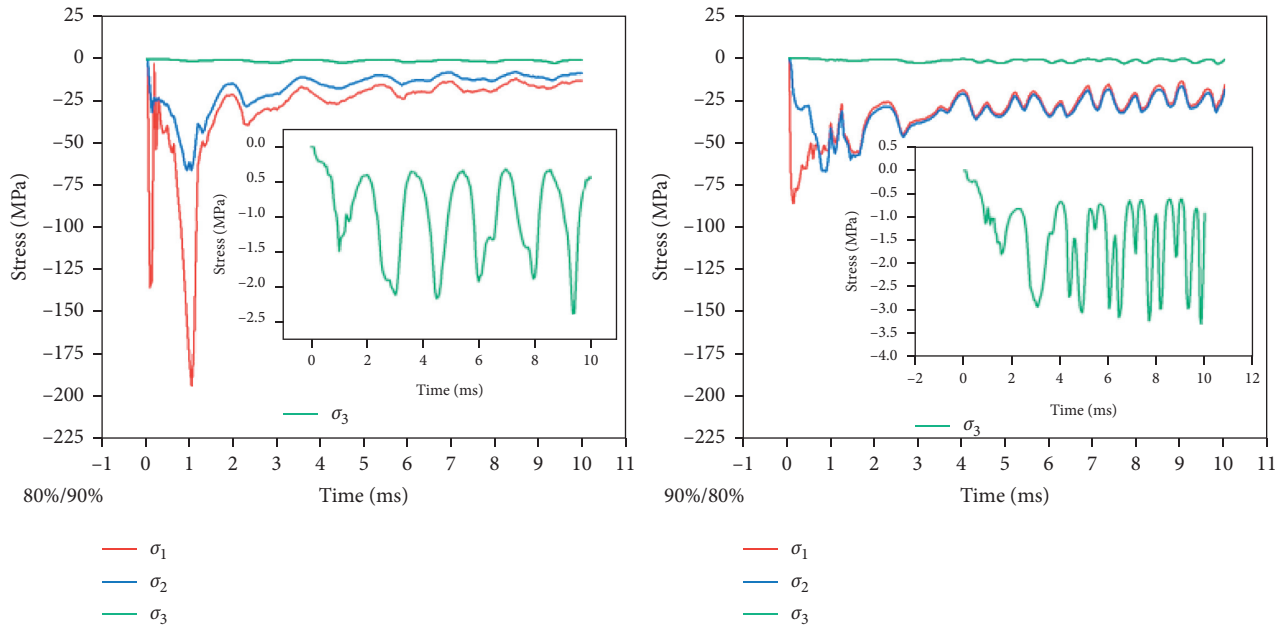

FIGURE 13: Double-layer aluminum foam with porosity of 80% and 90%.

aluminum to the bottom plate after transmission through the interface decreases, while the shock wave reflected from the interface near the explosion source end may further compress the deformed area of the aluminum foam, so delamination of the aluminum foam may increase the energy absorption value of the sandwich structure core of the foam aluminum sandwich. At the same time, the load acting on the protected structure is reduced. Therefore, we established a three-dimensional mesoscopic model of double-layer aluminum foam and quantitatively analyzed the attenuation effect of stress wave strength of double-layer aluminum foam sandwich structure.

When the porosity combination of aluminum foam is 80% and 90%, the distribution of stress waves in the sandwich structure is shown in Figure 13. Intuitively, in Figure 13, the stress value of the first layer reached 135.94 MPa at 0.102 ms and reached the second peak at 1.057 ms due to emission, indicating that, in the steel plate, the change rate of stress wave is extremely high, the stress wave intensity of the second layer is 31.17 MPa, and the stress wave intensity of the third layer is 2.38 MPa. The attenuation of the explosion shock wave is as high as 77.07% after passing through the first layer of aluminum foam, the attenuation of the explosion wave after passing through the second layer of aluminum foam reaches 92.36%, and the overall wave dissipation rate is 98.25%. The rising edge of the stress wave in the first layer is  $10.2 \mu\text{s}$ , the rising edge of the stress wave in the second layer is  $14.9 \mu\text{s}$ , and the rising edge of the stress wave in the third layer can reach 0.9 ms. After aluminum foam, the rising time of stress wave has been greatly improved. When the porosity of the upper layer of aluminum foam is 90% and the porosity of the lower layer of aluminum foam is 80%, the stress value of the first layer is 86.70 MPa, the attenuation of explosion shock wave after the first layer of aluminum foam is 64.46%, the stress value of explosion

wave after the second layer of aluminum foam is 2.94 MPa, the attenuation rate is 90.45%, and the overall wave dissipation rate is 96.61%. It can be found that whether it is the first layer of aluminum foam or the second layer of aluminum foam, the positive sequence arrangement of porosity has higher wave dissipation rate and the phenomenon of interface delamination is more obvious.

When the porosity combination of aluminum foam is 80% and 85%, the distribution of stress waves in the sandwich structure is shown in Figure 14. When the upper porosity of the aluminum foam is 80% and the porosity of the lower aluminum foam is 85%, the stress value of the first layer of the explosion shock wave reaches 158.76 MPa, and the attenuation is as high as 59.07% after passing through the first layer of aluminum foam; the stress value of the explosion wave after passing through the second layer of aluminum foam is 2.38 MPa, the attenuation rate is 95.80%, and the overall wave dissipation rate is 98.51%. When the porosity of the upper layer of aluminum foam is 85% and that of the lower layer is 80%, the stress value of the first layer is 151.01 MPa, and the attenuation rate of the explosion shock wave after the first layer of aluminum foam is 49.02%. After the second layer of aluminum foam, the stress value of the explosion wave is 2.27 MPa, the attenuation rate is 95.34%, and the overall wave dissipation rate is 98.49%. It is also found that whether it is the first layer of aluminum foam or the second layer of aluminum foam, the positive sequence arrangement of porosity has a higher wave dissipation rate and the phenomenon of interface delamination is more obvious.

When the porosity combination of aluminum foam is 85% and 90%, the distribution of stress waves in the sandwich structure is shown in Figure 15. When the porosity of the upper layer of aluminum foam is 85% and that of the lower layer is 90%, the stress value of the first layer is

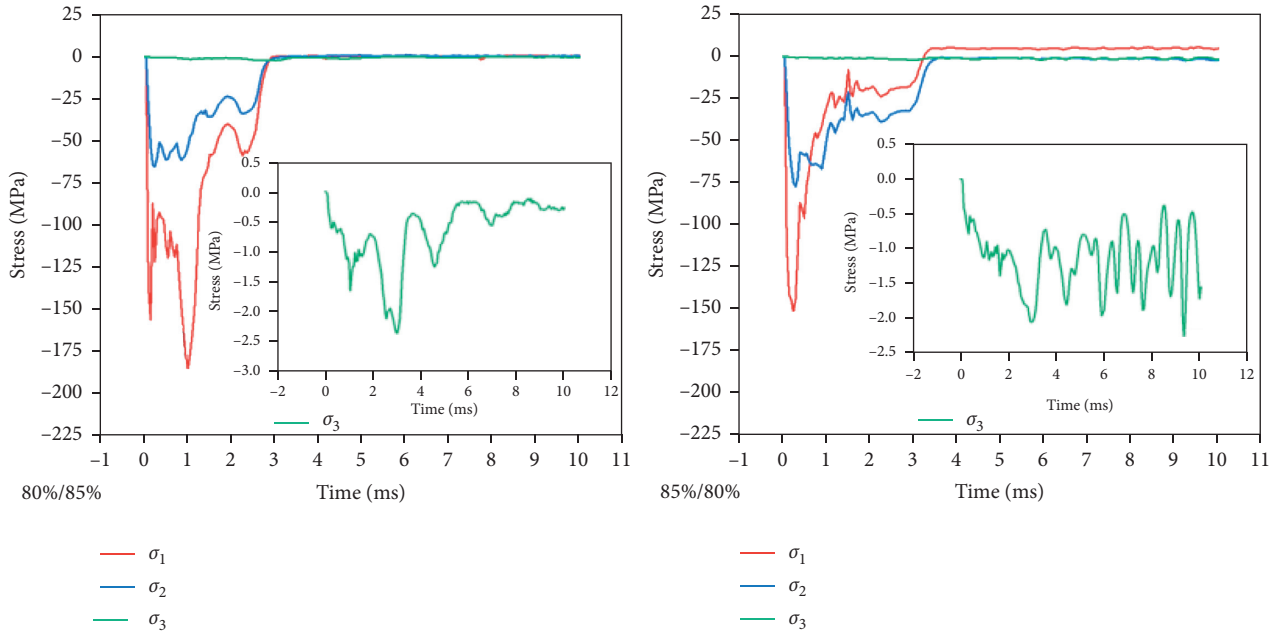

FIGURE 14: Double-layer aluminum foam with porosity of 80% and 85%.

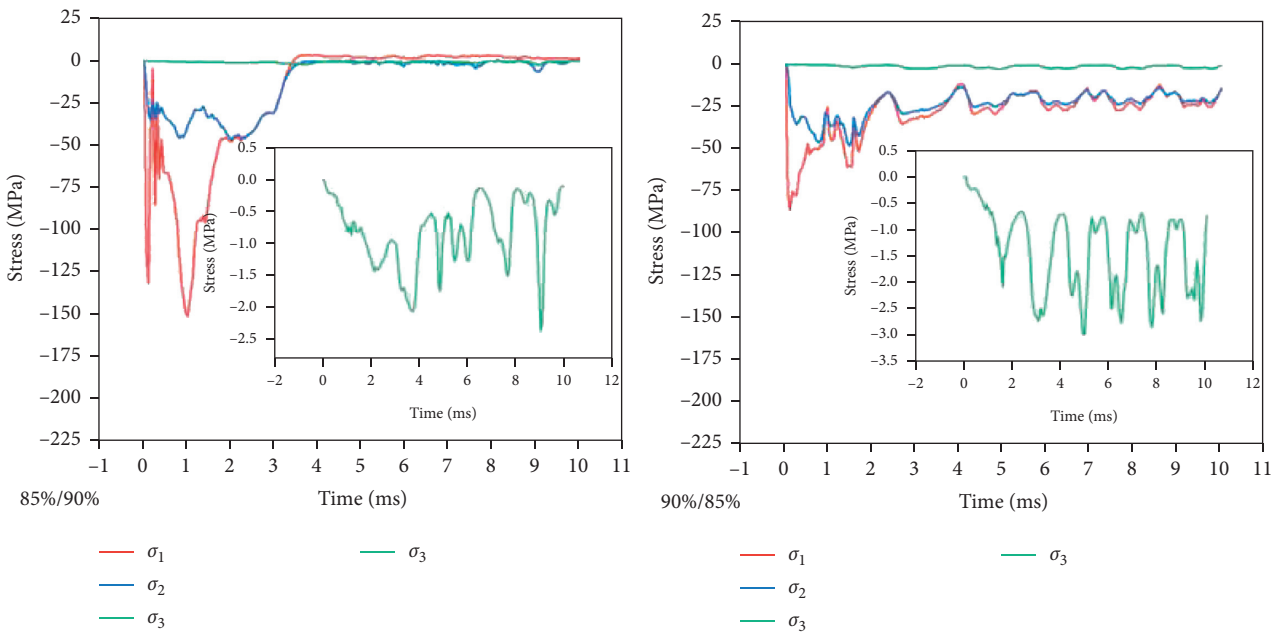

FIGURE 15: Double-layer aluminum foam with porosity of 85% and 90%.

129.36 MPa. The shock wave of the explosion after the first layer of aluminum foam attenuates by 71.44%. After the second layer of aluminum foam, the stress value of the explosion wave is 2.013 MPa, the attenuation rate is 96.81%, and the overall wave dissipation rate is 98.43%. When the porosity of the upper layer of aluminum foam is 90% and the porosity of the lower layer of aluminum foam is 85%, the stress value of the first layer is 86.63 MPa; the explosion shock wave attenuates 59.15% after the first layer of aluminum foam, and the stress value of the explosion wave after

the second layer of aluminum foam is 2.72 MPa; the attenuation rate is 92.31%, respectively, and the overall wave dissipation rate is 96.86%. It is also found that whether it is the first layer of aluminum foam or the second layer of aluminum foam, the positive sequence arrangement of porosity has a higher wave dissipation rate and the phenomenon of interface delamination is more obvious.

Due to different porosity of aluminum foam, different reflection and refraction phenomena occur after explosion wave propagation, so there is stress difference between upper

surfaces of aluminum foam layer. It can be concluded from the above picture that the overall wave dissipation rates of six groups of aluminum foams with different porosity have little difference. By comparison, it is found that the porosity is arranged in positive order, and the difference between the upper and lower layers is small, and the wave dissipation rate of the lower layer aluminum foam is higher. To sum up, the antiexplosion and wave-absorbing ability of the double-layer foam sandwich structure of 80%/85% group is the best, and the greater the porosity is, the better the antiexplosion ability is.

## 6. Conclusions

In this paper, a three-dimensional mesoscopic model of double-layer aluminum foam sandwich panel is established, and the fluid-solid coupling method is used to analyze the flow field motion of explosion shock wave of aluminum foam with different porosity. A series of conclusions are obtained through numerical simulation and analysis:

- (1) On the basis of Voronoi algorithm, the aluminum foam generation algorithm with random three-dimensional pore size and wall thickness is compiled by using Python language and Fortran language. The three-dimensional mesoscopic model of double-layer closed-cell aluminum foam sandwich panel is established by using LS-DYNA and ABAQUS software, and the random wall thickness is set to better simulate the real aluminum foam model.
- (2) The strain test values of 80%/90% group and 80%/85% group of aluminum foam were randomly selected and compared with the simulation results. The experimental results are consistent with the simulation results, which verifies the correctness of the three-dimensional meso-model.
- (3) Six kinds of three-dimensional mesoscopic models of explosive loading of double-layer aluminum foam with different porosity arrangement were established in LS-DYNA. The numerical simulation results show that, in the group with the same porosity combination, when the porosity of the upper layer aluminum foam is greater than that of the lower layer aluminum foam, the compression amount of the sandwich structure of double-layer aluminum foam is larger, but the displacement of the bottom plate is small; it is not that the greater the compression amount of aluminum foam, the better the anti-explosion and wave absorption capacity. When the aluminum foam reaches the ultimate bearing capacity, the foam aluminum produces stress enhancement due to compaction.
- (4) Through the mesoscopic simulation of aluminum foam, it is found that the changes of porosity are very important factors affecting the energy absorption capacity of aluminum foam.
- (5) Through the analysis of the compression amount, floor deformation, wave dissipation capacity, and energy ratio of aluminum foam, it is concluded that

the antiexplosion wave absorption effect of the sandwich structure of aluminum foam with 80%/85% group is the best.

This paper aims to investigate the property and behavior of the hysteretic nonlinear energy sink (HNES) coupled to a half vehicle system which is a nine-degree-of-freedom, nonlinear, and semiactive suspension system in order to improve the ride comfort and increase the stability in shock mitigation by using the computer simulation method. The HNES model is a semiactive suspension device, which comprises the famous Bouc–Wen (B-W) model employed to describe the force produced by both the purely hysteretic spring and linear elastic spring of potentially negative stiffness connected in parallel, for the half vehicle system. Nine nonlinear motion equations of the half vehicle system are derived in terms of the seven displacements and the two dimensionless hysteretic variables, which are integrated numerically by employing the direct time integration method for studying both the variables of vertical displacements, velocities, accelerations, chassis pitch angle, and the ride comfort and driver safety, respectively, based on the bump and random road inputs of the pseudoexcitation method as excitation signal. Simulation results show that, compared with the HNES model and the magnetorheological (MR) model coupled to the half vehicle system, the ride comfort and stability have been evidently improved. A successful validation process has been performed, which indicated that both the ride comfort and driver safety properties of the HNES model coupled to half vehicle significantly improved.

## 1. Introduction

To achieve both ride comfort and driver safety is the main objective of the vehicle industry, and there are two ways to achieve ride comfort of high quality; to this end, the first way is to minimize the axis and angular acceleration of the gravity center of the vehicle body, while the second way is to maintain the tire contacts with the ground while the tire strikes a bump. Minimizing the vertical displacement of the vehicle can facilitate the ride stability.

Passive, active, and semiactive suspension vehicle systems are three available classifications of suspensions which depend on the ability of the suspension system to absorb, add, or extract energy. More recently, one of the oldest passive vibration control devices is the tuned mass damper (TMD) which was proposed by Watts in 1883 [1] and patented by Frahm [2], consisting of a mass, a spring, and a viscous

damper which is attached to a primary vibrating system in order to suppress undesirable vibrations. The property of the TMD can be significantly reduced for the environmental influences, and other external parameters may alter its properties and disturb its tuning [3]. To help reduce the vibration, a large oscillating mass is generally required. Both construction and placement are rather difficult. In light of the above drawbacks, to overcome the disadvantages of the TMD, new nonlinear strategies in vibration absorption have been introduced, and among them, researchers investigated the targeted energy transfer (TET) through different designs of NES, so they have gained more attention and are more prevalent [4]. According to [5], definitely, the NES is a nonlinear attachment coupled to a linear system which dissipates energy irreversibly through nonlinear stiffness elements. To help dissipate energy effectively, compared with the TMD, the NES does not need to be tuned to a special

frequency. The performance of nonsmooth NES in the presence of gravity has also been investigated where the pure cubic nonlinearity is broken in vertical configurations as the gravity induces asymmetry to the system [6, 7].

The concept of hysteretic nonlinear energy sink (HNES) was proposed by Tsiatas and studied by Tsiatas and Charalampakis in 2018 [8]. The HNES is the modification of the NES [9, 10], i.e., apart from a small mass and a nonlinear elastic spring of the duffing oscillator, the HNES also comprises a purely hysteretic spring and a linear elastic spring of potentially negative stiffness, connected in parallel. The BoucWen (B-W) model is used to describe the force produced by the purely hysteretic and linear elastic springs and has been investigated in NES dynamics previously [11, 12].

Eltantawie has studied the mechanical behavior of the magnetorheological damper (MRD) as a semiactive device of the vehicle suspension system for decentralized neurofuzzy control method previously. In this paper, the HNES model is employed as a semiactive suspension device and coupled to the linear half vehicle system in order to improve the ride comfort and increase the stability.

This study proposes a comprehensive design by using the HNES model as the semiactive suspension device, and the motion equations of the vehicle system which consist of the HNES model have been established, followed by employing the new direct time integration method, which is presented for solution of motion equations describing the dynamic response of multi-degree-of-freedom, structural linear and nonlinear systems in 2014 [13], for the solution of the system of first-order ordinary differential equations which represent semidiscrete diffusion equations in 2016 [14], and for solution of the motion equations of the vehicle model by means of the computer simulation method.

The rest of this paper is organized as follows: Section 2 describes and analyzes both half vehicle system and the HNES coupled to a primary model. The differential equations of the HNES coupled to a primary model and the semiactive suspension system are analyzed by employing the new direct time integral method, which be formulated in Section 3. The responses of the displacements, velocity, acceleration, and chassis pitch angle in the time domain are simulated by the parameters of half vehicle system in Section 4. The ride comfort and drive safety of half vehicle system are solved numerically, which are described in the Section 5. The main conclusions and findings are drawn in Section 6.

## 2. Half Vehicle and the HNES Model

**2.1. Half Vehicle Coupling with the HNES Model.** In this paper, a semiactive suspension system of the half vehicle model, which consists of sprung mass supported on front and rear suspensions as shown in Figure 1, is proposed. Both the front and rear suspensions which are considered as unsprung masses with the front and rear tire mass are connected to their tire axles, respectively. Damper  $C_f$ , elastic device  $K_f$  and HNES model (details of the HNES model is described in Section 2.2) are connected through chassis mass  $M_2$  and front tire directly in parallel, same as the front suspension, damper

$C_r$ , elastic device  $K_r$  and HNES model connected through chassis mass  $M_2$  and rear tire in parallel. The model is a nine-degree-of-freedom system and represented by the displacements of vertical driver  $U_5$ , vertical vehicle body  $U_4$ , body pitch  $U_3$ , front and rear tire deflections  $U_{f1}$  and  $U_{r1}$  and  $U_{f2}$  and  $U_{r2}$  of the mass  $M_1$ , and the displacements  $U_{Zf}$  and  $U_{Zr}$  which indicates the BoucWen model (Figure 1).

The mathematical model is derived by applying Newton's second law; the motion equations can be formulated as follows:

$$M_3\ddot{U}_5 + C_{f2}(\dot{U}_5 - (\dot{U}_4 - \dot{U}_3L_3)) + K_{f2}(U_5 - (U_4 - U_3L_3)) = 0, \quad (1)$$

$$\begin{aligned} M_2\ddot{U}_4 - C_{f2}(U_5 - (\dot{U}_4 - \dot{U}_3L_3)) - K_{f2}(U_5 - (U_4 - U_3L_3)) \\ + K_f(U_4 - U_3L_1 - U_{f1}) + C_f(\dot{U}_4 - \dot{U}_3L_1 - \dot{U}_{f1}) \\ + C_2(\dot{U}_4 - \dot{U}_{f2} - \dot{U}_3L_1) + K_{NL}(U_4 - U_{f2} - U_3L_1)^3 \\ + K_r(U_4 - U_{r1} + U_3L_2) + C_r(\dot{U}_4 - \dot{U}_{r1} + \dot{U}_3L_1) \\ + C_2(\dot{U}_4 - \dot{U}_{r2} + \dot{U}_3L_2) + K_{NL}(U_4 - U_{r2} + U_3L_2) \\ = -F_{BWf} - F_{BWr}, \end{aligned} \quad (2)$$

$$\begin{aligned} M_1\ddot{U}_{f2} - C_2(\dot{U}_4 - \dot{U}_{f2} - \dot{U}_3L_1) - K_{NL}(U_4 - U_{f2} - U_3L_1)^3 \\ + C_1(\dot{U}_{f2} - \dot{U}_{f1}) + K_{EL}(U_{f2} - U_{f1}) = F_{BWf}, \end{aligned} \quad (3)$$

$$\begin{aligned} M_1\ddot{U}_{r2} - C_2(\dot{U}_4 - \dot{U}_{r2} + \dot{U}_3L_2) - K_{NL}(U_4 - U_{r2} + U_3L_2)^3 \\ + C_1(\dot{U}_{r2} - \dot{U}_{r1}) + K_{EL}(U_{r2} - U_{r1}) = F_{BWr}, \end{aligned} \quad (4)$$

$$\begin{aligned} M_f\ddot{U}_{f1} - K_f(U_4 - U_{f1} - U_3L_1) - C_f(\dot{U}_4 - \dot{U}_{f1} - \dot{U}_3L_1) \\ - C_1(\dot{U}_{f2} - \dot{U}_{f2}) - K_{EL}(U_{f2} - U_{f1}) + K_{tr}(U_{f1} - q_1) = 0, \end{aligned} \quad (5)$$

$$\begin{aligned} M_r\ddot{U}_{r1} - K_r(U_4 - U_{r1} + U_3L_2) - C_r(\dot{U}_4 - \dot{U}_{r1} + \dot{U}_3L_2) \\ - C_1(\dot{U}_{r2} - \dot{U}_{r1}) - K_{EL}(U_{r2} - U_{r1}) + K_{tr}(U_{r1} - q_2) = 0, \end{aligned} \quad (6)$$

$$\begin{aligned} J\ddot{U}_3 + C_{f2}(\dot{U}_5 - (\dot{U}_4 - L_3\dot{U}_3))L_3 + K_{f2} \\ \cdot (U_5 - (U_4 - L_3U_3))L_3 - K_f((U_4 - L_1U_3) - U_{f1})L_1 \\ - C_f((\dot{U}_4 - L_1\dot{U}_3) - \dot{U}_{f1})L_1 \\ - C_2((\dot{U}_4 - L_1\dot{U}_3) - \dot{U}_{f2})L_1 - K_{NL} \\ \cdot ((U_4 - L_1U_3) - U_{f2})^3L_1 + K_r((U_4 + L_2U_3) - U_{r1})L_2 \\ + C_r((\dot{U}_4 + L_2\dot{U}_3) - \dot{U}_{r1})L_2 + C_2 \\ \cdot ((\dot{U}_4 + L_2\dot{U}_3) - \dot{U}_{r2})L_2 + K_{NL}((U_4 + L_2U_3) - U_{r2})^3L_2 \\ = -F_{BWf}L_1 - F_{BWr}L_2, \end{aligned} \quad (7)$$

FIGURE 1: Half vehicle system coupling with the HNES model.

$$F_{\text{BWf}} = \alpha\kappa(U_4 - U_3L_1 - U_{f2}) + (1 - \alpha)\kappa DZ_f(t), \quad (8)$$

$$F_{\text{BWr}} = \alpha\kappa(U_4 + U_3L_2 - U_{r2}) + (1 - \alpha)\kappa DZ_r(t), \quad (9)$$

$$\begin{aligned} \dot{Z}_f(t) = & D^{-1}(\dot{U}_4 - \dot{U}_3L_1 - \dot{U}_{f2}) \\ & \cdot \left( (1 - |Z_f(t)|^n)(\gamma \text{sgn}(\dot{U}_4 - \dot{U}_3L_1 - \dot{U}_{f2})Z_f(t) + \beta) \right), \end{aligned} \quad (10)$$

$$\begin{aligned} \dot{Z}_r(t) = & D^{-1}(\dot{U}_4 + \dot{U}_3L_2 - \dot{U}_{r2})(1 - |Z_r(t)|^n) \\ & \cdot (\gamma \text{sgn}(\dot{U}_4 + \dot{U}_3L_2 - \dot{U}_{r2})Z_r(t) + \beta). \end{aligned} \quad (11)$$

Equations (1)–(11) can be rewritten in the matrix form as follows:

$$[\mathbf{M}]\{\ddot{\mathbf{U}}\} + [\mathbf{C}]\{\dot{\mathbf{U}}\} + [\mathbf{K}]\{\mathbf{U}\} = [\mathbf{F}]\{\mathbf{Q}\}, \quad (12)$$

where  $F_{\text{BWf}}$  and  $F_{\text{BWr}}$  are the BoucWen damper forces of the front and rear of the half vehicle system, respectively,  $\mathbf{M}$ ,  $\mathbf{C}$ , and  $\mathbf{K}$  denote matrices of mass, damper, and spring stiffness,  $\ddot{\mathbf{U}}$ ,  $\dot{\mathbf{U}}$ , and  $\mathbf{U}$  are vectors of acceleration, velocity, and displacements, and  $\mathbf{F}$  and  $\mathbf{Q}$  denote excitation vector coefficient matrix and the road inputs vector of the half vehicle system, respectively. For the definition of matrices and vectors  $\mathbf{M}$ ,  $\mathbf{C}$ ,  $\mathbf{K}$ ,  $\ddot{\mathbf{U}}$ ,  $\dot{\mathbf{U}}$ ,  $\mathbf{U}$ ,  $\mathbf{F}$ , and  $\mathbf{Q}$ , refer to Appendix A, and for expressing intuitively in the figures of this paper, the subscript of symbols  $\ddot{U}_n$  and  $\dot{U}_n$  are represented by  $A_n$  and  $V_n$ ,  $n = 1, 2, \dots, 9$ , respectively.

**2.2. Dynamic Responses of Single-Degree-of-Freedom Primary System Coupling with HNES.** The schematic representation of single-degree-of-freedom linear primary system coupling with HNES, which is considered as the HNES model, is

shown in Figure 2. The HNES model is constituted apart from a small mass  $m_2$  and a nonlinear elastic spring of the duffing oscillator; it also comprises a purely hysteretic spring and a linear elastic spring of potentially negative stiffness, which constitute the BoucWen model, connected in parallel. The BoucWen model is used to describe the force produced by the purely hysteretic and linear elastic springs. In light of the above, the single-degree-of-freedom (SDoF) primary system coupling with HNES (the HNES model) is constituted from the BoucWen model, a linear damp  $C_2$ , and a cubic nonlinear spring  $K_{\text{NL}}$  in parallel. Damper  $C_1$  and elastic linear spring  $K_{\text{EL}}$  are connected to mass  $m_1$  in parallel. The BoucWen model, damper  $C_2$ , and cubic nonlinear spring  $K_{\text{NL}}$  are connected between the masses  $m_2$  and  $m_1$  of the constituted attachments of the HNES in parallel.

Assume that the rear tire travels over the same path as the front tire except for a time delay  $\tau$  which can be mentioned as equation (25) in this study. The excitation function of road inputs  $q_1$  and  $q_2$ , which is a stationary random process, acts on the center of the tire and road surface contact point. The BoucWen model, which was introduced by Bouc [15] and extended by Wen [16], is employed to describe the force produced by both the purely hysteretic and linear elastic springs.

The SDoF primary system coupling with HNES (the HNES model) is shown in Figure 2; the hysteresis force is expressed by referring to [17, 18]:

$$F_{\text{BW}} = \alpha kx(t) + (1 - \alpha)k Dz(t), \quad (13)$$

where  $k > 0$ ,  $D > 0$ ,  $t$  is the time history of the input variable, and  $z(t)$  is a dimensionless hysteretic variable which is governed by the following differential equation:

$$\dot{z}(t) = D^{-1}(A - (\beta \text{sgn}(z(t)\dot{x}) + \gamma)|z(t)|^n)\dot{x}, \quad (14)$$

FIGURE 2: The SDoF primary system coupling with HNES (the HNES model).

where  $n > 0$ ,  $\text{sgn}(\cdot)$  denotes the signum function,  $x$  is the displacement,  $k$  is the initial stiffness,  $\alpha$  is the ratio of postyield to preyield stiffness,  $D$  indicates the yield displacement, the dimensionless exponential parameter  $n$  governs the abruptness of transition between preyield and postyield response, and the values of  $\alpha, A, \beta, D, \gamma$ , and  $n$  are set in Table 1 [8].

The HNES model is derived by applying Newton's second law, and the equations of motion can be formulated as follows:

$$m_1 \ddot{x}_1 + C_2 \dot{x}_1 + K_{EL} x_1 - F_{BW} - C_2 (\dot{x}_2 - \dot{x}_1) - K_{NL} (x_2 - x_1)^3 = 0, \quad (15)$$

$$m_2 \ddot{x}_2 + F_{BW} + C_2 (\dot{x}_2 - \dot{x}_1) + K_{NL} (x_2 - x_1)^3 = 0, \quad (16)$$

$$\dot{z}(t) = D^{-1} (\dot{x}_2 - \dot{x}_1) (1 - |z(t)|^n (\text{sgn}(\dot{x}_2 - \dot{x}_1) z(t)) + b). \quad (17)$$

In this investigation, only the direct impulsive force of the primary system is considered, and thus, the initial conditions of the problem are as follows:

$$\begin{aligned} \dot{x}_1(0) &= v_0, \\ x_1(0) = \dot{x}_2(0) = \dot{x}_2(0) &= 0, \end{aligned} \quad (18)$$

where  $m_1, x_1, K_{EL}$ , and  $C_1$  are the mass, displacement, stiffness of spring, and damping coefficient of the linear primary system, respectively, and  $m_2, x_2, K_{NL}$ , and  $C_2$  are the mass, displacement, damping coefficient, and cubic nonlinear stiffness of the HNES's attachments.

### 3. State Space Form of the Motion Equations and the Excitation of Road Inputs

**3.1. State Space Form.** Equations (15)–(18) can be reorganized into state space form as follows:

TABLE 1: Parameters of HNES (dimensionless).

| Parameter | $\alpha$ | $A$ | $\beta$ | $D$ | $\gamma$ | $n$ |
|-----------|----------|-----|---------|-----|----------|-----|
| Value     | -0.3     | 1   | 0.5     | 0.1 | 0.5      | 1   |

$$\{\mathbf{X}_n\} = \begin{cases} X_1 = x_1 \\ X_2 = \dot{x}_1 \\ X_3 = x_2 \\ X_4 = \dot{x}_2 \\ X_5 = z(t) \end{cases}, \quad (19)$$

$$\left\{ \begin{aligned} \dot{X}_1 &= X_2 \\ \dot{X}_2 &= \frac{F_{BW} - C_1 X_2 - K_{EL} X_1 + C_2 (X_4 - X_2) + K_{NL} (X_2 - X_1)^3}{m_1} \\ \dot{X}_3 &= X_4 \\ \dot{X}_4 &= \frac{-F_{BW} - C_2 (X_4 - X_2) - K_{NL} (X_3 - X_1)^3}{m_2} \\ \dot{X}_5 &= D^{-1} (X_4 - X_2) (1 - |X_5|^n (\gamma \text{sgn}(X_4 - X_2) X_2) + \beta) \end{aligned} \right\}. \quad (20)$$

Together with the pertinent initial conditions, the following can be expressed:

$$\{\dot{X}_n(0)\} = \left\{ \begin{aligned} \dot{X}_1(0) &= v_0 \\ \dot{X}_2(0) &= \frac{(C_1 + C_2)v_0}{m_1} \\ \dot{X}_3(0) &= \frac{C_2 v_0}{m_2} \\ \dot{X}_4(0) &= \frac{C_2 v_0}{m_2} \\ \dot{X}_5(0) &= \frac{v_0}{D} \end{aligned} \right\}, \quad (21)$$

where  $v_0 = \dot{x}_1(0)$  denotes the initial value.

Equations (19)–(21) can be rewritten as follows:

$$\begin{aligned} \mathbf{M}_i^{-1} \mathbf{F}(t) - \mathbf{M}_i^{-1} \mathbf{P}(\mathbf{X}_n(t), \dot{\mathbf{X}}_n(t)) \\ = f(\mathbf{X}_n(t) + \mathbf{X}_n(t), t) = \mathbf{0}, \quad n = 1, 2, \dots, 5, \end{aligned} \quad (22)$$

where  $\mathbf{M}_i$ ,  $i = 1, 2$ , denotes the mass matrix which consists of  $m_1$  and  $m_2$  and function  $f(\mathbf{X}_n(t) + \mathbf{X}_n(t), t)$  is already expressed in equation (20).

It should be noteworthy that equation (22) is a typical nonlinear initial value problem, which are solved numerically using the new direct time integration method

introduced by Katsikadelis [13], and that for multidegree of freedom systems is described as follows:

$$\mathbf{X}_{n-k} = \dot{X}_{n-k-1}(t) + \frac{h}{2}\dot{X}_{n-k}(t) + \frac{h}{2}\dot{X}_{n-k-1}(t), \quad (23)$$

where  $\mathbf{X}_{n-k}$  denotes the responses of the displacement vector, of which elements are the value in different time histories for  $k = 1, 2, \dots, (T/h)$ .  $T$  is the simulation period, and  $h$  is the sampling interval.  $\dot{X}_{n-k}$  and  $\mathbf{X}_{n-k}$  can be solved by coupling equations (22) and (23) with  $k = 1, 2, \dots, T/h$ .

Figure 3 depicts the responses of displacements  $X_1$  and  $X_3$  of the masses  $m_1$  and  $m_2$  of primary system coupling with HNES against the impulse magnitude  $v_0 = 0.35$  m/s,  $h = 0.01$ , and  $T = 500$  seconds (Figure 3(a)) and  $v_0 = 2$  m/s,  $h = 0.01$ , and  $T = 500$  seconds (Figure 3(b)). It can be observed that displacements  $X_1$  and  $X_3$  against time are similar in shape during 500 seconds, and the amplitude changes more slowly over the entire time domain, and the maximum values of amplitudes are  $X_1 = 2.1$  m and  $X_2 = 2.3$  m (Figure 3(b)) and  $X_1 = 0.12$  m and  $X_3 = 0.01$  m (Figure 3(a)).

### 3.2. Excitation of Road Inputs

**3.2.1. Bump Road Inputs.** The bump road excitation method is one of the simple inputs for a vehicle, which has the equations as follows [19]:

$$q_i(t) = \begin{cases} \frac{u_r(1 - \cos(8\pi t))}{2}, & 0.5 \leq t \leq 0.75, \\ 0, & \text{otherwise,} \end{cases} \quad (24)$$

where  $i (=1, 2)$  represents the front and rear tire, respectively,  $u_r = 0.11$  m denotes the amplitude of bump road excitation, simulation period  $T = 4$  seconds, the bump road excitation for the rear tire is assumed to be that of the front but with a time delay (seconds) of  $\tau$ , and sampling interval  $h = 0.01$  seconds in this study. Time delay  $\tau$  is formulated as follows:

$$\tau = \frac{L_1 + L_2}{v}, \quad (25)$$

where symbol  $v$  denotes the vehicle velocity and  $L_1$  and  $L_2$  are the front and rear wheelbase; the excitation signals for bump road inputs are shown in Figure 4(a).

The road excitation of rear tire inputs  $q_2(t)$  is formulated as

$$q_2(t) = q_1(t - \tau). \quad (26)$$

**3.2.2. Random Excitation of Road Surface Roughness.** The road power spectral density (PSD) about the spatial frequency is  $G_q(n)$ ,  $n_1 < n < n_2$  ( $n = f/v$ ), where  $v$  is the average vehicle velocity and  $n$  is the spatial frequency. The road surface roughness variance of  $\sigma_q^2$  by using the frequency spectrum properties of average stationary random process can be expressed as follows [20]:

$$\sigma_q^2 = \int_{n_1}^{n_2} G_q(n) dn. \quad (27)$$

Dividing the area ( $n_1, n_2$ ) into  $m$  smaller intervals, the frequency of the power spectral density value is  $G_q(n_{\text{mid-}i})$  instead of  $G_q(n)$  at each small interval of the central part, where  $n_{\text{mid-}i}$ ,  $i = 1, 2, \dots, m$ . Throughout, the area between the value of the formula after discretization approximation can be written as follows:

$$\sigma_q^2 \approx \sum_{i=1}^m G_q(n_{\text{mid-}i}) \cdot \Delta n_i. \quad (28)$$

Corresponding to each small range, we need to find the frequency for  $n_{\text{mid-}i}$  ( $i = 1, 2, 3, \dots, m$ ) and the standard deviation of  $\sqrt{G_q(n_{\text{mid-}i}) \cdot \Delta n_i}$  sine wave function, and such sine wave function can be expressed as

$$\sqrt{G_q(n_{\text{mid-}i}) \cdot \Delta n_i} \cdot \sin(2\pi n_{\text{mid-}i} x + \theta_i). \quad (29)$$

Then, the corresponding sine wave function in each area is added up to obtain the road random displacement input on the time domain:

$$q_j(t) = \sqrt{2} \sum_{i=1}^m \sqrt{G_q(n_{\text{mid-}i}) \cdot \Delta n_i} \cdot \sin(2\pi n_{\text{mid-}i} t + \theta_i), \quad j = 1, 2, \quad (30)$$

where  $\theta_i$  is uniformly distributed random numbers between  $[-\pi, \pi]$ , of which probability density and distribution function can be referred to in Appendix B. And,  $t$  denotes the time history which can be normalized by  $s/v$  ( $s$  is the total distance traveled by the vehicle in this study). According to reference [21], the spatial frequency  $n$  of road is distributed between  $[0.011, 2.83] \text{ m}^{-1}$ . In this study, considering both the relevant regulations and practical life experience, the range of vehicle velocity  $V_v \in [V_{n-\text{min}}, V_{n-\text{max}}] = [10, 30] \text{ m/s}$  (36–108 km/h).

Relationships between time frequency  $f$  and spatial frequency  $n$  of the vehicle can be formulated as equation  $f = vn$  (Hz). Therefore, the range of road spatial frequency in this paper can be expressed as follows:

$$\begin{aligned} \mathbf{A}_n &= \mathbf{A}_{n1} \cap \mathbf{A}_{n2} = [V_{n-\text{min}} \times 0.011, V_{n-\text{min}} \times 2.83] \\ &\cap [V_{n-\text{max}} \times 0.011, V_{n-\text{max}} \times 2.83] = [0.33, 28.3]. \end{aligned} \quad (31)$$

Here,  $\mathbf{A}_{n1}$  and  $\mathbf{A}_{n2}$  denote the spatial frequency range at lowest velocity  $V_{n-\text{min}}$  and at the highest velocity  $V_{n-\text{max}}$  and symbol  $\cap$  denotes a mathematical operation for the intersection of two sets.

The random excitation signal of road surface roughness is shown in Figure 4(b).

## 4. Simulation Response in the Time Domain

Equations (1)–(11) can be altered into equation (12) which is a nonlinear equation and can be written using the direct time integration method numerically as follows:

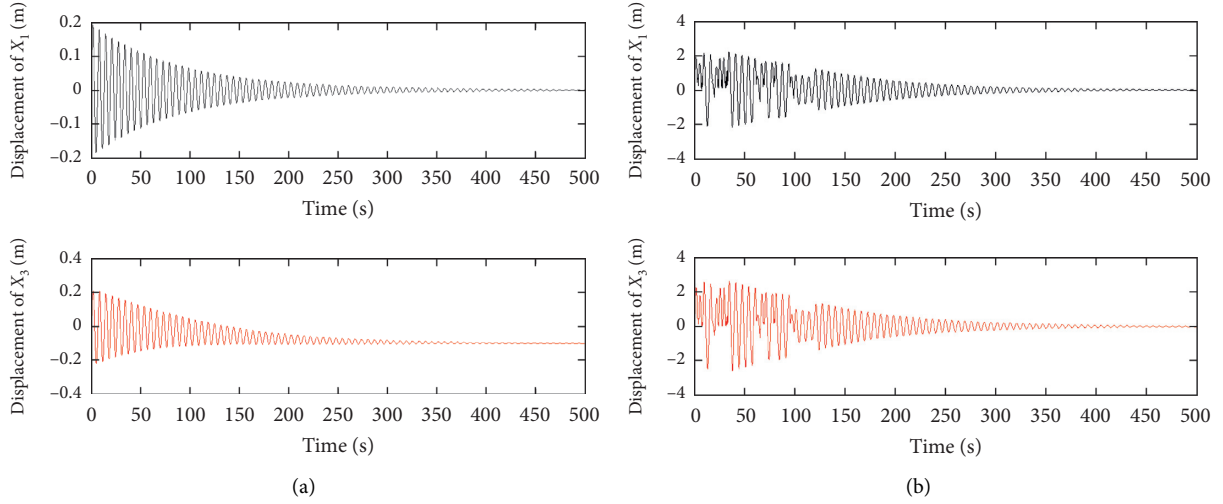

FIGURE 3: The response of displacements of the primary system coupling with the HNES model for  $v_0 = 0.35$  m/s,  $h = 0.01$ , and  $T = 500$  seconds (a) and  $v_0 = 2$  m/s,  $h = 0.01$ , and  $T = 500$  seconds (b).

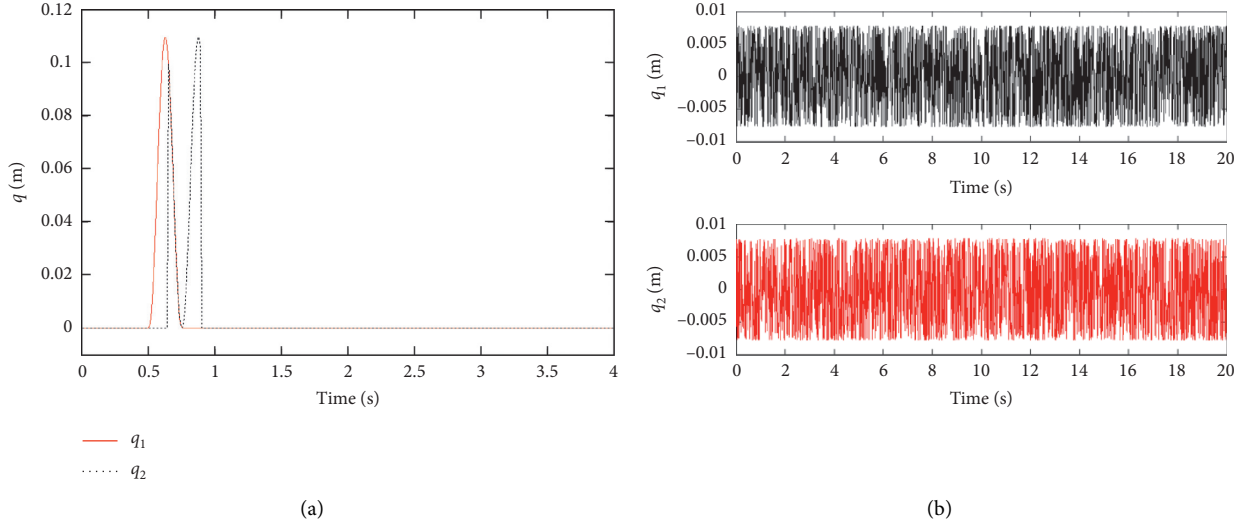

FIGURE 4: Two types of excitation signal for (a) the bump road inputs, where simulated period  $T = 4$  seconds, sampling interval  $h = 0.01$  second, and vehicle velocity  $v = 20$  m/s, and (b) the random road inputs, where simulated period  $T = 20$  seconds, sampling interval  $h = 0.01$  seconds, and vehicle velocity  $v = 20$  m/s.

$$\mathbf{M}\ddot{\mathbf{U}}_n + \mathbf{F}(\dot{\mathbf{U}}_n, \mathbf{U}_n) = \mathbf{P}_n, \quad (32)$$

$$\begin{bmatrix} -h\mathbf{I} & \mathbf{I} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{U}}_n \\ \mathbf{U}_n \end{Bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{U}}_{n-1} \\ \mathbf{U}_{n-1} \end{Bmatrix} + \begin{bmatrix} \frac{\mathbf{r}_1}{2}\mathbf{I} \\ \frac{\mathbf{r}_2}{2}\mathbf{I} \end{bmatrix} \ddot{\mathbf{U}}_n + \begin{bmatrix} \frac{\mathbf{r}_1}{2}\mathbf{I} \\ \frac{\mathbf{r}_2}{2}\mathbf{I} \end{bmatrix} \ddot{\mathbf{U}}_{n-1}, \quad (33)$$

$$\ddot{\mathbf{U}}_0 = \mathbf{M}^{-1}(\mathbf{P}_0 - \mathbf{F}(\dot{\mathbf{U}}_0, \mathbf{U}_0)), \mathbf{U}(0) = \mathbf{U}_0, \dot{\mathbf{U}}(0) = \dot{\mathbf{U}}_0, \quad \det(\mathbf{M}) \neq 0, \quad (34)$$

where  $r_1 = (h_2/2)$ ,  $r_2 = h$ ,  $h$  is the sampling interval time (second), and size  $(\mathbf{I}) = [9 \times 9]$  is the unit matrix.

$\ddot{\mathbf{U}}_n$ ,  $\dot{\mathbf{U}}_n$ , and  $\mathbf{U}_n$  can be solved by combining equations (32) and (33) with  $n = 1, 2, \dots, T/h$ .  $\dot{\mathbf{U}}_n$  and  $\mathbf{U}_n$  can be solved using equation (33) which is a linear equation and then substituting into equation (32) which is a nonlinear equation and can be solved to yield  $\ddot{\mathbf{U}}_n$ . The function “fsovl” of *Matlab 2017a* has been employed to obtain the numerical results of both equations.

## 5. Performance Index and Numerical Simulation

**5.1. Response of Half Vehicle System Coupling with the HNES Model.** By querying the power spectral density coefficient (PSD) of standard road surface excitation  $G_q(n_0)$ [22] and referring a 10-degree-of-freedom (DOF) passenger vehicle model determine six state variables related to the longitudinal, lateral, and heave velocities and roll, pitch, and yaw rates [23]. Equations (32)–(34) can be solved using the software programming *Matlab 2017a* numerically. The parameters of half vehicle system coupling with the HNES model are given in Table 2.

Figure 5 depicts the response of vertical displacements of driver  $U_5$  and chassis  $U_4$  and pitch angle of chassis  $U_3$  against the road inputs for the bump excitation, of which simulation period  $T=10$  seconds, sampling interval  $h=0.01$ , and different velocities of the vehicle  $v=1.1256$  m/s (Figure 5(a)) and  $v=20$  m/s (Figure 5(b)), respectively. From these figures, it can be observed that for the bump road excitation with the amplitude  $A=0.11$  m, the chassis (sprung mass) reached a maximum of 0.05 m (Figure 5(a)) and 0.09 m (Figure 5(b)). Also when the inputs dropped to zero, the chassis (sprung mass) vertical displacement went down for only  $-0.001$  m (Figure 5(a)) and  $-0.01$  m (Figure 5(b)) which is almost zero. The overall amplitude achieved by the chassis is equal to that against the front and rear tire inputs. The response of the angular displacement of chassis had a maximum peak value of 0.021 rad (Figure 5(a)) and 0.04 rad (Figure 5(b)). However, when the rear tire of the vehicle received the input of road excitation, the maximum displacement response of the driver is  $-0.024$  m while the vehicle velocity is 1.1256 m/s, and  $-0.022$  m while the vehicle velocity is 20 m/s. Both values are smaller than the response values of the model in reference [24]. The output data obtained from Figure 5(a) for the maximum displacement of the vehicle body against time is 0.036 m, and the maximum angular displacement of the vehicle pitch angle is 0.02 rad which is smaller than of the model mentioned in reference [24].

The solution data obtained from the programs of the motion equations of the half vehicle system for velocity of the drive  $V_5$ , chassis (sprung mass)  $V_4$ , and angular velocity of the chassis  $V_3$  are plotted against time in Figure 6. It can be grasped that for bump excitation road inputs, the peak value is 0.11 m, simulation period  $T=10$  seconds, sampling interval  $h=0.01$  seconds, and different velocities of the vehicle  $v=1.1256$  m/s (Figure 6(a)) and  $v=20$  m/s (Figure 6(b)), respectively. When the front tire of the vehicle passed road excitation  $q^1(t)$ , the maximum velocity responses of the vehicle body are 0.21 m/s (a) and 0.272 m/s (b), respectively. When the rear tire excitation  $q^2(t)$  received by the vehicle gradually approaches 0 m, the velocity of the vehicle body only decreases by  $-0.08$  m/s (a) and  $-0.18$  m/s (b). These two values gradually tend to be stable after 10 seconds. The response of the driver velocity  $V_5$  stabilizes faster than others.

The responses of the displacements  $U_5, U_4$ , and  $U_3$ , velocities  $V_5, V_4$ , and  $V_3$ , and the accelerations  $A_5, A_4$ , and  $A_3$  against the road inputs were recorded for both the front and rear tire random excitation road inputs in Figures 7–9. It is obvious that the amplitude of displacement, velocity, and acceleration against time for the vehicle

TABLE 2: Main parameters of half vehicle system coupling with the HNES model.

| Parameter                | Meaning of the symbols   | Value and units        |
|--------------------------|--|------------------------|
| $M_3$                    | Driver mass  | 65 kg                  |
| $M_2$                    | Chassis mass   | 708 kg                 |
| $M_f, M_r$               | Front/rear unsprung mass                                       | 80 kg                  |
| $J$                      | Chassis inertia  | 2700 kg·m <sup>2</sup> |
| $L_1$                    | Horizontal distance from chassis mass center to the front axle | 1.011 m                |
| $L_2$                    | Horizontal distance from chassis mass center to the rear axle  | 1.803 m                |
| $L_3$                    | Horizontal distance from chassis mass center to the driver     | 0.779 m                |
| $U_5$                    | Driver vertical displacement                                   | m                      |
| $U_4$                    | Chassis vertical displacement                                  | m                      |
| $U_3$                    | Chassis pitching angle   | rad                    |
| $U_f, U_r$               | Vertical displacement of the front and rear axis               | m                      |
| $K_{j2}$                 | Stiffness of connecting the chassis to the driver              | 23071 N/m              |
| $K_f, K_r$               | Stiffness of connecting chassis to the front and rear axle     | 1600 N/m               |
| $K_{f\beta}, K_{r\beta}$ | Stiffness of the front and rear tire                           | 16000 N/m              |
| $C_{t2}$                 | Damping coefficient connecting the chassis and driver          | 1500 N·s/m             |
| $C_f, C_r$               | Damping coefficient connecting chassis to front and rear axle  | 980 N·s/m              |
| $C_1$                    | Damping coefficient of the linear primary system               | 0.001 N·s/m            |
| $C_2$                    | Damping coefficient of the HNES attachments                    | 0.01 N·s/m             |
| $m_1$                    | Mass of the linear primary system                              | 1 kg                   |
| $F_{BWf}, F_{BW_r}$      | Force of the hysteretic restoring of the front/rear tire axle  | N                      |
| $K_{NL}$                 | Cubic nonlinear stiffness of the HNES attachment               | 1 N/m <sup>3</sup>     |
| $K_{EL}$                 | Stiffness of the linear primary system                         | 1 N/m                  |
| $U_{j2}, U_{r2}$         | Front and rear tire displacements of the linear primary system | m                      |

velocity in Figure 7(a), Figure 8(a), and Figure 9(a) is smaller than that in Figure 7(b), Figure 8(b), and Figure 9(b), respectively. It can be seen that the displacement of vehicle body had a series random value, of which the maximum is 0.51 m, against the time for road inputs of random excitation, while the velocity of the vehicle is 20 m/s. It can be observed that the response of the displacement, velocity, and the acceleration of half vehicle system coupling with the HNES model against the road inputs for random excitation is very consistent with the vehicle theory, while the velocity is in the range [1.1256, 20] m/s. Therefore, from the dynamic response analysis, it can be known that it is reasonable and reliable to apply the HNES model to the vehicle system.

**5.2. Performance of the Half Vehicle System Coupling with the HNES Model.** Another simulation program has created with the aid of the semiactive suspension of half vehicle system coupling with the HNES model to obtain the drive safety and the ride comfort property. The drive safety and the quality of the contact between the tire and the road are described by

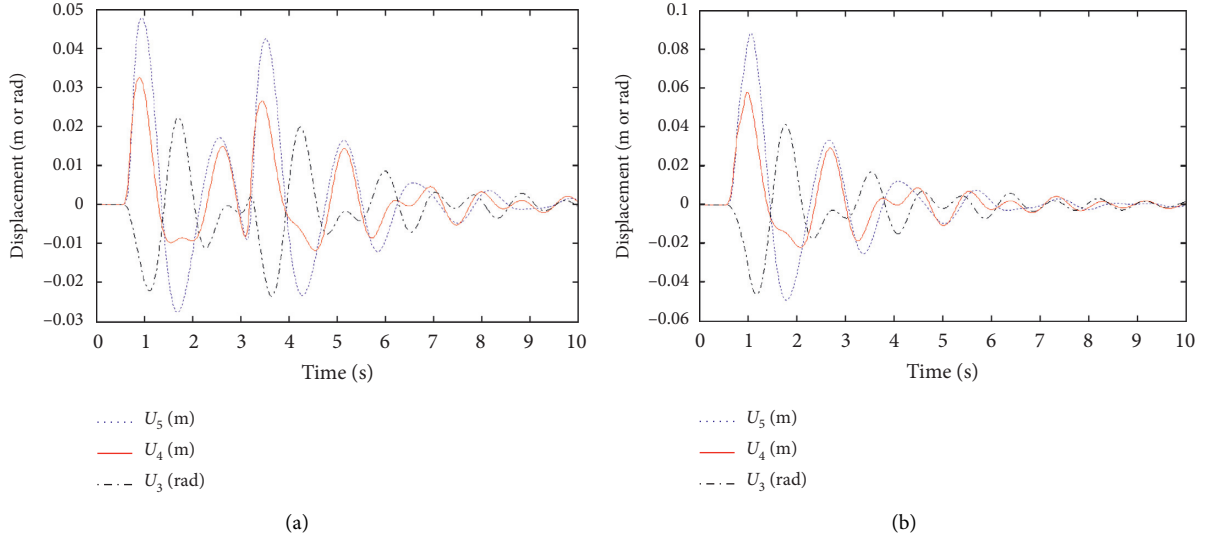

FIGURE 5: Responses of displacement  $\mathbf{U}_n$  of the half vehicle system while the excitation is bump road inputs. The vector  $\mathbf{U}_n$  represents the displacements of the driver  $U_5$ , the chassis  $U_4$ , and the pitch angle  $U_3$ , i.e.,  $\mathbf{U}_n = (U_5, U_4, U_3)^T$ , respectively. Simulation period  $T=10$  seconds, sampling interval  $h=0.01$  seconds, vehicle velocity  $v=1.1256$  m/s (the time delay  $\tau=2.5$  s) and (b) same as (a) except for the vehicle velocity  $v=20$  m/s (the time delay  $\tau=0.0938$  s).

FIGURE 6: Responses of velocities  $\dot{\mathbf{U}}_n$  of half vehicle system coupling with the HNES model while excitation is bump road inputs and the velocity of vehicle is 1.1256 m/s (a) and 20 m/s (b). The vector  $\dot{\mathbf{U}}_n$  presents the velocities of the driver, the chassis, and the pitch angle.

the RMS (root mean square) value of the forces, which are dynamically exchanged by the tire and the road that is defined in [21]:

$$F_{U_{i1}Dyn} = K_{ti}(U_{i1} - q_j). \quad (35)$$

Ride comfort can be formulated as

$$\ddot{U}_4^{RMS} = \sqrt{\frac{1}{T} \int_0^T \left( \frac{\ddot{U}}{g} \right)^2 dt}. \quad (36)$$

Drive safety can be formulated as

$$F_{U_{i1},dyn}^{RMS} = \sqrt{\frac{1}{T} \int_0^T \left( \frac{F_{U_{i1},dyn}}{F_{U_{i1},stat}} \right)^2 dt}. \quad (37)$$

The steady-state load on the tire can be formulated as

$$F_{U_{i1},stat} = (M_1 + M_i + M_2)g, \quad (38)$$

where  $i$  represents the front and rear suspensions, respectively, and  $j=1, 2$ .

Figure 10 shows the ratio of dynamic loads to static loads for the front (rear) tire, and the square of the ratio of

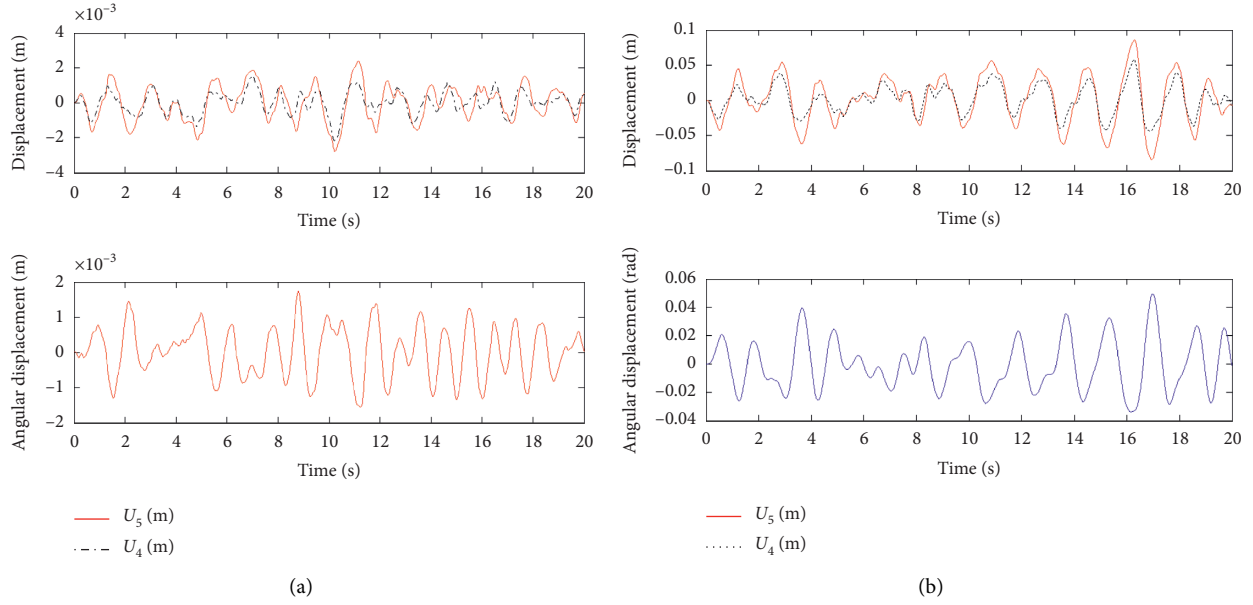

FIGURE 7: Responses of displacements  $U_n$  of half vehicle system coupling with the HNES model while the excitation is random road inputs and the velocity of vehicle is 1.1256 m/s (a) and 20 m/s (b).

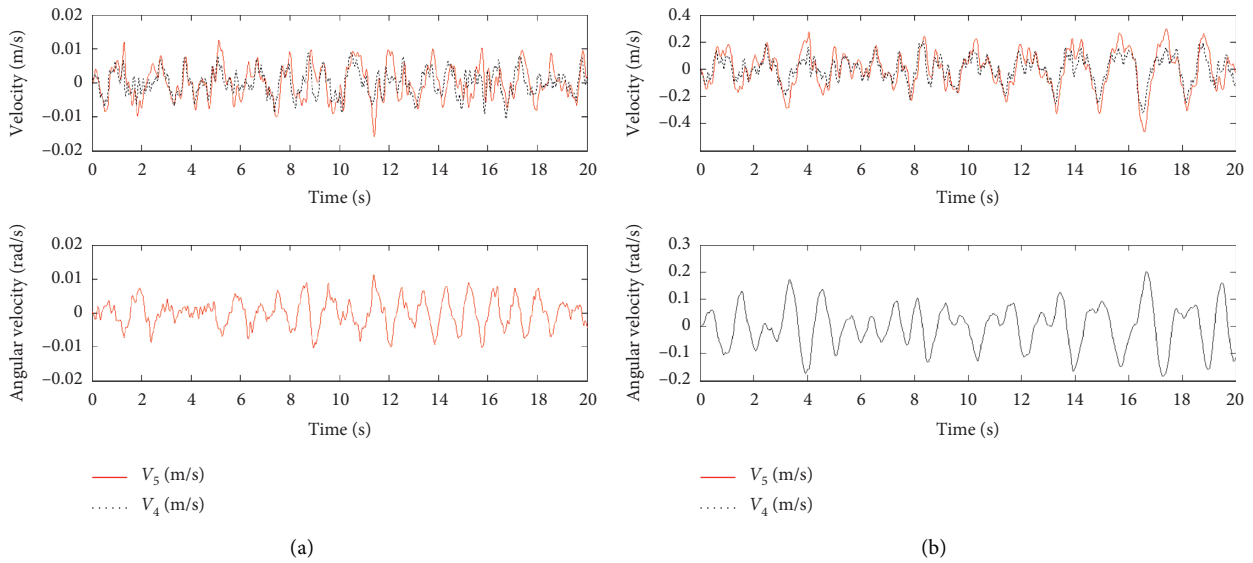

FIGURE 8: Responses of velocities  $V_n$  of half vehicle system coupling with the HNES model while the excitation is random road inputs and the velocity of vehicle is 1.1256 m/s (a) and 20 m/s (b).

acceleration to gravity acceleration  $g$  against the road inputs is recorded for bump road excitation in Figure 10(a) and road inputs for random excitation in Figure 10(b) while the vehicle velocity  $v = 1.1256$  m/s (the delay time is 2.5 seconds). It is obvious that the ratio of dynamic loads to static loads of the front tire had a maximum peak value of 0.48 against the road inputs for bump excitation in the time range of [0.5, 0.75] seconds, of which rear tire had a maximum peak value of 0.058 after the time delay of 2.5 seconds in Figure 10(a). The square of ratio of acceleration to gravity acceleration against the road inputs for bump excitation had a maximum peak value of 0.041 in the time range of [0.7, 0.75] seconds.

The maximum peak value of 0.58 was reached after the delay time of 2.5 seconds in Figure 10(a). The ratio of dynamic loads to static loads of the front (rear) tire, and the square of the ratio of acceleration to gravity acceleration against the road inputs for random excitation is very small which tends to zero as shown in Figure 10(b).

It can be observed from Tables 3 and 4 that the responses of displacements, velocities, and accelerations of the half vehicle system coupling with the HNES model are smaller. The ride comfort and driver safety properties are lower than those in the semiactive suspension of the MR model with the same parameters. However, ride comfort

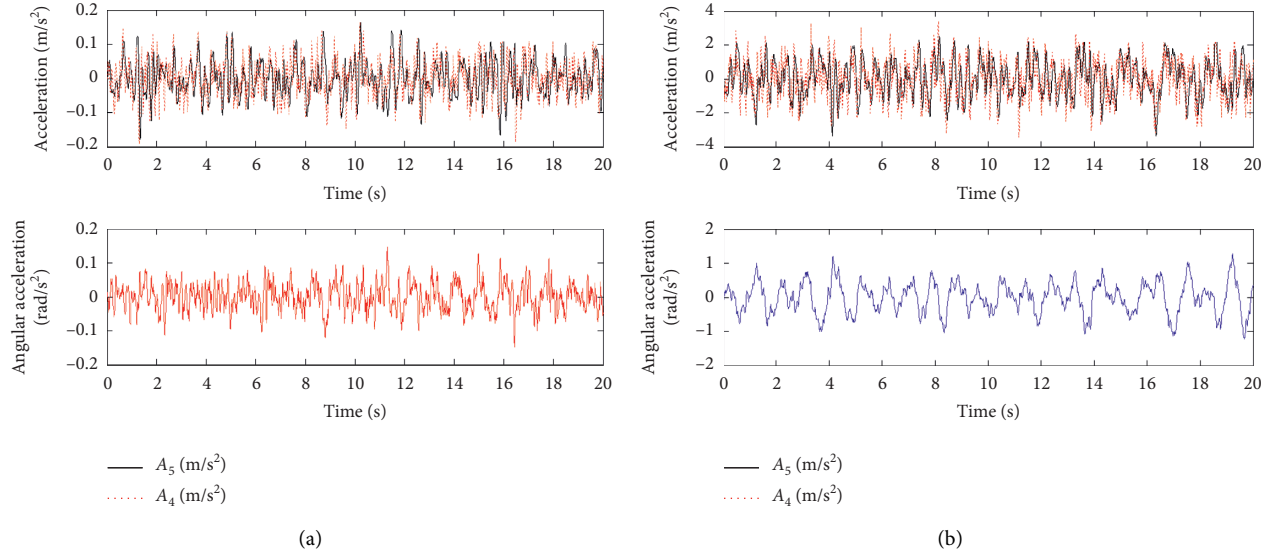

FIGURE 9: Responses of accelerations  $A_n$  of half vehicle system coupling with the HNES model while the excitation is random road inputs and the velocity of vehicle is 1.1256 m/s (a) and 20 m/s (b).

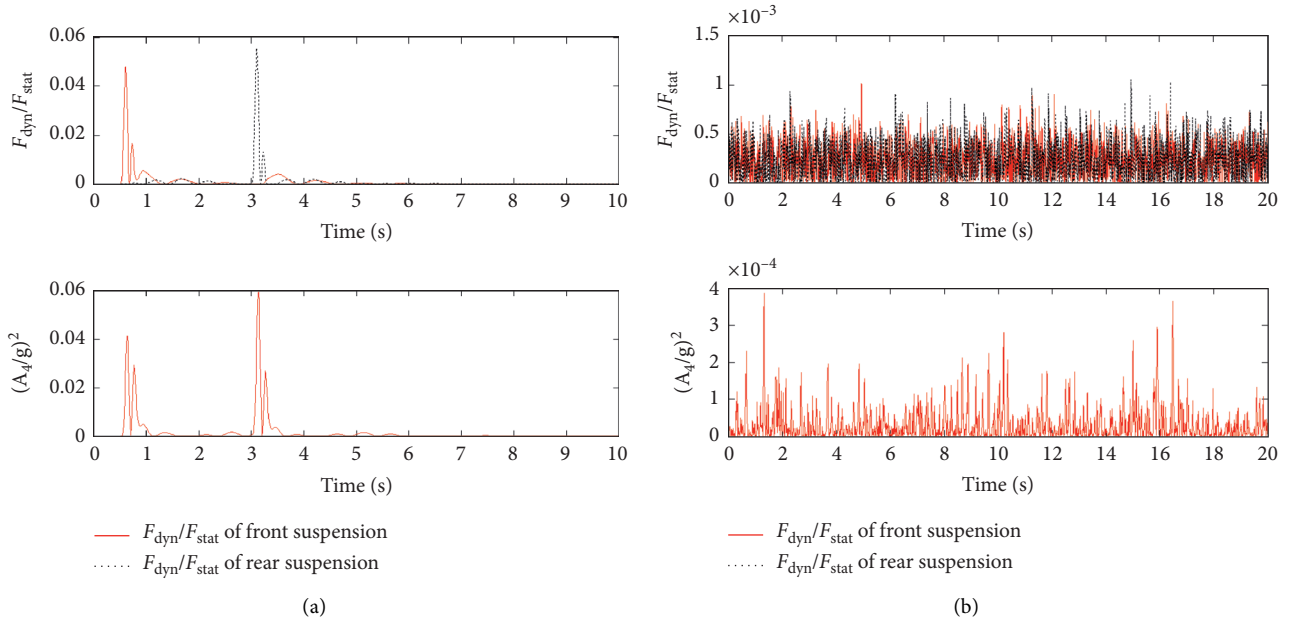

FIGURE 10: Responses of the ratio of dynamic loads and static loads of the front and rear tire against road inputs and the square of ratio of acceleration and gravity acceleration against the road inputs (a) for bump excitation and (b) for random inputs. The vehicle velocity  $v = 1.1256$  m/s (the time delay  $\tau = 2.5$  second), the simulation period  $T = 20$  seconds, and sampling interval ( $h$ ) = 0.01 seconds.

parameters of the half vehicle system coupling with the HNES model have only been achieved for bump road inputs.

## 6. Conclusions

In this paper, the behavior and performance of a semi-active suspension consisting of the HNES for the half vehicle system has been proposed and investigated in shock mitigation. A successful validation process has been performed to solve the half vehicle system coupling with HNES using the same parameters to compare the developed model to the MR model. The response of the half vehicle system coupling with HNES is solved numerically using the direct time integration method (analog equation method). The model is simulated against two kinds of road inputs which are bump road inputs and random road inputs. The great performance of the model is evident as the velocity of the vehicle changes from 1.1256 m/s to 20 m/s. The main conclusions that can be drawn from this investigation are as follows:

- (i) The HNES model as a semiactive suspension coupled to the linear half vehicle system was studied

- (ii) The performance of semiactive suspension in half vehicle system coupling with the HNES model has a significant potential of reducing the road input disturbance
- (iii) The responses of displacements, velocities, and accelerations of the HENS model as a semiactive suspension in the half vehicle system are much better than those of the MR model as a semiactive suspension system for the same parameter in the time domain ( $v = 1.1256(\text{m/s})$ )
- (iv) The ride comfort and the drive safety of the HNES as a semiactive suspension in the half vehicle system both against the bump road inputs and random road inputs are much higher than those of the MR model given in the study [23]

## Appendix

### A. Matrices M, K, and C and Vectors F, Q, and U in equation (12)

Matrices M, K, and C and vectors F, Q, and U are

$$\begin{aligned}
 \mathbf{M} &= \text{diag}(M_3 \ M_2 \ J \ M_1 \ M_1 \ M_f \ M_r), \\
 \mathbf{K} &= \begin{pmatrix} K_{f2} & -K_{f2} & K_{f2}L_3 & 0 & 0 & 0 & 0 \\ -K_{f2} & K_{f2} + K_{f2} + K_{NL} + K_r + K_{NL} & -K_{f2}L_3 - K_fL_1 - K_{NL}L_1 - K_rL_2 + K_{NL}L_2 & -K_{NL} & -K_f & -K_{NL} & -K_r \\ K_{f2}L_3 & K_{f2}L_3 + K_fL_1 + K_{NL}L_1 + K_rL_2 + K_{NL}L_2 & K_{f2}L_3^2 - K_fL_1^2 - K_{NL}L_1^2 + K_rL_2^2 + K_{NL}L_2^2 & K_{NL}L_1 & -K_fL_1 & -K_{NL}L_2 & -K_rL_2 \\ 0 & -K_{NL} & K_{NL}L_1 & K_{NL} + K_{EL} & -K_{EL} & 0 & 0 \\ 0 & -K_{NL} & -K_{NL}L_2 & K_{NL} + K_{EL} & -K_{EL} & K_{NL} + K_{EL} & -K_{EL} \\ 0 & -K_f & K_fL_1 & -K_{EL} & K_f + K_{EL} + K_{tf} & 0 & 0 \\ 0 & -K_r & -K_rL_2 & 0 & 0 & -K_{EL} & K_e + K_{EL} + K_{tr} \end{pmatrix}, \\
 \mathbf{C} &= \begin{pmatrix} C_{f2} & -C_{f2} & C_{f2}L_3 & 0 & 0 & 0 & 0 \\ -C_{f2} & C_r + C_{f2} + C_f + 2C_2 & -C_{f2}L_3 - C_fL_1 - C_2L_1 + C_rL_2 + C_2L_2 & -C_2 & -C_f & -C_2 & -C_r \\ -C_{f2}L_3 & C_{f2}L_3 + C_fL_1 + C_2L_1 + C_rL_2 + C_2L_2 & -C_{f2}L_3^2 - C_fL_1^2 - C_2L_1^2 + C_rL_2^2 + C_2L_2^2 & -C_2L_1 & -C_fL_1 & C_2L_2 & -C_rL_2 \\ 0 & -C_2 & C_2L_1 & C_2 + C_1 & -C_1 & 0 & 0 \\ 0 & -C_2 & -C_2L_2 & 0 & 0 & C_2 + C_1 & -C_1 \\ 0 & -C_f & C_fL_1 & -C_1 & C_f + C_1 & 0 & 0 \\ 0 & -C_r & -C_rL_2 & 0 & 0 & -C_1 & C_r + C_1 \end{pmatrix},
 \end{aligned}$$

$$\mathbf{F} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ -F_{\text{BWf}} & -F_{\text{BWr}} & 0 & 0 \\ -F_{\text{BWf}} & -F_{\text{BWr}} & 0 & 0 \\ F_{\text{BWf}} & 0 & 0 & 0 \\ 0 & F_{\text{BWr}} & 0 & 0 \\ 0 & 0 & K_{\text{tf}} & 0 \\ 0 & 0 & 0 & K_{\text{tr}} \end{pmatrix}, \quad (\text{A.1})$$

$$\mathbf{Q} = (1 \ 1 \ q_1 \ q_2)^T,$$

$$\mathbf{U} = (U_5 \ U_4 \ U_3 \ U_{f2} \ U_{f1} \ U_{r2} \ U_{r1} \ U_{Zf} \ U_{Zr})^T.$$

## B. Probability Density and Distribution Function of Random Variable $\theta$

The probability density of random variable  $\theta$  is

$$f(\theta) = \begin{cases} \frac{1}{\pi - (-\pi)}, & -\pi < \theta < \pi, \\ 0, & \text{otherwise.} \end{cases} \quad (\text{B.1})$$

The distribution function of random variable  $\theta$  is

$$F(\theta) = \begin{cases} 0, & \theta < -\pi, \\ \frac{\theta - (-\pi)}{\pi - (-\pi)}, & -\pi \leq \theta < \pi, \\ 1, & \theta \geq \pi. \end{cases} \quad (\text{B.2})$$

With the development of deep learning, many approaches based on neural networks are proposed for code clone. In this paper, we propose a novel source code detection model At-biLSTM based on a bidirectional LSTM network with a self-attention layer. At-biLSTM is composed of a representation model and a discriminative model. The representation model firstly transforms the source code into an abstract syntactic tree and splits it into a sequence of statement trees; then, it encodes each of the statement trees with a deep-first traversal algorithm. Finally, the representation model encodes the sequence of statement vectors via a bidirectional LSTM network, which is a classical deep learning framework, with a self-attention layer and outputs a vector representing the given source code. The discriminative model identifies the code clone depending on the vectors generated by the presentation model. Our proposed model retains both the syntactics and semantics of the source code in the process of encoding, and the self-attention algorithm makes the classifier concentrate on the effect of key statements and improves the classification performance. The contrast experiments on the benchmarks OJClone and BigCloneBench indicate that At-LSTM is effective and outperforms the state-of-art approaches in source code clone detection.

## 1. Introduction

In modern society, the application of computers and software has already pervasively permeated our lives. The necessities of life such as medical care, resources, communication, and public security depend on the running of the software of high quality. However, the development of software has always been very costly without adequate knowledge of our world. Software engineers are always busy fixing defects and refactoring code during the life cycle of software. The evolution of software tools and development process has never ceased. The industry has been exploring new methods to reduce the software complexity, improve the development efficiency, and enhance the reliability and maintainability of software.

Programmers often involve similar code with common operations such as copy-paste action, using framework, and generating code by automatic tools. The moderate use of code clone plays an active role in the software life cycle,

aiming at reducing errors and speeding software development. According to the research, code clone is common in software systems. There is around 15% to 25% similar code in Linux kernel [1], while in published JDK packages, people find more than 29% similar code [2].

However, the abuse of code clone is a huge challenge in the process of software testing, maintaining, and redevelopment, which may spoil code readability, duplicate code defects, and even bring in malicious code without intention [3, 4]. Especially, in the phase of software maintaining, ubiquitous clone of poor quality becomes the nightmare of programmers. The modification of duplicate code might expand the size of code base. The study on the code clone detection is hence attracted by scholars in software engineering. People proposed detection algorithms based on text, tokens, code structure, and program graphs successively.

Code clone, also known as similar code or duplicate code, refers to two or more identical or similar code snippets

in the source code library. The famous scholar Bellon [5] divides clone pairs into four categories in his paper. Type 1 and Type 2 are almost identical code segments, while Type 2 and Type 3 are heterogeneous code pairs with similar structure or semantics. The corresponding definitions are given in Section 3.1.

The traditional clone detection algorithms are mostly implemented with natural language processing technology. These approaches usually treat the source code as a plain text or a sequence of tokens and then calculate the similarity by means of line by line mapping or word vectors' distance [2, 6]. In addition, scholars [7, 8] try to represent the source code with other techniques such as the latent semantic index [9] and hash mapping [10], in order to improve the detection efficiency of the model. However, these representation approaches are based on NLP methods, which mean only simple clone pairs, i.e., type 1 and type 2 clones, are detectable.

In recent years, with the rapid development of deep learning technology, researchers in the field of code cloning detection begin to analyze the structural and semantic features of source code with deep learning approaches. Based on the common neural networks such as convolutional neural network, recursive neural network, and recurrent neural network, scholars exploit various deep encoders [11–13] to automatically extract deep features from the Abstract Syntactical Trees (ASTs), which are generated from the original source code. Compared to the traditional methods, deep neural networks are capable of extracting the features hidden in the AST, which improves the classification performance in detecting semantic cloning.

The LSTM network, which was invented in 1997, is a classical recurrent neural network framework. It contains a memory cell which can preserve states over long periods of time. The structure of LSTM is detailed in Section 3. Due to the ability of handling sequential data, more and more scholars tend to use LSTM to locate cloning code in software engineering. However, the training of the deep encoder based on LSTM is still affected by long-term dependency, as the hierarchy of the whole AST is too deep.

In this paper, we propose a source code clone detection model At-BiLSTM using bidirectional LSTM with self-attention mechanism, which retains both the syntactics and semantics of code in the process of representation. At-BiLSTM is a static analytical model based on the deep learning framework, including a source code representation model and a discriminative model. The representation model firstly transforms the source code into an AST and then splits it into a sequence of statement trees according to a preorder traversal algorithm. Each divided tree represents a legitimate programming statement in the source code, corresponding to a subtree rooted by a statement node in the whole AST. By the decomposition of AST, our model greatly reduces the risk of long-term dependence existing in other AST analytic models [12, 13] based on recurrent neural networks. The representation model then converts the statement trees into an ordered set of vectors via a specific LSTM encoder. Finally, the representation model obtains a single vector representation as an output from these

statement vectors based on a bidirectional LSTM encoder with a self-attention layer. Depending on self-attention mechanism, the output vector indicates a weighted average of all statements in the source code, in which core statements are enhanced with heavy weights. A discriminative model is attached to the output of the representation model in At-BiLSTM. It gives a reasonable prediction of code clone by comparing the code similarity in a supervised learning way.

As far as we know, we are the first to propose a clone detection model based on self-attention mechanism. The main contributions of our work are as follows:

- (i) We propose a novel neural source code representation model, which maps the AST, transferred from the source code, to a high dimensional space. Compared to the previous research, the output vector in our model retains the source code structure and semantics.
- (ii) Based on the decomposition of the whole AST, our model effectively reduces the depth and complexity of the original tree and alleviates the negative impact on the classification accuracy due to the long-term dependence and the gradient vanishing.
- (iii) To the best of our knowledge, we are the first to introduce self-attention mechanism, which was developed in NLP, into the area of code cloning. With the self-attention mechanism, the core statements in the source code are strengthened, which finally improve the classification performance.
- (iv) The achievements are made when we apply representation model in the detection of code clone. We improve the model parameters with supervised learning on dataset benchmarks. The experiments show that our model is superior to the state-of-art approaches.

The rest of this paper is organized as follows. Section 2 presents the related work in this area. Section 3 describes the notations and background in code clone. Section 4 describes the detailed design of our approach. Section 5 presents the comparison experiments; in Section 6, we make an analysis on the experiment results. Section 7 presents the threats to validity. Finally, we conclude the paper in Section 7.

## 2. Related Work

*2.1. Traditional Approaches.* By the analysis of text and tokens, most of the traditional code detection approaches treat source code as plain text or set of tokens, ignoring its structure and semantics. Such models often extract features manually or with NLP methods in the process of vectorization and then identify clone pairs via text similarity algorithm. Mostly applied in the early stage, these models were capable of identifying clone pairs of type 1 and type 2. Due to the low complexity and cross-platform features, these approaches are widely used in industry.

In the early studies, Mayrand et al. [14] defined specific sample features from the function names, expressions, and

control flow in the source code by manual extraction. They calculated the similarity of clone code pairs by comparing 21 function-level metrics. Based on the features generated manually, the approach strictly relied on the domain knowledge of experts. The adaptability of the model is poor as the structural features of various programming languages are different.

A famous plug-in in Eclipse platform, SDD [15], which is based on token detection, locates clone snippets in source code. Employing the inverted index and N-nearest neighbor algorithms, it effectively reduces the detection time, helping developers quickly locate the clone code in the IDE environment. SDD makes great achievements in the detection of type 1 and type 2 code, while it fails to identify clone pairs which are highly dissimilar syntactically but still perform the same function.

Another famous model Deckard [16], which is widely used for contrast experiments by later researchers, made an analysis on the AST, which is generated from the given the source code. Deckard manually generates the vectors with predefined rules when traversing the tree. After processing the vectors with local sensitive hash algorithm (LSH), the model calculates the similarity of the code according to Euclidean distance and finally outputs the probability of the clone pairs. Deckard might detect clone code pairs with statements in different orders because the corresponding AST retains the basic structure of source code, and it can be applied in different programming platforms with corresponding AST parsers. However, Deckard fails to be implemented in large-scale clone detection due to the complexity of clustering operations.

*2.2. Deep Learning Approaches.* With the development of deep learning theory, people tend to solve problems in every field with deep learning approaches. In recent years, researchers in the field of software engineering have introduced deep neural networks such as multilayer perceptron network, recurrent neural network, and convolutional neural network to solve the problem of code clone detection. Models with deep neural networks can automatically extract the structural and semantic features hidden in the source code. And the classifiers in these models, which are carefully trained by supervised or unsupervised learning, might have the ability to identify the clone pairs of type 3 or type 4.

White et al. [13] firstly employed recursive autoencoder to learn latent features for code clone. They transferred each leaf node in the AST into a feature vector via a word-embedding algorithm and then obtained the vectors of the nonterminal nodes with a bottom-up traversal algorithm recursively. The vector of the root became the representation of the whole AST at the end of the tree traversal. Finally, they identified the clone pairs by comparing the similarity of root vectors. In order to reduce calculating cost, the AST was transformed to the complete binary tree for encoding, which might cause the tree depth even heavier. Their model performed well in a small, author-defined dataset.

The unsupervised learning model often has worse classification performance than the supervised learning

model. Inspired by White's model, Wei et al. [12] developed a supervised learning model called CDLH. They made contrast experiments by sampling data from the famous code clone dataset BigCloneBench [17]. Their basic idea was to exploit AST-based LSTM to extract code features automatically, meanwhile use the similarity in functional behaviors as the supervised information to guide the deep feature learning process. Different from White's model, they vectorized the leaf nodes of AST by word2vector [18], which was very common in NLP. In order to reduce learning time, they calculated the similarity of hamming space instead of vector pairs, which was generated from binary hash functions, to identify the code clone. The experimental results showed their model was effective and well surpassed the previous models based on unsupervised learning.

Besides the detection models based on LSTM networks, researchers also attempted to obtain the semantic information from source code with special CNN. Yu et al. [11] generated both the original AST and the enhanced AST based on token information from the same code snippet, and then they extracted the feature vectors from these two trees via a specific convolution network. They innovatively used the triangle convolution kernel with a depth of 2 to traverse the corresponding trees layer by layer. In order to reduce the UNK values when encoding the AST leaf nodes, they proposed a new algorithm called PACE that combined one-hot encoding with the position of characters for vectorization.

Although recent work provides strong evidence that AST-based detection models can obtain better classification performance, they have two problems. First, these tree-based approaches are vulnerable to gradient vanishing and long-term dependency, especially when the size of grammar trees is very big and deep. Second, most approaches based on AST parsing either transform AST to or directly treat AST as a full binary tree for simplification or efficiency, which destroys the original structure of source code and makes the tree deeper. In order to solve these problems, Zhang et al. [19] proposed an ASTNN model in 2019. They split the AST into a sequence of small statement trees and encoded them with a recursive encoder. Finally they produced a vector representation of the given AST with a bidirectional GRU encoder [20] based on the sequence of statement vectors. They applied the representation approaches to the task of source code classification and code clone detection. Their experiments showed that ASTNN was superior to previous approaches.

The deep learning detection models based on AST parsing employ both the lexical and semantical information hidden in the source code, improving classifiers' performance. Moreover, the extraction of these features is highly automatic by the deep representation layers, which reduces the cost of expert intervention. The detection models determine the granularity of clone detection by the pruning of corresponding AST, which is not trivial with traditional approaches. Therefore, the AST-based traversal algorithms with deep learning have attracted more and more attention in the field of source code clone.

In addition to the detection approaches above, researchers have also exploited graph-based detection [21, 22]

models to detect clone pairs of type 3 and type 4. They used program dependency graphs (PDGs), which contained data flow graph and program control graph, to detect code clone in a semidynamic way. These approaches eventually transformed the problem of clone detection into the problem of finding isomorphic subgraphs over PDGs. Compared to the AST parsing detection, graph parsing detection technology relies on PDG generators, which cannot be used in various platforms easily. These models, often involved with graph mapping or hybrid mapping, are extremely difficult, which researchers fail to deploy in large-scale code base due to the computing cost.

### 3. Preliminaries

In this section, we briefly give some well-accepted definitions in the area of code clone and deep learning.

**3.1. Code Clone.** We give some definitions of code clone as follows:

- (i) Code fragments: also called code snippets, a continuous segment of source code, specified by the triple  $(l, s, e)$ , including the source file  $l$ , the line the fragment starts on,  $s$ , and the line it ends on,  $e$ .
- (ii) Clone pair: a pair of code fragments that are similar, specified by the triple  $(f_1, f_2, \emptyset)$ , including the similar code fragments  $f_1$  and  $f_2$ , and their clone type  $\emptyset$ .
- (iii) Clone class: a set of code fragments that is similar. Specified by the tuple  $(f_1, f_2, \dots, f_n, \emptyset)$ , each pair of distinct fragments is a clone pair:  $(f_i, f_j, \emptyset)$ ,  $i, j \in 1..n$ ,  $i \neq j$ .
- (iv) Earlier studies did not provide a clear classification of code clones until Bellon grouped code clones into 4 types, whose classification has been widely used in later studies. In this paper, we also employ their definitions of clone types.
- (v) Type 1 (T1): syntactically identical code fragments, except for differences in white space and comments.
- (vi) Type 2 (T2): in addition to Type 1 clone differences, syntactically identical code fragments, except for differences in identifier names and literal values.
- (vii) Type 3 (T3): in addition to Type 2 clone differences, syntactically similar code fragments that differ at the statement level. These fragments can have statements added, modified, or removed with respect to each other.
- (viii) Type 4 (T4): syntactically dissimilar code fragments that are still the same semantically. Bellon did not give an accurate definition of T4 clones. It is recognized in the industry that two code fragments with similar functionality, even if they are completely different in structure, are recognized as T4 clones. For example, one code fragment

implementing bubble sort and another code fragment implementing quick sort are considered a pair of T4 clones.

**3.2. Abstract Syntax Tree.** Abstract Syntax Tree is a kind of syntax tree representing the abstract syntactic structure of the source code. It has been widely used by programming compilers and software engineering tools due to the powerful representation ability. Different from concrete syntax trees (CTS), abstract syntax trees do not contain all the details of source code such as the punctuation and delimiters. They only include the syntax structure of the source code at an abstract level. AST contains both the lexical and syntax information of the source code, which is often employed in the industry as an intermediate tool to extract the hidden information.

Figure 1 depicts the structure of an AST. The left part of the graph is a simple IF statement written in Java, while the right part is an AST generated from the IF statement. Nodes of the AST are corresponding to the constructs or symbols of the source code. We conclude from the graph that the AST fully retains the structural information of the source code. However, the depths of the ASTs are usually very deep according to the grammar rules. Recent studies of code clone detection are mainly based on the traversal algorithms of the AST [19, 23, 24].

**3.3. Attention.** The attention mechanism is the internal process for machines to imitate the human observation of things in the world. When processing images, our vision quickly obtains the target area by a global scan, i.e., the focus of attention. Then, the brain pays more attention to the focus area for details, while suppressing irrelevant information.

Bahdanau et al. [25] firstly applied the attention mechanism in the field of machine translation, i.e., sequence to sequence learning. They successfully solved the problem of long-term dependency in machine translation, i.e., the translation models based on fixed vector representations often lost history information of long sentences in the decoding process. After that, people begin to study deep encoders with attention layers, which achieved amazing effects in all areas of NLP.

Mathematically, the attention is essentially a mapping function composed of Query, Key, and Value. The calculation of attention values is divided into three steps:

Step 1: Query is combined with each Key to calculate the attention weight. The similarity function  $f(Q, K)$  can be defined in multiple ways. The simplest calculation is shown as

$$f(Q, K) = K^T Q. \quad (1)$$

Step 2: the softmax function is used to normalize the attention weight obtained in step 1, as shown in equation (2). Sometimes, we have to scale the attention scores later as the original ones are too large to calculate:

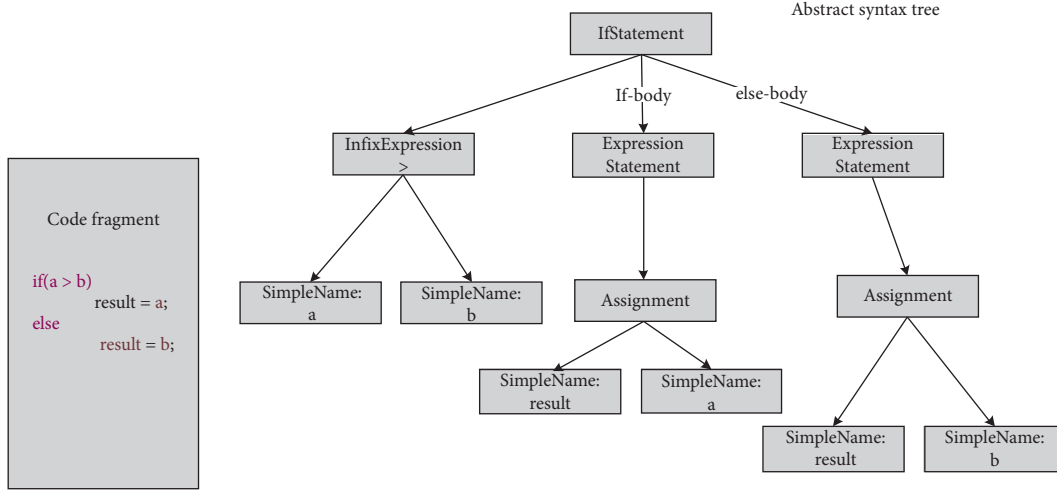

FIGURE 1: Abstract syntax tree.

$$a_i = \text{softmax}(f(Q, K)). \quad (2)$$

Step 3: the final attention is the weighted sum of normalized weights  $a_i$  and corresponding values, which is shown as

$$\text{Attention}(Q, K, V) = \sum a_i V. \quad (3)$$

The attention mechanism is widely used in RNN-based encoder-decoder models. The input of the decoder's current state is determined by the weighted average of all hidden layers' output values in the encoder. The attention algorithm is transformed to the self-attention algorithm when  $Q=K=V$  in the encoder. Our representation model in At-biLSTM is implemented with a specific self-attention encoder layer.

**3.4. LSTM Network.** Recurrent neural networks (RNN) are able to process input sequences of arbitrary length via the recurrent structure with shared weights. Unfortunately, a common problem with the traditional RNN is that components of the gradient vector can grow or decay exponentially over long sequences during training. Therefore, the LSTM architecture, which was invented by Hochreiter and Schmidhuber in 1997 [26], addresses this problem of learning long-term dependency by introducing a memory cell that is able to preserve states over long periods of time. The core part of the LSTM is a cell memory  $C_t$ , including an input gate  $i_t$ , an output gate  $o_t$ , and a forget gate  $f_t$ . Figure 2 describes the basic structure of LSTM. Different from the original RNN, the LSTM solves the problem of long-term dependency effectively with the special structure memory cell, discarding the trivial information in the history to avoid the gradient vanishing [27, 28].

The cell memory of LSTM is composed of three gate controllers. The forget gate  $f_t$  controls the extent to which the previous memory cell is forgotten, which is essential a sigmoid function. The entry of  $f_t$  is a weighted combination

of the previous output value and the current input value. The input gate  $i_t$  controls how much each unit is updated, and the output gate  $o_t$  controls the exposure of the internal memory state. The LSTM transition equations are the following:

$$\begin{aligned} f_t &= \sigma(W_f \cdot [h_{t-1}, x_t] + b_f), \\ i_t &= \sigma(W_i \cdot [h_{t-1}, x_t] + b_i), \\ C_t &= f_t \times C_{t-1} + i_t \times \tanh(W_f \cdot [h_{t-1}, x_t] + b_c), \\ o_t &= \sigma(W_o \cdot [h_{t-1}, x_t] + b_o), \\ h_t &= o_t \cdot \tanh(C_t), \end{aligned} \quad (4)$$

where  $W_i$ ,  $W_f$ , and  $W_o$  are the weighted matrices and  $b_i$ ,  $b_f$ , and  $b_o$  are the biases of LSTM to be learned during training, parameterizing the transformations of the input, forget, and output gates, respectively.  $\sigma$  and  $\tanh$  are the activation functions, and  $\cdot$  denotes the element-wise multiplication.  $x_t$  is the input of the LSTM cell unit, and  $h_t$  is the output of the hidden layer at the current time step.

Since LSTM has an amazing effect in dealing with long sequential data, researchers propose several variants, e.g., Gated Recurrent Unit (GRU), Bidirectional LSTM (Bi-LSTM), and Bidirectional GRU (Bi-GRU). These networks usually improve the performance when handling the sequential data.

## 4. Our Proposed Approach

In this section, we present our model At-biLSTM, which is an end-to-end learning approach that unifies the representation model and discriminative model. Figure 3 summarizes the overall architecture of At-biLSTM.

**4.1. General Framework.** As shown in Figure 3, At-biLSTM mainly contains two parts: the representation model and the discriminative model. As the core part of the detection system, the representation model transforms the source code into high-dimensional vectors in three steps.

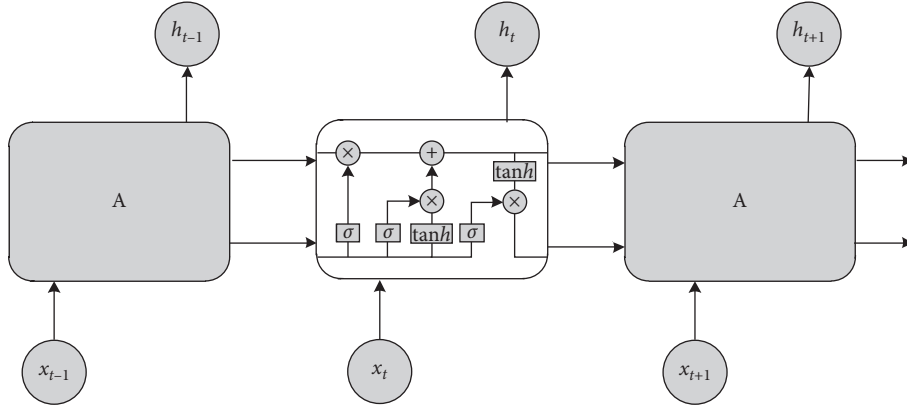

FIGURE 2: Structure of LSTM.

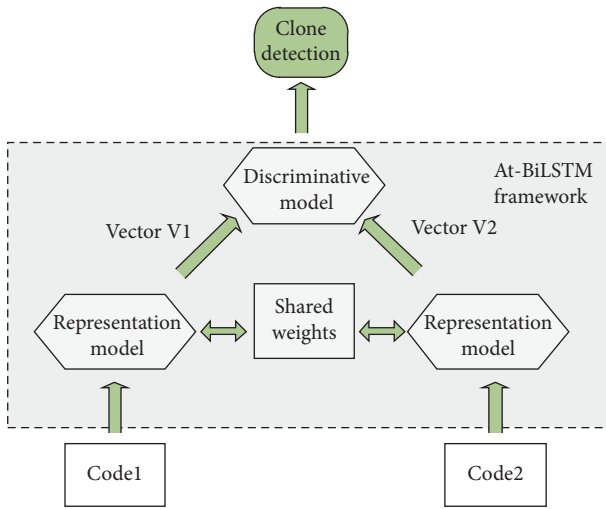

FIGURE 3: The architecture of At-BiLSTM.

Step 1: the source code fragments to be detected are transformed into abstract syntax trees by existing AST tools. For each AST, we decompose it by the granularity of language statement and extract the sequence of statement trees with a preorder traversal. The root of each statement tree is a statement in the corresponding code fragment.

Step 2: each statement tree is transformed into a statement vector via a LSTM encoder with a deep-first traversal algorithm. At that moment, the whole AST representing the source code fragment is transformed into an ordered set of statement vectors.

Step 3: the model generates the final representative vector from a sequence of statement vectors via a specific bidirectional LSTM encoder with the self-attention layer.

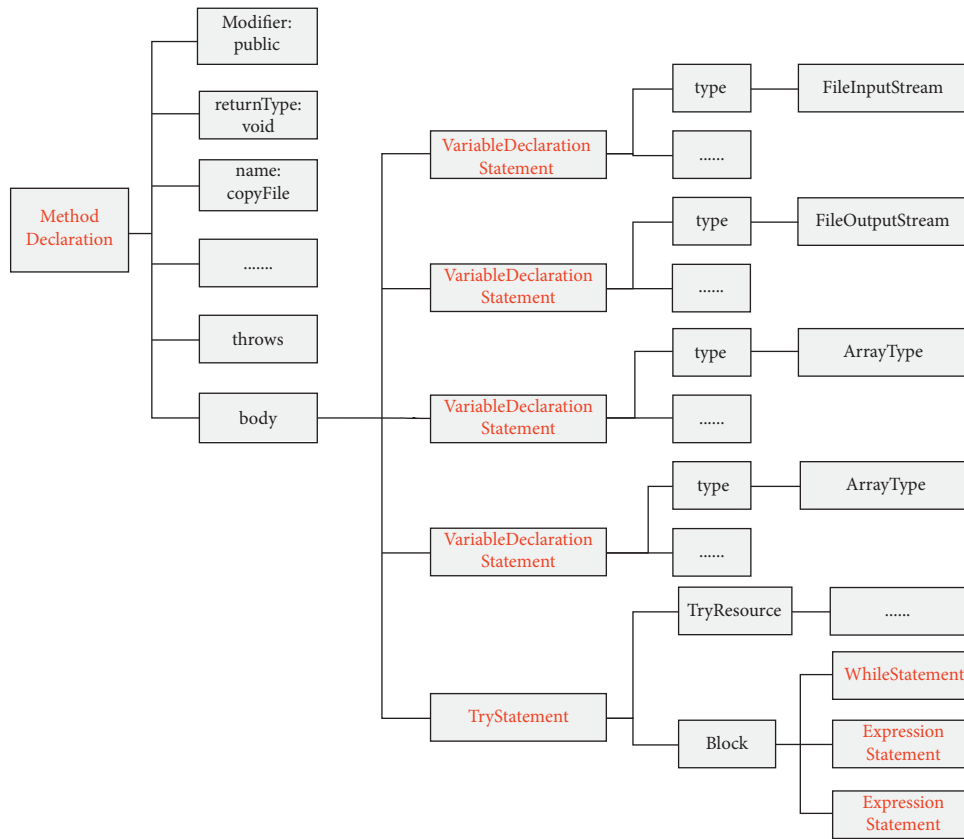

The pair of code vectors generated from the representation model is then loaded into the discriminative model. The discriminator predicts the probability of being clone for the code pair. We can also generate hard labels for the code pair by setting a probability threshold. The detailed design of our model is described in the following sections.

4.2. *Splitting the AST.* Firstly, the source code fragment is transformed to an AST with common parsing tools supplied by language developers, e.g., pycparser [29] and javalang [30]. However, the ASTs g

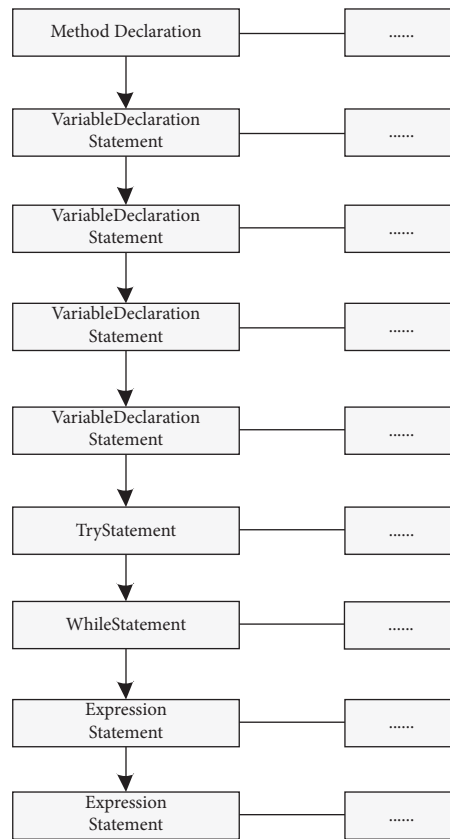

enerated by tools might be too deep to traverse due to the problem of long-term dependency, which reduces the generalization ability of the presentation model. Hence, the strategy to split the whole tree into a sequence of subtrees is adopted in our model to reduce the computational complexity.

There are many methods to decompose the AST into small subtrees without overlapping [31]. In our paper, inspired by the splitting algorithm in [19], we decompose it by the granularity of natural statements. The process of splitting is straightforward: the model firstly scans the AST with a preorder traversal. When it encounters a tree node representing a programming statement, the constructor generates a statement tree taking the node as its root; meanwhile, the new statement tree is added to a FIFO subtree queue. The splitting algorithm based on the preorder traversal ensures that the subtrees generated are arranged in the same way as the statements in the source code. Figure 4 depicts a simplified AST which is generated from a common Java code fragment. Due to the complexity of the AST expression, Figure 4(a) only shows the top 5 layers of the actual AST, and Figure 4(b) represents the execution order of the generated statement trees.

Formally, given an AST  $T$  and a set of statement nodes  $S$ , each statement node  $s \in S$  in  $T$  corresponds with a statement of source code, marked in red in Figure 4. The Method Declaration is treated as a special statement node; thus,  $S = S \cup \{\text{Method Declaration}\}$ . The compound statements with blocks are split into small statement nodes, each of which generates a new subtree. We define the set of separate nodes  $P = \{\text{block, body}\}$ , where block is for splitting the header and body of compound statements such as While and Try Statements, and body for the method declaration. We define  $D(s)$  as the descendants of the statement node  $s \in S$ , and define  $\text{Sub } S(s)$  as the set of substatement nodes of the statement node  $s$ . For any  $d \in D(s)$ , if there exists a path from  $s$  to  $d$  through a node  $p \in P$ , it means the node  $d$  is included by one statement in the body of statement  $s$ . We say that  $d \in \text{Sub } S(s)$  is a substatement node of  $s$ .

(a)

(b)

FIGURE 4: The decomposition of an AST. (a) AST and statement trees. (b) Statement naturalness.

Here, we give the formal definition of a statement tree. The statement tree rooted by the statement node  $s \in S$  in the tree is a syntactic tree consisting of node  $s$  and all of its descendants  $D(s)$  excluding its substatement nodes  $\text{Sub } S(s)$  in  $T$ . For instance, the first statement tree in Figure 4(a) is a subtree rooted by `MethodDeclaration`, including descendant nodes' `Modifier`, `returnType`, `throws`, and `body`. It excludes the nodes `variableDeclarationStatement`, `TryStatement`, and their descendants. According to the splitting algorithm the sequence of statement trees in Figure 4(b) is generated from the whole AST in Figure 4(a).

**4.3. Encoding the Statement Trees.** Recently, people tend to encode the AST with various recursive neural networks [12, 13]. The recursive encoder generates representative vectors when it traverses the syntactic tree from leaf nodes to the root node layer by layer in a bottom-up way. The final vector generated from the root is considered to be the representation of the whole AST, containing the syntactic information of the source code. In order to realize the recursive encoder, people have to transform the original AST into a complete binary tree, which will slightly change the structure. What is worse, the transformation further enlarges the size of AST, which may cause the model to collapse during training. Even if the loss function eventually converges during training, the classification performance of the model is probably affected by the long-term dependence. Inspired by the algorithms used in the field of code comment generation, we encode the statement tree with a simple LSTM network in our approach.

We use a simple encoding method based on a LSTM network in our approach. Each statement tree is encoded with a depth-first traversal algorithm, which is described in the following:

Step 1 (generating the token dictionary and node encoder): we firstly transform all the code fragments in the training set into ASTs and then generate a token dictionary by extracting all the nodes from the ASTs. Finally, we use the word2vec to train a node encoder  $E$  based on the token dictionary with unsupervised learning.

Step 2 (encoding the statement tree nodes): for the given statement tree ST, we encode all the internal nodes in ST with the encoder  $E$ .

Step 3 (generating an ordered set of node vectors): we traverse ST with a deep-first algorithm and then place all the node vectors into an ordered set  $V$  sequentially.

Step 4 (encoding the statement tree): all the vectors in  $V$  are input into a LSTM encoder sequentially, and the output of the LSTM is the vector representation of ST. The parameters in the LSTM encoder, together with other parameters in At-biLSTM, are trained by supervised learning on the training set.

**4.4. Representing the Sequence of Statement Vectors.** Based on the algorithms of Sections 4.2 and 4.3, the AST representing the given code fragment is now transformed to

an ordered vector set  $V_t = \{v_1, v_2, v_3, \dots, v_t\}$  with a weights shared encoder, where  $t$  denotes the number of statement trees and  $v_t$  denotes a vector encoded from the given statement tree.  $v_1, v_2, v_3, \dots, v_t$  are aligned according to the tree traversal order in Section 4.2.

In this paper, we exploit the LSTM network to track the naturalness of statements due to the sequence of statement tree vectors. Figure 5 shows the structure of representation model. The complicated representation model can be divided into 3 layers. The first layer in the bottom is the statement tree encoder, which is composed of a LSTM network with shared weights. Each substatement tree is transformed into a vector in this encoder sequentially. The second layer is a mixed layer which is composed of a bi-directional LSTM network. All the subtree vectors are placed into the mixed layer and transformed into hidden vectors  $h$ . The third layer is an attention layer, which summarizes all the hidden vectors with corresponding attention scores. The encoding process is detailed in the following paragraphs.

The elements  $v_1, v_2, v_3, \dots, v_t$  in  $V_t$  are sequentially placed into a LSTM network. In order to further strengthen the model's ability to capture sequential information, we employ a bidirectional LSTM, where the hidden states of both directions are concatenated to form the new states as follows:

$$\begin{aligned} \vec{h}_t &= \overrightarrow{\text{LSTM}}(v_t), \quad t \in [1, N], \\ \overleftarrow{h}_t &= \overleftarrow{\text{LSTM}}(v_t), \quad t \in [N, 1], \\ h_t &= \left[ \vec{h}_t, \overleftarrow{h}_t \right], \quad t \in [N, 1]. \end{aligned} \quad (5)$$

However, the effect of each statement is different in high-level programming languages, e.g., the statements dealing with business functionality are much more important than common declaration statements. In this paper, we attempt to introduce the self-attention algorithm in light of variant contribution of each statement to the system functionality. To the best of our knowledge, it is the first time to use attention mechanism in the field of code clone. Since our model only includes the encoder, we decide to use the self-attention algorithm. The attention scores can be calculated in many ways as there are various definitions of similarity function. In our paper, equations (6) and (7) are used to calculate the attention scores, which were defined in [29]:

$$\alpha_i = \frac{\exp(h_i^T K)}{\sum_i \exp(h_i^T K)}, \quad (6)$$

$$C = \sum_i \alpha_i h_i, \quad (7)$$

where  $h_i$  denotes the hidden states of the bidirectional LSTM and  $K$  denotes a context vector which is initialized randomly. The author [29] indicates that the inner product of  $h_i$  and  $K$  denotes the contribution of  $h_i$  to the source code vector. The value of  $K$  is updated continuously with other parameters via supervised learning.  $\alpha_i$  denotes the  $i$ th attention score,

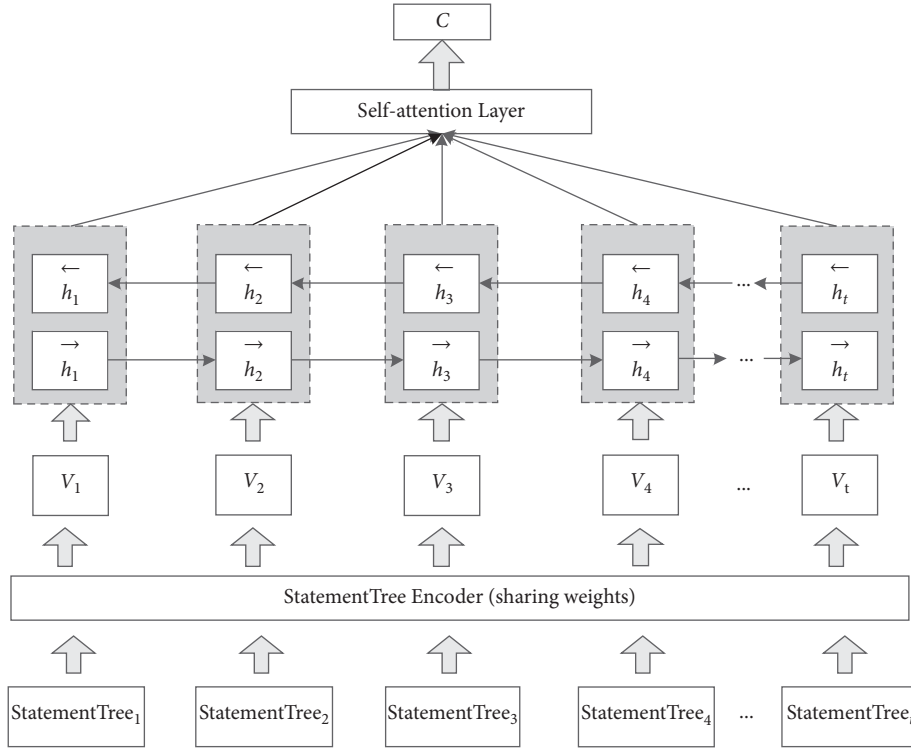

FIGURE 5: Representation model with self-attention.

corresponding with the hidden state  $h_i$ .  $C$  is the representative vector of the given code fragment, which is generated by the weighted average of all the hidden state vectors. Due to the structure of LSTM and self-attention, the vector  $C$  contains the sequential information of all the statements; meanwhile, it intensifies the contribution of key statements. The upper part of Figure 5 shows the encoding process with the self-attention layer.

**4.5. Loss Function and Similarity Computation.** The source code pair is mapped to two corresponding vectors in high-dimensional space via the representation model. We then compute the similarity of these vectors in the discriminator of At-BiLSTM. In this paper, our model is trained with supervised learning as the performance of supervised learning is much better than unsupervised learning. As a typical problem of the binary classification, binary cross-entropy is used as the lost function, which is defined in

$$L = \sum [y \ln \hat{y} + (1 - y) \ln (1 - \hat{y})], \quad (8)$$

where  $y$  is the real probability of code clone and  $\hat{y} \in (0, 1)$  is the prediction probability of our classifier. As the granularity of clone is measured according to the similarity of code pair in the model, we use the method [32] to compute the code pair similarity. Suppose there are two code fragment vectors  $v_1$  and  $v_2$ , which are generated via our representation model, and their distance is defined as  $r = |v_1 - v_2|$  for semantic relatedness. The probability of code pair similarity is computed as follows:

$$\hat{y} = \text{sigmoid}(W_o(r) + b_o), \quad (9)$$

where  $W_o$  is the weight matrix and  $b_o$  is the bias in the discriminative model. In the process of detection, we carefully define a proper threshold  $\tau$ . The detection system identifies the code pair as a clone pair if  $\hat{y} > \tau$ . In this paper, we set  $\tau$  to 0.5 via experiments. The code pairs are identified as clone if the similarity threshold is above 0.5.

**4.6. Evaluation Metrics.** The code clone detection is a typical binary classification problem in machine learning, so we define and calculate the following metrics to evaluate the effectiveness of any clone detection approach. True positive (TP) refers to the number of clone pairs that are identified as clone by the classification system. False positive (FP) refers to the number of nonclone pairs that are identified as clone. True negative (TN) refers to the number of nonclone pairs that are identified as nonclone. False negative (FN) refers to the number of clone pairs that are identified as nonclone. The goal of the clone detection system is to find the proper algorithm with the highest Precision, Recall, and F1 score.

**Precision:** it measures among all of the clone pairs reported by a clone detection approach, how many of them are actually true clone pairs:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \quad (10)$$

**Recall:** it measures among all known true clone pairs, how many of them are detected by a clone detection approach:

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \quad (11)$$

F1 score: it combines Precision and Recall to measure the overall accuracy of clone detection. The detection performance is better if the F1 score is higher:

$$F_1 = \frac{2 * \text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}}. \quad (12)$$

## 5. Experiments

*5.1. Dataset Description.* There are very few public datasets for code clone detection as it is very difficult to collect and identify clone pairs. We conduct our experiments on two public datasets BigCloneBench [17] and OJClone [24], which are frequently used to evaluate approaches of detecting code clones. BigCloneBench was released by Svajlenko et al. in 2015. It is the first big-data-curated benchmark of real clones to evaluate the performance of detecting models. According to the authors, the dataset was built by mining clones of frequently implemented functionalities from 25,000 Java projects. Based on the syntactical similarity which was measured as the ratio of lines or tokens that a code fragment shared with another after normalization, the clone pairs in BigCloneBench were divided into 5 groups: type 1, type 2, midtype 3, strong type 3, and type 4. Table 1 summarizes the data distribution in the first version of BigCloneBench in terms of clone types. We conclude from the table that more than 98% clone pairs in BigCloneBench are type 4 clones, which is quite appropriate to evaluate the detection of semantic clones.

Specifically, the clone labels in BigCloneBench were verified by three domain experts, taking 216 hours. The dataset is still been updated, and the current version has about 8 million tagged true clone pairs covering 43 functionalities. However, the authors of recent detection models always conducted experiments on the first version of BigCloneBench, which contains over 6 million true clone pairs and more than 260,000 false clone pairs, covering 10 functionalities. In this paper, we also sample data from the first version of BigCloneBench for comparison.

OJClone is a C language dataset released in 2016 by Mou et al., including 104 programming problems together with various source code solutions which students submit for each problem. There are no labels for code pairs in OJClone as the dataset was designed for code classification in the beginning. However, recent scholars consider any two different source code pairs solving the same programming problem to be T3 or T4 clone, as they realize the same functionality. OJClone is often used to identify T4 clones in recent years.

*5.2. Data Collection.* There are 59,668 code fragments in BigCloneBench, composing more than 6 million true clone pairs and 260,000 nonclone pairs. Due to the huge amount of data in BigCloneBench, we construct the experimental datasets by random sampling. For BigCloneBench, we randomly sample 40,000 pairs of negative samples, 20,000

TABLE 1: Percentage of clone types in BigCloneBench.

| Type 1 | Type 2 | Strong type 3 | Midtype 3 | Type 4 |
|--------|--------|---------------|-----------|--------|
| 0.005  | 0.001  | 0.002         | 0.01      | 0.982  |

pairs of positive samples in midtype 3 and type 4 clones, and 20,000 pairs of positive samples in type 1, type 2, and strong type 3 clones totally.

For OJClone, there are 104 programming problems. Similar to the previous works [12, 19], we select 500 program solutions from each of the first 15 programming problems to obtain 7500 code fragments in OJClone. Table 2 describes the data we collect in the experimental datasets. All the code fragments are parsed into ASTs. The tokens and depths of the ASTs are also shown in Table 2. Lack of domain knowledge, we expect two source code fragments for the same problem belong to a clone pair, and those for various problems are not clone pairs. The 7500 code fragments produce more than 28 million clone pairs, which is extremely time consuming for comparison. Therefore, we randomly select 50,000 samples to construct the experiment dataset for convenience. For each dataset, we randomly divide it into three pieces, of which the proportions are 80%, 10%, and 10% for training, validation, and testing.

*5.3. Experimental Setting.* All the experiments are conducted on a server, having a CPU of 16 cores with GPU acceleration. The model is implemented with a famous deep learning framework, pytorch. In order to generate ASTs from code fragments, we use javalang for java code and pycparser for C code, respectively. For token embedding, we train the token encoder for AST nodes using word2vec with Skip-gram algorithm and set the embedding size to be 128.

The neutral networks for the representation model and discriminative model are all implemented with pytorch. In the encoding of single statement tree, we exploit a common LSTM encoder, where the hidden dimension is set to be 120. In the encoding of statement vector sequence, we exploit a bidirectional LSTM encoder followed by a self-attention layer, where the hidden dimension is set to be 128. We use SGD to train the model and set Batch\_size to 64. We employ the optimizer Adam with a learning rate 0.005 to train our model.

*5.4. Experimental Result.* We compare our model with the existing state-of-the-art neural network approaches by different experiments.

- (i) RAE model [13]: the RAE model transforms the source code pairs into vectors by a recursive encoder, which is trained with unsupervised learning. The model identifies the clone pair by calculating the similarity distance between vectors. With the open-source tool provided by the authors, we use the RAE model to detect clone pairs on our datasets in a supervised learning way.
- (ii) CDLH model [12]: the CDLH model traverses AST with a tree-based LSTM network and then generates

TABLE 2: Statistics of datasets used for clone detection.

| Dataset                       | OJClone | BigCloneBench |
|-------------------------------|---------|---------------|
| Code fragments                | 7500    | 59688         |
| True clone pairs (percentage) | 6.8     | 95.6          |
| Avg tokens                    | 232     | 228           |
| Avg AST depth                 | 12.9    | 9.8           |
| Avg AST nodes                 | 184     | 205           |

the hashed code vectors via a specific hash function for efficiency. It identifies code clone by comparing the hamming distance between hashed vectors. CDLH is not made public by the authors, so we directly cite their results from the paper as their experiments are made on the same datasets.

- (iii) ASTNN model [19]: the ASTNN model is a new code representation tool based on the AST parsing proposed by Zhang et al. in 2019. Their model first decomposes the corresponding ASTs into statement trees and then encodes them, respectively, with a recursive encoder. Finally, through a bidirectional LSTM network with a pooling layer, the statement vectors are transformed into a unified vector representing the given code fragment. The authors indicate that ASTNN is superior to the state-of-the-art models on baseline datasets. Inspired by ASTNN, our model divides the generated AST with the same algorithm. The authors also public their system on GitHub, but we failed to repeat their experiments due to the hardware environment. We directly refer to their experimental result for a contrast in our paper.

Figure 6 shows the comparison of At-biLSTM and three models mentioned above on the OJClone dataset. We see that both the precision and recall rates of RAE and CDLH are relatively poor. It is because that OJClone contains only T3 and T4 clones, and RAE and CDLH are not good at detecting heterogeneous clone pairs. The detection performance of At-BiLSTM and ASTNN are much higher than the former models. At-BiLSTM is better than ASTNN in the aspect of recall rate, while ASTNN is superior in classification precision.

Figure 7 shows the experimental result of At-biLSTM and other models on the BigCloneBench dataset. We see that the classification performance of RAE and CDLH is better on BigCloneBench, as BigCloneBench contains many T1 and T2 clone pairs. Both of RAE and CDLH can detect low-level clone pairs, so their classification precision and recall rates are improved. At-biLSTM and ASTNN once again take the lead in the classification performance. Due to the excellent recall rate, the F1 value of At-BiLSTM is slightly higher than ASTNN, which means At-biLSTM can find more clone pairs in the candidate set.

The big size of generated ASTs, which is shown in Table 2, strengthens the effect of long-term dependency in the process of embedding. The lines of the code (LOC) play an important role in the identification of clone pairs. In BigCloneBench, more than 4.1% code fragments contain more

than 100 statements. We decide to investigate the performance of these classifiers by collecting codes with different lines. Figure 8 shows the classification performance of 4 models according to LOC in BigCloneBench. The X-axis in Figure 8 indicates LOC, which is represented by the lines of the longer code in the given clone pair. The Y-axis indicates the classification performance of the given model. It is clearly evident from Figure 8 that the precision rates of most classifiers reach the peak when the LOC is between 20 and 30. As the LOC increase, the precision rates decrease. In general, the performance of ASTNN and At-BiLSTM are superior to RAE and CDLH. The classifying precision of ASTNN is highest among all the models when LOC is below 50, but it fails to take lead when dealing with complicated codes (LOC > 90). The performance curve of At-BiLSTM is relatively gentle with the increase of LOC. The precision rate of At-BiLSTM overwhelms the other models when LOC is above 70. We guess the attention technique involved in At-BiLSTM has successfully weakened the impact of long-term dependency in the LSTM structure. All the nodes in the long chain are taken into account during embedding with the help of various attention scores.

## 6. Discussion

In this chapter, we take a discussion about the performance of At-BiLSTM and other popular detection models based on the contrast experiments in Section 5. We try to find the key components which affect the classification of At-biLSTM by further experiments.

*6.1. Comparing with Baseline Models.* Compared to other baseline models, we conclude from the experiments that the At-biLSTM model has excellent classification precision and recall rate in code clone detection. The performance of RAE and CDLH is not satisfying since they are both affected by long-term dependence and might lose details in the process of source code representation. ASTNN adopts the strategy of subtree decomposition and recursive encoding, combined with a bidirectional LSTM to leverage the naturalness of statements. The representation model of ASTNN not only reduces the depth of syntax trees but also employs the natural sequence of statements in the code. At-biLSTM decomposes the whole AST into a sequence of statement trees in the same way as ASTNN does. However, we apply a depth-first traversal algorithm in the encoding of statement trees instead of a recursive traversal algorithm which is more complicated in ASTNN. The use of self-attention mechanism in At-biLSTM strengthens the effects of core statements in the clone classification. Experimental results show that At-biLSTM is superior to other baseline models in the detection of type 3 and type 4 clone.

*6.2. The Splitting Granularity of ASTs.* Most of the current approaches [12, 13, 16, 23, 33] based on the AST analysis identify the code clone pairs by traversing the complete AST. In order to evaluate the splitting strategy of At-biLSTM, we conduct contrast experiments on the same dataset. The

FIGURE 6: Code clone detection models on OJClone.

FIGURE 7: Code clone detection models on BigCloneBench.

FIGURE 8: Precision of code clone detection models according to LOC.

original AST is decomposed with three different strategies according to the splitting granularity. (1) Model 1: we treat the whole AST as a special statement tree. It is encoded directly by the statement tree encoding algorithm in Section 4.3 without any splitting, and then the classifier predicts the

code clone by comparing the similarity of AST vectors without self-attention. (2) Model 2: we use At-biLSTM to identify code clones. (3) Model 3: we split the AST according to blocks (compound statements including multiple statements within the same brace pairs), e.g., the tree rooted by

TABLE 3: Classification performance depending on AST splitting methods (percentage).

| Description         | F1 score (BigCloneBench) | F1 score (OJClone) |
|---------------------|--------------------------|--------------------|

| Self-attention layer with no parameters | 92.4                     | 91.7               |
| At-BiLSTM                               | 94.3                     | 95.8               |

TryStatement is not divided into subtrees in Model 3. After splitting, the following encoding processes are the same as those in At-biLSTM. Table 3 shows the classification results of these models.

Through the above experimental results, it can be observed that model 1 shows the poorest performance for classification, as it fails to extract the structural information hidden in the AST. The hierarchy of the original AST is too complicated, leading to the long-term dependency problem in the process of encoding. All the statements in the code fragment are evaluated equally by the classifier without the self-attention layer. Model 3 treats the compound statement as an independent statement tree instead of making a further division. The performance of model 3 is close to At-biLSTM. We guess that At-biLSTM achieves the best performance because the splitting of our model better retains the semantic information of the AST.

**6.3. The Use of Self-Attention.** The use of self-attention layer, which stresses the effect of key statements in source clone detection, is a great innovation in our paper. In this section, we investigate the effect of self-attention layers on the classification performance by experiments. We collect data from three independent experiments, as shown in Table 4. The structures of these detection models are the same except the self-attention layers. The first model does not include the self-attention layer, and the vectors representing the code fragments are directly generated with a bidirectional LSTM network. The structure of the second classifier is the same with At-biLSTM, except that it computes the self-attention scores in another way, as shown in equation (13). It is another common calculation for self-attention scores, which is relatively simple without the introduction of other parameters in the model. The attention scores are calculated directly according to equation (13) without the training of parameters  $K$ . The rest part of the second model is the same as At-biLSTM except that all the attention scores of hidden vectors are computed according to equation (13). The third model is At-biLSTM, which trains the self-attention parameters, together with other parameters of the model in a supervised way.

Table 4 shows that the self-attention layer greatly improves the classification performance of the model. The contributions of different statements are various in high-

level programming languages. The core statements implementing the logical functionality are more important than the normal ones. The encoder with self-attention layers can strengthen the effectiveness of core statements in classification and weaken the impact of common statements such as variable declaration. The last two rows of Table 4 are the F1 scores of models implemented with two different self-attention algorithms, from which we find that the classification performances are slightly different. The performance of At-BiLSTM is higher when involving an independent parameter  $K$  in equation (6). We suspect that the classification performance of the second model is slightly affected due to the lack of some adjustments to the input when calculating the attention scores:

$$\alpha_i = \frac{\exp(h_i^T h_i)}{\sum_i \exp(h_i^T h_i)}. \quad (13)$$

**6.4. The GRU.** In the representation model of At-BiLSTM, we use LSTM by default. We have also made experiments by replacing LSTM with Gated Recurrent Units (GRU) in our model. Figure 9 shows the classification performance and training time of our model implemented with LSTM and GRU respectively in the dataset BigCloneBench. We find the GRU model has a slightly poor but comparative performance. However, the training of the GRU model is more efficient than the LSTM model as the structure of GRU is simplified according to LSTM. The researchers have to make a trade-off between the classifier’s precision and efficiency.

The threats to the validity stem from the datasets used in our experiments. The most popular datasets employed in the area of code clone detection are BigCloneBench and OJClone, as the clone data are difficult to accumulate. The data labels in BigCloneBench are considered to be correct, all of which are inspected manually. However, there are only 10 kinds of clone data in BigCloneBench, which are much fewer than those existing in the real world. The data in OJClone was collected for program classification in the beginning. Lack of domain knowledge, we cannot guarantee the programming solutions to the same question are of the same clone class, nor the answers to various questions are of different clone classes.

FIGURE 9: Performance of At-BiLSTM with LSTM and GRU on BigCloneBench.

## 7. Conclusion

In this paper, we have presented a novel source code clone detection model At-BiLSTM based on deep learning with self-attention mechanism, which successfully captures both the syntactic and semantic information of the code in the process of encoding. At-BiLSTM contains a representation model and a discriminative model. The contributions of core statements are deeply enhanced with the introduction of self-attention mechanism. Contrast experiments show that our model significantly outperforms most of the existing neural network models, especially in the detection of type 3 and type 4 clones.

We will focus on two aspects in the future. Firstly, the At-BiLSTM should be used to detect large-scale code clone. At present, both the algorithms for clone detection and data collected in the labs cannot be applied in the real world. We will study and improve the performance of At-BiLSTM in industry. Secondly, the source code representation model embedded in At-BiLSTM will be applied in different areas of software engineering, as the representation algorithm is general and cross platform. For future work, we plan to extend our representation algorithm to new applications in software engineering such as source code classification, code completion, code comment generation, and deep code search.

In order to remedy problems encompassing large-scale data being collected by photovoltaic (PV) stations, multiple dimensions of power prediction mode input, noise, slow model convergence speed, and poor precision, a power prediction model that combines the Candid Covariance-free Incremental Principal Component Analysis (CCIPCA) with Long Short-Term Memory (LSTM) network was proposed in this study. The corresponding model uses factor correlation coefficient to evaluate the factors that affect PV generation and obtains the most critical factor of PV generation. Then, it uses CCIPCA to reduce the dimension of PV super large-scale data to the factor dimension, avoiding the complex calculation of covariance matrix of algorithms such as Principal Component Analysis (PCA) and to some extent eliminating the influence of noise made by PV generation data acquisition equipment and transmission equipment such as sensors. The training speed and convergence speed of LSTM are improved by the dimension-reduced data. The PV generation data of a certain power station over a period is collected from SolarGIS as sample data. The model is compared with Markov chain power generation prediction model and GA-BP power generation prediction model. The experimental results indicate that the generation prediction error of the model is less than 3%.

## 1. Introduction

With the gradual implementation of the “Internet + energy” policy, the PV generation industry is rapidly developing. The proposed incorporation of artificial intelligence has instilled new incentives for the PV generation industry. PV generation is susceptible to influence from extreme weather, distorting the predicted results and adding trouble in dispatching when the power system is connected to the grid [1], which may even lead to power resource wastage. Numerous methods in artificial intelligence exist for photovoltaic generation prediction such as support vector machines [2], Markov chains [3], and neural networks. Neural networks are widely used in PV generation prediction, and a number of power generation prediction models have surfaced to this effect, including neural networks based on time series [4], GA-BP neural network [5], deep belief network [6], and fuzzy neural

network [7]. Such models find it difficult to overcome issues in convergence and local optimization, and they suffer from large prediction errors, mainly because many network input compositions are present, along with noises in the sample data. Various scholars have used principal component analysis (PCA) [8] and other algorithms to preprocess the collected data; however, PCA and other algorithms find it difficult to process large amounts of data collected in real time due to their own defects. In view of the above problem, this paper adopted CCIPCA, which is suitable in analysing large data sets to extract key data affecting power generation prediction, to reduce dimensions in data and eliminate noise. Simultaneously, combined with LSTM [9], a power generation prediction model was established to overcome problems such as local convergence and slow training speed, controlling the prediction error of PV generation within 3%.

## 2. Relevant Works

**2.1. Analysis of Correlation Factors in Power Generation Prediction.** The sample data adopted the data of PV station no. 11282, Zhangdian District, Zibo City, Shandong Province, China, which was provided by SolarGIS. Its geographical location is 118 degrees east longitude and 32 degrees north latitude. The data includes total solar radiation data such as horizontal radiation GHI and normal direct radiation DNI and meteorological parameters like temperature, humidity, and pressure, as well as environmental parameters such as elevation, surface inclination angle, and surface azimuth angle. There were a total of 37 dimensions and 30 minutes of resolution.

Considering that parameters like geographical location are constant and have little influence on power generation prediction, the prediction model will not be considered. Meteorological and historical power generation data were taken as the main influencing factors of the model, including power generation every 30 minutes, power generation at the moment in history, environmental temperature, environmental humidity, wind speed, wind direction, radiation amount, and other indicators. According to formula (1), the correlation analysis of the evaluation factors was carried out:

$$\zeta = \frac{\sum_{i=1}^N (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^N (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^N (y_i - \bar{y})^2}} \quad (1)$$

In Figure 1, the linear features denoted by (a) and (b) are consistent, which are either a line segment or a part of an object without any difference. However, given the overall information, the information represented by (c) is completely inconsistent. Thus, the question of how to extract this nonlinear feature effectively is raised. This question is determined by the micro network structure embedded in NIN network, that is, a full connection layer consisting of two layers of convolution. In the neural network, two-layer fully connected hidden neurons are capable of approximating arbitrary curves, where  $\zeta$  is the correlation coefficient,  $x_i$  is the  $i$ -th value of factor  $x$ ,  $\bar{x}$  is the mean of factor  $x$ ,  $y_i$  is the  $i$ -th value of factor  $y$ , and  $\bar{y}$  is the mean of factor  $y$ . Table 1 shows the correlation coefficient analysis of PV generation with meteorological factors and historical power generation.

Table 1 demonstrates that electricity generation is highly correlated with solar radiation and historical electricity generation, valued at 0.92 and 0.86, respectively. Moreover, it had a moderate correlation with environmental temperature of 0.56 and had a weak correlation with wind direction and wind speed, though it was found to be negatively correlated with environmental humidity. Therefore, the prediction model adopted environmental temperature, environmental humidity, solar radiation, and historical power generation as its input components, and the correlation between various input components was observed to be strong; hence, carrying out a principal component analysis was required.

**2.2. CCIPCA.** Due to the advent of big data in PV generation, data preprocessing is particularly important. The PV generation system possesses a simple structure; however, it contains a large amount of equipment and has many failure-prone points. Additionally, the collected data has noise, which introduces obstacles in processing big data. The traditional principal component analysis (PCA) reduces dimensions by eliminating data in the dimension having small variance, which maximizes the information of the original data and removes noise to a certain extent. However, PCA must input all sample data before starting the analysis, which does not align with the objectives of big data; hence, the Candid Covariance-free Incremental Principal Component Analysis (CCIPCA) method was proposed. Unlike the batch method, which uses the covariance matrix to calculate eigenvalues and eigenvectors, CCIPCA initially eliminates the calculation of the covariance matrix using the asymptotic method to estimate the principal component values obtained by approximating the batch method. This data processing technique satisfies the requirements of photovoltaic data processing.

Recently, research related to incremental principal component analysis has been ongoing. Oja and Karhunen et al. proposed the SGA algorithm [10], where, after receiving new sample data, the algorithm continuously refreshes the estimated value of feature vectors and normalizes the new estimated value with all of the previous feature vectors. Sanger put forward the GHA algorithm, which uses a single-layer linear neural network to extract principal elements [11]. Furthermore, Weng et al. described the CCIPCA algorithm [12], which is comprised of the following framework: gradually obtain data  $x_1, x_2, \dots, x_n, \dots$  and calculate the previous  $k$  principal elements  $v_{1n}, v_{2n}, \dots, v_{kn}$ . The calculation process of CCIPCA is given below.

According to derivation of PCA by the maximum variance theory [13], the total variance  $A$  of the data set  $X$  projected along a unit vector  $w$  is obtained as follows:

$$A = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})(x_i - \bar{x})^T = \frac{1}{n} \sum_{i=1}^n u_i u_i^T, \quad (2)$$

where  $\bar{x}$  denotes the mean of data set  $X$ ; that is  $\bar{x} = ((\sum_{i=1}^n x_i)/n)$ ,  $u_i = x_i - \bar{x}$ , and  $A$  denotes the covariance matrix of data set  $X$  (the general covariance matrix is divided by  $n - 1$ , where  $n$  is used).

The calculation formula of the  $i$ -th eigenvalue and the  $i$ -th eigenvector is as follows:

$$\lambda_{in} w_{in} = A w_{in}, \quad (3)$$

where  $w_{in}$  denotes the  $n$ -th eigenvector to be calculated at the  $i$ -th input and  $\lambda_{in}$  denotes the corresponding eigenvalue. In order to speed up the iteration of CCIPCA algorithm, the whole iteration is based on the product  $\lambda_{in} w_{in}$  of eigenvalues and eigenvectors. When the  $i$ -th data is input, the following formula is obtained:

$$v_{in} = \lambda_{in} w_{in} = A w_{in}. \quad (4)$$

ET: environment temperature; EH: environment humidity; WS: wind speed; WD: wind direction; RQ: radiation quantity; HQ: historical quantity; PG: power generation.

Based on formulae (2) and (4),

$$v_{in} = \frac{1}{n} \sum_{i=1}^n u_i u_i^T w_{in}. \quad (5)$$

The product  $v_{in}$  of eigenvalue and eigenvector is obtained by iteration. As the eigenvector is normalized,  $\lambda_{in}$  and  $w_{in}$  can be separately obtained with  $\|v_{in}\|$  and  $(v_{in}/\|v_{in}\|)$ .

Formula (5) uses  $(v_{i,n-1}/\|v_{i,n-1}\|)$  to approximate  $w_{in}$  and replace it. The basic iterative formula of CCIPCA can be obtained by transformation.

$$v_{in} = \frac{n-1}{n} v_{i,n-1} + \frac{1}{n} u_n u_n^T \frac{v_{i,n-1}}{\|v_{i,n-1}\|}, \quad (6)$$

where  $(n-1/n)$  denotes the weight of the previous iteration value  $v_{i,n-1}$  and  $(1/n)$  denotes the adjustment step size of the iteration.

With the adjustment of the iteration vector  $v_{in}$  by the new input data  $u_n$ , that is,  $u_n = x_n - \bar{x}$ ,  $v_{in}$  gradually converges to the  $i$ -th eigenvector. For different  $v_i$ , formula (6) can be used for iteration with the different input vectors  $u_n$ .

The first eigenvector has been obtained by iteration. Firstly,  $u_{1n} = u_n$  is projected onto the previous eigenvector (now the first eigenvector), and the residual data is obtained as follows:

$$u_{2n} = u_{1n} - u_{1n}^T \frac{v_{1n}}{\|v_{1n}\|} \frac{v_{1n}}{\|v_{1n}\|}. \quad (7)$$

$u_{2n}$  denotes the output of the second eigenvector. The third and fourth eigenvector can be similarly obtained. Since the residual data is orthogonal to the data recovered from the previous eigenvector, all orthogonal eigenvectors can be obtained. In addition, the mean should be updated every time when a new data is input. The mean of the  $n$ -th data input adopts the following iterative formula:

$$\bar{x}_n = \frac{n-1}{n} \bar{x}_{n-1} + \frac{1}{n} u_n^T. \quad (8)$$

The CCIPCA solution process is summarized in Algorithm 1.

The CCIPCA algorithm has been widely used in the field of big data processing as well as the decomposition of large matrices due to its good convergence, which has achieved beneficial results. Meanwhile, as a benchmark algorithm, CCIPCA has been cited in various incremental algorithms. In this paper, it was applied in big data preprocessing of the PV station with a time dimension to make up for PCA preprocessing defects.

**2.3. LSTM.** In recent years, the improvement of LSTM has been continuously carried out. Yao et al. [14] proposed an improved NLP method based on Long Short-Term Memory (LSTM) structure, whose parameters are randomly discarded when they are passed backwards in the recursive projection layer, and it is used to overcome practical problems, such as high training complexity, computational

```

Input data:
  original data sequence  $x_1, x_2, \dots, x_n, \dots$ ,
  % the algorithm can pause the output of projection matrix at any time.
  dimension of low-dimensional space  $k$ .
Initialization:  $\bar{x}_0 = 0$ 
Output: projection matrix  $W^* = \{w_1 = (v_1/\|v_1\|), w_2 = (v_2/\|v_2\|), \dots, w_k = (v_k/\|v_k\|)\}$ 
Iteration steps:
  For  $n = 1, 2, \dots$ , % Run the following steps to update  $k$  feature vectors
     $u_{1n} = u_n = x_n - \bar{x}_{n-1}$ ;
    If  $n == 1$ :  $\bar{x}_n = \bar{x}_{n-1} + u_n^T$ 
    Else:  $\bar{x}_n = (n-1/n)\bar{x}_{n-1} + (1/n)u_n^T$ ; % Update mean vector
    For  $i = 1, 2, \dots, \min\{k, n\}$  do:
      (a) If  $i = n$ :  $v_{in} = u_{in}$ ; % Initialize the  $i$ -th eigenvector
      (b) Otherwise:
         $v_{in} = (n-1/n)v_{i,n-1} + (1/n)u_{in}u_{in}^T(v_{i,n-1}/\|v_{i,n-1}\|)$ 
         $u_{i+1,n} = u_{in} - u_{in}^T(v_{in}/\|v_{in}\|)(v_{in}/\|v_{in}\|)$ 

```

ALGORITHM 1: CCIPCA solution process.

difficulties in large-scale content scenarios, high retrieval complexity, and lack of probabilistic significance. Tian et al. [15] proposed a hybrid prediction modelling strategy by combining the autocorrelation local characteristic-scale decomposition and the improved LSTM neural network. Zhang et al. [16] proposed a LSTM approach for bearing performance degradation evaluation. Numerical results show that the proposed LSTM method can effectively predict the remaining service life of the bearing. Li et al. [17] proposed a LSTM method for fault diagnosis and isolation of wind turbine, where stochastic forest algorithm is applied to make decision. Liu et al. [18] combined probabilistic decision-making methods and proposed a Bayesian LSTM algorithm for intelligent fault early-warning of nuclear power machinery. Mirza et al. [19] introduce efficient online learning algorithms based on the Long Short-Term Memory (LSTM) networks that employ the covariance information. They reduce the number of system parameters through the weight matrix factorization, where they convert the LSTM weight matrices into two smaller matrices in order to achieve high learning performance with low computational complexity.

LSTM is an evolutionary version of RNN, which effectively addresses the issue of long-term dependence of effective information in time series and has been broadly applied for different fields. In comparison to other models, the LSTM method is more sensitive to the trivial features in the historical data, easier to capture the details, suitable for big data processing, and more accurate in time series prediction. LSTM replaces the hidden layer of neurons in RNN with a memory unit to record the dependency relationship between time series data, which then rids itself of problems like gradient disappearance and gradient explosion occurring in RNN. LSTM utilizes a “gate” to control information selection. Compared with a dropout operation, this process is not random, though it implements Boolean selection based on sigmoid operation results with “0” signifying the

forgetting of information and “1” meaning the remembering of information. The LSTM structure includes three gate structures that adjust the information flow, namely, the forgotten gate, input gate, and output gate, as shown in Figure 1.

The forgotten gate determines the degree to which the unit state  $K_{t-1}$  at the last time is retained to the current state  $K_t$ , which is calculated as

$$f_t = \text{Sigmoid}(W_f[h_{t-1}, x_t] + c_f), \quad (9)$$

where  $f_t$  is the output value and the bias of the forgotten gate.

The input gate controls the extent to which network input  $x_t$  is saved to the cell state  $K_t$  at the previous time, which is calculated as

$$\begin{aligned} K_t &= f_t c_t + i_t \tilde{K}_t, \\ i_t &= \text{Sigmoid}(W_i[h_{t-1}, x_t] + c_i), \\ \tilde{K}_t &= \tanh(W_k[h_{t-1}, x_t] + c_k). \end{aligned} \quad (10)$$

The output gate controls the current output value  $h_t$  of unit state  $K_t$  outputting to LSTM, which is calculated as

$$\begin{aligned} o_t &= \text{Sigmoid}(W_o[h_{t-1}, x_t] + c_o), \\ h_t &= o_t \tanh(K_t). \end{aligned} \quad (11)$$

If the output value has reached the threshold value required by the memory unit, the product of the output value with the calculated value of the current layer is taken as the output, and the calculation is carried out in the next layer. If the threshold is not reached, the memory unit will forget it.

Different from the traditional RNN, LSTM can solve the issues of gradient disappearance and gradient explosion in the training process, yielding more accurate prediction of a long-term time series. LSTM is developed to address data uncertainty while considering complicated situation of the operation.

### 3. PV Generation Prediction

**3.1. Process of PV Generation Prediction.** Power generation prediction conducted by CCIPCA combined with LSTM conforms to current trends in photovoltaic big data. The prediction process initially processes the CCIPCA algorithm for the collected big data samples, which then establishes the LSTM networks and implements the training of the sample data on the LSTM network. After completion, the sample data is input in order to acquire the prediction results output, as shown in Figure 2. When training big data samples, it is necessary to continuously tune the discarded neuron probability, attenuation rate, and learning rate.

**3.2. Data Source and Preprocessing.** SolarGIS is a solar resource assessment tool developed by SolarGIS S.R.O. in Europe, which uses satellite remote sensing data, GIS technology, and advanced scientific algorithms to obtain a high-resolution database of solar resources and climatic factors. In this paper, data from January 1, 2014, to December 31, 2019, were collected from the SolarGIS database as sample data, of which its volume reached 39.4 PB. Using formula (1), the data within a certain period were used for factor correlation evaluation, and factors with an absolute value coefficient above 0.2 were selected. In addition to selecting highly correlated factors, this paper also required two historical PV power generation horizontal and vertical mean data as the model's input sequences to control the disturbance brought about by extreme weather, as extreme weather is a gradual process that takes place in a short amount of time. The formulae are as follows:

$$\begin{aligned}\bar{Q}_k &= \frac{(Q_{k-1} + \dots + Q_{k-m})}{m}, \\ \bar{Q}'_k &= \frac{(Q'_{k-1} + \dots + Q'_{k-n})}{n},\end{aligned}\quad (12)$$

where  $Q_{k-i}$ ,  $i = 1, 2, 3, \dots, m$ , represents the generating capacity of the previous continuous time units and  $\bar{Q}_k$  represents the average of horizontal generating capacity.  $\bar{Q}'_k$  is the average vertical generating capacity of the same time unit before the previous day and  $Q'_{k-i}$ ,  $i = 1, 2, 3, \dots, n$ , is the electrical generation of the previous  $n$  days.

Actual power generation always fluctuates around the mean curve of the horizontal and vertical power generation, which can be used as a stable factor in the prediction model to eliminate the interference of extreme weather in power generation prediction. Although weather conditions are very sporadic, the seasonal law always changes with Earth's revolution and rotation.

Here, the horizontal mean of the first 10 time units and the vertical mean of the same time unit of the first 5 days were selected as the input. This was done because if the number choices were more, the average value would change significantly, which was not conducive to the stability of the prediction model. If there were fewer number choices, the average value would not change significantly, which was not conducive to measuring the impact of extreme weather

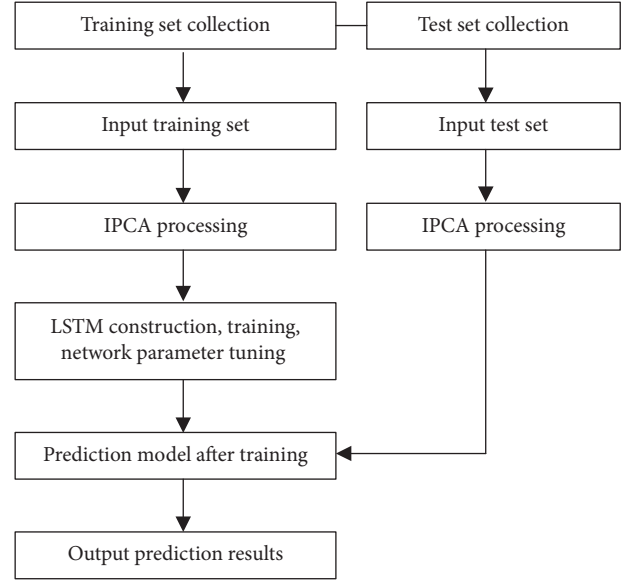

FIGURE 2: Flow chart of power generation prediction by IPCA combined with LSTM.

changes on the prediction model, resulting in inaccuracies of prediction.

After correlation coefficient analysis, the dimension of sample data was reduced to 18. Some sample data are listed in Table 2. After the sample data were sorted, the data was preprocessed with Z-Score standardization to eliminate influences from different feature dimensions and improve the convergence speed of the model. Following completion of the prediction, a reverse operation would be carried out to achieve the real predicted value recovery. Subsequently, CCIPCA was preprocessed to map the sample data to dimensions set by the investigators, such as solar radiation amount and historical power generation. Finally, orthogonalization removed influences in the relationship between noise and dimensions.

Solar radiation adopts two aspects: global horizontal radiation (GHI) and direct normal radiation (DNI). Meteorological parameters are air temperature (TEMP) at 2 m, RH, average WS and WD at 10 m, precipitation RH, and atmospheric pressure.

CCIPCA preprocessing was implemented. 48 pieces of data on June 6, 2019, were used as data series input one by one. The low-dimensional spatial dimension was set to 18. The eigenvector and eigenvalue were calculated, and principal component analysis was conducted to remove the influence of noise and the relationship between dimensions. The results of principal component analysis are shown in Table 3.

It can be determined from Table 3 that the cumulative variance contribution rate of the first six eigenvalues is more than 80%. Therefore, six principal components were selected, and the corresponding eigenvectors of the six principal components were selected to construct the transformation matrix. The original data and the transformation matrix are calculated, and the input variables obtained were input into LSTM for prediction.

**3.3. Evaluation Indexes.** After the completion of the model training, the generation capacity of the PV station in 1 day of continuous time was selected for prediction to judge the accuracy and efficacy of the entire model. Here, the mean square error was used as a loss function to test and measure the model's efficacy. The mean square error was calculated as

$$\text{MSE} = \frac{1}{m} \sum_{i=1}^m (y_i - \hat{y}_{ii})^2, \quad (13)$$

where MSE is the mean square error,  $y_i$  is the actual power generation at time  $I$ ,  $\hat{y}_i$  is the prediction value of the model at time  $I$ , and  $m$  is the amount of sample data. Accordingly, the smaller the mean square error, the higher the model precision.

In addition, the maximum error was used to measure the prediction error range of the model. The larger the value of ME, the worse the accuracy of the model, which was computed as

$$\text{ME} = \max \left\{ \frac{|y_i - \hat{y}_i|}{y_i}, \quad i = 1, 2, 3, \dots, m \right\}. \quad (14)$$

**3.4. Model Building and Experimental Results Analysis.** The experimental environment is Intel i9 processor, Linux + anaconda3 + tensorflow2.0 platform, Spyder software, and Python 3.7 programming language.

The LSTM model structure determines the optimization and prediction accuracy of the training process. In this paper, the LSTM network structure having 4 hidden layers of LSTM and 1 ordinary layer was adopted. The number of neurons in each layer was 512, 256, 128, and 64, respectively.

Specifically, 64 neurons were used as the ordinary layer, and dropout operations were used between layers. The overall structure of LSTM is shown in Figure 3.

Relevant literature discusses the setting of training parameters of LSTM. When the learning rate and attenuation rate are different, the network performance is not the same, and the prediction effect is also different. If LSTM has dropout layers, the probability of dropping neurons is also the key to parameter optimization. According to the comprehensive literature [9, 11], the learning rate is generally small, or the learning rate is degraded dynamically; that is, when the accuracy rate in the network training process is no longer improved, the learning rate will be reduced to one-tenth of the original or lower. The probability of discarded neurons is 0.2 and its vicinity, and the decay rate is 0.9 and its vicinity.

The data taken between 2014 and 2018 were used as the training set, while the data taken from 2019 acted as the test set. After the sample data were standardized, PCA and CCIPCA pretreatment were performed, respectively, and training and testing were conducted on the LSTM. The probability of dropping neurons in the dropout layer was {0.1, 0.2, 0.3}; the attenuation rate was {0.8, 0.9} and the learning rate was 0.001. Moreover, the number of training iterations was 100. The experimental results are shown in Table 4.

Table 4 demonstrates that the prediction accuracy of power generation obtained after CCIPCA processing of the sample data was better than that of PCA + LSTM and LSTM. The LSTM model of  $N = 0.3$  and  $P = 0.9$  was selected to draw the loss function value curve of the training set after 100 iterations. As shown in Figure 4, CCIPCA + LSTM exhibited better convergence as well as a better convergence rate than that of LSTM and PCA + LSTM.

| CCIPCA + LSTM | 0.062     | 0.059     | 0.046     | 0.048     | 0.044     | 0.041     |

FIGURE 4: Loss function curve of training set and test set.

From the period of 2019, multidays data were selected as test sets in different seasons, and the prediction accuracy of the model was compared with the real power generation.

The data from January 3, 2019, was selected as the test set for comparison with the actual power generation, as shown in Figure 5(a). According to the record, it was light snow, but it was heavy snow three days ago and it turned to clear up after 14:00. On that day, the temperature range was  $-2\text{--}4^\circ\text{C}$ , with no wind, the wind speed range was  $0\text{--}0.4\text{ m/s}$ , and the

absolute humidity was  $1.02\text{--}1.70\text{ g/m}^3$ . Then, the data from January 4, 2019, was selected to verify the model, as shown in Figure 5(b). It was sunny, accompanied by weak solar radiation and breeze, temperature range was  $-5\text{--}1^\circ\text{C}$ , wind speed range was  $0.6\text{--}1\text{ m/s}$ , and the humidity was the same as the previous day.

The meteorological conditions on January 3 and January 4 were similar, and the difference between two days was solar radiation, and solar radiation on January 4 was stronger than that on January 3. Compared with Figures 5(a) and 5(b), the peak of power generation on January 4 was much higher than that on January 3, which indicates that solar radiation is an important factor in power generation prediction. It can also be found from the power generation prediction curve that the photovoltaic power generation efficiency was reduced accompanied by the solar radiation gradually weakening, since the sunlight irradiated the snow surface and reflected, and the ambient temperature sharply dropped in relative to normal times after 14:00 o'clock. When the night came, there was no sunlight and the ambient temperature dropped below zero, and the photovoltaic power generation was zero.

The data on April 3, 2019, were selected as the test set and compared with the real power generation, as shown in Figure 6. According to the data, April 3 was sunny, the temperature range was  $9\text{--}14^\circ\text{C}$ , the wind direction was strong, the wind speed ranged from  $17.2\text{ to }21\text{ m/s}$ , and the absolute humidity was  $2.7\text{--}3.2\text{ g/m}^3$ .

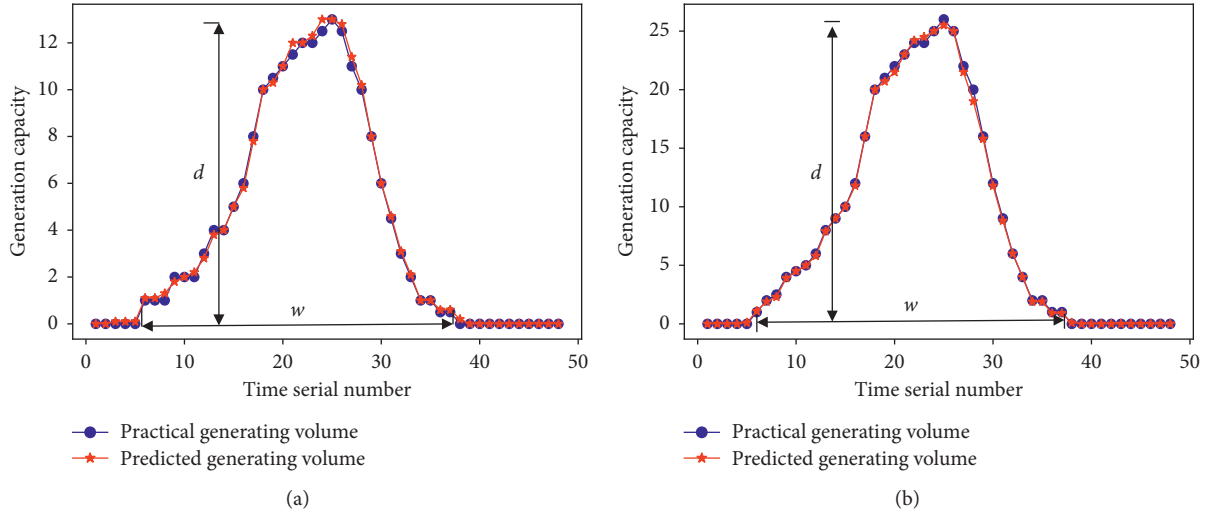

FIGURE 5: Power generation forecast of two days in winter. (a) Comparison between predicted curve and real value of power generation on January 3. (b) Comparison between predicted curve and real value of power generation on January 4. Note:  $w$  represents the time zone of daily effective generation and  $d$  represents the peak value of daily generation.

FIGURE 6: Forecast of one-day power generation in spring.

It can be found from Figure 6 that the predicted curve of the whole-day power generation was basically consistent with the real power generation curve, and the two curves were relatively smooth, which indicates that the power generation efficiency of photovoltaic equipment was not affected by wind direction and wind speed.

The data from July 7, 2019, were selected as the test set for comparison with the actual power generation. Figure 7 illustrates that the data recorded exhibited three thunderstorms and severe convection weather on July 7, with periods of 3: 00–4: 00, 7: 00–7: 30, and 14: 00–14: 30, respectively. The meteorological conditions were temperature range of 20–32°C, gust, wind speed of 10.8–13.8 m/s, and absolute humidity of 22.22–25.76 g/m<sup>3</sup>.

Figure 8 illustrates that the photovoltaic power generation efficiency is sensitive to the influence of solar radiation and ambient temperature. In the three periods of July 7, the solar radiation and environmental temperature changed rapidly, and the photovoltaic power generation also changed

rapidly. The prediction results of the model are basically consistent with the real power generation under the condition of rapid changes of photovoltaic power generation factors.

The data on November 11, 2019, were selected as the test set and compared with the real power generation, as shown in Figure 9. According to the record, it was sunny, the temperature range was 9–15°C, the breeze level was 2–3, the wind speed reached 3.1–4.0 m/s, and the absolute humidity was 1.08–2.12 g/m<sup>3</sup>.

From Figures 6 and 7, it can be found that photovoltaic power generation has some relationship with environmental humidity. The meteorological conditions on November 11 and April 3 were basically the same; only the environmental humidity was different, but the peaks of the two pictures were inconsistent, which indicates that the environmental humidity has a negative effect on photovoltaic power generation. On November 11, the environmental humidity was lower, but the power generation effect was better. On April 3, the humidity was higher, and the power generation effect was poor.

It can also be found from Figures 5–7 that the efficiency of photovoltaic power generation is higher in summer,  $d$  in Figure 5 was much higher than that in other graphs, and the photovoltaic power generation efficiency in winter is the worst. Furthermore,  $w$  in Figure 5 was much longer than that in other graphs, which indicates that the photovoltaic equipment uses more time to generate electricity in summer.

The 62-day power generation data from July 1, 2019, to August 31, 2019, were selected as the test set and compared with the real power generation; the prediction accuracy of the model is investigated. As shown in Figure 9, the curve between the actual power generation and the predicted power generation in 62 days was shown.

Figure 9 showed that the two curves were relatively similar, indicating that the prediction accuracy of CCIPCA combined with LSTM was relatively high, and its prediction effect was satisfactory.

FIGURE 7: Forecast of one-day power generation in autumn.

FIGURE 8: One-day power generation forecast in summer.

FIGURE 9: Comparison of photovoltaic power generation forecast from July 1 to August 31.

In view of the practicability of the prediction model, horizontal experiments were conducted to compare the prediction model with the GA-BP neural network [21] and Markov chain model (MC) [22], as shown in Table 5.

By comparison, prediction effect of MC is not as good as neural network, while prediction effect of LSTM is higher than GA-BP network due to the advantage of network layer number, and the maximum error is 6.4%; under the

TABLE 5: ME comparison between models.

| Model | ME    | Model       | ME    | Model          | ME    |
|-------|-------|-------------|-------|----------------|-------|
| MC    | 0.074 | PCA + MC    | 0.052 | CCIPCA + MC    | 0.048 |
| GA-BP | 0.068 | PCA + GA-BP | 0.044 | CCIPCA + GA-BP | 0.032 |
| LSTM  | 0.064 | PCA + LSTM  | 0.040 | CCIPCA + LSTM  | 0.023 |

dimension reduction operation of PCA for photovoltaic data, the three prediction models are significantly improved, but, due to the limitations of PCA algorithm, the function mapping from high-dimensional space to low-dimensional space is linear. However, in many practical tasks, it may need nonlinear mapping to find the proper low-dimensional embedding, which leads to the poor dimensionality reduction effect of photovoltaic data. The prediction error of PCA combined with LSTM is 4%, which is higher than that of PCA combined with MC and GA-BP. However, the dimensionality reduction of PV data using IPCA avoids the complex covariance matrix calculation of PCA, and the regularization effect of IPCA is better than that of PCA, which is suitable for LSTM. The prediction error of IPCA combined with LSTM is 2.3%. In a word, the prediction model combining CCIPCA with LSTM displayed better prediction than other models, with an error range of prediction results within 3%.

#### 4. Conclusions

In view of issues such as data being collected by PV stations in a matter of minutes, daily data volume reaching the GB or PB level, data scale being large, multiple instances of data dimensions [23], and existence of noise [24], this paper proposed a prediction model for PV generation by combining CCIPCA with LSTM. According to the simulation of the proposed prediction model, the following conclusions were drawn:

- (1) CCIPCA has handled the super-large-scale data of PV station, realized the dimensionality reduction of data, made use of orthogonalization following dimensionality reduction of data, eliminated the influence of noise, and improved the convergence speed and training speed of the model.
- (2) During model training, the historical horizontal and vertical mean values of PV generation were added to eliminate the disturbance of extreme weather conditions on the model, and 48 sets of data from a certain day were selected for testing. The obtained results aligned with the real values of power generation, demonstrating the model's stable performance.
- (3) The model was compared to the other two PV generation prediction models horizontally, and the power generation prediction error was determined to be less than 3%, illustrating its practicality.

#### Data Availability

The SolarGIS data used to support the findings of this study are included within the article.

#### Additional Points

In the experiment, adopting SolarGIS Meteosat (EUMETSAT, DE) and GOES (NOAA, USA) radiation of satellite remote sensing data, combined with Meteosat (EUMETSAT, DE) and GOES (NOAA, USA) of cloud and snow index and Global Forecast System (GFS) database (NOAA, USA) of water vapor data, a series of meteorological elements including solar radiation and temperature value are calculated. Taking photovoltaic power station no. 11282 in Zhangdian district, Zibo city, Shandong province, China (118 east longitude, 32 north latitude), as an example, the generation data from 2014 to 2019 are selected/studied. All data can be downloaded from <http://solargis.cn>.

#### Disclosure

Some of the authors of this publication are also working on the following related projects: (1) higher vocational education teaching fusion production integration platform construction projects of Jiangsu province under Grant no. 2019 (26), (2) Natural Science Fund of Jiangsu Province under Grant no. In this paper, through the improved decision tree algorithm, the handles in multimedia English assistance are parsed and simulated. In order to better perceive the sense of language in English composition and improve the rationality of intelligent evaluation, an N element based on association analysis is proposed. Sense value quantification calculates its support in the corpus by obtaining N-tuples of the composition. If the degree of support is lower than the threshold, the part where the language sense problem occurs is analyzed, and the type of language sense problem is judged for the students to provide assistance in modifying the composition. In addition, this paper also extracts word features, sentence features, and text structure features in the composition to fit the English handles analytical score. By testing the test set, the experiment shows that, by extracting the language sense features of the candidate's English composition, it can not only judge whether there is a problem with the language sense of the candidate, but also provide a basis for the overall evaluation of the composition.

## 1. Introduction

With the rapid development of information technology, people can use mobile phones, handheld computers, and other handheld mobile devices to obtain, process, and send information at any time or place, so that communication is everywhere, information is everywhere, and we also rely on handheld mobile devices. Carrying out educational activities and transmitting educational information with wireless networks has provided the possibility for human lifelong learning [1]. In this era of the popularity of handheld mobile devices, especially smart phones and tablets, almost every college student has one. In this environment, where learning can be done anytime, anywhere, people's learning habits and behaviors are quietly changing, and fragmented learning has also become one of our main learning methods. The learner's pronunciation problem is influenced by the phonological system mainly in that pronunciation-related organs or pronunciation actions are not standard, and there are large differences in phoneme discrimination. Learners often pronounce by blind imitation. They cannot fundamentally recognize how

to pronounce correctly, and pronunciation problems cannot be found in time, and if they are not found, there is no feedback to correct them. Therefore, learners sometimes do not even know whether their pronunciation is standard. In order to ensure that your pronunciation is correct, there are many people who are willing to pay high tuition fees and ask foreign teachers to correct their pronunciation. With the popularity of online language learning, an automatic pronunciation error detection and correction system has been spawned [2]. At present, there are only a few products on the market that has pronunciation problems, and most of the functions are relatively simple. Learners can only imitate the audio and video learning materials played by follow-up, and then the system plays the recording. There are only a few software that has feedback for detecting spoken pronunciation, but the flaw is that the feedback function is not enough to solve the root problem of the learner [3]. This function is only available after the learner has followed the pronunciation. It can be pointed out that the learner's pronunciation is not good enough, but the learner cannot understand where his pronunciation is wrong, and how to improve the

pronunciation, so that the learner cannot get the most valuable feedback to correct the information, and often this does not improve the learner's oral ability [4, 5].

The current research related to providing guidance for logging statement-level decisions is not that rich. In the empirical research on long practice, Ji et al. found that the revision history of logging statements by developers accounted for 72% of the changes at the logging statement level, so a simple logging statement level check was designed [6]. Their checker principle is based on the observation if the log code in a similar code block has an inconsistent logging statement level. Pan infers part of the execution path by mapping log messages to source code [7]. Cai et al. analyzed the logs to understand the correct dependencies between log messages from normal execution and used this information to identify anomalies in failed execution [8]. In addition, machine learning and data mining technologies also show great potential in tracking the scale and complexity of large-scale system monitoring and diagnostic challenges [9, 10]. Some studies learn statistical features to detect and diagnose abnormalities. Lai and Chen used classification techniques to group similar log sequences into a set of classes based on certain string distance metrics [11].

Subecz Z first extracted  $n$  graphs as the features of the system call sequence and then used support vector machines to classify the trajectories according to the similarity of the trajectories of known problems [12]. Ma et al. introduced the specific implementation of the text classification system in detail, which provided a basis for the subsequent text classification research [13]. McLarnon and O'Neill produced the L1-L2MAP tool, which included manually input phoneme data and then used this data to create a list of expected pronunciation errors [14]. Similarly, for learners whose mother tongue is Vietnamese, Professor Ha's research team studied the common phoneme substitution errors between Vietnamese and English [15]. Yan studied the distinguishing characteristics of flat tongue and tongue-twisted sounds. The research results show that there is a big difference between the peaks of the spectrum energy. Therefore, the energy concentration segment is selected as the distinguishing feature to discriminate between flat tongue and tongue phonemes [16]. Ma and Chow studied the pronunciation of consonants by Japanese learners while learning English. The study shows that, due to the aspirated variants of unvoiced stop sounds in Japanese, the use of non-aspirated/aspirated feature as a distinctive pronunciation feature can well distinguish the categories of consonant pronunciation [17]. An improvement of 17.35% reduction in error rate can be achieved. Finally, they also applied this technology to the CAPT system [18].

At present, although there are many related researches on the location of logging statements, they provide corresponding guidance for developers in the industry, but the relevant content in the recording content is relatively insufficient. In order to fill the gap, it provides developers with practical work. Logging statement-level recommendation functions. This paper implements a text classification technology based on machine learning and recommends levels through code block-related features. The paper conducts a comprehensive research on text classification technology

based on machine learning. The process and the text reprocessing, text representation, spatial dimensionality reduction, classification method, and classification performance evaluation were analyzed and discussed. After that, we focus on the random forest algorithm in the classification algorithm and propose improvements based on the analysis of its principles and characteristics [19]. The improvement mainly includes two aspects: on one hand, the paper explores and optimizes the handle simulation mechanism of the decision tree classification algorithm, performs weighted handle simulation based on the classification effect and prediction probability of the decision tree, and uses the weighted handle simulation to improve the traditional random forest classification algorithm. In the handle simulation mechanism, and text classification experiments to verify the improved effect. On the other hand, the concept of hyperparameters in the algorithm and commonly used hyperparameter adjustment algorithms are introduced. Based on the analysis of text classification scenarios and the random forest algorithm, an algorithm based on random handle simulation and grid handle simulation is proposed to carry out the random forest algorithm. Parameter optimization and, finally, design experiments prove the effectiveness of the algorithm.

## 2. Improved Decision Tree Algorithm for Simulation Design of English Handle Resolution

*2.1. Improved Decision Tree Algorithm.* Decision tree algorithm is an instance-based inductive learning algorithm. It focuses on inferring the classification rules in a set of unordered and irregular examples, which are represented by decision trees. The purpose of constructing a decision tree is to get the relationship between attributes and categories and use this relationship to predict the category labels of samples of unknown categories. The algorithm uses a top-down recursive method, compares the attributes of the nodes within the decision tree, judges the branch of the node based on different attribute values, and draws conclusions from the leaf nodes of the decision tree. The main decision tree algorithms are ID3, C4.5 (C5.0), CART, PUBLIC, SLIQ, and SPRINT algorithms. The decision tree classification method has the advantages of processing both data-type and regular-type attributes, insensitivity to intermediate values, processing samples with missing attribute values, and easy to understand output results [20]. However, there are shortcomings that are prone to overfitting, and the results are biased toward features with more values, as shown in Figure 1. The decision tree algorithm is a meta-classifier of the random forest algorithm studied in this paper, which will be studied in more depth below.

There are various evaluation indicators according to different text classification application backgrounds. The metrics for classification performance evaluation include error rate, accuracy rate, recall rate, accuracy rate,  $F$  balance, microaverage and macroaverage, and ROC curve. The error rate is the proportion of samples with incorrect classification results to the total number of samples, and the accuracy rate is the proportion of samples with correct classification results to

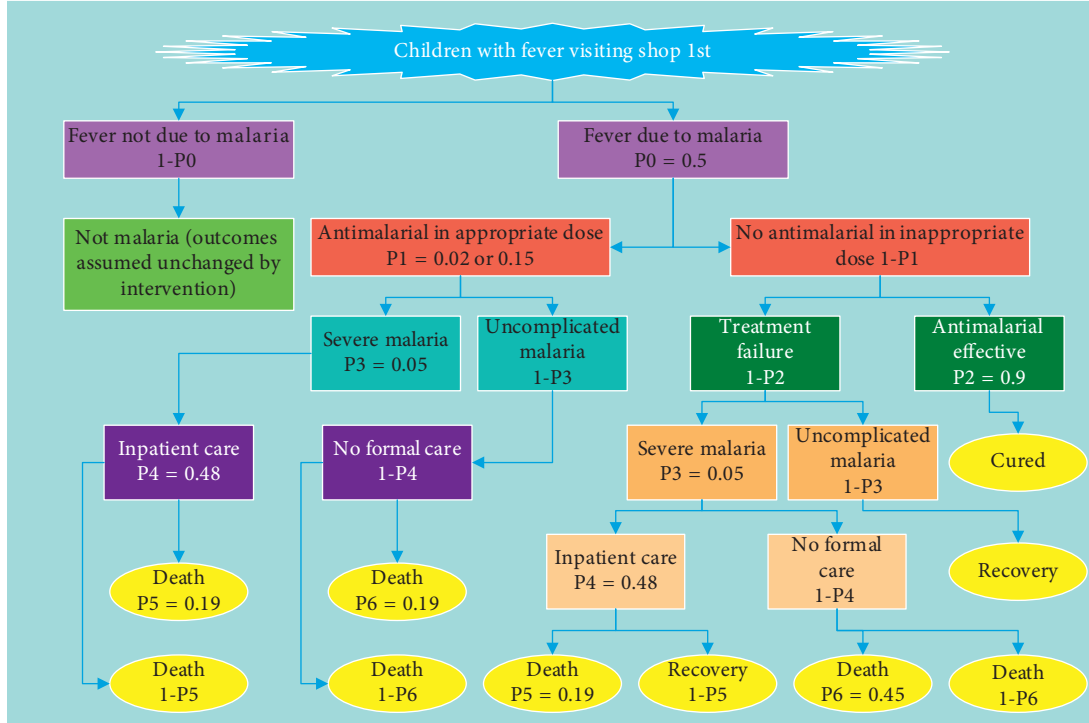

FIGURE 1: Improved decision tree algorithm model.

the total number of samples. They can be used for binary classification or multicategory. But this does not comprehensively reflect the performance of classification models, especially the problem of unbalanced classification [21]. The recall rate and accuracy rate can be calculated based on the confusion matrix established by the classification results. The confusion matrix is shown in Table 1. TP indicates that the text in category C is judged to belong to the text of category C, that is, the text with the correct classification result in category C. FP Text that does not belong to category C is judged to belong to category C; that is, text that is not classified in category C is incorrect, FN is the classification error in category C, and TN is the classification result in noncategory C. The recall rate is the ratio of the number of samples correctly judged to be in this category and the total number of samples belonging to this category, also called the recall (Recall), and the calculation method is formula (1).

$$\text{STFT}[A(t, w)] = \int_{-\infty}^{+\infty} a(\tau)g(\tau - t)e^{-jw\tau} d\tau. \quad (1)$$

Precision is the proportion of samples whose true category is C in the number of samples whose classification result is C, also known as the precision rate, and the calculation method is

$$R_m = \frac{E}{A \times F} * \beta. \quad (2)$$

$F$  equilibrium is an evaluation index that takes into account both the recall rate and the accuracy rate, and its calculation method is shown in formula (3), where  $\beta$  is a value greater than 0, as well as the accuracy and recall weight adjustment parameters.  $\beta < 1$  has a greater impact on the

accuracy rate, and  $\beta > 1$  has a greater impact on the recall rate. When  $\beta = 1$ , the recall rate and accuracy rate have the same weight, and the  $F$  equilibrium at this time is the  $F1$  indicator.

$$R_f = \frac{c}{A \times D} * \beta. \quad (3)$$

Microaverage and macroaverage are the evaluation indicators when evaluating the classifier on the entire data set. They average the results of all categories. They are different from the single-category classification evaluation indicators such as recall rate, accuracy rate, and  $F$  balance. The calculation methods of microaverage and macroaverage are formula (4) and formula (5), respectively. Micro-averaging first calculates the total number of instances with correct and incorrect classification results in all categories and then calculates the recall rate and accuracy rate of all categories. It also emphasizes the impact of the category with a larger number of samples on the overall result. Macroaverage first calculates the recall rate and accuracy rate of each category and then performs arithmetic average to get the recall rate and accuracy rate of all categories.

$$GJ_{ik} = \frac{GJ_{ik}^{jint}}{\sum_{i=1}^d GJ_{ik}^{jint}}, \quad (4)$$

$$D = \frac{(n-1)d_n}{\sum_{i=1}^{n-1} d_i}. \quad (5)$$

The full name of the ROC curve is the Receiver Operating Characteristic Curve, which is a curve in a two-dimensional plane. The horizontal coordinate of the plane is

TABLE 1: Classification result confusion matrix.

| Type                                    | Text for category C | Noncategory C text |
|---|---------------------|--------------------|
| Judge text that belongs to category C   | 14                  | 22                 |
| Text that does not belong to category C | 18                  | 42                 |

negative positive rate (False Positive Rate, FPR), which represents that the sample predicted by the classifier as positive is actually negative. The proportion of samples in all negative samples is True Positive Rate (TPR), which represents the proportion of actual positive samples to all positive samples in the samples predicted by the classifier as positive [22]. The ordinate is True Positive Rate (TPR), which represents the proportion of actual positive samples to all positive samples in the samples predicted by the classifier as positive. The curve is usually located on the coordinate lines (0, 0) and (1, 1), the area under the ROC curve is AUC, it is a number, and the effect of the classifier can be evaluated more intuitively. The larger the value, the better the classification effect.

The decision tree algorithm is the base classifier of the random forest. It is an inductive learning algorithm. It learns the classification rules in the form of a tree structure with a large number of samples without order and rules and uses this rule to predict unknown samples. The decision tree is composed of nodes and directed edges, and nodes have intermediate nodes and leaf nodes. Each intermediate node has 4 parameters. One is the decision function, which is the value of a feature. When the feature is less than or equal to this value, the decision path is to the left, and when the feature is greater than this value. The decision path is to the right. The second is the impurity value, which reflects the prediction ability of the current node. The third is the number of covered samples, which refer to the number of samples participating in the decision of this node. The more the covered samples, the more stable the decision functions.

The learning process of decision tree mainly includes feature selection, decision tree generation, and decision tree pruning. Feature selection is to select features from the features of the training data as the segmentation criteria of the current node, where different criteria for feature selection produce different decision tree algorithms. Decision tree generation is a recursive process that generates child nodes recursively from top to bottom according to the selected feature evaluation criteria and stops generating after reaching certain constraints. Pruning is because decision trees are prone to overfitting. To reduce overfitting of decision trees, methods such as prepruning and postpruning can be used to reduce the structure and size of the decision tree. The core algorithm for decision tree growth is the branching criterion, including how to select the best grouping variable from many variables, and how to select the best segmentation point of multiple values of the grouping variable. According to the different methods of decision tree node splitting, it can be divided into two categories; one is ID3, C4.5, and other decision trees based on information entropy splitting, and the other is the CART decision tree based on the Gini index classification.

The full name of CART is Classification and Regression Trees, which can do both classification and regression. It is a classification tree when the result to be predicted is a discrete value, and a regression tree when the result to be predicted is a continuous value. CART is a binary tree, and non-leaf nodes have two branches because it recursively divides the samples on the current node into two subsets during the node splitting process. CART uses the Gini coefficient when the nodes are split and uses the Gini coefficient minimization principle. The calculation method of the Gini coefficient is

$$k_{nm}(x) = \sum_{i=1}^N w_i s_i(x) = W^T S(x), \quad (6)$$

$$M^* = \arg \min \left\{ \sup_{x \in \Omega_x} |b(x) - W^T S(x)| \right\}. \quad (7)$$

Constraints for the decision tree to stop growing, that is, to no longer perform node splitting, include the node's impurity purity reaching the threshold, the node's sample number reaching the threshold, the attributes to be split reduced to a certain value, and the depth of the decision tree growing to a certain value.

*2.2. Design of Multimedia English Auxiliary Handle Analysis Simulation System.* The main function of this system is to provide a self-learning method, especially for those who have left school but want to take the exam. It is difficult to get the teacher's timely examination. Students may not approve test questions, and teachers may not have time to approve a large number of test papers. This system is a learning system for simulated exams developed to solve the actual needs of this society. The overall design of this system is designed based on the independence of the modules. Module independence is in the design and development process, the function of each module is independent, and it has less interaction with other modules. The independence of modules can make effective modular software easy to develop, and independent modules are more convenient for testing and maintenance. The modules of this system are loosely coupled with each other, and the internal elements of the modules are closely combined.

The system contains a module of question bank management and test paper management. The question bank management module provides teachers with the functions of adding, modifying, and deleting test questions. The test paper management module adds or deletes the test questions in the question bank to the test paper. When adding test questions, it is only the question bank management module that has an impact. Since the test paper just added does not

add to the test paper, it does not have any impact on the test paper management module. When adding test questions in the test paper, only rely on the foreign key to generate the association relationship, so as to form a test paper. This shows that the independence between the two modules is high, so the coupling relationship is loose, as shown in Figure 2.

For the test bank management module, its function is to maintain the test bank. You can add, delete, modify, and check the test questions. You can only operate the large and small question databases in the database, and you cannot and are not allowed to operate the content in other databases. That is to say, the only thing the question bank management module does is to maintain the test question bank. Things that are not within its responsibilities can only be requested by other modules to complete. This is called high cohesion.

In addition to the basic requirements of the system, there are the most important functional business requirements for pronunciation correction. Automatic pronunciation correction system mainly includes two functional modules: a user information management module and a pronunciation correction module. The user management module includes student users, teacher users, and system administrators. Pronunciation correction module includes pronunciation data collection module and pronunciation data error detection module, pronunciation data correction module, and historical data display module. Figure 3 is a functional block diagram of the automatic pronunciation error correction system.

The server is the core of the automatic pronunciation correction system. All functions are implemented through the server Java code. The server uses the framework of spring + spring MVC + Mybatis. Among them, spring is like a container to automatically create and manage the instances in the project. By configuring parameters in the configuration file to call Java entity classes to create objects, its core idea is control inversion (IOC) and dependency injection (DI); using the Spring framework to develop projects can enable developers to focus on the development of business functions and improve development efficiency without paying attention to the creation and management of instance objects. Spring MVC based on Java is a popular lightweight Web MVC pattern framework, which simplifies our development through a request-response driving model. MyBatis is a database interaction layer framework used by many companies. MyBatis does not need JDBC code to operate the database and result set. Simply configure the mapping relationship in XML to complete the mapping between database fields and Java entity class attributes.

*2.3. Analysis and Simulation Evaluation Analysis.* The running efficiency of the algorithm can be evaluated by the time and space resources required by the computer when running the algorithm. The time resource required by the computer when running the algorithm is also called the time complexity of the algorithm, which mainly

depends on the following factors: the time required for the input of the algorithm data, the time required for the algorithm to be compiled into an executable program, and the time required for the computer to execute each instruction, and the number of times to execute the algorithm statement repeatedly. Since the first three factors mainly depend on the performance of the device, it is customary to use the number of times the algorithm statement is repeatedly executed as the time complexity of the algorithm. When comparing, generally do not care about its precise measurement; only care about the order of magnitude. In the actual environment, there is a more convenient way to measure the time complexity of the algorithm, for example, by comparing the time difference before and after the execution of the algorithm on the same machine.

The storage space resource occupied on the computer memory when running the algorithm is also called the space complexity of the algorithm. The space complexity of the algorithm includes static storage space, storage space required for the input and output data of the algorithm, and variable storage space. The static storage space is a fixed part, and its size does not have a great relationship with the needs of users, including the space occupied by the algorithm code and the space occupied by variable constant characters in the algorithm. The storage space required for the input and output data of the algorithm depends on the problem to be solved. The input and output data are passed through the calling function, and the storage space they need is not different due to the difference of the algorithm. Variable storage space refers to some auxiliary space temporarily generated when running the algorithm. This part has no great relationship with the algorithm itself but is related to the auxiliary algorithm storage structure called by the operating system to execute the algorithm. These spaces are larger than those required by the algorithm itself and are issues that require objective consideration. Because of the rapid development of hardware technology, computers have more and more storage space, and the limitation of storage capacity has little effect on the algorithm. When analyzing the running efficiency of the algorithm, we cannot consider the space complexity of the algorithm more and consider the time complexity of the algorithm more, as shown in Figure 4.

The value range of Brier Score is 0 to 1. The lower the score, the better the performance of the model. Brier Score represents the error between the predicted probability and the actual observation value. That is, the probability of the predicted logging statement level is the same as the actual logging statement level. Probability prediction can assign a very high probability correct logging statement level to instance data or just assign the correct category with a probability that is only slightly higher than the error level probability to instance data. Brier Score is conducive to identifying the ability of the classification model to accurately predict the corresponding category in the former case and can also explain the performance of the classifier model in predicting the category compared to random guessing.

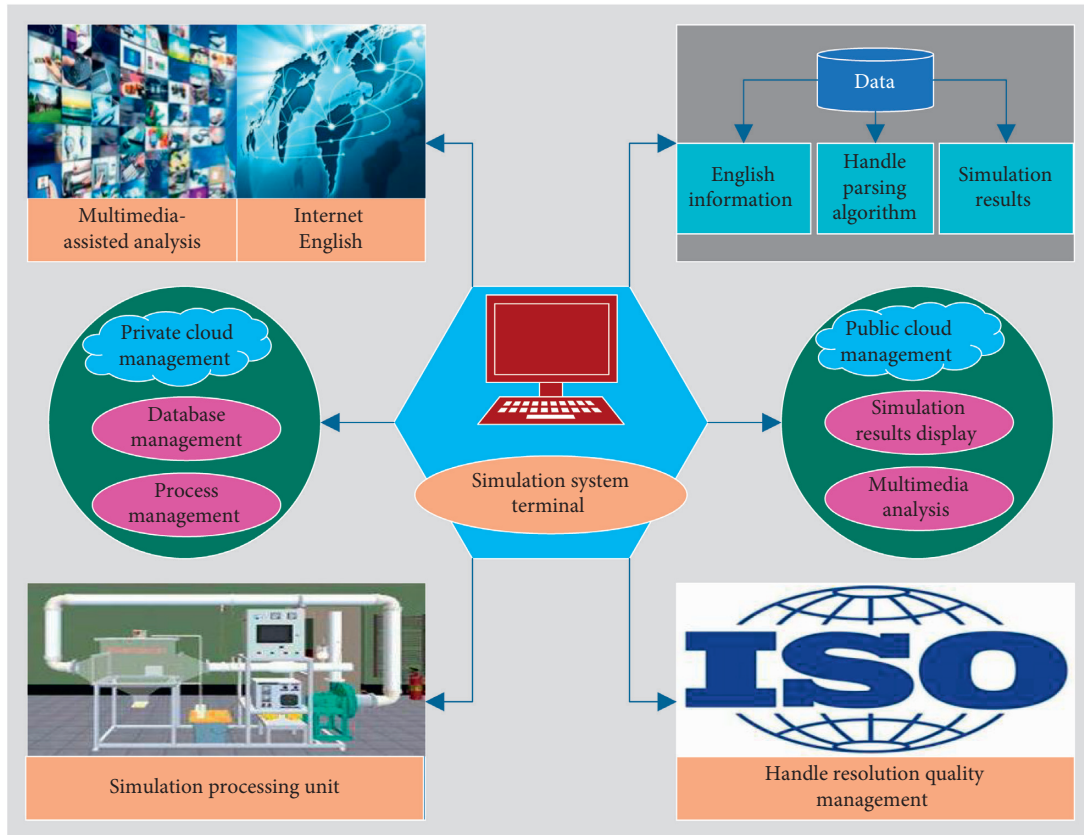

FIGURE 2: Multimedia English auxiliary handle parsing simulation system design.

### 3. Result Analysis

3.1. *Evaluation of Experimental Results.* The main work of this paper is to use machine learning text classification technology to implement a logging sentence level recommendation method. As an important source of experience for machine learning, this article selects the top 100 ranked GitHub and uses the logging statements in the Java

language project to build a classification model. The AUC and Brier Score performance results of the classification models constructed by the three classic classification algorithms are shown in Figure 5.

It can be seen from Figure 5 that the AUC of the three classification algorithms is up to 0.815, and only 0.798 when the learning effect is poor. Although the experimental dataset in this paper (25 GitHub projects) is

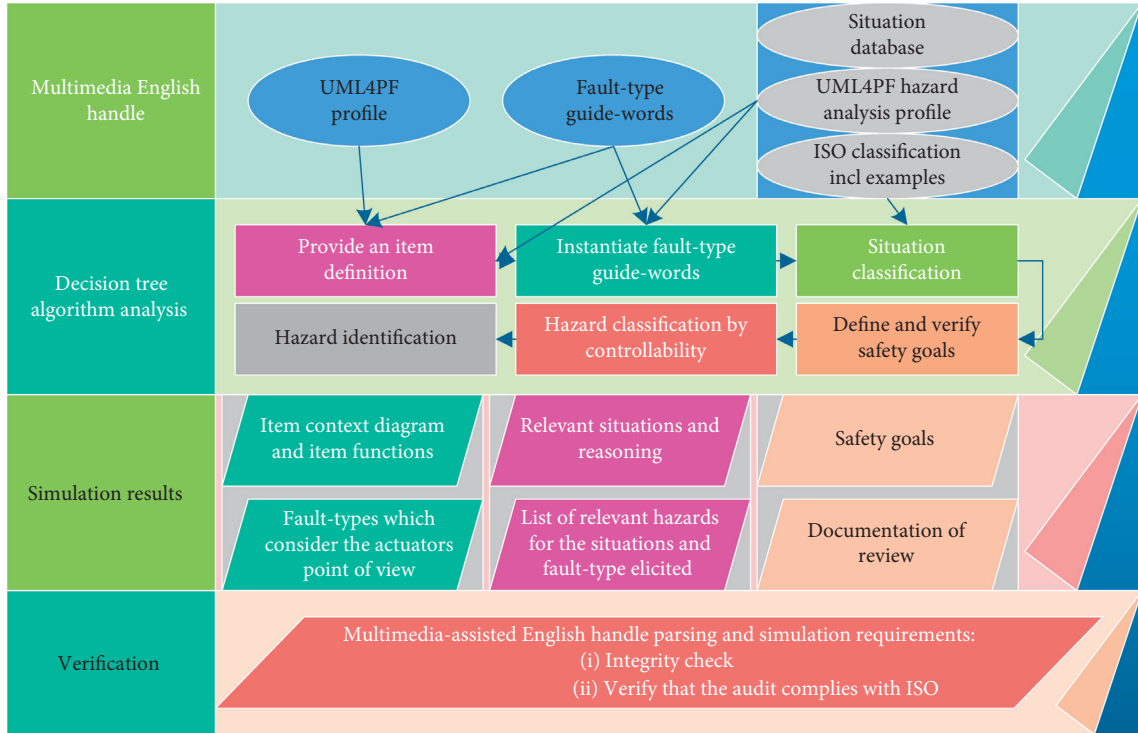

FIGURE 4: Analysis and simulation evaluation design.

FIGURE 5: ROC and AUC after decision tree classification.

different from the approximate study in the field of logging statement-level recommendations (4 open source projects), it is different from the AUC score in the approximate study (0.75 to 0.81). In contrast, the experimental results of this article are generally equivalent to them, with a slight advantage. Moreover, considering that the increase in the number of items may lead to an increase in the difference in the characteristics of logging statements, the AUC score of 0.798 to 0.815 is sufficient to illustrate that the text classification model constructed in this paper can well overcome the uneven distribution of cross-project machine learning predictions. And

regarding other challenges, it has a better performance in distinguishing different levels of logging statements.

On the other evaluation standard, Brier Score, three classification algorithms selected in this paper can reach 0.440 at the best time and 0.462 at the worst time. Compared with the Brier Score of 0.44 to 0.66 in the approximate study, it has better performance. It shows that, as a probabilistic prediction algorithm, the machine learning model constructed in this paper has a high accuracy rate, which provides a reliable guarantee for the correct recommendation of logging statement level.

It can be seen from the two evaluation indicators that the decision tree is the best among the three selected algorithms. In the ROC curve, one point that needs attention is (0, 1), which represents  $FPR=0$  and  $TPR=1$ , which means that  $FN=0$  and  $FP=0$ , and the classifier in this state can use all the samples. The datum is classified into the correct category, which means that it is an ideal classifier. Therefore, the closer the value of AUC to 1, the stronger the classification performance of this classifier.

This article conducted multiple samplings and then split the sample data in the same way according to the ratio of 9:1. 90% of the data was used for training, and the remaining data was used as test data to verify the performance of the model. Considering the influence of the number of data on the performance of the classification model, this paper selects from four to four representative sampling data of the experimental results for display, as shown in Figure 6, and the number of logging statements for each sample data has been Callout.

It can be seen from Figure 6 that when the number of items decreases and the differences in the factors that affect

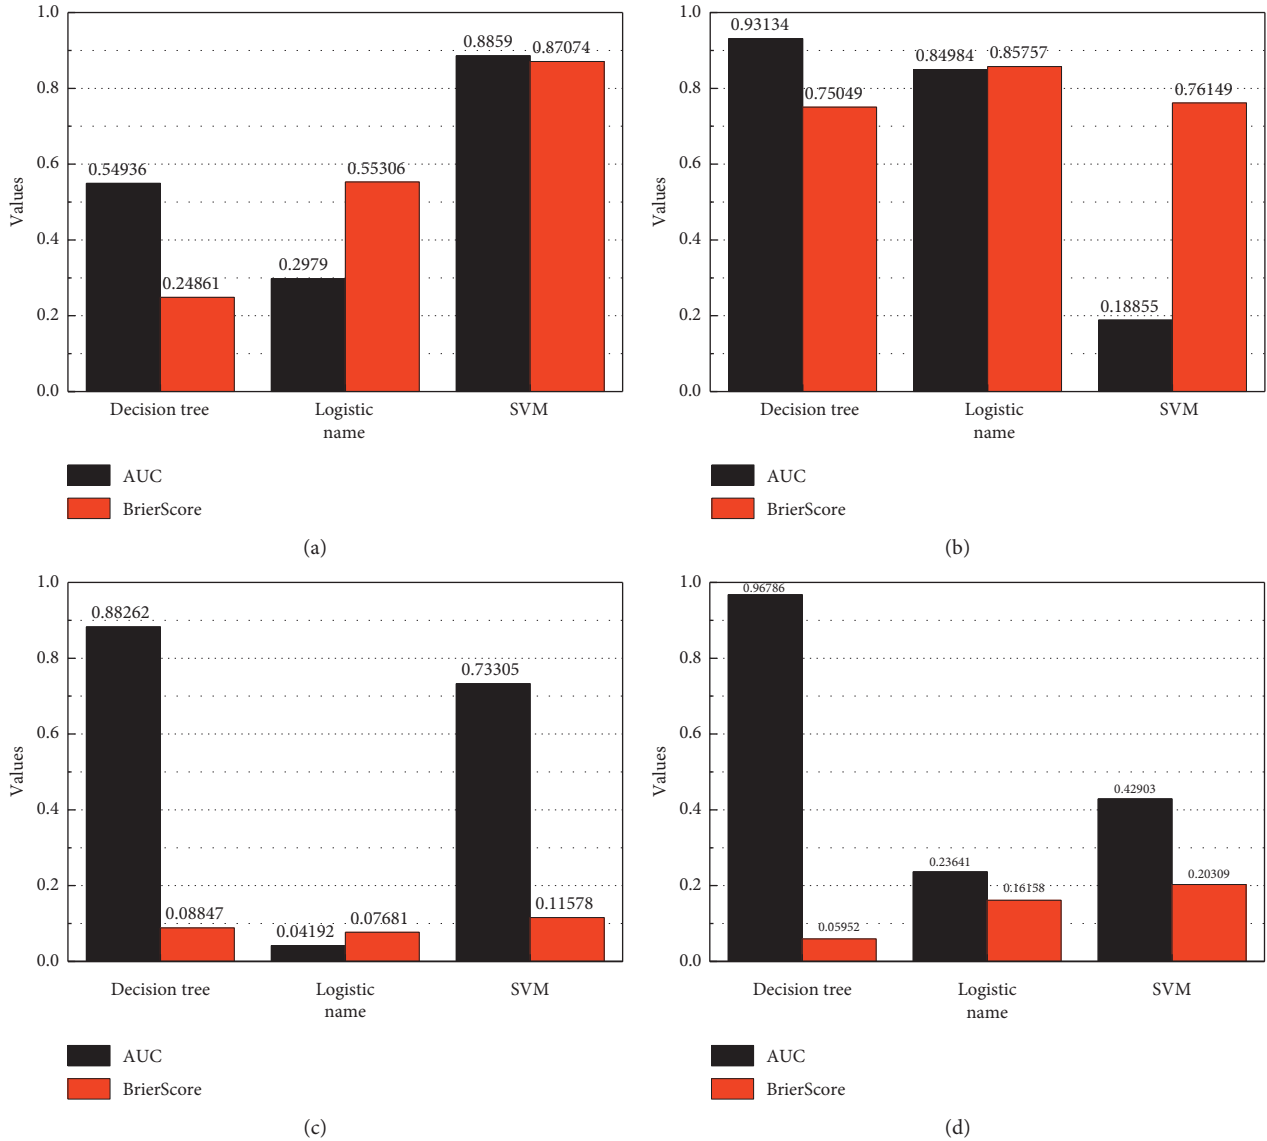

FIGURE 6: Sample experimental results.

the logging statement level become less, the method proposed in this article performs excellent in both AUC and Brier Score indicators. Compared with the test results on multiple projects, the AUC of each sample experiment has a certain degree of improvement, and it can reach 0.836 when the performance is the best. Such a high value means the distance between its ROC curve and the upper left corner. In the process of classifying the log statements, it is likely to be classified into the correct category, and the prediction results of the model are very reliable. The Brier Score indicator has also made no small progress, from the lowest 0.440 on the multi-project data set to the lowest 0.373, successfully below 0.4, and closer to 0, indicating that there is feature learning on approximate regular data; the method proposed in this paper can accurately predict the level of logging statements, and the error in probability prediction is small.

*3.2. Optimal Decision Tree Algorithm Handles Analysis Mechanism Result Analysis.* Aiming at the traditional random forest classification algorithm and the random forest classification algorithm optimized in this paper to optimize the handle simulation mechanism in text classification, a comparative experiment is conducted. The experimental data use all the data in the 20 news by date data sets, use the training set in the data set to train the classifier, and use its test set to evaluate the classification effect of the algorithm, and the selection time of the evaluation indexes of the performance of the two classification algorithms and the accuracy rate of the algorithm prediction. The time is the time used by the algorithm to train the data set to obtain the classifier and use the classifier to predict the test set for the category result. The prediction accuracy of the algorithm is the ratio of the number of samples that the algorithm

predicts the test samples to obtain the correct classification result to the total number of test samples. Since the number of decision trees in the random forest will have an impact on the performance of the algorithm, when conducting a comparative experiment on text classification using the traditional random forest classification algorithm and the random forest classification algorithm with the optimized handle simulation mechanism in this paper, we should ensure that the number of decision trees is excluded. Under the same conditions except for others, choose different numbers of decision trees for text classification. In the experiment, choose the number of decision trees as 10, 30, 50, 100, 200, 300, 400, and other hyperparameters are the default values for comparison experiments. In addition, in order to eliminate the effect of randomness on the experimental results, comparison experiments under the same number of decision trees are conducted 10 times, and then the average value of the 10 results is taken as the final result.

According to the experimental design, the text classification experiment is carried out, and it is concluded that, under different numbers of decision trees, the traditional random forest classification algorithm and the random forest classification algorithm with optimized handle simulation mechanism in this paper are used. The time for text classification is shown in Figure 7.

It can be seen from Figure 7 that the number of decision trees in the random forest classification algorithm has a certain impact on the time of text classification under the two algorithms. As the number of decision trees in the random forest classification algorithm increases, the two algorithms are used for text classification. The time spent is increasing accordingly. Figure 7 lists the time to use two algorithms for text classification under different numbers of decision trees. Although the random forest classification algorithm that optimizes the handle simulation mechanism in this paper is more complicated than the traditional random forest algorithm used in handle simulation, according to the prediction training accuracy of the out-of-bag data, each decision tree is given a certain weight. When the handle simulation is performed, it is not just outputting the category of the sample, but the probability that the sample belongs to each category. There is no significant increase.

The traditional random forest classification algorithm and the random forest classification algorithm with optimized handle simulation mechanism in this paper are used for text classification experiments. The prediction accuracy of the two algorithms is shown in Figure 8.

It can be seen that the number of decision trees in the algorithm has a greater impact on the accuracy of the algorithm. Generally speaking, the larger the number of decision trees, the higher the accuracy of the algorithm prediction. In the case of different decision tree numbers, the prediction accuracy of the random forest classification algorithm using the optimized handle simulation mechanism in this paper is improved to a certain extent compared with the traditional random forest algorithm. Combining the time comparison used in the text classification experiment using the two algorithms in Figure 8, the random forest

FIGURE 7: Algorithm time comparison.

FIGURE 8: Comparison of algorithm prediction accuracy.

classification algorithm that optimizes the handle simulation mechanism in this paper improves the prediction accuracy of text classification on the basis of almost no increase in time resources, compared with the traditional Random forest algorithm that has higher performance. In addition, the prediction accuracy of the two algorithms has not reached a high level, which is related to the use of default values for the hyperparameters of the algorithm except for the number of decision trees, which also illustrates the importance of optimizing the hyperparameter values of the algorithm.

**3.3. Handle Simulation Result Analyses.** The design comparison experiment proves that combining the optimized handle simulation mechanism and the proposed hyperparameter optimization algorithm has improved the effectiveness of the traditional random forest algorithm. Because the values of the number of decision trees and the number of feature attribute subsets in the random forest algorithm have

a great influence on the performance of the random forest algorithm, these two hyperparameters are selected in the experiment. First, the proposed hyperparameter optimization algorithm is used to find the hyperparameter optimization value of the random forest algorithm with the optimized handle simulation mechanism, then two text classifications are performed, and the first time the hyperparameter optimization value of the random forest algorithm with the optimized handle simulation mechanism is used to perform text classification. For the second time, the traditional random forest algorithm hyperparameters use default values for text classification.

Using a random handle simulation algorithm to perform hyperparameter handle simulation, the experimental results of random handle simulation are shown in Figure 9. Figure 9 is a scatter plot of three-dimensional coordinates, where the  $x$  and  $y$  coordinates represent the number of decision trees and the number of features in the feature attribute subset, respectively, and the  $z$  coordinate is the evaluation index of the experimental algorithm, that is, the average score of the scores on the test set. Each point corresponds to the score on the test set under the condition that the hyperparameter value is taken.

It can be seen from Figure 9 that, in the case where the number of decision trees and the number of features in the feature attribute subset are different value combinations, the score on the test set is significantly different. When the number of decision trees is small and the number of features in the subset of feature attributes is large, the score on the test set is significantly lower. If only one of the number of decision trees and the number of features in the subset of feature attributes is considered, basically the greater the number of decision trees, the higher the score on the test set; the smaller the number of features in the subset of feature attributes, the higher the score on the test set high. According to the results, the best five sets of experimental hyperparameter values are shown in Figure 10.

Results of random handle simulation are analyzed to determine the number of grid handle simulation. By analyzing the five sets of hyperparameter value combinations in Figure 10, it can be seen that the first set of experimental results is significantly better than the other four sets. According to the algorithm proposed above, the hyperparameter values of the five sets of results are similar in performance. The gap is large, and a grid handle simulation is performed around the optimal value. That is, only one grid handle simulation is needed near  $k = 279$  and  $m = 3$ . Carry on the grid handle simulation to get the final hyperparameter value. Set the hyperparameter range of the grid handles simulation algorithm. The range of  $k$  is  $250 \leq k \leq 340$ , the step size is 10, the range of  $m$  is  $2 \leq m \leq 6$ , and the step size is 1. The handle simulation result of the grid handles simulation algorithm, as shown in Figure 11. Figure 11 is a graph under three-dimensional coordinates, where the  $x$  coordinate and the  $y$  coordinate represent the number of decision trees and the number of features in the feature attribute subset, and the  $z$  coordinate is the evaluation index of the experimental algorithm, that is, the average score of the score on the test set. The points on each grid represent the

FIGURE 9: Random handle simulation results.

FIGURE 10: The best five sets of experimental parameter values and experimental results.

score of the algorithm on the test set when the number of decision trees and the number of features in the subset of feature attributes are the corresponding horizontal and vertical coordinates. Connect each point in a line to form a grid-like graph. Different colors are used to distinguish the score of different test sets. The transition from dark blue to red corresponds to the high to low score on the test set. According to the results of the grid handle simulation, the

FIGURE 11: Grid handle simulation results.

optimal value of the hyperparameters of the algorithm is obtained,  $k = 270$ ,  $m = 2$ , and the mean value of the score is the highest at 0.8362.

After text-processing the data set and expressing it as a data set suitable for training the classifier, the random forest algorithm that performs the traditional random forest algorithm and the optimization method of the handle simulation mechanism based on weighted handle simulation proposed in the paper are used for text classification, experimental algorithm comparison experiment. Using time and algorithm prediction accuracy as indicators to evaluate the performance of the two algorithms, the experimental results can be concluded by analyzing the experimental results. The random forest algorithm proposed in this paper based on the optimization method of the handle simulation mechanism based on weighted handle simulation has more advantages than the traditional random forest classification algorithm.

#### 4. Conclusion

In this paper, through the improved decision tree algorithm, multimedia English-assisted handle parsing and simulation are studied. After analyzing the research status, the vacancies in the current price segment pronunciation error detection research field are summarized, and a classification error detection model method based on machine learning algorithms is proposed. To solve the pronunciation problem caused by the learner's pronunciation is not standard, so as to make more intuitive suggestions for the learner's pronunciation. A random forest model that optimizes the handle simulation mechanism is proposed. Handle simulation weight of each decision tree is obtained by the classification correct rate of the decision tree. The probability that the output sample belongs to each class when deciding on the sample result is determined. The output of the decision tree is used. The class probabilities and the weight of the decision tree are weighted to simulate the handles to

obtain the handle simulation of samples belonging to each class, and the final classification result is obtained. Design text classification experiments to compare the traditional random forest algorithm and the random forest algorithm of the optimized handle simulation mechanism proposed in this paper. The analysis of the experimental results proves that the random forest algorithm of the optimized handle simulation mechanism improves when the acceptable time complexity increases. The handle simulation ability of the algorithm is improved, and the purpose of improving the classification performance is achieved.

Online education has developed rapidly due to its irreplaceable convenience. Under the severe circumstances caused by COVID-19 recently, many schools around the world have delayed opening and adopted online education as one of the main teaching methods. However, the efficiency of online classes has long been questioned. Compared with traditional face-to-face classes, there is a lack of direct, timely, and effective communication and feedback between teachers and students in the online courses. Previous studies have shown that there is a close and stable relationship between a person's facial expressions and emotions generally. From the perspective of computer simulation, a framework combining a face expression recognition (FER) algorithm with online courses platforms is proposed in this work. The cameras in the devices are used to collect students' face images, and the facial expressions are analyzed and classified into 8 kinds of emotions by the FER algorithm. An online course containing 27 students conducted on Tencent Meeting is used to test the proposed method, and the result proved that this method performs robustly in different environments. This framework can also be applied to other similar scenarios such as online meetings.

## 1. Introduction

Facial expression is one of the most powerful, natural, and universal signals for human beings to convey their emotional states and intentions regardless of national borders, race, and gender [1, 2], and there were multitudinous related applications such as the health management [3], aided driving [4, 5], and others [6–9]. In the earlier researches on facial expressions of emotion, Ekman and Friesen argued that human beings perceive certain basic emotions in the same way regardless of their cultural background, and they defined the typical facial expressions into 6 categories: anger, disgust, fear, happiness, sadness, and surprise [10, 11]. Based on studies of Ekman and Friesen, Ekman and Heider [12–14], Matsumoto [15] provided enough proofs for another universal facial expression, contempt. Additionally, FER2013 [16], a large-scale and unconstrained database introduced in the ICML 2013 Challenges in Representation Learning,

labeled its facial images into anger, disgust, fear, happiness, sadness, surprise, and neutral, which has been widely used in designing facial expression recognition (FER) systems. In subsequent researches, although researchers introduced many models that can provide a wider range of emotions to deal with the complexity and subtlety of facial expressions [17–20], the classification that describes basic emotions discretely is still the most widely used method in FER due to its generality and intuitive definition of facial expressions [21], and Figure 1 displays the 8 basic facial expression phenotypes from datasets CK+ [22] and FER2013 [16].

For determining facial expressions, Ekman and Friesen [23] proposed a Facial Action Coding System (FACS) for determining facial expressions, which is based on a fact that expressions result from the change of facial parts. With the assistance of the computers, more advanced methods have been proposed during the last decades [24], and the feature points can be seen in Figure 2.

FIGURE 1: Basic facial expression phenotypes from CK+ and FER2013: from left to right are anger, contempt, disgust, fear, happiness, neutral, sadness, and surprise.

FIGURE 2: Facial analysis points used for facial expression [25].

With the development of artificial intelligence and deep learning, numerous FER algorithms have been proposed to deal with the expression information in facial representations, which has improved the accuracy of recognition gradually and achieved better performance than traditional methods [26, 27]. The tasks of FER can be mainly divided into two categories: static images (represented by photographs) [28–30] and dynamic sequence (represented by videos) [31–33] that take the dynamic relationship between the continuously changing images into account and therefore pose additional challenges than the former. In addition to the vision-based methods, other biometric techniques [34, 35] can also be adopted to assist the recognition of expression.

Sufficient labeled training databases that include as many variations of the populations and environments as possible are important for researchers to design and test a FER model or system; the existing databases are mainly divided into controlled and uncontrolled. On one hand, the controlled databases, represented by CK+ [22], Jaffe [36], and MMI [37], are collected from laboratory environments with sufficient light and simple backgrounds. Nowadays, because most actual scenes are complex and changeable due to factors such as lighting, FER in laboratory or controlled environments is generally considered to be of little practical significance and used mainly for the proof of concept of features extraction and classification methods. On the other hand, the uncontrolled databases, such as FER2013 [15] and AFEW [38], are collected from complex environments with vastly different backgrounds, occlusions, and illuminations; these scenes are more similar to the actual situations and have been increasingly used in more and more researches.

Limited by the hardware and insufficient processing capability, the majority of the traditional methods for FER

employed hand-craft features or shallow learning, such as local binary patterns (LBP) [28] and nonnegative matrix factorization (NMF) [39]. With the development of processing capabilities and computer simulation, all kinds of machine learning algorithms, such as Artificial Neural Networks (ANNs), Support Vector Machines (SVM), and Bayesian classifiers, were applied to FER, and the high accuracy has been verified in controlled environments so that the faces can be detected effectively. However, these methods were weak in generalization ability while this is the key to evaluate the practicality of a model [40]. Deep learning algorithms can solve this problem, and it is also robust in the uncontrolled environments. Recent works have shown that convolutional neural networks (CNNs), because of their effectiveness in feature extraction and classification tasks, performed well in addressing the computer vision problems especially in FER [41, 42], and numerous models based on CNN structure are proposed constantly and have achieved better results than previous methods. Simonyan and Zisserman [43] adopted an architecture of very small ( $3 \times 3$ ) convolution filters to conduct a comprehensive evaluation of networks with increasing depth and the two best-performing ConvNet models were available publicly to facilitate the further research in this field. By increasing the depth and width of the network while keeping the computational budget constant, Szegedy et al. [44] introduced a deep convolutional neural network architecture named “Inception” in which the utilization of the computing resources can be improved significantly, and Jahandad et al. [45] worked on 2 convolutional neural network architectures (Inception-v1 and Inception-v3) based on “Inception” and proved that these 2 models performed better than others, and Inception-v1 with 22-layer-deep network performed better than 42-layer-deep Inception-v3 network when facing low-resolution input images and 2D images of signatures; however, Inception-v3 outperformed in ImageNet challenge. The general trend of neural networks is to increase the depth of the network and the width of layer. In theory, the deeper the neural network models, the stronger the learning capabilities, but the more difficult to train. He et al. [46] proposed a residual learning framework to reduce training difficulty of deeper networks and proved thoroughly that these residual networks are easier to optimize while increasing accuracy from the considerably increased depth. In addition, a part of researchers proposed that the accuracy of recognition can be further improved by combining CNNs with recurrent neural networks (RNNs) in which the CNNs are adopted as the inputs to RNNs [47, 48].

During the past decades, online education has developed rapidly whether at universities or training institutions [49], which offers potential application opportunities for FER.

Significantly different from the traditional face-to-face courses, online courses are often considered of less constraining force and effective communication, which will inevitably lead to faculty's suspicions towards this novel educational method [50, 51] while there are several studies that argue that the students' learning outcomes achieved by online education may be comparable to traditional face-to-face courses [52, 53], except for the skills that require optimum precision and a greater degree of haptic awareness [54]. It is undeniable that the rapid growth of online education can effectively provide the convenience and flexibility for more students, so it also has broad development space in the future; therefore, how to ensure that students keep the same level of concentration and learning efficiency as the traditional courses during online education is critical to promote the further development of online education.

In brief, the main contribution of this paper is as follows. By combining the existing online education platforms with facial expression recognition model based on the architecture of convolutional neural network, this work proposed a framework that enables real-time monitoring of students' emotions in online courses and ensures that the feedback expressed by facial expression can be provided to teachers timely, so that they can flexibly adjust the teaching programs and ultimately improve the quality and efficiency of online education.

## 2. Proposed Framework

The framework mainly consists of two parts: online courses platforms, in this paper we took Tencent Meeting as an example for mode testing, and a deep learning model based on CNN, inspired by Kuo et al. [27], before which it is noted that the original images collected from online courses need to be preprocessed, including face detection, alignment, rotation, and resize, according to the different elements in the original images. Figure 3 exhibits the process of the FER, and the detailed steps of the proposed framework are as follows: first, the cameras built in the electronic devices are utilized to capture the facial images of the attending students. Second, the facial expression recognition algorithm trained by the standard facial expression database is employed to detect the faces and classify the facial expressions in terms of anger, disgust, fear, happiness, sadness, surprise, contempt, and neutral. Third, the histogram of probability distribution about the expression is plotted and provided for the teacher so that the teaching plan can be adjusted timely.

*2.1. Online Education Platforms.* The advances in technological delivery modalities have spawned a large number of online education platforms and greatly improved the flexibility of education, enabling teachers to adopt diverse technical methods to assist teaching without worrying about the limit on the number of students in traditional classroom-based course, and students in different regions can communicate in real time without having to consider the traffic and other issues. The same teaching materials as traditional

classes can be uploaded to these platforms for students' reference. Currently, in platforms that have online teaching functions, such as DingTalk, Zoom, and Rain classroom, teachers can adopt the method of video meeting and take advantage of the camera built in devices to capture and recognize students' facial expressions in real time. The captured images will be preprocessed and then used as the input of CNN.

*2.2. The Preprocessing Based on IntraFace.* Effective preprocessing can reduce the interference of face-like objects in the background when detecting faces in an image and then standardize the face images according to the heuristic knowledge, which will effectively improve the efficiency of the deep learning model. We employed IntraFace [55], a publicly available software package that integrates algorithms for facial feature tracking, head pose estimation, facial attribute detection, etc., as the tool of preprocessing. As shown in Figure 4, IntraFace can also be used to detect multiple faces at the same time. The key features of each face including eyebrows, eyes, nose tip, and mouth can be recognized effectively, and the facial expression can be detected by rectangular outlines accordingly; these outlines are constructed by the feature points at the edge of every face, including the uppermost and the lowermost, which determined the vertical width, and the rightmost and the leftmost, which determined the horizontal width of the face image. In order to prevent the omission of facial information while reducing the noise of background, we enlarge the rectangular outlines by 1.05 times to cover more facial content. Furthermore, considering that the size of images input into the learning model is preset to  $48 \times 48$ , the detected images will be rotated with nose tip as the center and resized appropriately to make it consistent with the input size.

*2.3. The Learning Model Based on CNN.* The architecture of the applied deep learning model based on CNN is illustrated in Figure 5, which referred to the research results proposed by Kuo et al. [27], and the prior performance of this model in FER over the other similar has also been proven. After a convolutional layer of 32 feature maps, the input layer is followed by 2 blocks, which consists of 2 convolutional layers and 1 max-pooling layer with 64 feature maps separately. And the size of kernels in the first convolutional layer is set to  $3 \times 3$ , the second is  $5 \times 5$ , the max-pooling layers both consist of a kernel of size  $2 \times 2$  and stride 2, and as a consequence, the input image will be compressed to a quarter. And there are 2 following fully connected layers of 2048 and 1024 neurons, respectively, in which Rectified Linear Units (ReLUs) [56–59] are adopted as the activation function. In order to prevent overfitting, a Dropout is added after each of the 2 fully connected layers, which will release a part of neurons according to the presetting drop-probability; in this paper, the 2 values are both set to 0.5. The following output layer is composed of 8 units, and softmax [60] is adopted as the activation function to classify the expressions examined in terms of anger, disgust, fear, happiness, sadness, surprise, contempt, and neutral.

FIGURE 3: The process of FER.

FIGURE 4: Automatic output of IntraFace to measure audience reaction [55].

FIGURE 5: The structure of the applied CNN model.

The proposed model was trained by databases Jaffe, CK+, and FER2013 that include the above 8 basic expressions at the same time. Because the small FER databases usually only contain a few hundreds of images, obviously this is not enough for model training; we adopt online augmentation strategy with both horizontal flipping and random shifting to increase the images of training sets. More details about the CNN model are given in Table 1.

And in this model, the output size  $N$  of each convolutional layer can be formulated as

$$N = \frac{I - F + 2P}{S} + 1, \quad (1)$$

where  $I, F, P$ , and  $S$  denote the input size, kernel size, padding size, and stride size, respectively.

In each max-pooling layer, the padding size is 0, and the output size can also be expressed as

$$N = \frac{I - F}{S} + 1. \quad (2)$$

Rectified Linear Units (ReLU) are adopted as the activation function in the convolutional layers and max-pooling layers to avoid gradient explosion and ensure faster convergence speed during the back-propagation operation, which can be formulated as

$$f(x) = \begin{cases} 0, & x \leq 0; \\ x, & x > 0. \end{cases} \quad (3)$$

Softmax is used as the activation function in the output layer, the input of which is the matrix  $z_i = w_i^T x + b_i$

TABLE 1: The parameters of the applied CNN model.

| Layers            | Kernel number | Kernel size   | Steps | Image size               |
|-------------------|---------------|---------------|-------|--------------------------|
| Input             | 0             | 0             | None  | $48 \times 48 \times 1$  |
| Convolutional 0   | 32            | $1 \times 1$  | 1     | $48 \times 48 \times 32$ |
| Convolutional 1-1 | 64            | $3 \times 3$  | 1     | $48 \times 48 \times 64$ |
| Convolutional 1-2 | 64            | $5 \times 5$  | 1     | $48 \times 48 \times 64$ |
| Pooling 1         | 0             | $2 \times 2$  | 2     | $24 \times 24 \times 64$ |
| Convolutional 2-1 | 64            | $3 \times 3$  | 1     | $24 \times 24 \times 64$ |
| Convolutional 2-2 | 64            | $5 \times 5$  | 1     | $24 \times 24 \times 64$ |
| Pooling 2         | 0             | $2 \times 2$  | 2     | $12 \times 12 \times 64$ |
| Fully connected 1 |               | Dropout = 0.5 |       | $1 \times 1 \times 2048$ |
| Fully connected 2 |               | Dropout = 0.5 |       | $1 \times 1 \times 1024$ |
| Output            | 0             | 0             | None  | $1 \times 1 \times 8$    |

output from the fully connected layers. The formulation is given as

$$S_i = \frac{e^{z_i}}{\sum_{k=1}^K e^{z_k}}, \quad (4)$$

where  $K$  represents the output dimensions of the layer, meaning there are  $K$  kinds of results, and  $S_i$  represents the probability of result  $i$ ,  $i = 1, 2, \dots, K$ .

And Softmax loss, which is used for gradient derivation and update, can be calculated by the following:

$$L = - \sum_{i=1}^K y_i \log S_i,$$

$$\frac{\partial L}{\partial z_k} = \frac{\partial L}{\partial S_i} \frac{\partial S_i}{\partial z_k},$$

$$\frac{\partial L}{\partial S_i} = \sum_{i=1}^K \left( -\frac{y_i}{S_i} \right),$$

$$\frac{\partial S_i}{\partial z_k} = \begin{cases} \frac{e^{z_i} \sum_{k=1}^K e^{z_k} - e^{z_i} e^{z_k}}{(\sum_{k=1}^K e^{z_k})^2} = S_i(1 - S_k), & i = k; \\ \frac{e^{z_i} \cdot e^{z_k}}{(\sum_{k=1}^K e^{z_k})^2} = -S_i S_k, & i \neq k, \end{cases} \quad (5)$$

$$\begin{aligned} \frac{\partial L}{\partial z_k} &= \frac{\partial L}{\partial S_i} \frac{\partial S_i}{\partial z_k} = - \sum_{i=1}^K \frac{y_i}{S_i} \cdot \frac{\partial S_i}{\partial z_k} \\ &= -S_k(1 - S_k) \cdot \frac{y_k}{S_k} + \sum_{i \neq k} \left( -\frac{y_i}{S_i} \right) \cdot (-S_i S_k) \\ &= -y_k + y_k S_k + \sum_{i \neq k} y_i S_k = S_k - y_k, \end{aligned}$$

where  $L$  denotes the loss function and  $y_i$  is the label variable, the value of which is 1 or 0 according to whether the output is consistent with the actual value.

### 3. Experiment and Results

In order to test the performance of the proposed framework in practical applications, we captured an image that includes 27 people from an online meeting held on Tencent Meeting and input it into the CNN model. This image is taken before the end of the meeting; the moderator was making a concluding speech in a pleasant atmosphere. In addition, everyone was told that the meeting was coming to an end, according to the experiment conducted by Tonguç and Ozkara [61], students' happiness will be significantly improved within a few minutes before the end of a lecture, so under the similar circumstance, it can be inferred that the emotions presented by most of the faces in this image are happy or neutral. Figure 6 shows the input (left) and output (right) images of the CNN model. It can be seen clearly from the result that all the faces were recognized and marked by the rectangular outlines, and the responding facial expressions were also labeled. In the total 27 faces, 10 were labeled "happy," 15 were labeled "neutral," and 2 were labeled "sad," noting that the 2<sup>nd</sup> image in the last line and the 3<sup>rd</sup> image in the 4<sup>th</sup> line from last, marked by red outlines, were not detected by the outlines precisely; the reason may be that the 2 face images are so incomplete that the features presented are too insufficient to recognize. Figure 7 shows the probability distribution histogram of emotions, from which we can observe the overall emotions intuitively and judge the emotional state of class accordingly. It is worth noting that the probability of happiness is significantly higher than that of neutral in this figure, while the faces labeled "happy" are less than "neutral" as exhibited in Figure 6. The difference can be explained as follows: there may be features of multiple expressions on a face at the same time; the expression presented on this face will be labeled according to the most likely expression decided by these features, but the overall expression of an image including multiple faces is decided by the sum of various expression features contained in each face. In some faces that are marked as "happy," the probability of happiness may be much higher than neutral, while in some faces that are marked as "neutral," the probability of happiness may be only slightly lower than neutral. Overall, the result of this experiment can provide favorable support for the performance of the model when applied to real environment.

#### 4. Conclusion and Discussion

In this study, by combining the online courses platforms and a compact deep learning model based on the architecture of CNN, we construct a framework to analyze students' emotions according to their facial expressions from the perspective of computer simulation. The overall result can be

presented in a histogram intuitively, and teachers can adjust their teaching strategies accordingly to improve the efficiency of online teaching.

With reference to the studies of Ekman et al. and FER2013, the emotions were classified into anger, disgust, fear, happiness, sadness, surprise, contempt, and neutral in the proposed framework. To verify the applicability of this

framework in a real environment, we captured an image including the facial images of all participants at one time in a real online meeting; there were 12 participants in this meeting, and the captured time was determined at the end of meeting. A total of 12 faces were captured, of which 11 were effectively recognizable faces that contain enough feature points. By inputting this image into the applied CNN model, we obtained the emotional tags for each valid face and got the overall emotion at that time. It has been proved that the framework has good applicability in practical activities and plays a positive role in solving the problems, such as the lack of binding force on students, and teachers cannot get timely feedback. Ultimately, it will contribute to improving the quality of online education.

Despite the above benefits, there is still much room for improvement in this framework and its applications. From the perspective of technologies, with the development of computer simulation, algorithms with better performance and shorter operation time, including preprocessing and deep learning models, will be continuously developed over time. For instance, the image preprocessing contains face detection, alignment, rotation, and resize, but when facing problems, such as backlight, shadows, and facial incompleteness, caused by complex environments, these current methods are always powerless, and these shortcomings may be solved in the future. What is more, although the CNN model in the proposed framework currently performs well, it will be replaced by models with higher learning capabilities and higher classification accuracy in the future. In order to ensure the competitiveness of the framework in a longer period, it needs to be adjusted and maintained regularly, and more advanced algorithms and technologies should be adopted to update it.

In addition, with a large number of participants in the online courses, we have no way to ensure that everyone keeps the high level of concentration, and then students' expressions may not fully represent their emotions due to these subjective factors. Taking measures like setting thresholds can filter out some invalid information and highlight the main emotions in the image. Finally, the teaching efficiency can be improved as a result.

### Data Availability

The data used in this manuscript can be accessed by readers via the authors' BaiduPan at <https://pan.baidu.com/s/1dbKUfeKp5joeYh4wSOU7Qw> with the extraction code "qin6."

This paper proposes an innovative ducted fan aerial manipulator, which is particularly suitable for the tasks in confined environment, where traditional multirotors and helicopters would be inaccessible. The dynamic model of the aerial manipulator is established by comprehensive mechanism and parametric frequency-domain identification. On this basis, a composite controller of the aerial platform is proposed. A basic static robust controller is designed via H-infinity synthesis to achieve basic performance, and an adaptive auxiliary loop is designed to estimate and compensate for the effect acting on the vehicle from the manipulator. The computer simulation analyses show good stability of the aerial vehicle under the manipulator motion and good tracking performance of the manipulator end effector, which verify the feasibility of the proposed aerial manipulator design and the effectiveness of the proposed controller, indicating that the system can meet the requirements of high precision operation tasks well.

## 1. Introduction

In recent years, the application of unmanned autonomous robots is increasingly diverse, and the interaction between the autonomous robot system and the environment is developed from information interaction (such as sound, light, picture) to physical interaction (replacing manpower to complete operation work) [1]. On the one hand, using autonomous robots for operation work can greatly save labor costs and significantly improve work efficiency; on the other hand, it can liberate people from heavy labor, especially the labor in dangerous and harmful environments. At present, some ground mobile robots have been applied to postearthquake rescue [2], some underwater robots have been applied to oceanic biological sample collection [3], and some space robots have been used in space exploration [4]. Although ground mobile robots, underwater robots, and space robots have been widely used, the application of aerial

robots is still in its infancy all over the world. The current unmanned aerial vehicles play an important role in monitoring activities, such as aerial photography and high-voltage line inspection [5], but do not have the ability to physically interact with the environment. However, the aerial operation robot (aerial manipulator) has great application value in the following three aspects: (1) replacing manpower to complete dangerous tasks, such as urban antiterrorism and high-rise building firefighting [6]; (2) replacing manpower to improve efficiency, as in wide-area scientific examination and collection [7]; (3) replacing manpower to reduce costs, as in infrastructure maintenance and remote operation in complex environment [8].

The configuration of the aerial robot commonly consists of an aerial platform and an operation manipulator, but their combination brings completely new features to the system. The main challenges in the aerial robot system design include two aspects. First, since the aerial robot usually works

in confined spaces that require operation, it should have high traffic ability and contact ability with the complex environment. Under this premise, it also should have as large operating payload as possible. Second, there is a serious coupling effect between the aerial platform and the robot arm, which makes the system face enormous challenge in terms of stability and manipulation accuracy, and physical contact and manipulation further exacerbate it. The research of aerial robots has begun to attract worldwide attention since 2010, and the representative work includes AIRobots Project [9], ARCAS Project [10], AEROWORKS Project [11].

In respect to structure, most of aerial robots use helicopter or multirotor as aerial platform. Yale University designed a helicopter with a single DOF (degree of freedom) underactuated gripper, as shown in Figure 1(a), and studied the quasi-static compliance control problem during the grabbing process through PID control method [12]. University of Drexel also used helicopter as base platform to expand the 1-DOF gripper into a multi-DOF manipulator and completed the grasping and placement tasks of cylindrical objects [13]. National Taipei University of Technology designed a small quadrotor with a 2-DOF manipulator and carried out simulation analysis of kinematic control in 2D plane based on a simplified vector model [14]. University of Seville designed a dual-arm system based on quadrotor, as shown in Figure 1(b), which expands the maneuvering range and enables more complex operations [15]. However, because of the inherent characteristics of open rotor, the helicopter or multirotor structure is unable to interact with the environment closely, and the arm can only manipulate objects above [10] or below [12], which greatly limits the application scenarios. In order to grab the target side-on, Johns Hopkins University proposed a very long arm to avoid the rotor disc of the quadrotor platform [16], but the changes in the center of mass and moment of inertia caused by the long arm exert serious impacts on the stability and effective payload of the system. Compared to helicopter and multirotor, ducted fan has greater thrust in a more compact structure [17], having contact capability and increasing the payload of the system, which is more suitable as the platform of an aerial robot. Figure 2 shows the comparison of flight area requirements of different types of aerial robots near a wall (namely, our innovative ducted fan aerial robot, quadrotor, and helicopter). It can be seen that, under the same effective load, ducted fan aerial robot can be closer to the target and operate it from side-on with a smaller joint motion range and can pass narrower confined space and be safer. University of Bologna completed a series of studies on contact dynamics of the single ducted fan with vertical wall [18], but their platform cannot carry the manipulator due to the payload and controllability limitations.

With regard to control, because of the serious coupling between aerial platform and manipulator, on the one hand, the manipulation process will have three effects on the aerial platform: (1) the effects of the manipulator gravity, and the gravity moment caused by the noncoincidence of the center of mass between the aerial vehicle and the manipulator, (2) the inertia force and moment generated

by manipulator dynamics, and (3) the impact of the external environment during contacting and operating; on the other hand, the drift of the aerial platform also affects the positioning accuracy of the end effector [19]. Some studies ignored the existence of manipulator and only considered the aerial vehicle [20], and some tried to improve the robustness of the aerial vehicle basic controller to ensure system stability [21–23], but both of them are only suitable for small size arm (e.g., lightweight 1-DOF gripper) and lightweight object. DLR in [20] proposed an impedance controller to stabilize the system in the presence of external forces, ignoring the coupling effects between the aircraft and the arm by limiting the motion of the arm. Shenyang Institute of Automation of CAS in [23] designed a linear LQR controller of a helicopter with 1-DOF arm. The simulation results show that the controller has good performance when the arm moves in a small range near the equilibrium point, but the LQR controller cannot stabilize the system when the swing range of the arm is relatively large. AGH University of Science and Technology considered the change in the system's center of mass caused by the arm movement and compensated for the influence through variable-parameter PID control to achieve system's stability [24], while the University of Pennsylvania considered the impact of the payload acting on the system's center of mass [25]. The University of Seville designed a controller to compensate for the change of both the center of mass and the moment of inertia when the arm is in different positions, but the dynamic characteristics of the arm are not considered [26]. The University of Naples Federico II designed a Cartesian space impedance controller based on the integrated dynamic model of the aerial manipulator, which fully considered the coupling effect between the aerial vehicle and the robot arm [27]. However, the controller is highly dependent on the model and has a complicated structure, which is not easy in practice.

Based on the discussion above, the contribution of this paper mainly includes two parts. First, an innovative aerial manipulator based on tandem ducted fans is proposed, which has both great trafficability and effective payload. The dynamic model of the aerial manipulator is established by comprehensive mechanism and parametric frequency domain identification. Owing to the small lateral size, the aerial manipulator can easily realize the omnidirectional manipulation of side-on and below and is particularly suitable for the tasks in confined environment, where traditional multirotor and helicopter would be inaccessible. The application aims of this novel design are canopy sampling in dense forests and insulator lubricating in dense high-voltage wires. Second, a composite controller of the aerial platform is proposed, considering and compensating for both the static and the dynamic disturbances of the manipulator on the vehicle. A basic static robust controller is designed via H-infinity synthesis for basic performance, and an additional adaptive loop is designed for disturbance estimation and compensation from the manipulator to improve the platform stability and the end effector tracking accuracy. The computer simulations verify the effectiveness of the proposed controller.

FIGURE 2: Comparison of flight area requirements of different types of aerial robots.

The organization of this paper is as follows. In Section 2, the structure of the innovative ducted fan aerial manipulator is introduced and the dynamic model is established. Then, based on the dynamic model, a control-oriented state space model of the aerial platform is derived based on parametric identification to facilitate the controller design. In Section 3, the basic robust controller and the adaptive auxiliary controller are designed and analyzed in detail. In Section 4, the simulation results and analysis of the proposed controller are carried out. Finally, some conclusions are drawn in Section 5.

## 2. Modeling of the Ducted Fan Aerial Manipulator

**2.1. System Description.** The configuration of the proposed aerial manipulator mainly includes two ducted fan systems with coaxial rotors, two sets of control rudders, a 3-DOF manipulator, the control unit, and the landing gears, as shown in Figure 3. The pitch channel of the vehicle is controlled by the thrust difference between the front and the rear ducted fans, which is caused by the difference of rotor speed; the roll channel is controlled by the rudder systems setting below the duct; the yaw channel is controlled by the reaction torque difference between the upper and lower rotor disc. The total mass of the aerial vehicle is 4.6 kg, with an effective payload of 2 kg. The manipulator weight is 0.9 kg, with a max grasping weight of 0.5 kg. The parameters of the system are detailed in Table 1, where the mass and the structural dimension parameters of the platform are measured directly, and the moments of inertia and the effective

FIGURE 3: The configuration of the novel aerial manipulator.

TABLE 1: Structural parameters of the system.

| Parameter     | Physical description                               | Value                   |
|---------------|--|-------------------------|
| $m_b$         | Vehicle mass (including battery)                   | 4.6 kg                  |
| $m_r$         | Manipulator mass                                   | 0.9 kg                  |
| $m_{grasp}$   | Max grasping mass                                  | 0.5 kg                  |
| $I_{xx}$      | Inertia tensor of the vehicle around $x$ -axis     | 0.092 kg·m <sup>2</sup> |
| $I_{yy}$      | Inertia tensor of the vehicle around $y$ -axis     | 0.283 kg·m <sup>2</sup> |
| $I_{zz}$      | Inertia tensor of the vehicle around $z$ -axis     | 0.245 kg·m <sup>2</sup> |
| $p_{cd}$      | Distance between duct center and CG of vehicle     | 0.32 m                  |
| $D$           | Duct diameter                                      | 0.33 m                  |
| $S_x$         | Vehicle effective resistance area around $x$ -axis | 0.034 m <sup>2</sup>    |
| $S_y$         | Vehicle effective resistance area around $y$ -axis | 0.127 m <sup>2</sup>    |
| $S_z$         | Vehicle effective resistance area around $z$ -axis | 0.133 m <sup>2</sup>    |
| $n$           | Blade number of each disc                          | 4                       |
| $c$           | Blade chord length                                 | 0.027 m                 |
| $\theta_0$    | Attack angle at the root of blade                  | 35 deg                  |
| $\theta_{rw}$ | Torsion rate of blade                              | 18 deg                  |
| $\sigma$      | Blade tip clearance                                | 0.001 m                 |

resistance areas along three axes of the vehicle are estimated by the CATIA® 3D model. The airfoil used in the prototype is NACA 0012, and the airfoil parameters can be obtained from [28]. The manipulator is installed on the center of the vehicle body and has 3 DOF (one lumbar joint, one shoulder joint, and one elbow joint) to reach any position in 3D space. The end effector is a gripper, and, from the perspective of our application purpose, the posture of the gripper is not considered. The parameters of the arm are described using standard D-H (Denavit–Hartenberg) method [29], as shown in Table 2.

The hardware of control unit is shown in Figure 4. The on-board controller is Emlid® Navio2 based on Raspberry Pi® 3, which integrates dual IMU module, GPS module, barometer module, and 14 PWM output channels. The rotors are driven by four GARTT® motors, and the motors are driven by HOBBYWING® Electronic Speed Controllers (ESC), which are controlled by the main controller via PWM signals. Each duct system has two sets of control rudders, which are driven synchronously by one KST® servo. The servos are also controlled by PWM signals from the main controller. The Dynamixel® XH430 servo is chosen as arm joint servo, since it has both position control mode and torque control mode and has feedback function of actual position, velocity, and torque of the joint. The on-board main controller communicates with the ground station through the 3DR® radio telemetry.

**2.2. Dynamic Model.** The coordinate system of the aerial manipulator is introduced in Figure 5. The aerial manipulator is modeled as a multibody system consisting of four interconnected rigid bodies. Let  $\Sigma$  be the earth-fixed Cartesian coordinate frame following the north-east-down rules,  $\Sigma_b$  be the vehicle body-fixed coordinate frame at the center of mass of the vehicle,  $\Sigma_0$  be the manipulator base-fixed coordinate frame, and  $\Sigma_i$  ( $i = 1, 2, 3$ ) be the coordinate frame of each link of the manipulator following the D-H rules. Notice that  $\Sigma_0$  coincides with the origin of  $\Sigma_b$ , only rotated  $90^\circ$  around the  $Z_b$  axis. In the following, the superscript  $i$  means that the variable is related to the coordinate system  $\Sigma_i$ .

The dynamic formulation is established using iterative Newton–Euler method [29], which is widely used in dynamic modeling [30, 31]. First, give the definition of the motion states of the system. Let  $p_b = [x \cdot y \cdot z]^T$  and  $\Phi_b = [\varphi \cdot \theta \cdot \psi]^T$  be the position vector and Euler angle vector of the aerial vehicle platform in earth-fixed frame, and let  $q_i \cdot (i = 1 \cdot 2 \cdot 3)$  be the joint angle of the manipulator. Let  $v_b$  and  $\omega_b$  be the velocity vector and angular rate vector of the aerial vehicle, and let  $v_i$  and  $\omega_i$  be the velocity and angular rate of the origin of link  $i$  of the manipulator. Then, the acceleration of the multibody system can be calculated outward iteratively from the aerial vehicle platform to the manipulator end effector as

TABLE 2: D-H parameters of the manipulator.

| Link | a (m) | $\alpha$ (deg) | d (m) | $\theta$ range (deg) |
|------|-------|----------------|-------|----------------------|
| 1    | 0     | 90             | 0.08  | 180 $[-90, 90]$      |
| 2    | 0.15  | 0              | 0     | 150 $[0, 150]$       |
| 3    | 0.16  | 0              | 0     | 150 $[-150, 0]$      |

$$\left\{ \begin{array}{l} \mathbf{v}_b^b = [u \ v \ w]^T = \dot{p}_b^b = \mathbf{R}_b^T \dot{p}_b, \\ \boldsymbol{\omega}_b^b = [p \ q \ r]^T = \mathbf{R}_b^T \boldsymbol{\omega}_b = \mathbf{R}_b^T \mathbf{T}_b \dot{\Phi}_b = \mathbf{Q}_b \dot{\Phi}_b, \\ \mathbf{v}_0^0 = \mathbf{R}_b^0 \mathbf{v}_b^b, \\ \boldsymbol{\omega}_0^0 = \mathbf{R}_b^0 \boldsymbol{\omega}_b^b, \\ \boldsymbol{\omega}_i^i = \mathbf{R}_{i-1}^i \boldsymbol{\omega}_{i-1}^{i-1} + \dot{q}_i \mathbf{e}_{zi}, \\ \dot{\boldsymbol{\omega}}_i^i = \mathbf{R}_{i-1}^i \dot{\boldsymbol{\omega}}_{i-1}^{i-1} + \mathbf{R}_{i-1}^i \boldsymbol{\omega}_{i-1}^{i-1} \times \dot{q}_i \mathbf{e}_{zi} + \ddot{q}_i \mathbf{e}_{zi}, \\ \dot{v}_i^i = \mathbf{R}_{i-1}^i (\dot{\boldsymbol{\omega}}_{i-1}^{i-1} \times \mathbf{p}_i^{i-1} + \boldsymbol{\omega}_{i-1}^{i-1} \times (\boldsymbol{\omega}_{i-1}^{i-1} \times \mathbf{p}_i^{i-1})) + \dot{v}_{i-1}^{i-1}, \\ \mathbf{a}_{C_i}^i = \dot{\boldsymbol{\omega}}_i^i \times \mathbf{p}_{C_i}^i + \boldsymbol{\omega}_i^i \times (\boldsymbol{\omega}_i^i \times \mathbf{p}_{C_i}^i) + \dot{v}_i^i, \end{array} \right. \quad (1)$$

where the superscript  $b$  refers to the body-fixed coordinate system, the superscript  $i$  refers to the  $i^{\text{th}}$  link coordinate system, and in particular  $i = 0$  for the manipulator base-fixed (link 0) coordinate system, as shown in Figure 5. Specifically,  $v_b^b$  and  $\omega_b^b$  are the velocity and angular rate of the aerial vehicle with respect to the body-fixed coordinate frame,  $v_i^i$  and  $\omega_i^i$  are the velocity and angular rate of the origin of link  $i$  with respect to the  $i^{\text{th}}$  link coordinate frame.  $\mathbf{a}_{C_i}^i$  is the acceleration of the center of mass of link  $i$ .  $\mathbf{p}_i^{i-1}$  is the position vector of the origin of  $i^{\text{th}}$  link frame with respect to the  $(i-1)^{\text{th}}$  link coordinate frame,  $\mathbf{p}_{C_i}^i$  is the position vector of the center of mass of  $i^{\text{th}}$  link with respect to the  $i^{\text{th}}$  link coordinate frame, and  $\mathbf{e}_{zi}$  refers to the projection along the  $z$ -axis of link  $i$ .  $\mathbf{R}_{i-1}^i$  refers to the transformation matrix from the  $(i-1)^{\text{th}}$  link coordinate frame to the  $i^{\text{th}}$  link coordinate frame. In particular,  $\mathbf{R}_b^0$  refers to the transformation matrix from the body-fixed frame to the arm base-fixed (link 0) frame.  $\mathbf{R}_b$  and  $\mathbf{Q}_b$  are the linear velocity and angular rate transformation matrix between the earth-fixed frame and body-fixed frame expressed in the form of Euler angles.

Then, the Newton–Euler dynamics formulation can be derived as

$$\left\{ \begin{array}{l} \mathbf{F}_b^b = m_b (\dot{v}_b^b + \boldsymbol{\omega}_b^b \times v_b^b), \\ \mathbf{M}_b^b = \mathbf{I}_b \dot{\boldsymbol{\omega}}_b^b + \boldsymbol{\omega}_b^b \times \mathbf{I}_b \boldsymbol{\omega}_b^b, \\ \mathbf{F}_i^i = m_i \mathbf{a}_{C_i}^i, \\ \mathbf{M}_i^i = \mathbf{I}_i \dot{\boldsymbol{\omega}}_i^i + \boldsymbol{\omega}_i^i \times \mathbf{I}_i \boldsymbol{\omega}_i^i, \end{array} \right. \quad (2)$$

where  $m_b$  and  $m_i$  are the mass of the aerial vehicle and link  $i$ ,  $\mathbf{I}_b$  and  $\mathbf{I}_i$  are the inertia matrix of the aerial vehicle and link  $i$ .  $\mathbf{F}_b^b$  and  $\mathbf{F}_i^i$  are the total external force exerted on the aerial vehicle and link  $i$ , and  $\mathbf{M}_b^b$  and  $\mathbf{M}_i^i$  are the total external moment exerted on the aerial vehicle and link  $i$ , which can be calculated inward iteratively from the manipulator end effector to the aerial vehicle platform as

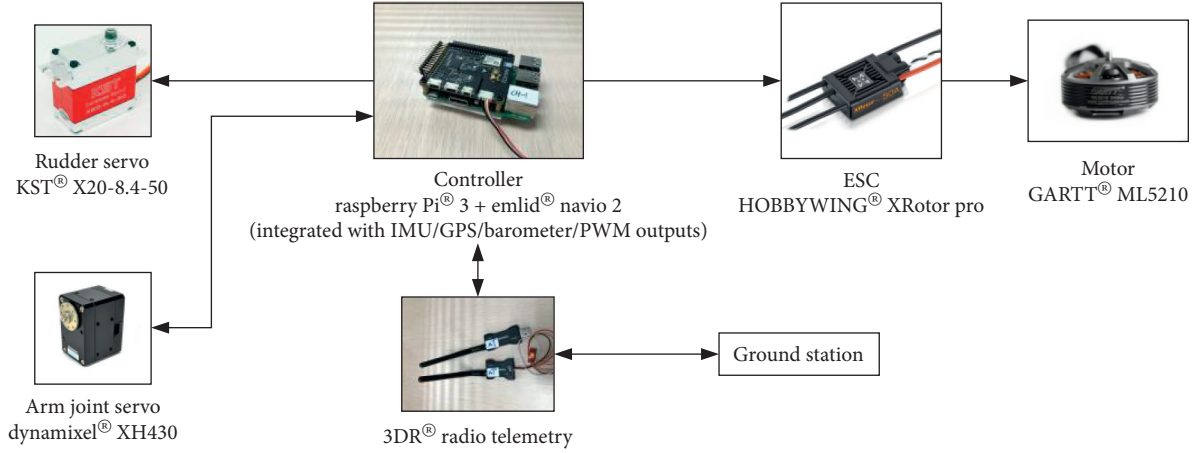

FIGURE 4: The hardware of control unit.

FIGURE 5: The coordinate system of the aerial manipulator.

$$\begin{cases}
 \mathbf{f}_i^i = \mathbf{F}_i^i + \mathbf{R}_{i+1}^i \mathbf{f}_{i+1}^{i+1} - \mathbf{R}_i^T m_i \mathbf{g}, \\
 \mathbf{n}_i^i = \mathbf{M}_i^i + \mathbf{R}_{i+1}^i \mathbf{n}_{i+1}^{i+1} + \mathbf{p}_{i+1}^i \times \mathbf{R}_{i+1}^i \mathbf{f}_{i+1}^{i+1} + \mathbf{p}_{C_i}^i \times (\mathbf{F}_i^i - \mathbf{R}_i^T m_i \mathbf{g}), \\
 \tau_i = (\mathbf{n}_i^i)^T \mathbf{e}_{z_i}, \\
 \mathbf{F}_b^b = \mathbf{F}_{\text{aero1}} + \mathbf{F}_{\text{aero2}} + \mathbf{F}_{\text{rudder1}} + \mathbf{F}_{\text{rudder2}} + \mathbf{F}_{\text{fus}} + \mathbf{R}_b^T m_b \mathbf{g} \\
 \quad - \mathbf{R}_0^b \mathbf{R}_1^0 \mathbf{f}_1^1, \\
 \mathbf{M}_b^b = \mathbf{M}_{\text{aero1}} + \mathbf{M}_{\text{aero2}} + \mathbf{p}_{cd1}^b \times \mathbf{F}_{\text{aero1}} + \mathbf{p}_{cd2}^b \times \mathbf{F}_{\text{aero2}} + \mathbf{p}_{cr1}^b \\
 \quad \times \mathbf{F}_{\text{rudder1}} + \mathbf{p}_{cr2}^b \times \mathbf{F}_{\text{rudder2}} + \mathbf{M}_{\text{gyro}} - \mathbf{R}_0^b \mathbf{R}_1^0 \mathbf{n}_1^1,
 \end{cases} \quad (3)$$

where  $\mathbf{f}_i^i$  and  $\mathbf{n}_i^i$  are the force and moment exerted on link  $i$  by link  $i-1$  and  $\mathbf{R}_i$  is the transformation matrix from the  $i^{\text{th}}$  link coordinate frame to the earth-fixed coordinate frame.  $\tau_i$  is the joint torque of the manipulator.

The total force of the aerial vehicle includes five parts: the aerodynamic force of the ducted fans, the resultant force generated by the rudders, the fuselage resistance, the gravity, and the reaction force of the manipulator. The total moment of the aerial vehicle also includes five parts: the aerodynamic moment of the ducted fans, the torque generated by the aerodynamic forces, the torque generated by the rudders, the reaction torque of the manipulator, and the gyro moment

produced by rotors, as shown in Figure 6. In equation (3), the subscript ‘‘aero’’ refers to the aerodynamic force and moment, subscript 1 denotes the front ducted fan system, and subscript 2 denotes the rear ducted fan system. Same as the above, the subscript rudder refers to the force of the front and the rear rudder system. fus refers to the fuselage resistance, and gyro refers to the gyro torque.  $\mathbf{p}_{cd}^b$  is the position vector of the center of duct with respect to the center of the vehicle, and  $\mathbf{p}_{cd}^b$  is the position vector of the aerodynamic center of rudder with respect to the center of the vehicle. These forces and moments belong to the ducted fan system dynamics, which provide the main thrust and attitude control moments for the aerial vehicle, and will be introduced in detail in the following section.

**2.3. Ducted Fan System.** As mentioned in the Introduction, most of the literature of aerial manipulator uses multirotor as aerial platform. Because of the simple, symmetrical, and decoupled open rotor structure, the rotor aerodynamics is usually simplified as a thrust and a reaction torque in quadratic relation to the rotor speed, ignoring any other effects of the aerodynamic characteristics (e.g., [22, 26, 27]). However, the aerodynamics of ducted fan is significantly different from the traditional open rotor [32]. First, the duct lip causes airflow deflection effect, which changes the inflow at the rotor disc, while additional thrust is generated by the suction flow of the duct lip; second, duct suppresses the rotor tip vortex and reduces the momentum loss; third, the duct exit prevents the airflow from contracting, which increases the outflow pressure of the rotor and thereby increases the thrust. Johnson and Turbe [17] propose a Blade Element Momentum Theory (BEMT) model for ducted-single-rotor system. By improving this method, the dynamic model of our ducted-coaxial-rotor system is proposed. The basic idea of BEMT is to establish a set of relationships between rotor aerodynamic force and induced velocity through momentum theorem and blade element theory, respectively, and then solve the simultaneous equations iteratively. The following is the derivation of the front ducted fan, and the rear one can be obtained in the same way.

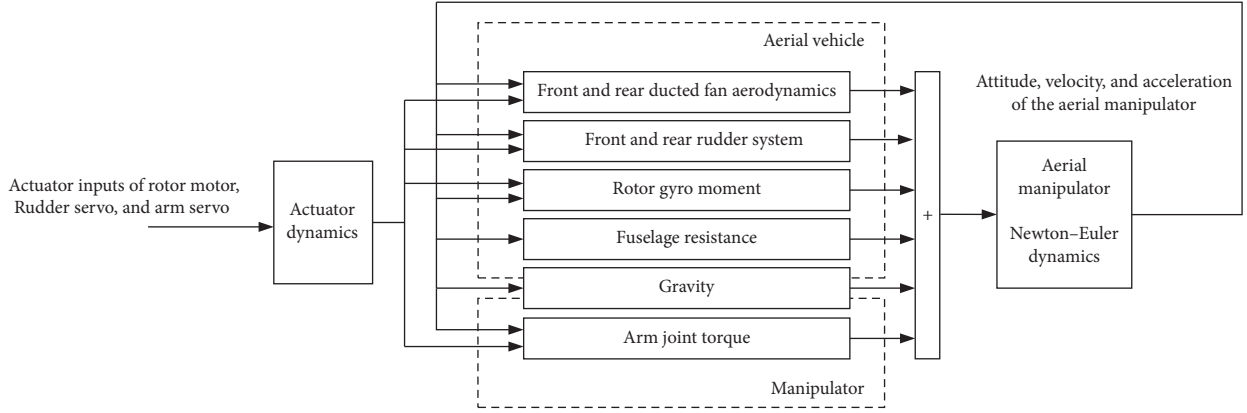

FIGURE 6: Diagram of the dynamic model.

*Momentum Theorem.* The inflow process of the coaxial ducted fan under airflow deflection effect is shown in Figure 7. It can be divided into five parts: the free inflow, the deflected airflow whose direction is deflected by duct lip, the airflow at upper rotor disc, the airflow at lower rotor disc, and the outflow of duct exit. The free flow at the ducted fan is

$$\mathbf{V}_a = [u_a \ v_a \ w_a]^T = \mathbf{v}_b^b - \mathbf{R}_b^T \mathbf{v}_w, \quad (4)$$

where  $\mathbf{v}_b^b$  is the body velocity of the aerial vehicle and  $\mathbf{v}_w$  is the local wind velocity. Express  $v_a$  in the inflow plane; the inflow velocity  $v_0$  is calculated as

$$\begin{cases} \mathbf{V}_0 = |\mathbf{V}_0| \cos \alpha i + |\mathbf{V}_0| \sin \alpha j, \\ |\mathbf{V}_0| = |\mathbf{V}_a|, \alpha = \arctan\left(\frac{w_a}{\sqrt{u_a^2 + v_a^2}}\right). \end{cases} \quad (5)$$

Then, the deflected airflow, the airflow at upper and lower rotor disc, and the outflow can be calculated by

$$\begin{cases} \mathbf{V}_t = |\mathbf{V}_0| \cos \alpha_t i + |\mathbf{V}_0| \sin \alpha_t j, \\ \mathbf{V}_{r1} = |\mathbf{V}_0| \cos \alpha_t i + (|\mathbf{V}_0| \sin \alpha_t + v_{i1}) j, \\ \mathbf{V}_{r2} = |\mathbf{V}_0| \cos \alpha_t i + (|\mathbf{V}_0| \sin \alpha_t + v_{i1} + v_{i2}) j, \\ \mathbf{V}_e = |\mathbf{V}_0| \cos \alpha_t i + (|\mathbf{V}_0| \sin \alpha_t + v_{\infty}) j, \end{cases} \quad (6)$$

where  $v_{i1}$  and  $v_{i2}$  refer to the induced velocities of upper and lower rotor,  $v_{\infty}$  refers to the overall impact of the ducted fan on free flow, and  $\alpha_t$  is the deflection angle caused by duct effect at duct lip, which can be expressed as a function of free inflow angle and airflow deflection factor as

$$\alpha_t = \alpha + k_t \left( \frac{\pi}{2} - \alpha \right). \quad (7)$$

According to momentum theorem and kinetic energy theorem, considering the control body from the free inflow

to the upper disc exit and from the upper disc exit to the duct exit and the entire duct, respectively, the following equations are obtained:

$$\begin{cases} T_{r1} (|\mathbf{V}_0| \sin \alpha_t + v_{i1}) = \frac{1}{2} \rho S_D |\mathbf{V}_0| \left( (|\mathbf{V}_0| \sin \alpha_t + v_{i1})^2 - (|\mathbf{V}_0| \sin \alpha)^2 \right), \\ T_{r2} (|\mathbf{V}_0| \sin \alpha_t + v_{i1} + v_{i2}) = \frac{1}{2} \rho S_D |\mathbf{V}_0| \left( (|\mathbf{V}_0| \sin \alpha_t + v_{\infty})^2 - (|\mathbf{V}_0| \sin \alpha_t + v_{i1})^2 \right), \\ T = (1 + k_{\text{duct}}) (T_{r1} + T_{r2}) = \rho S_D |\mathbf{V}_0| \left( (|\mathbf{V}_0| \sin \alpha_t + v_{\infty})^2 - (|\mathbf{V}_0| \sin \alpha)^2 \right), \\ T_d = \rho S_D |\mathbf{V}_0| (|\mathbf{V}_0| \cos \alpha_t - |\mathbf{V}_0| \cos \alpha), \end{cases} \quad (8)$$

where  $T_{r1}$  and  $T_{r2}$  are the thrusts of upper rotor and lower rotor in the vertical direction,  $T_d$  is the momentum resistance in the horizontal plane,  $k_{\text{duct}}$  is the thrust augment factor of duct, and  $SD$  is the rotor disc area.

*Blade Element Theory.* Blade element theory analyzes the aerodynamics of each micro element of the blade, then integrates it along the radial direction of the blade, and averages it along the circumferential direction to solve the forces and moments of the entire rotor. According to equations (5) and (6), the airflow velocities at the blades of upper and lower rotors are

$$\begin{cases} \mathbf{V}_{ra1} = [u_{ra1} \ v_{ra1} \ w_{ra1}]^T = \left[ |\mathbf{V}_0| \cos \alpha_t \frac{u_a}{\sqrt{u_a^2 + v_a^2}} \quad |\mathbf{V}_0| \cos \alpha_t \frac{v_a}{\sqrt{u_a^2 + v_a^2}} \quad |\mathbf{V}_0| \sin \alpha_t \right]^T, \\ \mathbf{V}_{ra2} = [u_{ra2} \ v_{ra2} \ w_{ra2}]^T = \left[ |\mathbf{V}_0| \cos \alpha_t \frac{u_a}{\sqrt{u_a^2 + v_a^2}} \quad |\mathbf{V}_0| \cos \alpha_t \frac{v_a}{\sqrt{u_a^2 + v_a^2}} \quad |\mathbf{V}_0| \sin \alpha_t + v_{i1} \right]^T. \end{cases} \quad (9)$$

FIGURE 7: The inflow process model.

Since the blade element theory is a common method, the results after integration of the rotor thrust  $T_{ri}$ , the reaction torque  $Q_{ri}$ , the pneumatic rolling torque  $L_{ri}$ , and the

pneumatic pitching torque  $M_{ri}$  of the upper and lower rotor are directly given below. Notice that  $i = 1$  for upper rotor and  $i = 2$  for lower rotor:

$$\left\{ \begin{array}{l} T_{ri} = \frac{n}{2\pi} \int_0^{2\pi} \int_0^R dT_{ri} d\psi_0 = \frac{n\rho c C_a \Omega_i^2 R^3}{4} \left( \left( \frac{2}{3} + \mu_{ui}^2 + \mu_{vi}^2 \right) \theta_0 - (1 + \mu_{ui}^2 + \mu_{vi}^2) \frac{\theta_{rw}}{2} - \lambda_{wi} \right), \\ Q_{ri} = \frac{n}{2\pi} \int_0^{2\pi} \int_0^R dQ_{ri} d\psi_0 = \frac{n\rho c C_a \Omega_i^2 R^4}{4} \left( \left( \frac{2}{3} \theta_0 - \frac{1}{2} \theta_{rw} - \lambda_{wi} \right) \lambda_{wi} + \frac{1}{2} (1 + \mu_{ui}^2 + \mu_{vi}^2) C_d \right), \\ L_{ri} = \frac{n}{2\pi} \int_0^{2\pi} \int_0^R dL_{ri} d\psi_0 = \frac{n\rho c C_a \Omega_i^2 R^4}{4} \left( \mu_{vi} \left( \frac{2}{3} \theta_0 - \frac{1}{2} \lambda_{wi} - \frac{1}{2} \theta_{rw} \right) \right), \\ M_{ri} = \frac{n}{2\pi} \int_0^{2\pi} \int_0^R dM_{ri} d\psi_0 = \frac{n\rho c C_a \Omega_i^2 R^4}{4} \left( \mu_{ui} \left( \frac{2}{3} \theta_0 - \frac{1}{2} \lambda_{wi} - \frac{1}{2} \theta_{rw} \right) \right). \end{array} \right. \quad (10)$$

In the above formula,  $n$  is the blade number of each disc,  $R$  is the rotor radius,  $\psi_0$  is the blade azimuth angle,  $c$  is the blade chord length,  $C_a$  is the lift coefficient slope,  $C_d$  is the resistance coefficient,  $\Omega_i$  is the rotor speed,  $\theta_0$  is the blade attack angle, and  $\theta_{rw}$  is the blade torsion rate.  $\mu_{ui}$ ,  $\mu_{vi}$ , and  $\lambda_{wi}$  denote the dimensionless ratios of forward velocity, lateral velocity, and inflow velocity:

$$\mu_{ui} = \left( \frac{u_{rai}}{\Omega_i R} \right), \mu_{vi} = \left( \frac{v_{rai}}{\Omega_i R} \right), \lambda_{wi} = \left( \frac{v_{ii} - w_{rai}}{\Omega_i R} \right). \quad (11)$$

Solve equations (8) and (10) simultaneously; the aero force and moment of the ducted fan in body-fixed frame can be derived as

$$\left\{ \begin{array}{l} \mathbf{F}_{aero} = \left[ -\frac{u_a}{\sqrt{u_a^2 + v_a^2}} T_d \quad -\frac{v_a}{\sqrt{u_a^2 + v_a^2}} T_d \quad -T \right]^T, \\ \mathbf{M}_{aero} = [L_{r1} - L_{r2} \quad M_{r1} - M_{r2} \quad Q_{r1} - Q_{r2}]^T. \end{array} \right. \quad (12)$$

*Rudder Dynamics.* Same as the ducted fan system, the following gives the analysis of the front rudder, and the rear one can be obtained in the same way. The rudder is in the outflow of the duct exit, and its attack angle can be calculated by

$$\alpha_v = \alpha_e + \delta, \quad (13)$$

where  $\alpha_e$  is the angle of the duct outflow velocity  $V_e$ , and  $\delta$  is the rudder control angle. Then the aero-lift and aero-drag of the rudder can be derived as

$$\begin{cases} L_v = \left(\frac{1}{2}\right)\rho|\mathbf{V}_e|^2 S_v C_{lv}, \\ D_v = \left(\frac{1}{2}\right)\rho|\mathbf{V}_e|^2 S_v C_{dv}, \end{cases} \quad (14)$$

where  $\rho$  is the airflow density,  $S_v$  is the rudder area, and  $C_{lv}$  and  $C_{dv}$  are the lift coefficient and drag coefficient, which are the functions of  $\alpha_v$ . The force of the control rudder in body-fixed frame can then be derived.  $n_v$  is the number of the rudders in one duct:

$$\mathbf{F}_{\text{rudder}} = [0 \quad n_v(L_v \cos \alpha_e + D_v \sin \alpha_e) \quad n_v(-L_v \sin \alpha_e + D_v \cos \alpha_e)]^T. \quad (15)$$

In summary, the expression of each component in equation (3) is obtained, and the comprehensive nonlinear mechanism model is established.

**2.4. Model Identification of the Aerial Platform.** The comprehensive nonlinear mechanism model established in the previous section can fully reflect the characteristics of the system in all-envelope range and be used for system performance prediction and comprehensive simulation analysis, but the complex mechanism is not suitable for the controller design process [33]. Since the working scenarios of the aerial vehicle in this paper are hovering or near-hovering conditions, in order to reduce the complexity of nonlinear identification and improve the identification accuracy under the noise of low-cost sensors, the parametric frequency domain identification is performed. First, a simplified parametric model can be derived from the nonlinear mechanism model of the aerial platform by small perturbation assumption under hover equilibrium point; then, a control-oriented state space model of the aerial platform is derived based on frequency domain identification method. The identification model is verified in both time and frequency domains.

The nonlinear mechanism model of the aerial vehicle can be described as

$$\begin{cases} \dot{\mathbf{x}}_b = \mathbf{f}(\mathbf{x}_b, \mathbf{u}_b), \\ \mathbf{x}_b = [u \quad v \quad w \quad p \quad q \quad r \quad \varphi \quad \theta \quad \psi]^T, \\ \mathbf{u}_b = [u_{\text{alt}} \quad u_{\text{rol}} \quad u_{\text{pit}} \quad u_{\text{yaw}}]^T, \end{cases} \quad (16)$$

where  $\mathbf{u}_b$  is the normalization control input vector, referring to the altitude channel, roll channel, pitch channel, and yaw channel, and is mapped to the rotor speed difference and rudder angle (described in 2.1). Find the partial derivative of equation (16) at hover equilibrium point to obtain the system's Jacobian matrix:

$$\begin{cases} \dot{\mathbf{x}}_b \approx \mathbf{A}(\mathbf{x}_b - \mathbf{x}_{\text{hover}}) + \mathbf{B}(\mathbf{u}_b - \mathbf{u}_{\text{hover}}), \\ \mathbf{A} = \left(\frac{\partial \mathbf{f}}{\partial \mathbf{x}_b}\right), \mathbf{B} = \left(\frac{\partial \mathbf{f}}{\partial \mathbf{u}_b}\right), \\ \mathbf{f}(\mathbf{x}_{\text{hover}}, \mathbf{u}_{\text{hover}}) = \mathbf{0}. \end{cases} \quad (17)$$

Then, the simplified parametric matrix A and B to be identified is obtained by small perturbation assumption. Since  $\mathbf{x}_{\text{hover}}$  and  $\mathbf{u}_{\text{hover}}$  are constant and  $\mathbf{x}_{\text{hover}} = \mathbf{0}$ , in the rest of this paper, for the simplicity of the symbol, let  $\mathbf{x}_b \equiv \mathbf{x}_b - \mathbf{x}_{\text{hover}}$ ,  $\mathbf{u}_b \equiv \mathbf{u}_b - \mathbf{u}_{\text{hover}}$ . Because the aerial vehicle platform is inherently unstable, the closed-loop identification is carried out following the procedure in [34]. A simple PID controller is used to ensure the stability during identification process. A set of Chirp sweep signals (introduced in [35]) is performed in each of the input channels, and the data is processed by CIFER<sup>®</sup> identification tool [35]. The model fitting process is an optimization problem as

$$\min J = \sum_{i=1}^n \left\{ \left( \frac{20}{n_\omega} \right) \sum_{\omega_1}^{\omega_{n_\omega}} W_\gamma \left[ W_g \left( |G_{fi}| - |G_i| \right)^2 + W_p \left( \angle G_{fi} - \angle G_i \right)^2 \right] \right\}, \quad (18)$$

where  $G_{fi}$  is the transfer function to be fitted corresponding to  $G_i$ , converting from the parametric state space equation, and  $n$  is the number of the transfer functions.  $|G|$  refers to the amplitude and  $\angle G$  refers to the phase.  $n_\omega$  is the number of the selected frequency sampling points, and  $\omega_1$  and  $\omega_{n_\omega}$  refer to the initial and termination sampling frequency respectively.  $W_\gamma$ ,  $W_g$ , and  $W_p$  are the weighting functions referring to coherence value, amplitude, and phase, respectively, and are chosen following the directions in CIFER<sup>®</sup>. The frequency response identification results are shown in Figures 8 and 9, and the identified model is

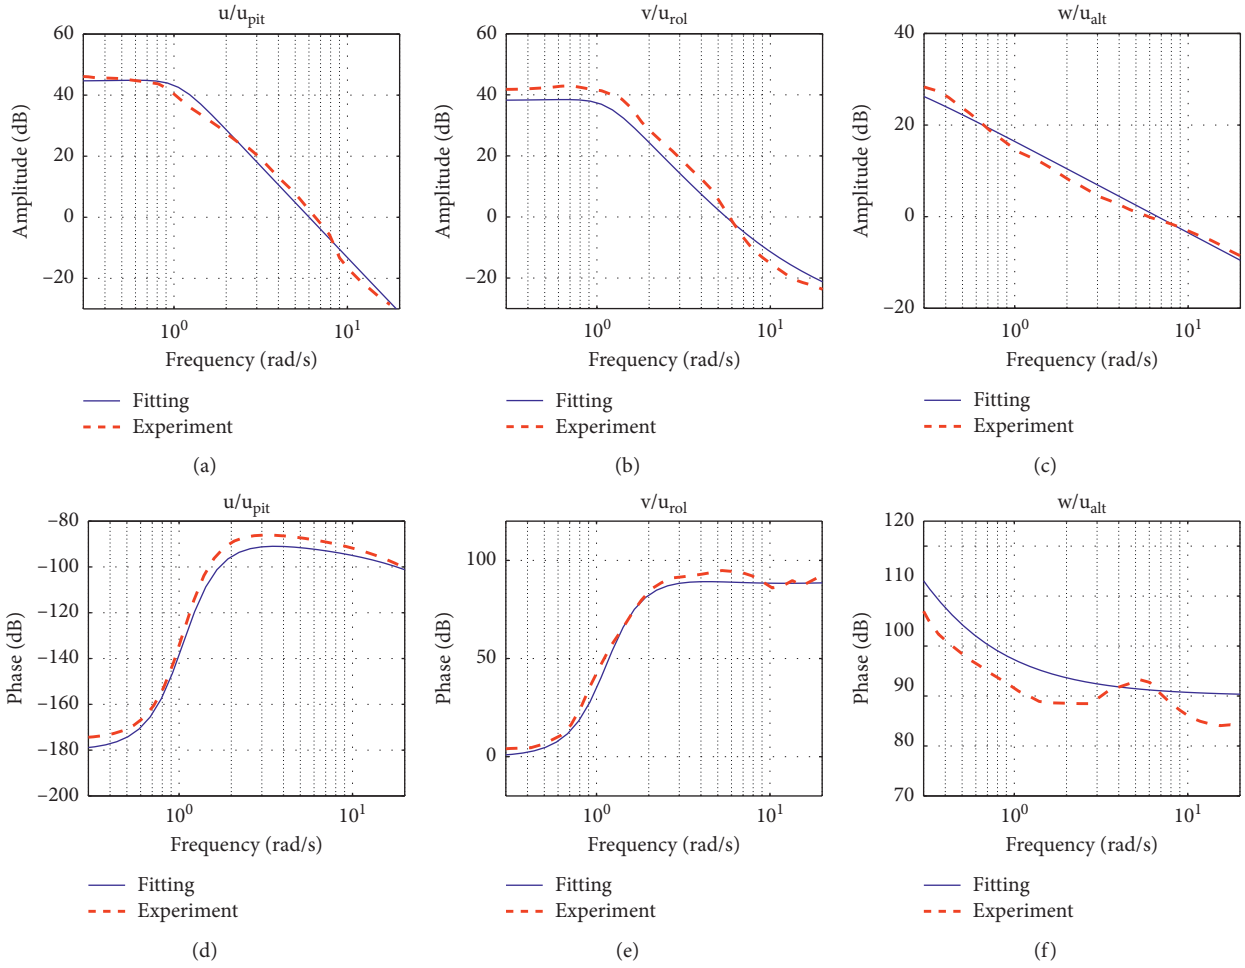

FIGURE 8: Frequency response identification results of linear velocities.

FIGURE 9: Continued.

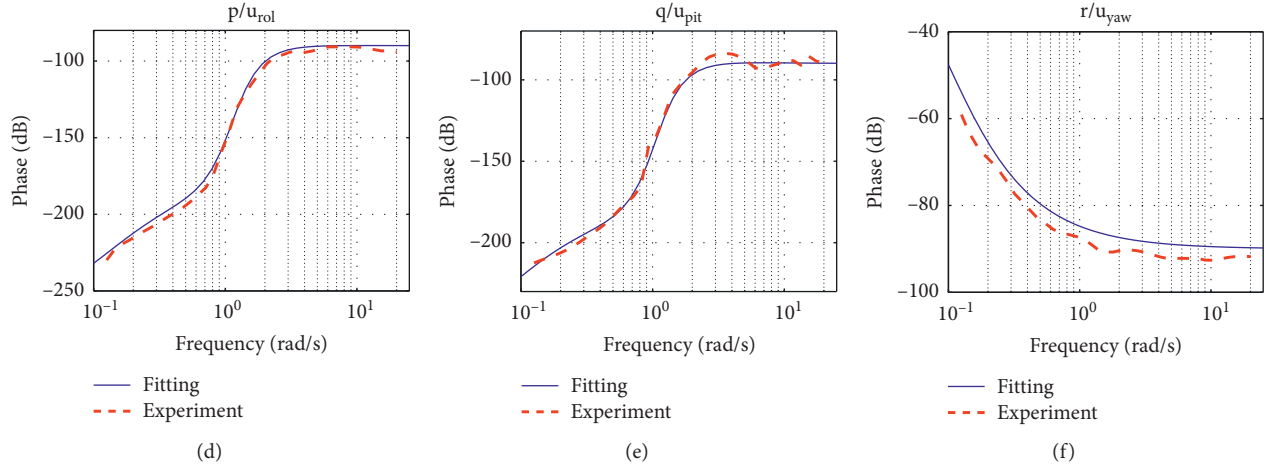

FIGURE 9: Frequency response identification results of angular rates.

$$\left. \begin{array}{l} \mathbf{A} = \begin{pmatrix} -0.0876 & 0 & 0 & 0 & 0 & 0 & 0 & -9.8010 & 0 \\ 0 & -0.0876 & 0 & 0 & 0 & 0 & 9.8010 & 0 & 0 \\ -0.1178 & -0.1172 & -1.0415 & -0.0012 & -0.0209 & -0.0509 & 0 & 0 & 0 \\ 0 & -0.6801 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.0940 & 0 & 0 & 0 & -1.0699 & 0.0132 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -0.0122 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \end{pmatrix} \\ \mathbf{B} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -20.9312 & 0 & 0.0547 & -0.0015 \\ 0 & 8.3494 & 0 & 0.0260 \\ 0 & -0.0025 & 10.0876 & -0.0281 \\ 0 & 0.0016 & 0.1337 & 3.3981 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \end{array} \right\} \quad (19)$$

In order to verify the accuracy of the identified model, a series of flight tests are carried out in time domain, as shown in Figure 10. The low-pass filtered bipolar square wave signal, which is different from the identification excitation signal, is used as the excitation signal in each channel, and the evaluation of the model is realized by comparing the output of the identified model simulation and the actual test measurement. Notice that the angular rate errors in Figure 10 are large while other variables match well, because the dynamic characteristics of angular rate are ignored in high frequency in the linearized model and the angular rate

channel has relatively large measurement noise. According to [35], Theil inequality coefficient (TIC) can be used to estimate the model fitting accuracy, which is calculated as

$$J_{\text{TIC}} = \frac{\sqrt{1/n \sum_{i=1}^n (\mathbf{y}_{\text{test}} - \mathbf{y}_{\text{sim}})^T (\mathbf{y}_{\text{test}} - \mathbf{y}_{\text{sim}})}}{\sqrt{1/n \sum_{i=1}^n \mathbf{y}_{\text{sim}}^T \mathbf{y}_{\text{sim}} + 1/n \sum_{i=1}^n \mathbf{y}_{\text{test}}^T \mathbf{y}_{\text{test}}}}, \quad (20)$$

where  $\mathbf{y}_{\text{sim}}$  and  $\mathbf{y}_{\text{test}}$  are the output vector of identified model simulation and actual flight test, and  $n$  is the number of sampling points. A smaller value of TIC indicates that the accuracy of the identified model is higher, and a value less

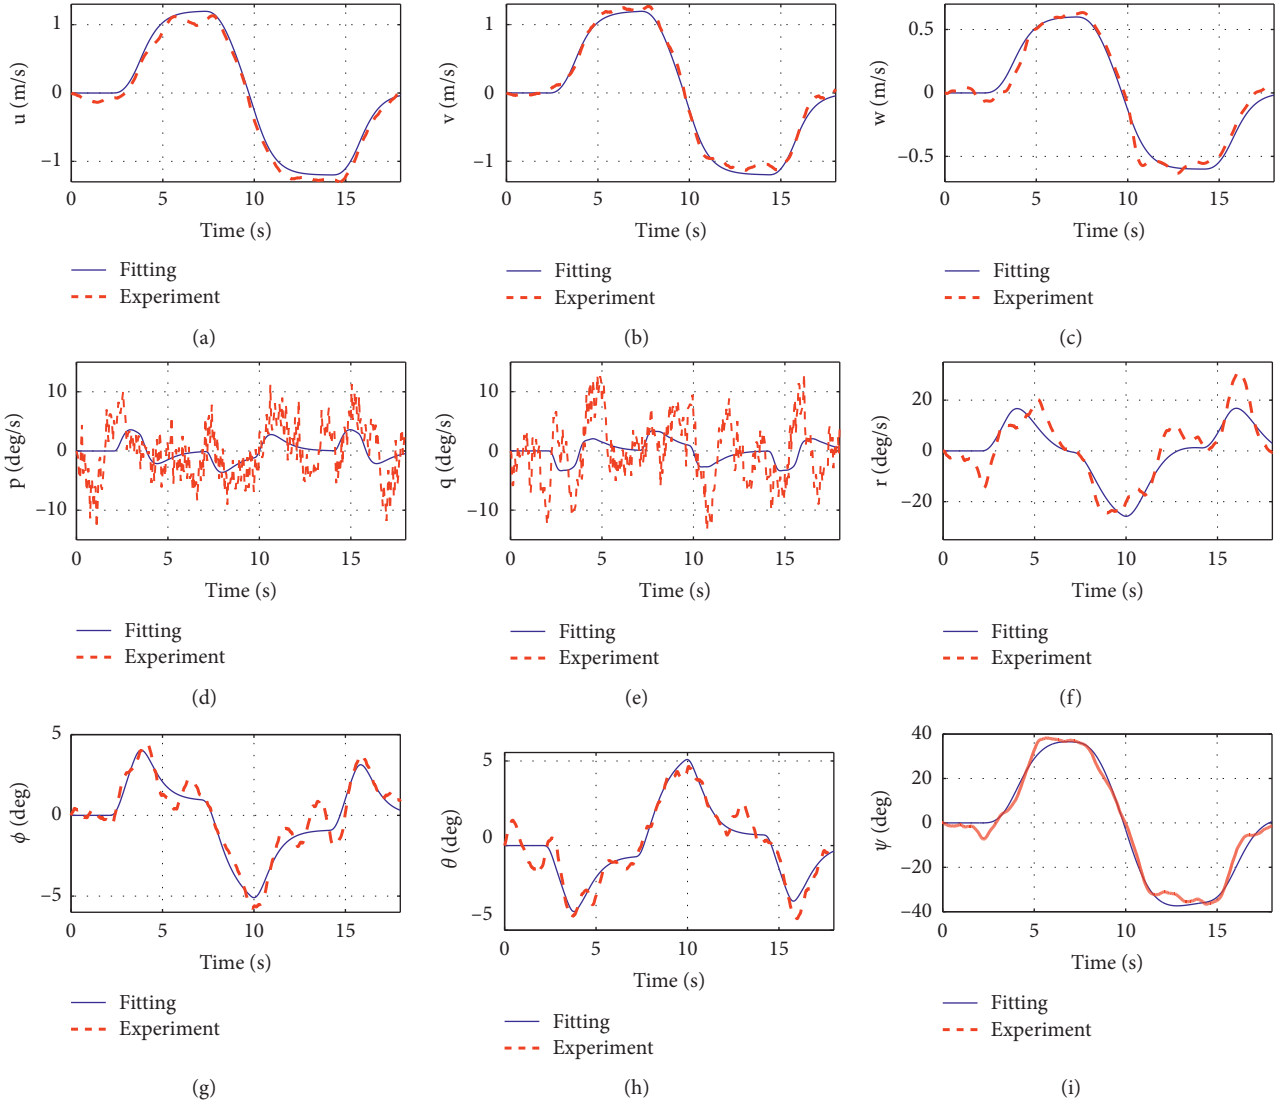

FIGURE 10: Time-domain verification of the identified model.

than 0.25 indicates that the model has good predictive performance [35].  $J_{TIC}$  of our model is 0.1596, indicating that the nominal model has satisfactory accuracy.

### 3. Composite Controller Design

The overall architecture of the aerial manipulator control system is shown in Figure 11. A typical application scenario of the aerial manipulator is that, given the reference position of the target object, the aerial vehicle flies near the target, and the manipulator moves, grabs the object, and then leaves. Since the process of arriving at the desired position of the aerial platform and completing the operation task of the manipulator is independent, and the control objectives, dynamic characteristics, and response speed of the aerial platform and the manipulator are different, the controllers of the aerial platform and the manipulator are designed separately for the purposes of reducing the controller complexity, reducing the hardware cost, and facilitating the

engineering practice. In this framework, the most important challenge is the aerial platform controller design under the motion of manipulator and external interaction disturbances of target object.

This section mainly focuses on the composite controller design of the aerial platform under the existence of manipulator disturbances. First, a two-layer basic controller is designed to ensure the stability, decoupling, and tracking performance of the platform. On the one hand, the aerial vehicle is a strongly coupled, nonlinear, multi-input multi-output (MIMO) system; thus, traditional controllers (such as PID controller) cannot guarantee good performance of the system. On the other hand, based on the premise of guaranteeing performance, the controller should have low complexity, clear structure, and high solution rate to be easy in practice. Considering these two aspects, a robust static feedback controller based on H-infinite synthesis and nonsmooth optimization is designed as the basic inner loop controller, which guarantees good robustness and stability

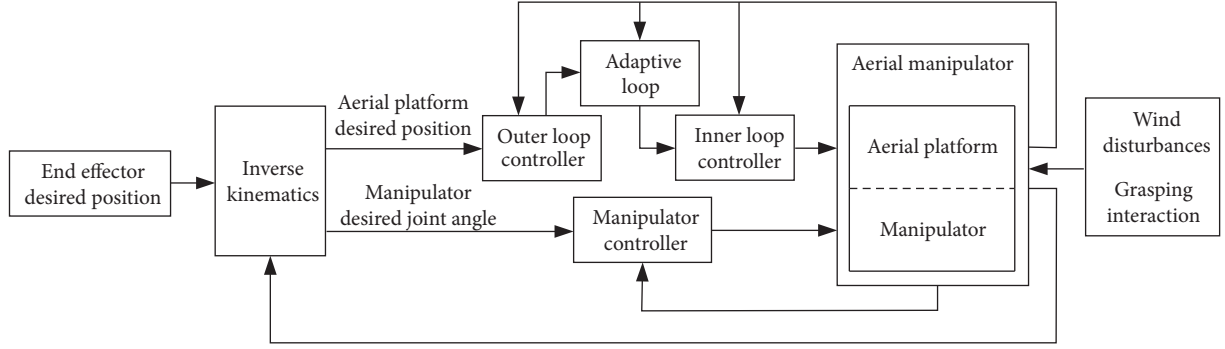

FIGURE 11: The architecture of the control system.

of the system while not increasing the system order. Second, considering the movement of the manipulator and the disturbances of the environment, an auxiliary adaptive loop is designed to estimate and compensate for the disturbances of the aerial platform. Both the static (gravity force and moment) and dynamic (inertia force and moment) disturbances of the manipulator are considered to improve the platform stability and the end effector tracking accuracy.

In addition, in order to improve the control accuracy of the manipulator under the motion of the aerial platform, a computed torque PID controller, considering the dynamics of the aerial platform, is used for manipulator control. Since the computed torque PID control is a conventional method, and the manipulator dynamics is elaborated in Section 2, the controller of the manipulator is not detailed in this paper.

**3.1. Robust Basic Controller Design.** The design objective of the basic controller is to achieve the stability and accurate position tracking of the aerial platform. The diagram of the basic controller is shown in Figure 12, which includes two loops. The inner loop is an H-infinite static full-state feedback controller  $K_b$  to ensure the decoupling and stabilization of the system, and a prepositive static controller  $K_f$  is proposed for tracking performance of the inner loop. Since the inner loop has been well decoupled and stabilized, the outer loop (position loop) is designed as a series of simple PD controllers for position tracking. According to (17), the control-oriented dynamic model of the aerial platform is

$$\begin{cases} \dot{\mathbf{x}}_b(t) = \mathbf{A}\mathbf{x}_b(t) + \mathbf{B}\mathbf{u}_b(t) + \mathbf{f}(t), \\ \mathbf{y}_b(t) = \mathbf{C}\mathbf{x}_b(t), \\ \mathbf{x}_b = [u \ v \ w \ p \ q \ r \ \varphi \ \theta \ \psi]^T, \\ \mathbf{y}_b = [u \ v \ w \ r]^T, \end{cases} \quad (21)$$

where  $\mathbf{f}$  is the disturbance vector. The reference command is  $\mathbf{r}_b = [u_{\text{ref}} \ v_{\text{ref}} \ w_{\text{ref}} \ r_{\text{ref}}]^T$ . Accordingly, the outer loop reference command is  $\mathbf{p}_r = [x_{\text{ref}} \ y_{\text{ref}} \ z_{\text{ref}} \ \psi_{\text{ref}}]^T$ . The kinematics module in Figure 12 converts the variables between the body-fixed coordinate frame and earth-fixed coordinate frame according to equation (1).

Focusing on the inner loop controller, we can define the output error as

$$\mathbf{e}_b = \mathbf{r}_b - \mathbf{y}_b. \quad (22)$$

Rewrite the system model in frequency domain and augment it, and the structured decoupling standard form of H-infinite synthesis problem [36] can be obtained as in Figure 13:

$$\begin{cases} \mathbf{y}_{\text{aug}} = [\mathbf{y}_b \ \mathbf{x}_{\text{aug}}]^T = \mathbf{G}_{\text{aug}}\mathbf{u}_{\text{aug}}, \\ \mathbf{x}_{\text{aug}} = [\mathbf{e}_b \ \mathbf{x}_b]^T, \\ \mathbf{u}_{\text{aug}} = [\mathbf{f} \ \mathbf{r}_b \ \mathbf{u}_b]^T, \\ \mathbf{G}_{\text{aug}}(\omega) = \begin{bmatrix} \mathbf{C}\mathbf{G}_f & 0 & \mathbf{C}\mathbf{G}_b \\ -\mathbf{C}\mathbf{G}_f & \mathbf{I} & -\mathbf{C}\mathbf{G}_b \\ \mathbf{G}_f & 0 & \mathbf{G}_b \end{bmatrix}, \end{cases} \quad (23)$$

where the control law of the robust controller can be calculated as

$$\begin{cases} \mathbf{u}_b = \mathbf{K}_f\mathbf{e}_b - \mathbf{K}_b\mathbf{x}_b = \mathbf{K}_{\text{st}}\mathbf{x}_{\text{aug}}, \\ \mathbf{K}_{\text{st}} = \begin{bmatrix} \mathbf{K}_f & 0 \\ 0 & -\mathbf{K}_b \end{bmatrix}. \end{cases} \quad (24)$$

For the augmented system, the closed-loop transfer function from the input  $m$  to the output  $n$  can be calculated by linear fractional transformation (LFT) as

$$\mathbf{T}_{m \rightarrow n}(s) = \mathbf{F}_l(\mathbf{G}_{\text{aug}}, \mathbf{K}_{\text{st}}). \quad (25)$$

Then, based on H-infinite synthesis method, the controller tuning process can be converted into an optimization problem as

$$\begin{aligned} \min_{\mathbf{K}_{\text{st}}} \quad & \mathbf{J} = \|\mathbf{W}_{\Delta}\mathbf{T}_{\Delta}(\mathbf{G}_{\text{aug}}, \mathbf{K}_{\text{st}})\|_{\infty} \\ \text{subject to} \quad & \mathbf{K}_{\text{st}} \text{ stabilizes } \mathbf{G}_{\text{aug}} \text{ internally} \end{aligned} \quad (26)$$

$$\|\mathbf{W}_{\Delta}\mathbf{T}_{\Delta}(\mathbf{G}_{\text{aug}}, \mathbf{K}_{\text{st}})\|_{\infty} < 1,$$

where  $\|\mathbf{W}_{\Delta}\mathbf{T}_{\Delta}\|_{\infty}$  are the performance constraint functions expressed by H-infinite norm and  $\mathbf{W}_{\Delta}$  are the corresponding weighting functions. The solvability of the optimization problem guarantees the robust stability of the closed-loop system. For the aerial platform in this paper, the following functions are carried out for ensuring tracking performance,

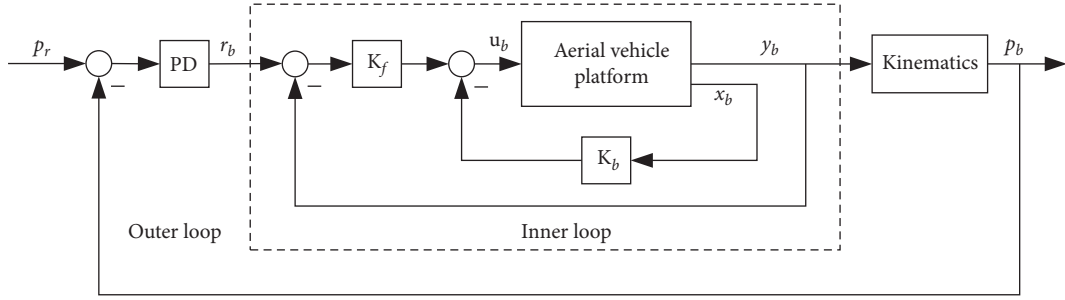

FIGURE 12: Basic controller architecture.

FIGURE 13: Standard structure of H-infinity synthesis.

disturbance rejection performance, and input energy limitation, respectively:

$$\begin{cases} \|W_e(s)T_{r_b} \rightarrow e_b(s)\|_{\infty} < 1, \\ \|W_b(s)T_{r_b} \rightarrow y_b(s)\|_{\infty} < 1, \\ \|W_f(s)T_{f \rightarrow y_b}(s)\|_{\infty} < 1, \\ \|W_u(s)T_{r_b} \rightarrow u_b(s)\|_{\infty} < 1. \end{cases} \quad (27)$$

Solve equation (26) using nonsmooth optimization algorithm [37]; the controller parameters are as follows. In addition, after the inner loop controller has been solved, the outer loop PD controller can be tuned easily by optimization, and the results are also given here:

$$\begin{cases} \mathbf{K}_b = \begin{bmatrix} 0.0056 & 0.0055 & 0.0498 & 0.0012 & -0.0001 & 0.0006 & 0.0086 & -0.0040 & 0.0001 \\ 0.0001 & -0.1648 & 0.0002 & 1.1658 & 0.0111 & 0.2514 & 9.3447 & -0.0118 & -0.0008 \\ 0.0751 & -0.0001 & -0.0001 & 0.0237 & 0.8012 & 0.0328 & 0.0148 & 7.3617 & -0.0003 \\ -0.0050 & 0.0078 & 0.0002 & 0.1888 & 0.0257 & 2.6449 & -0.8605 & -0.5168 & 0.0005 \end{bmatrix}, \\ \mathbf{K}_f = \begin{bmatrix} -0.0478 & 0.0009 & 0.0005 & -0.0019 \\ -0.0034 & 0.9542 & 0.0009 & 0.2473 \\ 0.0007 & 0.0049 & -0.7502 & 0.0351 \\ -0.0167 & -0.0700 & 0.0513 & 2.6541 \end{bmatrix}, \\ \text{PD} = \text{diag}(0.85 + 0.8s \quad 0.85 + 0.8s \quad 0.95 + 1.0s \quad 0.95 + 1.0s). \end{cases} \quad (28)$$

Figure 14 illustrates the robust stability margin of the closed-loop system, where the gain margin exceeds 6 dB, and the phase margin exceeds 45°. The results demonstrate that

the proposed robust controller can guarantee the basic performance of the system.

FIGURE 14: The robust stability margin with the basic controller.

**3.2. Adaptive Auxiliary Controller Design.** Although the designed robust controller has achieved basic stability and tracking performance and has antidisturbance ability to some extent, it cannot deal with the aerial manipulator system well because the disturbance caused by manipulator operation far exceeds the stability margin of the robust controller, which makes the system performance deteriorate dramatically. Therefore, it is necessary to design an adaptive auxiliary loop to compensate for the impact of the manipulator. The architecture of the adaptive controller is shown in Figure 15. The input of the adaptive loop is the output of the outer loop basic PD controller, and its output is the reference input of the inner closed-loop system. Because the inner loop robust controller is static, it does not increase or decrease the state variables and does not change the physical meanings of the system states; thus, the inner closed-loop system can be obtained easily from Section 3.1 as

$$\begin{cases} \dot{\mathbf{x}}_b(t) = \mathbf{A}_{\text{ad}}\mathbf{x}_b(t) + \mathbf{B}_{\text{ad}}\mathbf{u}_{\text{ad}}(t) + \mathbf{f}(t), \\ \mathbf{y}_b(t) = \mathbf{C}\mathbf{x}_b(t), \end{cases} \quad (29)$$

which is clearly bounded-input bounded-state (BIBS) stable relying on the condition of (26) in the inner loop controller design process, and  $\mathbf{A}_{\text{ad}}$  is Hurwitz matrix. Besides, according to the previous description, all the state variables are measurable and  $\mathbf{x}_b(0) = \mathbf{0}$ .  $\mathbf{f}(t)$  is the time-varying disturbance, which is bounded and differentiable, and also the differential is bounded. The boundary of  $\mathbf{f}(t)$  can be estimated by the manipulator dynamics and max grasping payload introduced in Section 2, with some redundancy on this basis. Thus, the following condition is given:

$$\begin{cases} \exists \text{compact set } \mathbb{F}, & \forall t \geq 0, \mathbf{f}(t) \in \mathbb{F}, \\ \exists \mathcal{F} \text{ and } d_F, & \forall t \geq 0, \|\mathbf{f}(t)\|_2 \leq \mathcal{F}, \|\dot{\mathbf{f}}(t)\|_2 \leq d_F, \end{cases} \quad (30)$$

The adaptive loop consists of three parts: first, a state predictor is designed for state prediction; then, the adaptive law is designed for disturbance estimation based on the prediction error; finally, the control law is reconstructed to compensate for the disturbance and track the desired reference. In particular, inspired by the theory in [38], a filter matrix  $\mathbf{C}(s)$  is applied to shape the control input, which decouples the adaptive rate from system robustness. Thus, the large adaptive gain can be adopted while avoiding adverse effects on the system states, which ensures the accurate estimation of disturbance and guarantees good transient and steady-state performance of the adaptive controller.

**3.2.1. Design of the Adaptive Auxiliary Controller.** Consider the following state predictor of the system in equation (29):

$$\begin{cases} \dot{\hat{\mathbf{x}}}_b(t) = \mathbf{A}_{\text{ad}}\hat{\mathbf{x}}_b(t) + \mathbf{B}_{\text{ad}}\mathbf{u}_{\text{ad}}(t) + \hat{\mathbf{f}}(t), \\ \hat{\mathbf{y}}_b(t) = \mathbf{C}\hat{\mathbf{x}}_b(t), \end{cases} \quad (31)$$

where the cap  $\hat{\cdot}$  denotes the estimation of the corresponding variable. Then, the estimation error dynamics can be calculated from (29) and (31) as

$$\begin{cases} \dot{\tilde{\mathbf{x}}}_b(t) = \mathbf{A}_{\text{ad}}\tilde{\mathbf{x}}_b(t) + \tilde{\mathbf{f}}(t), \\ \tilde{\mathbf{x}}_b(t) = \hat{\mathbf{x}}_b(t) - \mathbf{x}_b(t), \\ \tilde{\mathbf{f}}(t) = \hat{\mathbf{f}}(t) - \mathbf{f}(t). \end{cases} \quad (32)$$

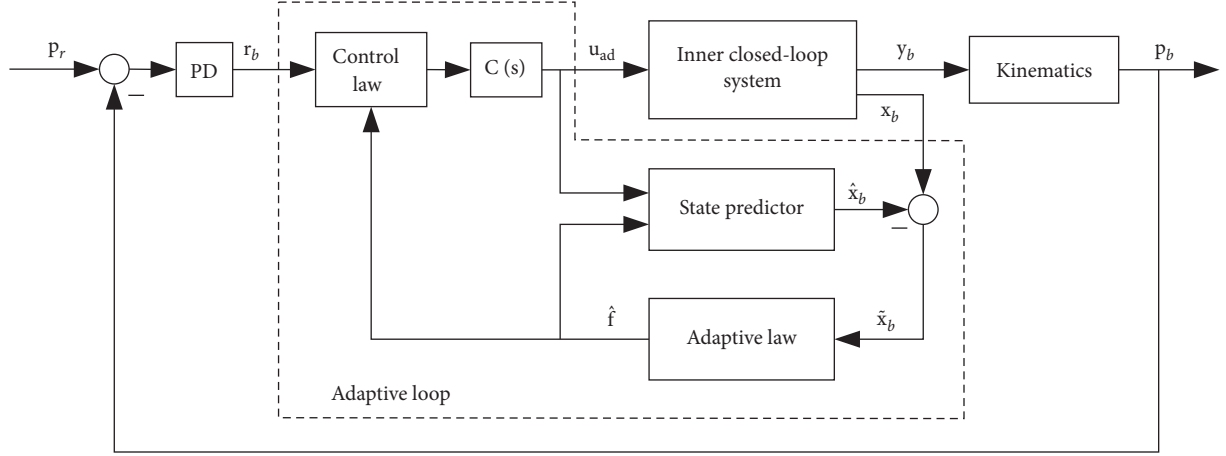

FIGURE 15: Adaptive controller architecture.

In order to ensure the stability of estimation error, consider the following candidate Lyapunov function:

$$V(\tilde{x}_b(t), \tilde{f}(t)) = \tilde{x}_b^T(t) \mathbf{P} \tilde{x}_b(t) + \Gamma^{-1} \tilde{f}^T(t) \tilde{f}(t), \quad (33)$$

where  $\Gamma$  is the adaptive gain. Since  $A_{ad}$  is Hurwitz,  $\mathbf{P}$  is the solution of the following algebraic Lyapunov equation:

$$\mathbf{A}_{ad}^T \mathbf{P} + \mathbf{P} \mathbf{A}_{ad} = -\mathbf{I}. \quad (34)$$

The derivation of (33) is

$$\begin{aligned} \dot{V}(t) &= \dot{\tilde{x}}_b^T(t) \mathbf{P} \tilde{x}_b(t) + \tilde{x}_b^T(t) \mathbf{P} \dot{\tilde{x}}_b(t) + \Gamma^{-1} \left( \dot{\tilde{f}}^T(t) \tilde{f}(t) + \tilde{f}^T(t) \dot{\tilde{f}}(t) \right) \\ &= -\tilde{x}_b^T(t) \tilde{x}_b(t) + 2\tilde{f}^T(t) \left( (\tilde{x}_b^T(t) \mathbf{P})^T + \Gamma^{-1} \dot{\tilde{f}}(t) \right). \end{aligned} \quad (35)$$

Based on Lyapunov stability criterion, let the adaptive law be

$$\dot{\tilde{f}}(t) = \Gamma \text{Proj} \left( \tilde{f}(t), -(\tilde{x}_b^T(t) \mathbf{P})^T \right), \quad (36)$$

where Proj denotes the projection operator, which prevents the divergence and ensures the boundedness of the adaptive parameter, detailed in [39]. Thus, (35) can be further derived as

$$\dot{V}(t) = -\tilde{x}_b^T(t) \tilde{x}_b(t) \leq 0. \quad (37)$$

Notice that in the adaptive law derivation in (35), it is assumed that the change rate of the disturbance  $f$  is slower than the convergence rate of the adaptive estimation; thus, its derivative is approximately 0. In the performance analysis of the next section, this assumption will be relaxed and more general situations will be considered. The estimation error stability under arbitrary disturbance including arbitrary fast time-varying disturbance will be proved in detail with the proposed adaptive law in (36).

Then the control law in Laplace form can be calculated as follows (refer to Figure 15):

$$\mathbf{u}_{ad}(s) = \mathbf{C}(s) \left( \mathbf{K}_g \mathbf{r}_b(s) - \mathbf{F}_1(s) \hat{f}(s) \right). \quad (38)$$

where  $\mathbf{K}_g = -(\mathbf{C} \mathbf{A}_{ad}^{-1} \mathbf{B}_{ad})^{-1}$ ,  $\mathbf{F}_1(s) = \mathbf{H}_1^{-1}(s) \mathbf{C} \mathbf{H}_0(s)$ , and  $\mathbf{H}_0(s) = (s\mathbf{I} - \mathbf{A}_{ad})^{-1}$ ,  $\mathbf{H}(s) = \mathbf{H}_0(s) \mathbf{B}_{ad}$ ,  $\mathbf{H}_1(s) = \mathbf{C} \mathbf{H}(s)$ .  $\mathbf{C}(s)$  is strictly proper and stable low-pass filter matrix. Following the idea in [38],  $\mathbf{C}(s)$  could decouple the adaptive rate from system robustness, and the selection of it should satisfy the following conditions:

$$\begin{cases} \mathbf{C}(s) \text{ is strictly proper and stable with } \mathbf{C}(0) = \mathbf{I}, \\ \exists \rho_{r1}, \|\mathbf{C}(s) \mathbf{H}_1^{-1}(s)\|_{L_1} < \rho_{r1}, \\ \exists \rho_{r2}, \|\mathbf{H}_0(s) (\mathbf{I} - \mathbf{B}_{ad} \mathbf{C}(s) \mathbf{F}_1(s))\|_{L_1} < \rho_{r2}, \end{cases} \quad (39)$$

where  $\|\Delta(s)\|_{L_1}$  refers to the  $L_1$  norm of  $\Delta(s)$  and the last two conditions indicate that the corresponding  $L_1$  norm gain is finite.

Thus, the design process of the adaptive controller is completed. To sum up, for the system in (29), choose the appropriate adaptive gain  $\Gamma$  and filter matrix  $\mathbf{C}(s)$  with satisfying condition (39); the control input is calculated via (31), (36), and (38) as

$$\begin{cases} \dot{\hat{x}}_b(t) = \mathbf{A}_{ad} \hat{x}_b(t) + \mathbf{B}_{ad} \mathbf{u}_{ad}(t) + \hat{f}(t), \\ \dot{\hat{f}}(t) = \Gamma \text{Proj} \left( \hat{f}(t), -(\hat{x}_b^T(t) \mathbf{P})^T \right), \\ \mathbf{u}_{ad}(s) = \mathbf{C}(s) \left( \mathbf{K}_g \mathbf{r}_b(s) - \mathbf{F}_1(s) \hat{f}(s) \right). \end{cases} \quad (40)$$

**3.2.2. Performance Analysis of the Adaptive Auxiliary Controller.** Consider the ideal form of the adaptive controller, which is assumed to compensate for the disturbance perfectly. The closed-loop reference system is defined as

$$\begin{cases} \dot{\mathbf{x}}_{ref}(t) = \mathbf{A}_{ad} \mathbf{x}_{ref}(t) + \mathbf{B}_{ad} \mathbf{u}_{ref}(t) + \mathbf{f}(t), \\ \mathbf{y}_{ref}(t) = \mathbf{C} \mathbf{x}_{ref}(t), \\ \mathbf{u}_{ref}(s) = \mathbf{C}(s) \left( \mathbf{K}_g \mathbf{r}_b(s) - \mathbf{F}_1(s) \mathbf{f}(s) \right), \end{cases} \quad (41)$$

and  $\mathbf{x}_{\text{ref}}(0) = 0$ . Using Laplace transformation, the closed-loop system (41) can be described as

$$\mathbf{x}_{\text{ref}}(s) = \mathbf{H}(s)\mathbf{C}(s)\mathbf{K}_g\mathbf{r}_b(s) + \mathbf{H}_0(s)(\mathbf{I} - \mathbf{B}_{\text{ad}}\mathbf{C}(s)\mathbf{F}_1(s))\mathbf{f}(s). \quad (42)$$

The following lemma describes the L1 norm stability theorem [38].

**Lemma 1.** *A continuous-time linear time-invariant (LTI) MIMO system  $y(s) = G(s)u(s)$  is BIBO stable if its L1 norm is bounded and for arbitrary bounded  $u(t)$  one has*

$$\|\mathbf{y}\|_{L_\infty} \leq \|\mathbf{G}(s)\|_{L_1} \|\mathbf{u}\|_{L_\infty}, \quad (43)$$

where  $\|\Delta(s)\|_{L_1}$  refers to the  $L_1$  norm of  $\Delta(s)$ , and  $\|\Delta(s)\|_{L_\infty}$  refers to the  $L_\infty$  norm of  $\Delta(s)$ .

$$\begin{aligned} \dot{V}(t) &= \dot{\tilde{\mathbf{x}}}_b^T(t)\mathbf{P}\tilde{\mathbf{x}}_b(t) + \tilde{\mathbf{x}}_b^T(t)\mathbf{P}\dot{\tilde{\mathbf{x}}}_b(t) + \Gamma^{-1}\left(\dot{\tilde{\mathbf{f}}}^T(t)\tilde{\mathbf{f}}(t) + \tilde{\mathbf{f}}^T(t)\dot{\tilde{\mathbf{f}}}(t)\right) \\ &= -\tilde{\mathbf{x}}_b^T(t)\tilde{\mathbf{x}}_b(t) + 2\tilde{\mathbf{f}}^T(t)\left(\left(\tilde{\mathbf{x}}_b^T(t)\mathbf{P}\right)^T + \Gamma^{-1}\dot{\tilde{\mathbf{f}}}(t)\right) - 2\Gamma^{-1}\tilde{\mathbf{f}}^T(t)\dot{\tilde{\mathbf{f}}}(t) \\ &\leq -\tilde{\mathbf{x}}_b^T(t)\tilde{\mathbf{x}}_b(t) + 2\tilde{\mathbf{f}}^T(t)\left(\left(\tilde{\mathbf{x}}_b^T(t)\mathbf{P}\right)^T + \mathbf{Proj}\left(\tilde{\mathbf{f}}(t), -\left(\tilde{\mathbf{x}}_b^T(t)\mathbf{P}\right)^T\right)\right) + 2\Gamma^{-1}\left|\tilde{\mathbf{f}}^T(t)\dot{\tilde{\mathbf{f}}}(t)\right| \\ &\leq -\tilde{\mathbf{x}}_b^T(t)\tilde{\mathbf{x}}_b(t) + 4\Gamma^{-1}d_{\mathcal{F}}\mathcal{F}. \end{aligned} \quad (45)$$

Also, from (30) and (33) one has

$$\begin{cases} \max_{t \geq 0} \left(\tilde{\mathbf{f}}^T(t)\tilde{\mathbf{f}}(t)\right) \leq 4 \max_{\mathbf{f} \in \mathcal{F}} \|\mathbf{f}\|_2^2 = 4F^2, \\ V(0) = \Gamma^{-1}\tilde{\mathbf{f}}^T(0)\tilde{\mathbf{f}}(0) \leq 4\Gamma^{-1}F^2. \end{cases} \quad (46)$$

Let  $\Omega_m := 4\lambda_{\max}(\mathbf{P})d_{\mathcal{F}}F + 4F^2$ ; if there exist some  $t > 0$  such that  $V(t) > \Gamma^{-1}\Omega_m$ , then, it follows from (33) and (46) that

$$\tilde{\mathbf{x}}_b^T(t)\mathbf{P}\tilde{\mathbf{x}}_b(t) > 4\Gamma^{-1}\lambda_{\max}(\mathbf{P})d_{\mathcal{F}}\mathcal{F}, \quad (47)$$

and thus,

$$\tilde{\mathbf{x}}_b^T(t)\tilde{\mathbf{x}}_b(t) \geq \lambda_{\min}^{-1}(\mathbf{P})\left(\tilde{\mathbf{x}}_b^T(t)\mathbf{P}\tilde{\mathbf{x}}_b(t)\right) > 4\Gamma^{-1}d_{\mathcal{F}}\mathcal{F}. \quad (48)$$

Then, from equations (45) and (48), one can deduce that

$$\dot{V}(t) < 0. \quad (49)$$

According to equation (46), it is derived that  $V(0) < \Gamma^{-1}\Omega_m$ . Based on the deduction above, it can be obtained that

$$\forall t \geq 0, \quad V(t) \leq \Gamma^{-1}\Omega_m. \quad (50)$$

Then, the bound of the state estimation error can be derived as

$$\begin{aligned} \lambda_{\min}(\mathbf{P})\|\tilde{\mathbf{x}}_b(t)\|_2^2 &\leq \tilde{\mathbf{x}}_b^T(t)\mathbf{P}\tilde{\mathbf{x}}_b(t) \leq V(t) \leq \Gamma^{-1}\Omega_m \\ &\Rightarrow \|\tilde{\mathbf{x}}_b(t)\|_2 \leq \sqrt{\lambda_{\min}^{-1}(\mathbf{P})\Gamma^{-1}\Omega_m}, \end{aligned} \quad (51)$$

Since  $A_{\text{ad}}$  is Hurwitz and the conditions in (30) and (39) are satisfied, for all  $t \geq 0$ , the L1 norm of system (42) is finite; thus,  $\|\mathbf{x}_{\text{ref}}\|_{L_\infty}$  is uniformly bounded, the closed-loop reference system (41) is BIBS stable, and the reference system has the following performance bound:

$$\|\mathbf{x}_{\text{ref}}\|_{L_\infty} \leq \|\mathbf{H}(s)\mathbf{C}(s)\mathbf{K}_g\|_{L_1}\|\mathbf{r}_b\|_{L_\infty} + \|\mathbf{H}_0(s)(\mathbf{I} - \mathbf{B}_{\text{ad}}\mathbf{C}(s)\mathbf{F}_1(s))\|_{L_1}\|\mathbf{f}\|_{L_\infty}. \quad (44)$$

For the defined state predictor (31), consider the candidate Lyapunov function (33) again; its derivation under arbitrary fast time-varying disturbance with the adaptive law (40) can be derived as

which proves that the estimation error is uniformly bounded and the state predictor is Lyapunov stable. It also can be drawn from equation (51) that the performance of the state predictor is inversely proportional to the square root of the adaptive gain  $\Gamma$ , which can be improved by increasing the adaptive gain.

It follows from equations (29) and (40) that

$$\begin{cases} \mathbf{x}_b(s) = \mathbf{H}(s)\mathbf{C}(s)\mathbf{K}_g\mathbf{r}_b(s) + \mathbf{H}_0(s) - (\mathbf{I} - \mathbf{B}_{\text{ad}}\mathbf{C}(s)\mathbf{F}_1(s)) \\ \mathbf{f}(s) - \mathbf{H}(s)\mathbf{C}(s)\mathbf{F}_1(s)\tilde{\mathbf{f}}(s), \\ \mathbf{u}_{\text{ad}}(s) = \mathbf{C}(s)\left(\mathbf{K}_g\mathbf{r}_b(s) - \mathbf{F}_1(s)\mathbf{f}(s) - \mathbf{F}_1(s)\tilde{\mathbf{f}}(s)\right). \end{cases} \quad (52)$$

Consider equations (32), (42), and (52) simultaneously; the adaptive state error can be calculated as

$$\mathbf{x}_{\text{ref}}(s) - \mathbf{x}_b(s) = \mathbf{H}(s)\mathbf{C}(s)\mathbf{H}_1^{-1}(s)\mathbf{C}\tilde{\mathbf{x}}_b(s). \quad (53)$$

According to the condition in equation (39) and the bound in equation (51), for all  $t \geq 0$ , the adaptive state error is uniformly bounded:

$$\begin{aligned} \|\mathbf{x}_{\text{ref}} - \mathbf{x}_b\|_{L_\infty} &\leq \|\mathbf{H}(s)\mathbf{C}(s)\mathbf{H}_1^{-1}(s)\mathbf{C}\|_{L_1}\|\tilde{\mathbf{x}}_b\|_{L_\infty} \\ &\leq \|\mathbf{H}(s)\mathbf{C}(s)\mathbf{H}_1^{-1}(s)\mathbf{C}\|_{L_1}\sqrt{\lambda_{\min}^{-1}(\mathbf{P})\Gamma^{-1}\Omega_m}. \end{aligned} \quad (54)$$

The adaptive input error can be calculated by equations (41) and (52), and in a similar way to the state error, the bound of adaptive input error for all  $t \geq 0$  can be derived as

$$\begin{aligned} \|\mathbf{u}_{\text{ref}} - \mathbf{u}_{\text{ad}}\|_{L_\infty} &\leq \|C(s)\mathbf{H}_1^{-1}(s)C\|_{L_1} \|\tilde{x}_b\|_{L_\infty} \\ &\leq \|C(s)\mathbf{H}_1^{-1}(s)C\|_{L_1} \sqrt{\lambda_{\min}^{-1}(\mathbf{P})\Gamma^{-1}\Omega_m}. \end{aligned} \quad (55)$$

Since the closed-loop reference system proved to be BIBS stable in (44), combined with (54) and (55), it can be derived that the closed-loop system with the proposed adaptive controller is BIBS stable, and the performance bound relies on the adaptive gain  $\Gamma$ .

Because the system robustness is decoupled with the adaptive gain by the filter matrix  $C(s)$ , a large  $\Gamma$  can be applied to guarantee good transient and steady-state performance. Theoretically, the choice of adaptive gain is limited only by the performance of the on-board processor hardware. In some literature works, the disturbance  $f$  is called unmatched uncertainty, and, for a general open-loop MIMO system, only its effect on the system output (not the system state) can be compensated for by the control input. However, our system for adaptive controller design is BIBS stable and the system states are equal to system outputs ( $C$  is an identity matrix), which are measurable with actual physical meanings, and the disturbance boundary can be obtained by the manipulator dynamics. Moreover, thanks to the filter matrix  $C(s)$  and the large adaptive gain, the good performance of the adaptive system can be achieved while not leading to adverse effect on the system states. Therefore, the disturbance  $f$  of our system can be estimated and compensated for well. Based on the above discussion, the parameters of the adaptive controller are given as

$$\begin{cases} C(s) = \left( \frac{25}{s^2 + 6s + 25} \right) \mathbf{I}, \\ \Gamma = 1000. \end{cases} \quad (56)$$

#### 4. Simulation Verification and Analysis

The aim of the simulation tests is to verify that the proposed aerial manipulator with the composite controller can meet the requirements of high precision operation tasks well. Concretely, they include three aspects: first, verifying the feasibility of the proposed innovative aerial manipulator design with tandem ducted fans; second, verifying the effectiveness of the proposed basic controller for the basic performance; third, comparing the stability performance and tracking performance of the aerial manipulator with and without the adaptive auxiliary loop to verify the effectiveness of the adaptive loop design.

There are three scenarios considered: (1) the basic test of the aerial platform without the manipulator moving to verify the basic performance; (2) the tracking test of the aerial platform under the random moving of the manipulator to verify the effectiveness of the adaptive auxiliary controller; (3) the three-dimensional space tracking test of the manipulator end effector with given ideal reference trajectory to verify the positioning and tracking accuracy of the gripper.

All simulation parameters follow the real physical system described in Section 2.1.

*Scenario 1.* Let the manipulator be in its initial posture, where the manipulator is vertically below the aerial vehicle (the corresponding initial joint angles are  $0^\circ$ ,  $90^\circ$ , and  $0^\circ$ , respectively). At this condition, the gravity center of the manipulator is located on the  $Z_b$ -axis of the vehicle body-fixed frame, and the manipulator is symmetrical with respect to the  $X_b$ - and  $Y_b$ -axis. Give the step references of the aerial platform position  $x$ ,  $y$ ,  $z$  and yaw angle  $\psi$  when the manipulator remains in its initial posture, and the system responses are shown in Figure 16, where BC refers to the basic controller and AC refers to the adaptive controller with the adaptive auxiliary loop.

The results show that when the manipulator is not moving, the basic controller can track the desired reference well with no overshoot and steady-state error. The response times of the longitudinal channel and the lateral channel are about 4 s, the altitude channel is about 3 s, and the yaw channel is the shortest, which is 2.5 s. The results illustrate that the innovative structure design of the aerial manipulator with tandem ducted fans is feasible, and the basic controller can achieve good performance in basic condition. The result with the adaptive auxiliary loop is also given in Figure 16, which has faster response time than the basic controller, especially in the longitudinal channel and the lateral channel, which are 2.5 s and 2 s, respectively. This is because the existence of the manipulator will produce gravity moment in the opposite direction when the vehicles roll or pitch to generate the control moment, which makes the actual control moment less than the ideal value, and the adaptive auxiliary controller can compensate for it so as to improve the response speed of the system. Since the initial posture of the manipulator coincides with the  $Z_b$ -axis of the vehicle, it has little effect on the altitude channel and yaw channel, and thus the response time of the adaptive controller is close to that of the basic controller.

*Scenario 2.* Let the manipulator joints move randomly; the tracking responses of the aerial platform position and yaw angle under the manipulator disturbances are shown in Figure 17. Similarly, BC refers to the basic controller and AC refers to the adaptive controller. The motions of the three joints of the manipulator are shown in Figure 18. Notice that the initial angles of the three joints are  $0^\circ$ ,  $90^\circ$ , and  $0^\circ$ , respectively, and the maximum ranges of the motion follow the limits in Table 2.

The results show that the system responses with the basic controller deviate significantly from the expected references and cannot meet the performance requirements under the random motion disturbances of the manipulator. The lateral channel has the largest fluctuation with a maximum close to 100%, the longitudinal channel takes the second place, and the influences of the altitude channel and the yaw channel are relatively small. This is consistent with the structural characteristics of the aerial manipulator. As shown in Figure 3, the manipulator extends from the lateral side of the aerial platform, so it mainly affects the lateral channel of the platform, and the main challenge of the control system is also in the lateral channel. In addition, when joint 1 of the manipulator rotates away from its initial angle, it will also

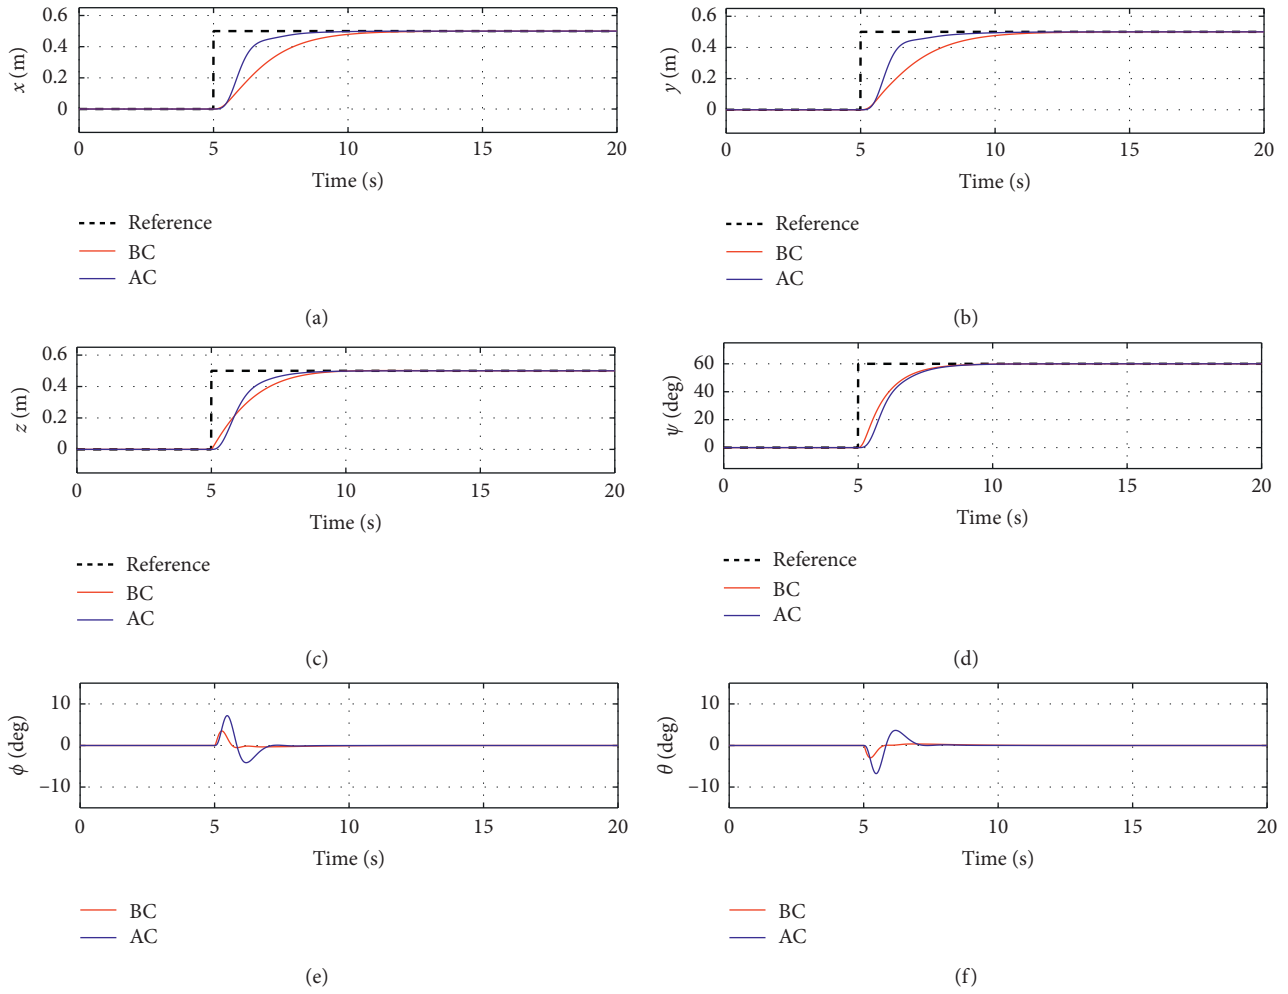

FIGURE 16: System responses in Scenario 1.

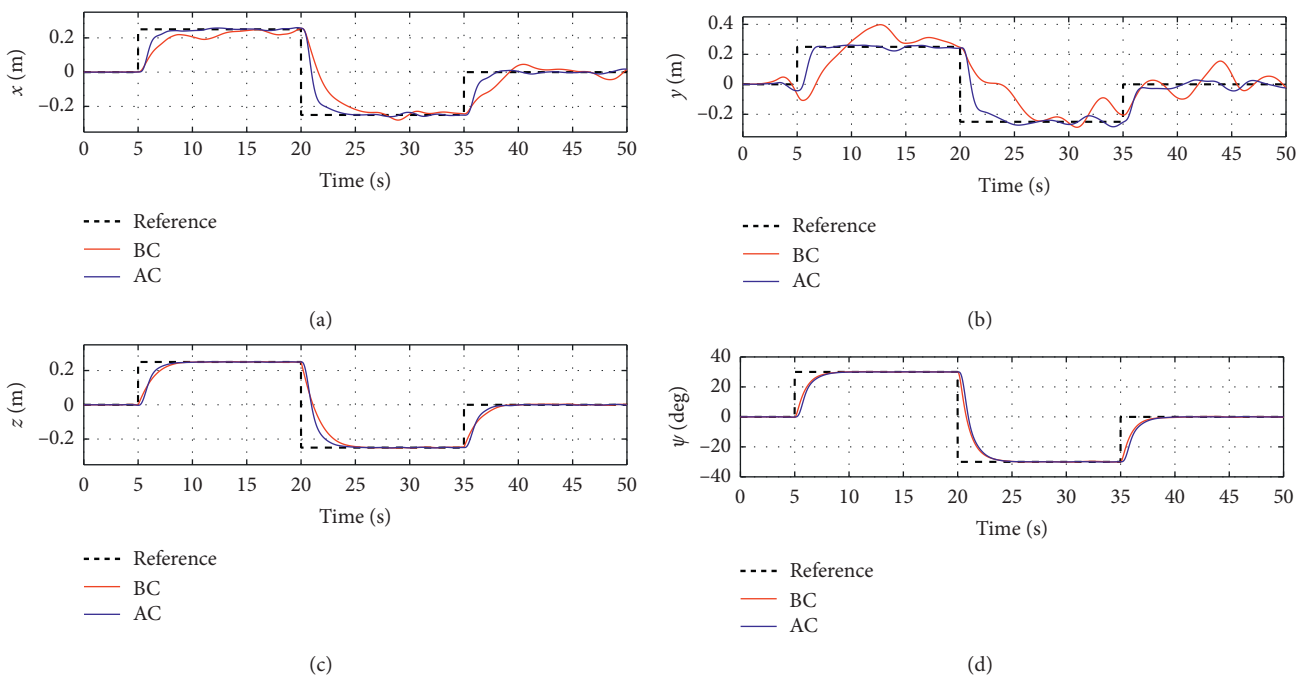

FIGURE 17: Continued.

FIGURE 17: System responses in Scenario 2.

FIGURE 18: Random motions of the manipulator joints in Scenario 2.

FIGURE 19: Disturbance estimation performance in Scenario 2.

TABLE 3: RMSE in Scenario 2.

| State variables     | $x$ (m) | $y$ (m) | $z$ (m) | $\psi$ (deg) |
|---------------------|---------|---------|---------|--------------|
| Basic controller    | 0.0981  | 0.1359  | 0.0759  | 8.8462       |
| Adaptive controller | 0.0782  | 0.0810  | 0.0750  | 9.0389       |

have some influence on the longitudinal channel. The adaptive controller can effectively estimate and compensate for the motion disturbance of the manipulator to ensure good disturbance rejection and tracking performance. Figure 19 also shows the disturbance estimation error of the adaptive controller, indicating that the controller has good estimation accuracy. In order to evaluate the performance of the adaptive controller more accurately, the root mean

square error (RMSE) values of the system responses under the two controllers are given in Table 3. The results show that, in the lateral channel, which has the largest fluctuation, the proposed adaptive auxiliary loop reduces the tracking error by more than 40%. The two controllers have similar performance in the altitude and yaw channel due to the correspondingly small disturbance caused by the manipulator.

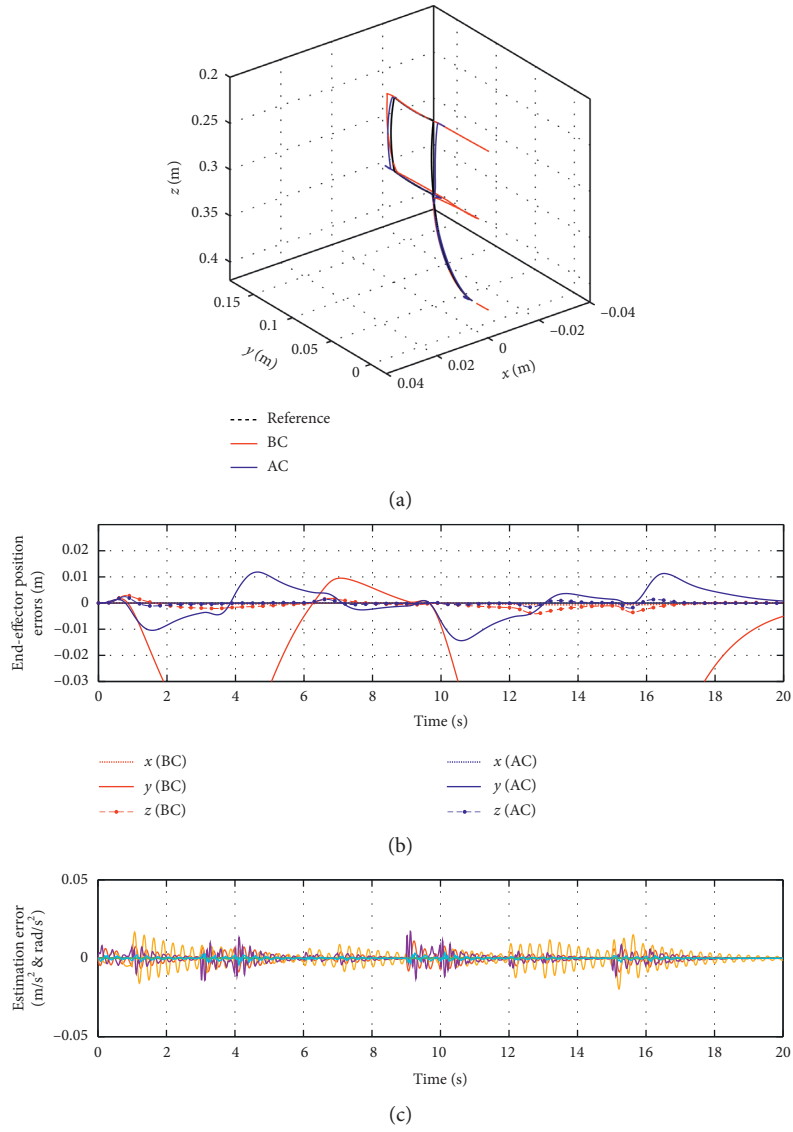

FIGURE 20: System responses in Scenario 3.1.

FIGURE 21: Continued.

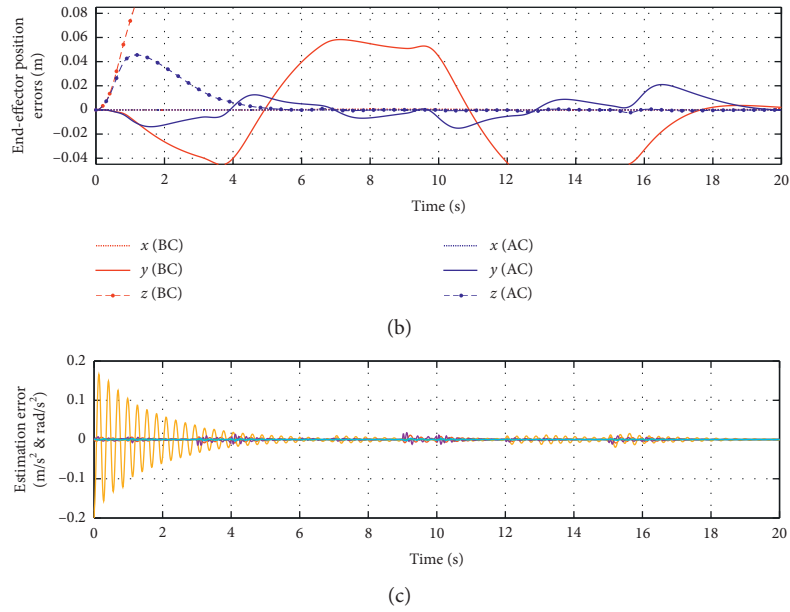

FIGURE 21: System responses in Scenario 3.2.

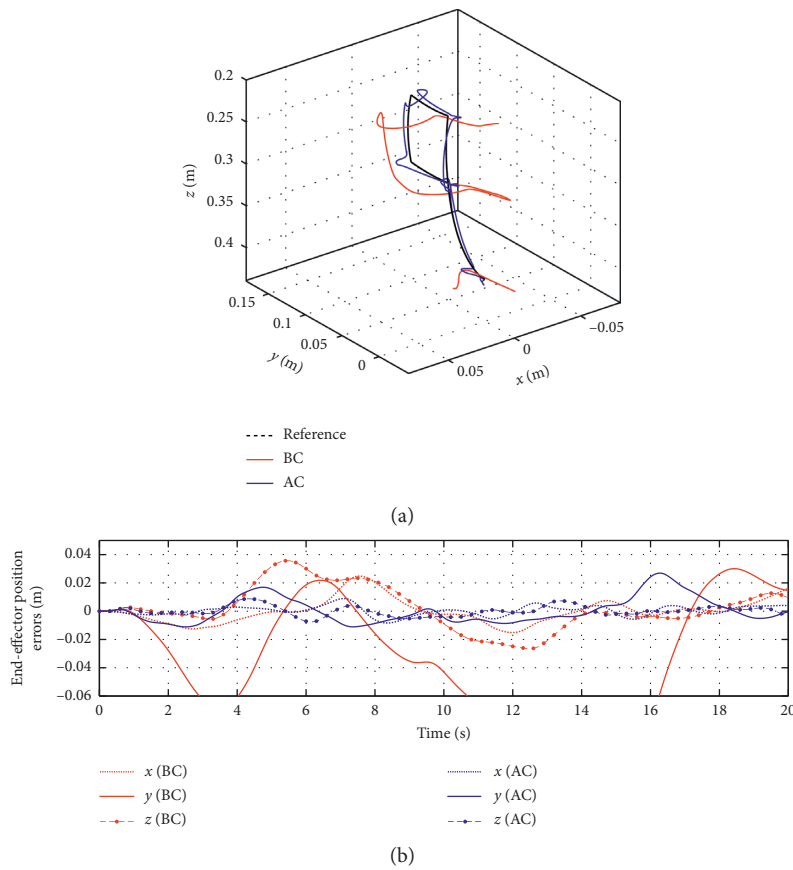

FIGURE 22: Continued.

FIGURE 22: System responses in Scenario 3.3.

*Scenario 3.* Given the reference trajectory of the end effector of the manipulator in three-dimensional space, the responses of the end effector with and without the adaptive loop are shown in Figures 20–22. The reference trajectory starts from the manipulator initial posture, then passes through four reference points in the  $Y$ - $Z$  plane, with each point staying for 3 seconds, and finally returns to the initial posture. In order to fully evaluate the performance of the controller, three conditions are considered, of which Scenario 3.1 is the nominal condition, Scenario 3.2 assumes that the end effector grabs a 100 g object, and Scenario 3.3 considers gust disturbances, simulated by the Dryden model [40].

In Scenario 3.1, the adaptive controller can achieve accurate trajectory tracking of the end effector with a tracking error of approximately  $\pm 0.01$  m. The response with the basic controller has a serious deviation in the  $Y$  direction, and the system cannot completely track the desired trajectory. Since the manipulator moves in the  $Y$ - $Z$  plane, the fluctuations of the system in the  $X$  and  $Z$  directions are relatively small. In Scenario 3.2, the adaptive controller can also track the desired position, but, due to the influence of the grasping object, the overall tracking accuracy of the system decreases compared with Scenario 3.1, and its maximum fluctuation in the  $Y$  direction is about 0.02 m. A 0.04 m offset occurs in the altitude direction under the action of the object, and then the adaptive controller quickly realizes the estimation convergence and compensation. Similar to Scenario 3.1, the trajectory with the basic controller also has a serious deviation in the  $Y$  direction. Moreover, it diverges rapidly in the  $Z$  direction. In Scenario 3.3, the responses of the system in all three directions have greater fluctuations due to the influence of wind gusts. The adaptive controller can still basically achieve the tracking of the reference, and by contrast the responses with the basic controller experience severe fluctuations, which cannot meet the system requirements. In conclusion, the proposed adaptive auxiliary controller can realize precise positioning and trajectory tracking of the end effector of the aerial manipulator.

## 5. Conclusion

This paper proposes an innovative aerial manipulator based on tandem ducted fans, which can easily realize the omnidirectional manipulation of side-on and below and is particularly suitable for the tasks in confined environment. The comprehensive nonlinear dynamic model of the aerial

manipulator is established, based on which a control-oriented state space model of the aerial platform is derived using frequency domain identification method. The identification model is verified in both time and frequency domain. A composite controller of the aerial platform is designed under the existence of manipulator. First, a robust  $H$ -infinite controller is designed to ensure the basic stability, decoupling, and robust performance of the platform. Then, an auxiliary adaptive controller is designed to estimate and compensate for the effect of the manipulator dynamics. The computer simulation tests verify the feasibility of the proposed innovative aerial manipulator design and the effectiveness of the proposed controller. The results show that, with the proposed composite adaptive controller, the aerial vehicle can achieve good performance under the manipulator motion, and the manipulator end effector can realize precise positioning and trajectory tracking with the grasping load and wind gusts.

In future work, the indoor positioning system will be studied and applied, so as to lay the foundation for actual flight tests. In addition, the trajectory planning of the aerial manipulator will also be studied. Then the actual grasping test will be carried out. Furthermore, the vision-based target recognition and the interaction dynamics would be considered to achieve more complex operation tasks.

With the gestation and development of new technologies, new products, new formats, and new models, venture capital investment, as one of the most important forms of open innovation in large companies, plays an increasingly important role in the innovation of mature large companies and entrepreneurial enterprises. To deal with the complex and dynamic environment, the niche of Corporate Venture Capital (CVC) ecological community is investigated from the perspective of the innovation ecosystem. By analyzing the innovation of CVC ecological community with the use of the logistic expansion model, this paper analyzes the stability of evolution game through the replicator dynamic equation and discusses ten parameters of niche state. In the end, we conclude that there are four optimization strategies in the coevolution of major corporations and entrepreneurial firms, namely, niche separation, niche expansion, niche K-R, and niche alliance.

## 1. Introduction

Innovation has become the endogenous driving force and core competitive advantage of a country's economic growth. In the complex and dynamic digital economy era, it is difficult for enterprises to maintain traditional competition barriers. To keep growing continuously, enterprises must deal with issues such as the increasingly uncertain environment, challenging value creation, and oversupply choices for customers. The traditional value chain creation model is changing to the shared destiny community with a symbiosis creation model. Therefore, large companies are constantly seeking the path of open empowerment. Corporate Venture Capital (CVC) has become an important model and tool for open innovation, access to external technology sources, and value creation. The global venture capital funding in 2018 reached 254 billion US dollars, and the financing amount in

2017 was 174 billion RMB, of which the global company's total venture capital investment was 312 billion US dollars. Investment activities increased by 19% over 2016, and total investment increased by 18% [1]. Companies in countries like Britain, China, and India have hit record highs in their venture capital. The global CVC investment industry has strong interests in areas with high technological innovation and fierce competitions such as Internet, healthcare, and mobile technology.

The company's venture capital originated in the United States in the 1960s. It is now one of the main ways for mature large companies to develop outwards. It has a strategic appeal because it provides multiple choice platforms for large companies to innovate. Corporate innovation requires venture capital as a mechanism and driving force. Corporate Venture Capital aims to achieve open innovation, obtain the latest technology in related fields, and overcome the soft

constraints of the company's internal R&D budget so that they can improve technology innovation efficiency. It could also reduce the risk of investment in independent R&D and improve organizational capabilities to foster an innovation culture. It benefits the corporate by realizing the value of strategic mergers and acquisitions and initiating entrepreneurial investment in strategic innovation projects. As company's venture capital has a high degree of risk tolerance and a long investment cycle, it can invest in the startups that are struggling to obtain traditional independent venture capital (IVC). It promotes and optimizes mutual regeneration and achieves a better evolutionary cycle for both parties. While mature companies deeply cultivate the Red Sea, they must also actively explore in the Blue Ocean. CVC is a hybrid model that stimulates innovation. It expands industrial boundaries, rebuilds market boundaries, explores cutting-edge technologies, encourages open innovation, and expands organizational structures for large companies. It is regarded as an effective paradigm to promote the evolution of the industry ecosystem. It is also an important way for large companies to acquire innovative technologies and industrial integration [2]. CVC activities are a "dual and two-way" value creation process that includes both strategic and financial values, while creating value for mature large companies and startups. With the advent of the digital economy 2.0 era, ecological collaborative innovation models have gradually taken shape. Typical digital economy companies in China, such as Alibaba, Tencent, Xiaomi, and Baidu, as well as traditional enterprises such as Haier and Fosun, are actively building open innovation enterprise ecosystems. They integrate the company's own technology, capital, and market advantages with external resources to develop new technologies, new products, and new models for new markets.

## 2. Related Work

Hannah and Eisenhardt proposed that, in addition to the relationship between competition and cooperation, enterprises also need to continuously meet customer needs through innovation [3]. Enterprises have evolved from the role of an individual player in the industry into part of the industrial ecosystem. Luo and Ratchford took Apple, IBM, Ford, and Wal-Mart as examples to study focal companies which develop service, technology, and value network platforms to build their own unique business ecosystems and obtain value returns [4]. Yao and Zhou used the theory of natural ecosystem evolution to study the innovation path of high-tech enterprises and found that the dependence of enterprise innovation paths has ecological genetic and variability characteristics [5]. Daniela et al. in "Evolutionary Theory of Economic Change" explain economic changes from a perspective of dynamic evolution. Evolutionary game theory pays attention to the change of population structure and uses evolutionary stable strategy (ESS) to represent a stable state that can resist the invasion of mutation strategy [6]. Levinthal proposed that corporate adaptation and environmental selection are the main paths of population evolution [7]. Zaman et al. believe that internal and external

resources of an enterprise are equally important. Enterprises use external resources and external channels to help commercialize their new technological achievements. They also emphasize that enterprises should quickly implement innovation, reduce innovation costs, and work with professional venture capital institutions to jointly improve innovation performance [8].

One of the most challenging 125 scientific issues in the 21st century in science is, "how does cooperative behavior evolve?" The innovation ecosystem has the same characteristics of natural evolution, integration, self-organization, periodicity, and openness as natural ecosystems and shares the same characteristics in power, genetics, evolution, and feedback. Important scholars in the CVC field, Jog and Mcconomy, creatively proposed that mature large companies have regarded CVC not only as the window for technology discovery but also as an ecosystem around large companies [9]. This conclusion is based on previous research on CVC enterprise value creation, CVC investment enterprise entrepreneurial performance, investment conditions, and cross-organizational knowledge acquisition. Based on the analysis of nearly 300 CVCs, Jog and Mcconomy proposed that the increasing number of CVCs would contribute in better short-term and long-term performance of the ecosystem, which extends a previous view shared by scholars that the CVC is only an incubator-level participant. Instead, as an ecosystem strategy, CVC intends to "build a constellation" [10]. Therefore, from the perspective of the ecosystem and the niche theory, it is proposed that the CVC ecological community, formed by mature large companies and startups in the form of CVC projects, achieves synchronization through interactions between CVC functions, behavioral processes, and the external environment. In the symbiotic mode, a symbiotic evolution can be developed with the growth of large companies and entrepreneurial enterprises.

## 3. CVC Niche for Major Corporations and Entrepreneurial Firms

In 1838, the Dutch mathematical biologist Verhulst proposed a logistic equation to study the growth of biological populations. It was found that the population grew fastest at the beginning. When it grew to a certain value, the speed began to slow down until it finally decreased to zero (i.e., stop growing). In 1900, Italian mathematician Volterra proposed the predator and prey populations model. In 1925, Lotka proposed mathematical ecology in chemical reactions. Then in 1926, Volterra used the Lotka-Volterra model to demonstrate the rule of fish population in the port of Fiume. Lotka-Volterra model, which evolved from the logistic extended model, can better explain the relationship between large companies and startups in the CVC ecological community. This model, as an evolutionary game for species or population formation, provides a new perspective to understand community structure optimization and niche evolution [11].

The growth of the corporate ecological community involved in CVC also generally conforms to the mechanism of

the logistic development; that is, the development of the CVC ecological community is relatively immature: the scale is not large; the growth space is large; and the development speed is fast at S1. However, at this stage, for large enterprises and startups, the initial capital investment, human investment, and technical investment are relatively large. The symbiotic subjects of the CVC ecological community are still in the running-in period with high risks. At node P1, either CVC is offside to enhance the niche, occupying a favorable position in the innovation and entrepreneurship ecosystem, or it may gradually decline. CVCs that operate smoothly, realize technological innovation, and have shared and coordinated development can successfully enter the second stage of the ecological niche beyond P1. In the second stage of S2, the ecological niche of CVC continued to expand; the benefits continued to increase; innovation results and innovative technologies were rapidly transformed; large companies achieved their strategic goals and financial goals; and startup companies also achieved growth. At the second branch point P2, with great innovation potential, the CVC ecological community, formed by large companies with startups, integrates more resources and continues to develop. The symbiotic system will rise to a higher stage, while the ecological shrinkage may also occur. Figure 1 is the trend of CVC ecological community evolution.

Therefore, the evolution of the niche also reflects the characteristics of repeated games between large companies and startups in the CVC ecological community. CVC activities are also innovative activities. Large companies form CVC ecological communities with startups through venture capital for technological innovation. They aim to realize value cultivation and value innovation and continuously develop new competitive advantages in the industry competition. By improving their own niche, they can achieve their strategic goals and financial goals.

From the perspective of biology and evolutionary games, the development of the CVC ecological community is constrained by various factors such as talent, technology, capital, and services, in specific time and space dimensions. The ecological factor domain  $C_i = f(z_1, z_2, z_3, \dots, z_n)$  is used to represent the various factors  $z_1, z_2, z_3, \dots, z_n$  that indicate the constraints for the development of the CVC ecological community. There is a range value  $N_i$  of the niche width  $W_i$  of ecological community  $i$ , which represents the competition coefficient  $\alpha_i$  of the CVC ecological community.  $\beta$  represents the niche overlap value of the CVC ecological community, and  $\chi_i$  indicates the impact of CVC investment strategies such as combination strategies, capital injection strategies, exit methods, and space preferences on the innovation of the CVC ecological community.  $S_i$  represents the niche status (i) of the CVC ecological community at time of  $t$ , and  $dS(t)/dt$  represents the rate of change in the niche width for large enterprises and entrepreneurial enterprises in the CVC ecology community. Adjusted from the Lotka-Volterra model, the niche evolution equations of the major corporations (MC) and entrepreneurial firms (EF) in the CVC ecosystem are set as follows:

FIGURE 1: The trend of CVC ecological community evolution.

$$\begin{cases} \frac{dS_1(t)}{dt} = r_1 S_1 (\rho_1 + \chi_1 - \alpha_1 - S_1 - \beta S_2), \\ \frac{dS_2(t)}{dt} = r_2 S_2 (\rho_2 + \chi_2 - \alpha_2 - S_2 - \beta S_1). \end{cases} \quad (1)$$

Here,  $S_1$  and  $S_2$  represent the niche width limit of MC and EF;  $\rho_1$  and  $\rho_2$  represent niche saturation coefficient of MC and EF in the CVC ecological community;  $\alpha_1$  and  $\alpha_2$  represent competition coefficients:  $\alpha_1$  is the competitive effect of EF on MC, while  $\alpha_2$  is the competitive effect of MC on EF; and  $\beta$  represents niche overlap between MC and EF in the CVC ecological community.

When  $\beta = 1$ , there is a complete niche overlap between MC and EF. When  $\beta = 0$ , there is a complete niche separation for MC and EF. If the value of  $\beta$  is between 0 and 1, there is partial overlap between MC and EF. The  $\beta$  is proportional to  $\alpha_1$  and  $\alpha_2$ , which means the bigger the overlap between MC and EF, the more the fierce competition.

According to the above differences in  $\beta$ , the evolution of the niche of large companies and startups in the CVC ecological community is discussed as follows [12]:

- (1) When  $\beta = 1$ , there is a complete niche overlap between MC and EF.

If  $\begin{cases} dS_1(t)/dt = 0 \\ dS_2(t)/dt = 0 \end{cases}$ , the balanced position includes

$$H_1(\rho_1 + \chi_1 - \alpha_1, 0), \quad H_2(\rho_2 + \chi_2 - \alpha_2, 0), \quad H_3(0, \rho_1 + \chi_1 - \alpha_1), \quad H_4(0, \rho_2 + \chi_2 - \alpha_2), \quad O(0, 0).$$

The equation for MC in the CVC ecological community is  $\rho_1 + \chi_1 - \alpha_1 - S_1 - S_2 = 0$ .

The equation for EF in the CVC ecological community is  $\rho_2 + \chi_2 - \alpha_2 - S_2 - S_1 = 0$ .

As there is an equal slope, the position of the two parallel straight lines  $L_1, L_2$  depends on the values of parameters  $\rho_1 + \chi_1 - \alpha_1$  and  $\rho_2 + \chi_2 - \alpha_2$ .

When  $\rho_1 + \chi_1 - \alpha_1 > \rho_2 + \chi_2 - \alpha_2$ , we can obtain Figure 2 in the following.

The niche width of the MC in the CVC ecological community is larger than the niche width of the EF.

FIGURE 2: Evolution of niche overlap, when MC contains EF.

MC completely includes the EF, indicating that the MC occupies the entire niche space.

When  $\rho_2 + \chi_2 - \alpha_2 > \rho_1 + \chi_1 - \alpha_1$ , we can get Figure 3 in the following.

Entrepreneurial firm's niche width ( $L_2$ ) in the CVC ecological community is larger than that of major corporation ( $L_1$ ). EF completely includes MC. This indicates that EF occupies the entire niche space. The result of evolution will also approach EF. Therefore, when the MC and EF in the CVC ecological community completely overlap, the direction of the niche evolution depends on the technologies, capital, human resources, and innovation resources used by the MC and EF. The one occupying the resource advantage will eventually control the evolution.

- (2) When  $\beta = 0$ , there is a complete niche separation for MC and EF.

If  $\begin{cases} dS_1(t)/dt = 0 \\ dS_2(t)/dt = 0 \end{cases}$ , the balanced position includes

$$H_1(\rho_1 + \chi_1 - \alpha_1, \rho_2 + \chi_2 - \alpha_2),$$

$$H_2(\rho_1 + \chi_1 - \alpha_1, 0), H_3(0, \rho_2 + \chi_2 - \alpha_2), O(0, 0).$$

The equation for MC in the CVC ecological community is  $L_1: S_1 = \rho_1 + \chi_1 - \alpha_1$ .

The equation for EF in the CVC ecological community is  $L_2: S_2 = \rho_2 + \chi_2 - \alpha_2$ .

We can obtain a separation as shown in Figure 4.

$L_1$  and  $L_2$  divide four areas in the quadrant. In the areas below  $L_1$  ( $dS_1(t)/dt < 0$ ), the evolution direction rises, while in the areas above  $L_1$  ( $dS_1(t)/dt > 0$ ), the evolution direction goes downward. In the areas on the left of  $L_2$  ( $dS_2(t)/dt < 0$ ), the evolution direction goes right, while in the areas on the right of  $L_2$  ( $dS_2(t)/dt > 0$ ), the evolution direction goes left.

In quadrant 1,  $dS_1(t)/dt > 0$  and  $dS_2(t)/dt < 0$ .

In quadrant 2,  $dS_1(t)/dt > 0$  and  $dS_2(t)/dt > 0$ .

In quadrant 3,  $dS_1(t)/dt < 0$  and  $dS_2(t)/dt < 0$ .

In quadrant 4,  $dS_1(t)/dt < 0$  and  $dS_2(t)/dt > 0$ .

Therefore, we can conclude that the result of evolution tends to equilibrium  $H_1(\rho_1 + \chi_1 - \alpha_1, \rho_2 +$

$\chi_2 - \alpha_2)$ , where the large companies and startups in the CVC ecological community occupy their respective niche. Its niche size is related to the niche saturation coefficients  $\rho_i$  of both parties, the competition coefficient  $\alpha_i$  of large enterprises and startups in the CVC ecosystem, and the impact coefficient  $\chi_i$  of CVC ecological community innovation CVC investment strategy (CVC portfolio strategy, CVC investment stage strategy, CVC exit method, CVC investment space preference).

- (3) When  $0 < \beta < 1$ , MC and EF niche partially overlap. The evolution path depends on the ecological domain space of their respective resources.

If  $\begin{cases} dS_1(t)/dt = 0 \\ dS_2(t)/dt = 0 \end{cases}$ , the balanced position includes

$$O(0, 0), H_1(\rho_1 + \chi_1 - \alpha_1, 0),$$

$$H_2(0, \rho_1 + \chi_1 - \alpha_1/\beta), H_3(\rho_2 + \chi_2 - \alpha_2/\beta, 0), \text{ and } H_4(0, \rho_2 + \chi_2 - \alpha_2):$$

$$G\left(\frac{\rho_1 + \chi_1 - \alpha_1 - \beta(\rho_2 + \chi_2 - \alpha_2)}{1 - \beta^2}, \frac{\rho_2 + \chi_2 - \alpha_2 - \beta(\rho_1 + \chi_1 - \alpha_1)}{1 - \beta^2}\right). \quad (2)$$

As the values of the parameters are different, the analytical expressions have different evolution trends. There are four competition situations between the two populations:

*Situation 1.* When  $(\rho_1 + \chi_1 - \alpha_1/\beta) > \rho_2 + \chi_2 - \alpha_2$  and  $(\rho_2 + \chi_2 - \alpha_2/\beta) < \rho_1 + \chi_1 - \alpha_1$ .

In the area surrounded by the quads  $H_1, H_2, H_3, H_4$  (Figure 5), where  $dS_1(t)/dt < 0, dS_2(t)/dt > 0$ , large companies have not reached the maximum capacity for growth; i.e., there is still room for growth and development. While, startups have reached the maximum capacity; i.e., there is little room for continued growth. Large companies have mastered related technological innovations. The corresponding evolution is shown in Figure 5.

*Situation 2.* When  $(\rho_1 + \chi_1 - \alpha_1/\beta) < \rho_2 + \chi_2 - \alpha_2$  and  $(\rho_2 + \chi_2 - \alpha_2/\beta) > \rho_1 + \chi_1 - \alpha_1$ .

In the area surrounded by the quads  $H_1, H_2, H_3, H_4$  (Figure 6), where  $dS_1(t)/dt > 0, dS_2(t)/dt > 0$ ,

FIGURE 3: Evolution of niche overlap, when EF contains MC.

FIGURE 4: Niche separation of CVC.

FIGURE 5: Large companies occupy part of the startup's niche.

FIGURE 6: Startups occupy the ecological domain of large companies.

entrepreneurial enterprises in the CVC ecosystem can continue to develop, but large companies have reached their limits. Therefore, entrepreneurial enterprises can invade some ecological domains for large companies, as shown in Figure 6.

*Situation 3.* When  $(\rho_2 + \chi_2 - \alpha_2/\beta) > \rho_1 + \chi_1 - \alpha_1$  and  $(\rho_1 + \chi_1 - \alpha_1/\beta) > \rho_2 + \chi_2 - \alpha_2$ ,  $L_1$  and  $L_2$  come across at point G, as shown in Figure 7.

$$G\left(\frac{\rho_1 + \chi_1 - \alpha_1 - \beta(\rho_2 + \chi_2 - \alpha_2)}{1 - \beta^2}, \frac{\rho_2 + \chi_2 - \alpha_2 - \beta(\rho_1 + \chi_1 - \alpha_1)}{1 - \beta^2}\right). \quad (3)$$

In the area of H2GH4, there is still room for growth of startups, while large companies have developed to the maximum capacity, approaching G. In the GH1H3 region, large companies continue to grow, while the growth of startups has reached the upper limit. The movement trends of both parties will gradually approach point G, where G is the equilibrium point for the coexistence of large enterprises and entrepreneurial enterprises in the CVC ecological community.

*Situation 4.* When  $(\rho_2 + \chi_2 - \alpha_2/\beta) < \rho_1 + \chi_1 - \alpha_1$  and  $(\rho_1 + \chi_1 - \alpha_1/\beta) < \rho_2 + \chi_2 - \alpha_2$ .

$L_1$  and  $L_2$  come across at point P, as shown in Figure 8.

In the H2PH4 and H1PH3 areas, both large companies and startups have room for continued innovation and growth. Both sides may have the opportunity to win in the competition process, so they have not reached an equilibrium state. The niche occupation depends on what the two parties have in the initial ecological domain. The larger the initial ecological domain is, the more resources it possesses, and the easier it is to win in the CVC ecological community. This also makes CVC ultimately achieve the strategic goals and financial goals of large companies by IPO, mergers, and acquisitions. While startups get mature, big companies can quit.

In the above analysis, situations (1), (2), and (4) are all unbalanced and stable. In the balanced state (3), large enterprises and startups in the CVC ecosystem can coexist and maximize their own added value.

#### 4. Construction of the Evolutionary Game Model for the CVC Ecological Community Innovation

Evolutionary game theory exists in Darwin's idea of natural selection. Based on the dual theory of game theory and biological evolution, this section analyzes the formation mechanism of interaction between populations in ecological communities and studies population growth, evolution, and stability [13].

*4.1. Evolutionary Game Analysis.* The symbiotic evolution between large companies and startups in the CVC ecological community will increase the adaptability of both parties and thus their respective niche. The evolutionary game theory has been used to analyze the operating mechanism of large

companies and startups. Here we use evolution stability strategy to analyze the evolution path of CVC ecological community. The strategy adjustment process, trends, and stability of large players and startups in priority game players are considered. ESS evolutionary stability strategy and Taylor and Jonker's replicator dynamic equations are used as well [14]. The niche evolution process of CVC ecological community innovation also requires mutation and selection mechanisms [15]. The formation and development of the CVC eco-community is the game behavior between large companies, startups, and other related entities. Its formation and development are also the result of the dynamic evolution of multiparty games. When there is a two-way causal relationship between a large company and a startup company under a certain feedback mechanism, the adaptive change of the large company will change the adaptability of the startup company, while the change of the startup company will further affect the change of the large company. By assessing their participation in CVC investment activities, the two parties will promote the continuous evolution of the CVC ecological community when the results of multiple rounds of game play with other entities are greater than their nonparticipation.

#### 4.2. Research Hypothesis and Model Building

*4.2.1. Research Hypothesis.* The changes in the niche of large companies and startups in the CVC ecosystem are affected by a variety of ecological factors in the symbiotic environment of venture capital. At the same time, the strategy obtained by the opponent based on the irrational selection is an important factor. Entrepreneurial enterprises will play dynamic games. First, assuming that the strategy set of MC is niche maintenance and niche expansion, the strategy set of an entrepreneurial company can be participation in competition and acceptance. In this case, there is a two-stage game in the CVC investment activity process. This can be regarded as an evolutionary game of dual population and dual strategy [16]. Second, assuming that both large companies and startups are bounded in rationality, they choose the best strategy based on their own situation and environment. Third, in the CVC ecological community, large companies, and startups make strategic adjustments based on their strategy and the external environment. A repeated game would happen as the adjustment also depends on the choices and the performance of these companies.

*4.2.2. Construction of Fitness Function Matrix.* Assuming that the niche separation of large companies and startups does not affect them, the two types of corporate populations in their own ecological space and time have the benefits of independent innovation  $R_1$  and  $R_2$ . When the MC population chooses to expand its niche through CVC activities, it can realize innovation benefits, including the benefits created by knowledge sharing as a result of sharing various resources and technology spillovers. It can be represented by  $\lambda(a + b)\Delta r$ , where  $\lambda$  is the absorptive capacity coefficient of the large company population;  $a$  and  $b$  are the knowledge

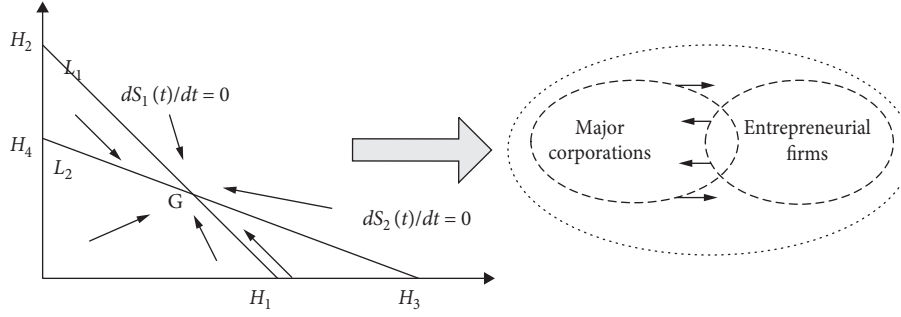

FIGURE 7: Ecological stability of large companies and startups.

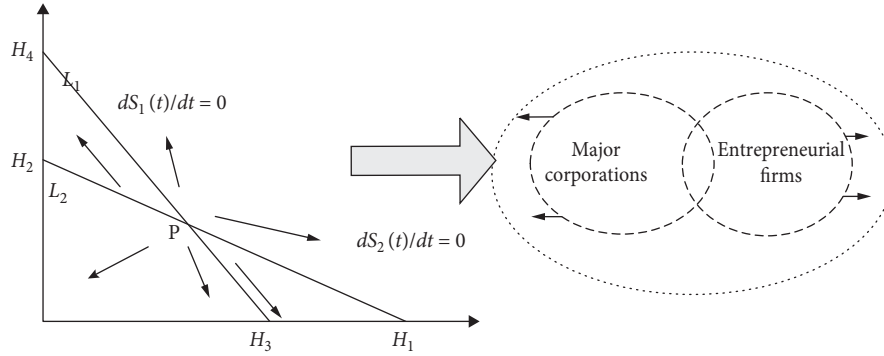

FIGURE 8: Large companies and startups continue to grow and cannot reach balance.

sharing coefficient and the technology spillover coefficient, respectively; and  $\Delta r$  is unit excesses benefit. If the MC expands, the EF also carries out the niche expansion, which can achieve excess returns. Both parties need to pay a certain cost during the niche expansion process. The cost paid by the large company can be expressed as  $C_1$ , and the cost paid by startup company is represented by  $C_2$ . There are also large companies that expand their niche, and startups choose to keep the same niche. In this case, they can get a profit  $e$ . The probability that a large company will expand its niche is  $p$ , and the probability of maintaining it is  $1 - p$ . The probability of participating in competition based on feedback from startups is  $q$ , and the probability of maintaining the original ecology is  $1 - q$ . The game fitness payment matrix is established in Table 1.

#### 4.3. Evolution Path Analysis

**4.3.1. Replicator Dynamic Equation Solving.** According to the game fitness function matrix above, it can be concluded that, for the MC, which chooses to expand the niche, that is, to carry out CVC investment activities, the expected return is

$$\begin{aligned} U_{11} &= q(R_1 + \lambda(a+b)\Delta r - C_1) + (1-q)(R_1 - C_1) \\ &= R_1 + q\lambda(a+b)\Delta r - C_1, \\ U_{12} &= q(R_1 + e) + (1-q)R_1 = qe + R_1, \end{aligned} \quad (4)$$

$$\begin{aligned} \bar{U}_1 &= pU_{11} + (1-p)U_{12} \\ &= p(q\lambda(a+b)\Delta r - qe - C_1) + qe + R_1. \end{aligned}$$

TABLE 1: Niche game fitness function matrix.

| Subject niche in CVC |             | EF   |                          |
|----------------------|-------------|--|--------------------------|
|                      |             | Expanding niche  | Maintaining niche        |
| MC                   | Expanding   | $R_1 + \lambda(a+b)\Delta r - C_1$<br>$R_2 + [1 - \lambda(a+b)]\Delta r - C_2$ | $R_1 - C_1$<br>$R_2 + e$ |
|                      | Maintaining | $R_1 + e$<br>$R_2 - C_2$   | $R_1$<br>$R_2$           |

In the same way, for the EF, the expected income and expansion of the niche expansion are  $U_{21}$  and  $U_{22}$ , while the average expectation of the startup enterprise is  $\bar{U}_2$ :

$$\begin{aligned} U_{21} &= p[R_2 + [1 - \lambda(a+b)]\Delta r - C_2] + (1-p)(R_2 - C_2) \\ &= R_2 + p[1 - \lambda(a+b)]\Delta r - C_2, \\ U_{22} &= p(R_2 + e) + (1-p)R_2 = e + R_2, \\ \bar{U}_2 &= qU_{21} + (1-q)U_{22}, \\ &= q[R_2 + p[1 - \lambda(a+b)]\Delta r - C_2] + (1-q)[pe + R_2] \\ &= q[p[1 - \lambda(a+b)]\Delta r - pe - C_2] + pe + R_2. \end{aligned} \quad (5)$$

According to the replicator dynamic formula of the evolutionary game, the replicator dynamic equations of large companies and startups in the CVC ecosystem can be obtained as follows:

$$\begin{aligned}
F(p) &= \frac{dp}{dt} = p(U_{11} - \overline{U}_1) \\
&= p(1-p)[q(\lambda(a+b)\Delta r - e) - C_1], \\
F(q) &= \frac{dq}{dt} = q(U_{22} - \overline{U}_2) \\
&= q(1-q)\{p[[1 - \lambda(a+b)]\Delta r - e] - C_2\}.
\end{aligned} \tag{6}$$

4.3.2. *Evolutionary Stability Strategies for MC.* According to the dynamic equations for MC, we have

$$\begin{aligned}
F(p) &= \frac{dp}{dt} = p(U_{11} - \overline{U}_1) \\
&= p(1-p)[q(\lambda(a+b)\Delta r - e) - C_1].
\end{aligned} \tag{7}$$

Three stable points of the equation can be obtained, namely,  $p_1^* = 0$ ,  $p_2^* = 1$ , and  $p_3^* = C_1/\lambda(a+b)\Delta r - e$ . If an evolutionary stable strategy is required, the derivative dynamic equation needs to be derived and satisfy  $d^2p/d^2t < 0$ . We will obtain

$$\frac{d^2p}{d^2t} = (1-2p)[q(\lambda(a+b)\Delta r - e) - C_1]. \tag{8}$$

When  $q > C_1/\lambda(a+b)\Delta r - e$ , we get  $p_2^* = 1$ , an evolutionary expansion strategy, which means MC will choose niche expansion strategy. When  $q < C_1/\lambda(a+b)\Delta r - e$ , we get  $p_1^* = 0$ , an evolutionary stability strategy, which means MC will choose strategies to maintain their original niche. When  $q = C_1/\lambda(a+b)\Delta r - e$ ,  $dp/dt$  equals zero, which is always a stable status.

4.3.3. *Evolutionary Stability Strategies for EF.* According to dynamic equations for EF, we have

$$\begin{aligned}
F(q) &= \frac{dq}{dt} = q(U_{22} - \overline{U}_2) \\
&= q(1-q)\{p[[1 - \lambda(a+b)]\Delta r - e] - C_2\}.
\end{aligned} \tag{9}$$

Three stable points of the equation can be obtained, namely,  $q_1^* = 0$ ,  $q_2^* = 1$ , and  $q_3^* = C_2/[1 - \lambda(a+b)]\Delta r - e$ .

When  $p = C_2/[1 - \lambda(a+b)]\Delta r - e$ , we get  $dq/dt = 0$ , with  $q$  being in stable status. When  $p > C_2/[1 - \lambda(a+b)]\Delta r - e$ , we get  $dq/dt < 0$ , which is an evolutionary expansion strategy. EF also chooses to expand its niche to enter MC's related industries. When  $p < C_2/[1 - \lambda(a+b)]\Delta r - e$ , we get  $q_1^* = 0$ , which is an evolutionary stable strategy. EF maintains its original niche.

The above discussion does not consider the relationship and size of the parameters. When the combination of parameters changes, the game strategy of large enterprises and entrepreneurial enterprises in the CVC ecological community changes.

4.3.4. *Impact of Parameter Changes on Evolutionary Game Strategies.* The first topic is about the effect of parameter changes on the evolutionary stability strategy of MC:

- (1) For  $0 < C_1/\lambda(a+b)\Delta r - e < 1$ , evolutionary stable equilibrium is determined by two situations of  $q$ . When  $q > C_1/\lambda(a+b)\Delta r - e$ , we get  $p_2^* = 1$ , an evolutionary expansion strategy (EES), while when  $q < C_1/\lambda(a+b)\Delta r - e$ , we get  $p_1^* = 0$ , an evolutionary stable strategy (ESS).
- (2) For  $C_1/\lambda(a+b)\Delta r - e \geq 1$ , we always get  $q < C_1/\lambda(a+b)\Delta r - e$ , and  $p_1^* = 0$ , which is ESS. That is, the cost of niche expansion is high, and large companies maintain their original niche.

The second topic is about the impact of changes in parameters on the evolutionary stability strategy of EF:

- (1) For  $0 < C_2/[1 - \lambda(a+b)\Delta r - e] < 1$ , there are two possibilities. When  $p > C_2/[1 - \lambda(a+b)\Delta r - e]$ , we get  $q_2^* = 1$ , an EES. When  $p < C_2/[1 - \lambda(a+b)\Delta r - e]$ , we get  $q_1^* = 0$ , an ESS.
- (2) For  $C_2/[1 - \lambda(a+b)\Delta r - e] \geq 1$ , we always get  $p < C_2/[1 - \lambda(a+b)\Delta r - e]$ ,  $q_1^* = 0$ , which is an ESS.

By a comprehensive analysis of the stability strategies of the two sides of the game analyzed above, we get five balance points, namely,  $O(0, 0)$ ,  $P(1, 0)$ ,  $Q(0, 1)$ ,  $R(1, 1) = E(C_1/\lambda(a+b)\Delta r - e, C_2/[1 - \lambda(a+b)]\Delta r - e)$ .

#### 4.4. Game Process with Niche Parameters

4.4.1. *Evolution Strategy of MC in the CVC Ecological Community.* When considering the status and momentum of large companies and startups in the CVC ecosystem, that is, the growth of large companies' innovation efforts and potential innovation capabilities, the fitness function needs to consider the status value of the large company population (T1) and potential value (S1). The game player's entrepreneurial state value is T2, and the potential value is S2. The higher the values of T1, S1, T2, and S2, the stronger the ability to obtain innovative resources and the stronger the ability to expand the niche. The matrix above can be adjusted to Table 2.

The corresponding income formula is as follows:

$$\begin{aligned}
U_{11} &= q(R_1 + \lambda(a+b)\Delta r - C_1) + (1-q)(R_1 - C_1), \\
U_{12} &= q(R_1 + e + T_1S_1) + (1-q)R_1 = q(e + T_1S_1) + R_1, \\
\overline{U}_1 &= pU_{11} + (1-p)U_{12} \\
&= p(q\lambda(a+b)\Delta r - q(e + T_1S_1) - C_1) + q(e + T_1S_1) + R_1.
\end{aligned} \tag{10}$$

The dynamic equation is as follows:

$$\begin{aligned}
F(p) &= \frac{dp}{dt} = p(U_{11} - \overline{U}_1) \\
&= p(1-p)[q(\lambda(a+b)\Delta r - e + T_1S_1) - C_1].
\end{aligned} \tag{11}$$

TABLE 2: Population fitness function matrix in CVC ecological community.

| Subject niche<br>in CVC |             | EF   |                                   |
|-------------------------|-------------|--|-----------------------------------|
|                         |             | Expanding niche  | Maintaining<br>niche              |
| MC                      | Expanding   | $R_1 + \lambda(a+b)\Delta r - C_1$<br>$R_2 + [1 - \lambda(a+b)]\Delta r - C_2$ | $R_1 - C_1$<br>$R_2 + e + T_2S_2$ |
|                         | Maintaining | $R_1 + e + T_1S_1$<br>$R_2 - C_2$  | $R_1$<br>$R_2$                    |

For  $F(p) = 0$ , the stable points are  $q_1^* = 0$ ,  $q_2^* = 1$ , and  $q_3^* = C_2/[1 - \lambda(a+b)]\Delta r - (e + T_1S_1)$ :

- (1) When  $q = C_1/\lambda(a+b)\Delta r - (e + T_1S_1)$ ,  $dp/dt$  equals zero, and the value of  $p$  is stable
- (2) When  $q > C_1/\lambda(a+b)\Delta r - (e + T_1S_1)$ ,  $d^2p/d^2t < 0$ , we obtain  $p_2^* = 1$ , an EES
- (3) When  $q < C_1/\lambda(a+b)\Delta r - (e + T_1S_1)$ ,  $d^2p/d^2t > 0$ , we obtain  $p_1^* = 0$ , an ESS

4.4.2. *Evolutionary Strategies of EF.* The corresponding income formula is as follows:

$$\begin{aligned}
U_{21} &= p[R_2 + [1 - \lambda(a+b)]\Delta r - C_2] + (1-p)(R_2 - C_2) \\
&= R_2 + p[1 - \lambda(a+b)]\Delta r - C_2, \\
U_{22} &= p(R_2 + e + T_2S_2) + (1-p)R_2 = p(e + T_2S_2) + R_2, \\
\overline{U}_2 &= qU_{21} + (1-q)U_{22} \\
&= q[R_2 + p[1 - \lambda(a+b)]\Delta r - C_2] \\
&\quad + (1-q)[p(e + T_2S_2) + R_2] \\
&= q[p[1 - \lambda(a+b)]\Delta r - p(e + T_2S_2) - C_2] \\
&\quad + p(e + T_2S_2) + R_2.
\end{aligned} \tag{12}$$

The dynamic equation is as follows:

$$\begin{aligned}
F(q) &= \frac{dq}{dt} = q(U_{22} - \overline{U}_2) \\
&= q(1-q)\{p[[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)] - C_2\}.
\end{aligned} \tag{13}$$

For  $F(q) = 0$ , the stable points are  $q_1^* = 0$ ,  $q_2^* = 1$ , and  $q_3^* = C_2/[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)$ :

- (1) When  $p = C_2/[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)$ , any value of  $q$  is an ESS
- (2) When  $p > C_2/[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)$ , we get  $q_2^* = 1$ , an ESS
- (3) When  $p < C_2/[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)$ , we get  $q_1^* = 0$ , an ESS

4.4.3. *Coevolution Strategy of MC and EF in the CVC Ecological Community.* By unifying the above various game results into a coordinate quadrant, we get comprehensive

game process of large companies and startups in CVC ecological community in Figure 9.

It can be seen from the figure that, in the regional QOPE, the evolutionary stability strategy of large companies and startups is (0,0); that is, neither party adopts the strategy of niche expansion in CVC activities. The evolutionary and stable strategies of both enterprises and startups are (1,1), which means that both large companies and startups are actively expanding their niche. However, the strategic actions of large enterprises and startups depend on the position of E. Through discussing the position of E, the factors that affect the strategic actions of large and startups can be identified.

$$\begin{aligned}
S_{QOPE} &= \frac{1}{2} \times 1 \times E_x + \frac{1}{2} \times 1 \times E_y = \frac{1}{2}(E_x + E_y) \\
&= \frac{1}{2} \left[ \frac{C_1}{\lambda(a+b)\Delta r - (e + T_1S_1)} + \frac{C_2}{[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)} \right].
\end{aligned} \tag{14}$$

As long as the probability of more actions taken by large companies and startups on both sides of the game is within  $S_{QOPE}$ , both parties choose not to expand the niche. At this time, the evolution direction depends on  $S_{QOPE}$  and  $S_{QRPE}$ . When  $S_{QOPE} > S_{QRPE}$ , the evolution converges to point O. When  $S_{QOPE} < S_{QRPE}$ , the evolution converges to point B. When  $S_{QOPE} = S_{QRPE}$ , the probability of the two sides converging toward O or R is equal.

4.5. *Evolution Strategy of CVC Ecological Community.* Through the above analysis, 10 parameters that influence the direction of evolution are obtained. The common evolution path is discussed separately for each parameter by seeking partial derivatives:

- (1) Impact of  $C_1$  and  $C_2$  on  $S_{QOPE}$ :

$$\frac{\partial S}{\partial C_1} = \frac{1}{2} \times \frac{1}{\lambda(a+b)\Delta r - (e + T_1S_1)} > 0, \tag{15}$$

$$\frac{\partial S}{\partial C_2} = \frac{1}{2} \times \frac{1}{[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)} > 0.$$

This shows that  $S_{QOPE}$  is a monotonically increasing function for  $C_1, C_2$ . For MC and EF, the higher the cost of forming a CVC ecological community is, the more it tends to maintain the original niche.

- (2) Impact of  $(a+b)$  on  $S_{QOPE}$ :

$$\begin{aligned}
\frac{\partial S}{\partial a} &= \frac{1}{2} \left[ \frac{C_2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2S_2)]^2} \right. \\
&\quad \left. - \frac{C_1}{[\lambda(a+b)\Delta r - (e + T_1S_1)]^2} \right].
\end{aligned} \tag{16}$$

Since  $a$  is not monotonic for  $S_{QOPE}$ , a second-order derivative is performed:

FIGURE 9: Comprehensive game process of large companies and startups in CVC ecological community after comprehensive situational factors.

$$\frac{\partial^2 S}{\partial^2 a} = \frac{C_2 \Delta r^2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^3} - \frac{C_1 \Delta r^3}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^3} > 0. \quad (17)$$

Therefore, there is a minimum value for  $S_{QOPE}$ .

When

$$\frac{\partial^2 S}{\partial^2 a} = \frac{C_2 \Delta r^2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^3} - \frac{C_1 \Delta r^3}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^3} = 0, \quad (18)$$

we obtain

$$\frac{C_2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^2} = \frac{C_1}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^2}. \quad (19)$$

At this time, the stable strategy of MC and EF is (1,1). Both of them implement niche expansion strategies. The parameter  $b$  is derived from the above  $a$ .

(3) Impact of  $T_1$ ,  $S_1$ ,  $T_2$ , and  $S_2$  on  $S_{QOPE}$ :

$$\begin{aligned} \frac{\partial S}{\partial T_1} &= \frac{1}{2} \frac{C_1}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^2} > 0, \\ \frac{\partial S}{\partial S_1} &= \frac{1}{2} \frac{C_1}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^2} > 0, \\ \frac{\partial S}{\partial T_2} &= \frac{1}{2} \frac{C_1}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^2} > 0, \\ \frac{\partial S}{\partial S_2} &= \frac{1}{2} \frac{C_1}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^2} > 0. \end{aligned} \quad (20)$$

$S_{QOPE}$  is a monotonically increasing function of  $T_1$ ,  $S_1$ ,  $T_2$ , and  $S_2$ , indicating that the larger the state and potential of the niche of large companies and startups in the CVC ecosystem (that is, the technology, talents, capital, and social resources of large companies and startups), the better the foundation, and the greater the real dominance and influence that large companies and startups have on the innovation environment. It is more likely that two sides tend to maintain their original niche.

(4) The impact of  $e$  on  $S_{QOPE}$ :

$$\frac{\partial S}{\partial e} = \frac{1}{2} \left[ \frac{C_2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^2} + \frac{C_1}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^2} \right] > 0. \quad (21)$$

It shows that  $S_{AECO}$  is a monotonically increasing function of  $e$ , which means that the greater the innovation income from maintaining the original niche is, the more likely the large enterprises and startups tend to maintain the original niche.

(5) The impact of  $\Delta r$  on  $S_{QOPE}$ :

$$\frac{\partial S}{\partial \Delta r} = \frac{1}{2} \left[ \frac{(1 - \lambda(a+b))C_2}{[[1 - \lambda(a+b)]\Delta r - (e + T_2 S_2)]^2} + \frac{\lambda(a+b)C_1}{[\lambda(a+b)\Delta r - (e + T_1 S_1)]^2} \right] < 0. \quad (22)$$

$S_{QOPE}$  is a monotonic reduction function for  $\Delta r$ ; that is, the larger the excess returns, the larger the result of the game between the large enterprise and the entrepreneurial enterprise. Both parties choose to expand the niche strategy.

(6) The impact of  $\lambda$  on  $S_{QOPE}$ :

$$\frac{\partial S}{\partial \lambda} = -\frac{1}{2} \left[ \frac{(1 - \lambda(a + b))C_2}{[[1 - \lambda(a + b)]\Delta r - (e + T_2S_2)]^2} + \frac{\lambda(a + b)C_1}{[\lambda(a + b)\Delta r - (e + T_1S_1)]^2} \right]. \quad (23)$$

$S_{QOPE}$  is a monotonic reduction function for  $\Delta r$ ; that is, the larger the excess returns, the larger the result of the game between the MC and the EF. Both parties choose to expand niche strategy.

## 5. Optimization Strategy for CVC Niche Evolution in Ecological Community

The evolution of the ecological niche of the CVC ecological community is subject to the combined effects of multiple mechanisms, and competition and symbiosis are affected by interest-driven and ecological balance. The benefit-driven mechanism is the inherent growth mechanism of the CVC ecological community under a certain environment of innovation and entrepreneurship. The source of motivation is the maximum pursuit of individual interests by large enterprises and entrepreneurial enterprises. Large enterprise populations and entrepreneurial enterprise populations integrate related resources through horizontal symbiosis, vertical symbiosis, or dynamic alliances to eliminate or reduce resource bottlenecks and promote the smooth development of large enterprises and individual entrepreneurial enterprises. Therefore, the CVC ecological community, as a core part of the innovation and entrepreneurship ecosystem, presents a nonlinear and exponential growth trend. As a self-protection mechanism of the ecological niche of the CVC ecological community, the ecological balance mechanism can ensure the self-sustainability and steady evolution of the CVC niche. In addition to the innovation, entrepreneurship, and ecological resources, the growth of the population is affected by material, energy, and information accumulation but is also balanced and stabilized by self-organization and self-regulation because of environmental factors.

The CVC ecological niche represents the status of the CVC ecological community with large companies and startups as the core to own and control human resources, technical resources, capital, and other social resources, as well as the adaptability to the innovative ecological environment and the comprehensive use of various resources. The healthy growth of CVC ecological communities requires specific analysis of internal and external environmental ecological factors, including limiting factors and interest factors. The limiting factor is the bottleneck that restricts the development of the CVC ecological community. Both the large enterprise population and the entrepreneurial enterprise population focus on easing the constraint of the limiting factor to enhance the evolution capacity of the entire CVC ecological community. At the same time, the CVC ecological community also has benefit factors as its

driving force for development. The enhanced interest factors of core populations can enable their respective niche evolution to achieve sustainable competitiveness and become an irreproducible and far-reaching advantage through the formation of core competitiveness. The large enterprise population and entrepreneurial enterprise population in the CVC ecological community are usually in different positions in the value chain. Therefore, the CVC ecological community should make full use of the symbiotic resources on the value chain, unblock the symbiotic channels, or form strategic alliances or virtual industries to achieve coevolution for the niche. The large enterprise population and the entrepreneurial enterprise population within the CVC ecological community implement corresponding niche separation strategies, niche expansion strategies, niche K-R strategies, and niche alliance strategies.

*5.1. CVC Niche Separation Strategy.* If the niche overlap between large enterprises and startups in the CVC ecological community indicates that there is a certain industry correlation between large companies and startups, the competition is fierce when the niche overlaps between the two. In order to obtain more living space, the two sides can implement niche separation strategy. Large enterprises and startups can find the most suitable position for their own development through CVC activities. The core of niche separation is to (a) use and integrate innovation and entrepreneurial resources, (b) choose a combination of ecological factors that are different from those of competitors, (c) have a stronger advantage at a certain position of talent, technology, capital, and social resource gradients, and (d) achieve heterogeneity and symmetry. Whether it is a mature large enterprise or a startup enterprise, it can choose two different niche separation strategies: specialization strategy and generalization strategy. The specialization strategy is for narrow-niche enterprises, which can provide a small range of products and services with characteristics to form an agglomeration strategy to concentrate the various resources of species in a limited ecological space, that is, to focus on a certain step in the value chain, so that the niche overlap with other species is reduced. The generalized strategy is similar to the no-difference strategy for relatively wide niche companies, and the risks are relatively small.

In the CVC ecological community, whether large companies and startups choose specialization or generalization strategies is related to the richness of resources they can use. Generalization strategies can provide more survival for large companies with strong competitiveness. However, early stage startups, which have limited resources while still implementing generalisation strategies, would easily fail or be acquired by large companies. . Therefore, for startup companies, specialization strategies are more conducive to maintaining their own niche and reducing the ecology overlap with large enterprises, to reduce competition. Startups in the CVC eco-community can also consider adopting a niche separation strategy from the time, space, and target market dimensions.

**5.2. CVC Niche Expansion Strategy.** The investment of mature large enterprises in startup enterprises through CVC activities is a niche expansion strategy. It uses open-ended innovation through venture capital to open up new resource spaces, acquire innovative technologies, and thus achieve the purpose of expanding the niche. They aim to alleviate the competitive pressure brought by overlapping niche. For large enterprises, the introduction of new and efficient ecological elements is their original intention when choosing CVC. It is also an effective means of exploring and developing suitable options for their own development so that they can acquire financial benefits. The introduction of new ecological elements can improve the utilization of various resources in the innovation and entrepreneurship ecosystem. Due to the obvious industry attributes of CVC and the high degree of innovation in the high-tech industry, the technology has a high rate of change; i.e., products and technologies will be updated faster. The uncertainty of independent research and development is high, so large enterprises need to expand their niche through CVC. For large enterprises and startups with weak innovation ability, weak interorganizational learning ability, and low absorptive capacity and involvement, especially for large companies, it is worthwhile to raise the basic niche or explore potential niche through CVC activities [17].

**5.3. CVC Niche K-R Strategy.** Ray proposed a niche selection strategy. The K strategy indicates that, by increasing competitiveness, improving resource utilization efficiency, and increasing the environmental capacity of species in a stable environment, a higher saturation density can be achieved. The R strategy means that, by breeding in large numbers, new offspring can be adapted to the unstable environment, thereby identifying its own niche [18].

The choice of K strategy will be limited by the environment. When the niche develops to a certain degree, it will reach the limit of affordability. In the CVC ecological community, the development of large enterprise populations also follows the KR strategy. The large enterprise population of the K strategy is characterized by a low reproduction rate and slow growth, but it can achieve strategic goals through CVC and continuously adapt to new environmental changes. It has unique core competitiveness in related industries. Its products and services are not easily copied and imitated. When large enterprises become the leading companies in an industry, environmental resources will be the biggest obstacle to their development [19]. The startups of R strategy are usually small in size, are not constrained by the environment, and have a fast reproduction capacity. When they grow to a certain degree, the growth rate also starts to decline.

The CVC ecological community uses the R strategy and the K strategy, respectively. The abscissa indicates the size of niche space occupied by the large enterprises and startups in the ecological community at time  $t$ , while the ordinate represents the size of the niche space occupied by species at time  $t + 1$ . The dotted line indicates that the size of the niche space has not changed ( $N_{t+1}/N_t = 1$ ). The part above the

dotted line indicates that the ecology of large enterprises or startups has become larger; that is,  $N_{t+1} > N_t$ . The curve below the dotted line indicates that the niche space has become smaller; that is  $N_{t+1} < N_t$  (Figure 10).

There are two intersections between the growth curve and the dotted line for K strategy. X is an unstable equilibrium point [20]. There may be two situations for large enterprises or startups at point X. First, when the CVC ecological community survives, there are large niche spaces that have not been occupied yet. Companies using K strategy to grow rapidly. Second, the overall space of the CVC ecological community has continued to shrink during the recession period, until the K strategy companies die out. When it is at a stable point, it indicates the maximum capacity of the ecosystem space and the maximum market capacity of technology, talent, capital, social resources, etc. When the K strategy prevents the individual from falling below stability, the scale is expanded to achieve stability. When the K strategy enterprise is above the stability point, its downsizing resumes [21]. The sustainable development of the CVC eco-community can be achieved if the large enterprise population and the entrepreneurial enterprise population in the CVC eco-community can adjust the niche countermeasures in a timely and accurate manner at different stages in the development process.

**5.4. CVC Niche Alliance Strategy.** In the CVC ecological community, large companies and startups can expand their niche by establishing a mutually beneficial symbiotic relationship. This strategy is called the niche alliance strategy. When the weaker startups and the stronger large companies can improve their respective competitiveness through symbiotic relationships, symbiotic parties in the CVC ecosystem can either choose their own appropriate niche or expand the boundaries of the entire ecological community from the perspective of enhancing the symbiotic system, promoting the metabolism of the entire CVC ecological community based on innovation. If the implementation of the niche alliance strategy requires the evaluation of their respective niche, the niche overlap and market crossover of both sides should be minimized to avoid parasitic or favorable symbiosis and form conflicts of interest [22]. Large enterprises and startups can seek intersections, that is, new requirements between the two sides. They can use the positive feedback effect of the innovation and entrepreneurship environment to create higher-level niche that is beneficial to both sides and can realize the coevolution of the niche. The main motivation of CVC activities is that large enterprises need to seek technological progress. Entrepreneurs in small and medium habitats in the industry can obtain more cooperation resources through the form of CVC, so that they can expand their survival through cooperative technological innovation, management innovation, and differentiated service innovation. In this case, they can expand the width of the niche and then penetrate or embed other industries. The formation and evolution of large enterprises and entrepreneurial enterprises in the CVC ecological

FIGURE 10: Coevolution of niche-cooperation relationships in CVC ecological communities.

community will also generate greater benefits in their own or other fields.

Multiobject detection tasks in complex scenes have become an important research topic, which is the basis of other computer vision tasks. Considering the defects of the traditional single shot multibox detector (SSD) algorithm, such as poor small object detection effect, reliance on manual setting for default box generation, and insufficient semantic information of the low detection layer, the detection effect in complex scenes was not ideal. Aiming at the shortcomings of the SSD algorithm, an improved algorithm based on the adaptive default box mechanism (ADB) is proposed. The algorithm introduces the adaptive default box mechanism, which can improve the imbalance of positive and negative samples and avoid manually set default box super parameters. Experimental results show that, compared with the traditional SSD algorithm, the improved algorithm has a better detection effect and higher accuracy in complex scenes.

## 1. Introduction

With the continuous improvement of deep learning related theories, computer vision technologies [1–3] have achieved great success. As the basis of computer vision tasks, object detection [4–6] has been applied in many fields such as intelligent security [7], automatic driving [8], and intelligent medical treatment [9]; even some industrial applications are based on object detection algorithms [10–13]. In the past few years, in order to improve the real-time performance and accuracy of object detection in complex scenes, many scholars have conducted a lot of research on this, and the object detection algorithms based on deep learning have achieved remarkable achievements.

In 2014, the Region with CNN features (RCNN) algorithm [14] was published in Computer Vision and Pattern Recognition (CVPR) by Ross Girshick et al. The advent of this algorithm marked a new era in object detection technology. After that, Spatial Pyramid Pooling in Deep Convolutional Networks (SPPNet) algorithm [15] makes up for the shortcomings of the RCNN algorithm in repetitive convolution calculation and fixed output scale, but it still has

the defects of tedious training steps and slow process. In order to improve the real-time performance of the RCNN detection algorithm, Ross Girshick proposed the Fast RCNN object detection algorithm [16] in 2015. The processing mode of shared convolution makes the calculation amount of this algorithm drop sharply. In addition, the method of the region of interest (RoI) pooling is introduced to enable the network to process input images of any size. However, in this method, the problem of time loss caused by the selective search method [17] has not been solved. As a result, the Faster RCNN [18] algorithm was published in Neural Information Processing Systems (NIPS) in 2015. The highlight of this algorithm is to propose region proposal network (RPN) network structure, which combines region generation with convolution neural network based on the default box mechanism. It further improves the real-time performance of the Fast RCNN algorithm and becomes the most representative algorithm in the two-stage detection algorithm. Based on the Faster RCNN algorithm, Mask RCNN [19], fully convolutional network Region-based Fully Convolutional Networks (R-FCN) [20], Cascade RCNN [21], and other improved algorithms were proposed. Compared

with the two-stage structure of Faster RCNN and other algorithms, the You Only Look Once (YOLO) series of algorithms [22–25] and the SSD algorithm [26] adopt the single-stage structure to directly predict the location and category of the object. The real-time performance of the algorithm is greatly improved, but the accuracy of object detection in complex scenes is obviously insufficient. In order to improve the accuracy of the single-stage detection algorithm, Fu et al. [27] proposed a feature fusion method for multiscale prediction based on the SSD algorithm and used deconvolution operation to enhance the semantic information of shallow features. Jeong et al. [28] tried pooling fusion, deconvolution fusion, rainbow fusion, and other schemes and finally designed the Rainbow Single Shot Multibox Detector (RSSD) network model, which improved the object detection effect in complex scenes to some extent. Tsung et al. [29] considered that the reason for the lack of accuracy of the single-stage detection model was the imbalance of positive and negative samples and proposed a new classification loss function “Focal Loss” to improve the problem. Based on Focal Loss, the team of Tsung built a RetinaNet network, which effectively balanced the proportion of positive and negative samples to avoid the imbalance of samples.

This paper is based on the SSD algorithm, and we improve it from the following two aspects in view of the shortcomings of the SSD algorithm. On the one hand, in order to enhance the characterization capability of the low feature layers and the detection effect of small objects, the improved algorithm introduces feature layers fusion (FLF) and multireceptive field fusion (MRFF) mechanisms. On the other hand, through the adaptive default box mechanism, the steps of manually setting default box hyperparameters are avoided, the generation of negative sample box is reduced, and the problem of positive and negative sample imbalance is improved. Under the premise of real-time detection, the improved algorithm greatly improves the accuracy of small object detection in complex scenes.

## 2. Related Work

*2.1. SSD Algorithm.* The traditional SSD algorithm takes Visual Geometry Group Network (VGGNet) [30] as the backbone network and adds several additional convolution layers to participate in the detection of related objects. Firstly, sufficient data enhancements have been made through optical changes, geometric transformations, etc., which greatly enriched the relevant data sets. Secondly, the SSD algorithm expands 4 convolutional layers and performs object detection based on convolutional layers of different depths. Therefore, the output feature maps have different scales and receptive fields, and objects of different sizes can be detected. Thirdly, the SSD algorithm sets multiple default boxes of fixed size and ratio on the six feature maps. The algorithm sets a series of smaller default boxes on the shallow feature maps to detect small objects and sets several larger default boxes on the deep feature maps to detect large objects. Finally, the network model uses  $3 \times 3$  convolution kernels to extract features on the relevant feature maps to

complete objects classification and bounding boxes regression.

The SSD algorithm completes object detection through the single-stage network and has a better effect compared with the algorithm in the same period. Correspondingly, the SSD algorithm also has some shortcomings. On the one hand, due to the lack of semantic information in the shallow feature maps, the classification and regression effect of small objects is poor and the detection accuracy is insufficient. On the other hand, the default box parameters of each feature layer depend on the manual setting, so the generalization of the SSD is poor in different detection tasks.

*2.2. Design Criteria and Defects of Default Box in Traditional Detector.* A series of default boxes are generated by using the sliding window method in the relevant feature maps of the models, which is the mainstream method adopted by various object detection models at present. Firstly, the model defines several default boxes with specific scales and aspect ratios. Secondly, a large number of default boxes for object detection tasks are generated by sliding in the relevant output feature maps with a certain step size. The traditional default box generation method has the following disadvantages:

- (1) The traditional object detection models need to define a series of aspect ratios and scales for the default box. The selection of the default box aspect ratios and scales of the model will directly affect the detection effect of the models. In addition, for different data sets and detection methods, the parameters of the default box need to be adjusted according to the situation. If the selected default box parameters are not appropriate, the recall rate of the model will be too low, and the detection effect of object detection model will be poor
- (2) In the output feature maps of the relevant models, a large number of default boxes are distributed in the background area of the input image, which cannot play a good role in the detection of relevant objects
- (3) For the objects with a large difference in size and aspect ratio, a series of predefined default boxes may not be able to meet the detection requirements of the model
- (4) A large number of default boxes will directly lead to the degradation in the precision rate and real-time performance of the detection model

## 3. Improved Algorithm Design

*3.1. Fusion Mechanism in the Improved Algorithm.* In order to fuse the low-level output feature maps of different scales, on the one hand, the feature maps of Conv4\_3, FC7, and Conv6\_2 were dimensionally reduced to 256. The feature maps of FC7 and Conv6\_2 were adjusted to  $38 \times 38$  by bilinear interpolation method and concat operation is carried out for the relevant feature maps after processing. On the other hand, the dimension of the FC7 feature map is reduced to 512, the dimension of the Conv6\_2 output feature

map remains unchanged, and the dimension of Conv7\_2 is transformed to 512. The bilinear interpolation method is used to adjust the output feature maps of Conv6\_2 and Conv7\_2 to  $19 \times 19$ . Similarly, the concat operation is performed based on the processed feature maps.

The size of the human receptive field will change with the eccentricity of retinal imaging, and the size of the receptive field is proportional to the eccentricity. In order to further improve the detection efficiency of the traditional SSD object detection model, the multireceptive field fusion mechanism was added to the improved model by referring to the human visual perception mechanism.

Based on convolution kernels of different sizes and dilated convolution of different scales [31], the relevant mechanism fuses multiple scales of receptive fields to make the improved model have stronger feature expression ability. The fusion mechanism of multiple receptive fields in the improved model is shown in Figure 1.

The multireceptive field fusion mechanism consists of three branches. Firstly, convolution kernels of  $1 \times 1$ ,  $3 \times 3$ , and  $5 \times 5$  are used to simulate receptive fields of different sizes. Secondly, dilated convolution with rates of 1, 3, and 5 is used to simulate different degrees of eccentricity. In addition, for the  $3 \times 3$  and  $5 \times 5$  branches, the dimension of the feature map is reduced by using  $1 \times 1$  convolution kernel, so as to reduce the number of parameters. The feature map after dimension reduction is then sent into the convolution kernels of  $3 \times 3$  and  $5 \times 5$ . Finally, the fusion of 3 branches is completed by channel concat, and the number of feature channels is reduced by  $1 \times 1$  convolution kernel.

**3.2. Adaptive Default Box Mechanism.** The parameters' setting of the default box is the key part of the SSD object detection method. Similar to most mainstream object detection methods, the setting and generation of default boxes in the SSD algorithm also rely on the artificial unified setting. A series of preset default boxes are applied to the output features of relevant detection layers in the SSD algorithm. Since there are a large number of default boxes in the background area of the input image, and the aspect ratio of predefined default boxes may not be applicable to the objects to be detected in the relevant image, therefore, the detection efficiency of the model is greatly reduced by using this scheme.

The distribution of the objects in the input image is usually uneven, and the generation of default boxes is usually related to the content of the input image, the location, and the shape of the objects to be detected. Accordingly, the improved SSD object detection algorithm no longer uses the traditional default box generation strategy. The semantic information obtained by the algorithm is used to guide the generation of a series of appropriate size default boxes. The default box of an object is represented as  $(x, y, w, h)$ , where  $(x, y)$  represents the central coordinate position, and  $w$  and  $h$  represent the width and height, respectively. Assuming that  $A$  is an object to be detected on the input image  $G$ , the distribution of the corresponding default box can be represented by

$$A: p(x, y, w, h | G) = p(x, y | G)p(w, h | x, y, G). \quad (1)$$

According to equation (1), we can obtain two aspects of information. On the one hand, the object  $A$  to be detected may only appear in a partial area of the input image  $G$ . On the other hand, the distribution and scale of the corresponding default box are closely related to the location of object  $A$ . Therefore, the adaptive default box mechanism of the improved SSD model is shown in Figure 2.

The adaptive default box generation mechanism includes two parts: position prediction and shape prediction. Assuming that the input image is  $G$ , on the one hand, the position feature map is generated through the position prediction branch of the mechanism. The probability and position distribution of the objects to be detected in the input image can be obtained through the position feature map. On the other hand, according to the position prediction and shape prediction branches, the sizes and aspect ratios of the default boxes are predicted to generate the default boxes with different sizes and aspect ratios. Therefore, the default boxes in the improved SSD model are variable, and different contents can be obtained according to the features in different positions of the output feature maps. Considering that the shape of the default box is not fixed, by introducing the feature adaptive module, we carry out the feature adaptive adjustment for the improved model.

**3.3. Default Box Position and Shape Prediction.** In the process of position prediction, the improved SSD detection model first generates a series of location feature maps.

We assume that  $(i, j)$  is the coordinate of a point in the position feature map, and its probability value  $P$  corresponds to the coordinate  $Q$  in the input image, which can be expressed by

$$\begin{aligned} p(i, j | F_{\text{Conv} \in \{\text{Conv4}_3, \text{Conv6}, \text{Conv7}, \text{Conv8}_2, \text{Conv9}_2, \text{Conv10}_2, \text{Conv11}_2\}}) \\ \longleftrightarrow Q((i + 0.5)s, (j + 0.5)s), \end{aligned} \quad (2)$$

in which  $F_{\text{Conv}}$  represents the output feature map of a certain detection layer and  $s$  represents the step size of the output feature map. The  $1 \times 1$  convolution kernel is used to process the output feature map of the relevant detection layer, and the score map of the objects to be detected in the input image is obtained. The position prediction map of  $F_{\text{conv}}$  is further generated by the Sigmoid function. A certain probability threshold is set to identify the possible position of the object to be detected.

Based on the position prediction of the default box, the default bounding boxes of the objects to be detected are predicted by the shape prediction branch. According to the output feature map of the relevant detection layer, the shape prediction branch of the default box will predict the best default box shape at each location in the feature map. That is, by predicting the width and height of the default box, the maximum IoU value can be generated as far as possible with the nearest ground truth bounding box. Due to the fact that the range generated when directly predicting the width and

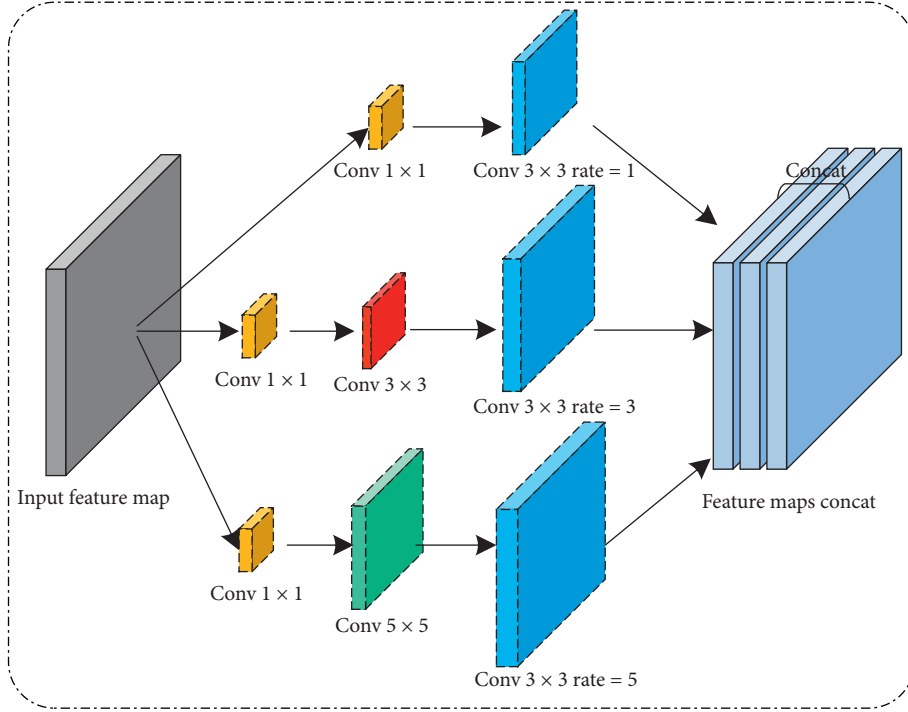

FIGURE 1: Multireceptive field fusion.

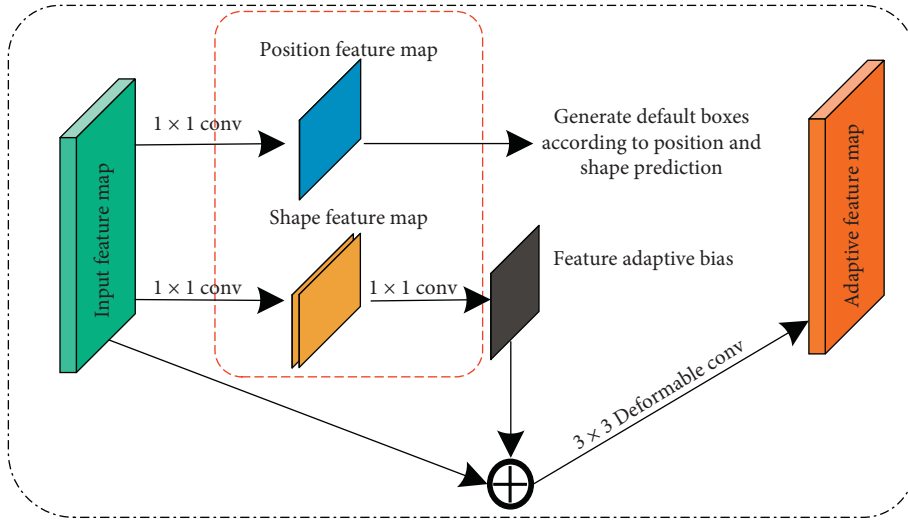

FIGURE 2: Adaptive default box mechanism for improved SSD model.

height of the bounding box is wide, and the prediction result is unstable, so it can be converted byt

$$w = \delta \cdot s \cdot e^{dw}, h = \delta \cdot s \cdot e^{dh}, \quad (3)$$

where  $s$  represents the step size and  $\delta$  represents the relative parameters controlling the default box size. Through equation (3), the output space can be mapped from  $[0, 1000]$  to  $[-1, 1]$ , so that the improved SSD object detection model can detect relevant objects more stably. The shape prediction branch uses the convolutional kernel of  $1 \times 1$  to predict the  $dw$  and  $dh$  values of the default box and completes the pixel-

level transformation of the relevant feature map through equation (3).

Compared with SSD, YOLO, RSSD, DSSD, and other object detection models, on the one hand, each position in the traditional models corresponds to a set of preset default bounding boxes. Each position in the feature maps of the improved model corresponds to only one prediction default box. The number of default boxes is greatly reduced, and the generated default boxes are more closely related to the objects to be detected. On the other hand, in the default box prediction scheme of the improved model, the aspect ratio of the default box does not need to be set manually. So, it also

has a better detection effect for the abnormal size objects existing in the input image.

**3.4. Feature Adaptive Module.** In most object detection networks such as SSD, RSSD, and DSSD, the sizes and aspect ratios of the default box are consistent at each position of the feature map. Therefore, the general convolution can be used to extract features in the output feature maps of the detection layers. Furthermore, the relevant features of each default bounding box are expressed. Compared with the existing SSD, RSSD, DSSD, and other object detectors, the default boxes with different shapes are automatically generated in the improved model. The output feature maps of the detection layers cannot predict the shape of its default boxes, but it is necessary to predict the categories and position offsets of these default boxes in the subsequent stages. That is to say, there is a mismatch between the default box and the features of the default box in the improved SSD model. In order to solve the above problem, the improved model introduces the relevant feature adaptive module and adjusts the relevant output feature maps according to equation (4) based on the default box shape of each position:

$$f'_i = N_T(f_i, w_i, h_i), \quad (4)$$

where  $f_i$  represents the feature at the  $i^{\text{th}}$  position in the output feature map and  $(w_i, h_i)$  represents the width and height of the default box corresponding to the  $i^{\text{th}}$  position. After the prediction of the default box, in order to realize the relevant position transformation and adapt to the shape of the default bounding box, a  $3 \times 3$  deformable convolution is applied to the output feature map to realize  $N_T$ . Different from the ordinary deformable convolution, the bias value in the feature adaptive module comes from the predicted default boundary box; that is,  $1 \times 1$  convolution kernel is used to act on the predicted default bounding box. From the perspective of specific functions, the feature adaptive module of the improved SSD model is similar to the RoI Pooling layer in the Faster RCNN algorithm. The structure of the improved SSD model is shown in Figure 3.

**3.5. Loss Function Setting.** Different from the traditional object detection models, the loss in the improved model includes not only the general classification loss  $L_{\text{cls}}$  and regression loss  $L_{\text{reg}}$  but also the position loss  $L_{\text{loc}}$  and shape loss  $L_{\text{shape}}$  during the default bounding box prediction. The final loss function can be expressed by equation (5), and the position loss and shape loss are balanced by the parameters  $\beta_1$  and  $\beta_2$ :

$$L_{\text{all}} = \beta_1 L_{\text{loc}} + \beta_2 L_{\text{shape}} + L_{\text{cls}} + L_{\text{reg}}, \quad (5)$$

where the classification loss  $L_{\text{cls}}$  adopts Cross Entropy (CE) loss [32] and the regression loss  $L_{\text{reg}}$  adopts smooth  $L_1$  loss.  $L_{\text{cls}}$  and  $L_{\text{reg}}$  can be expressed by

$$L_{\text{cls}} = \frac{1}{N_{\text{Pos}}} \left( \sum_{i \in \text{Pos}} \text{CE}(p_i, \hat{p}_i) + \sum_{i \in \text{Neg}} \text{CE}(p_i, \hat{p}_i) \right), \quad (6)$$

$$L_{\text{loc}} = \frac{1}{N_{\text{Pos}}} \sum_{i \in \text{Pos}} \sum_{m \in \{cx, cy, w, h\}} \text{smooth}_{L_1}(\tilde{l}_i^m - \hat{g}_i^m), \quad (7)$$

where  $p_i$  represents the probability that sample  $i$  is predicted to be of a certain class.  $\hat{p}_i$  indicates that the  $i^{\text{th}}$  sample belongs to a label of a certain category, and its value is 0 or 1.  $l$  and  $g$ , respectively, represent the deviation between the prediction box and the ground true box with the default box. When the default boundary box is generated, since the number of positive samples is smaller than that of negative samples, the focal loss is adopted to solve the problem of unbalanced positive and negative samples in position prediction. It can effectively reduce the loss of positive samples and the weight of negative samples in the training process. The loss can be expressed in equation (8). The value of the balance factor  $\alpha$  is set to 0.25 and the value of the regulation coefficient  $\gamma$  is set to 2:

$$L_{\text{Focalloss}} = \begin{cases} -\alpha(1-p)^\gamma \log p, & \hat{p} = 1, \\ -(1-\alpha)p^\gamma \log(1-p), & \hat{p} = 0. \end{cases} \quad (8)$$

When calculating the shape loss of the model,  $\text{IoU}_{\text{max}}$  is taken as a measure of the relevant loss. Based on the position feature map of each detection layer, several groups of different aspect ratios are sampled at each positive sample point position to complete the matching of IoU and determine the optimization object. Correlation matching can be expressed by equation (9). The shape loss of the improved model is shown in equation (10), where  $w_p$ ,  $h_p$ ,  $w_g$ , and  $h_g$ , respectively, represent the shapes of the prediction bounding box and the real bounding box:

$$\text{IoU}_{\text{max}} = \max_{w>0, h>0} \text{IoU}(\text{box}_{\text{wh}}, \text{box}_{\text{gt}}), \quad (9)$$

$$L_{\text{shape}} = \text{smooth } L_1 \left( 1 - \min \left( \frac{w_p}{w_g}, \frac{w_g}{w_p} \right) \right) + \text{smooth } L_1 \left( 1 - \min \left( \frac{h_p}{h_g}, \frac{h_g}{h_p} \right) \right). \quad (10)$$

## 4. Experimental Exploration

**4.1. Experimental Data Sets.** In view of the distribution of the objects in complex scenes, the ideal object detection model should have good generalization performance, which can not only effectively detect all kinds of different sizes of objects but also stably detect dense scenes. Based on Crowd Human [33], Pascal VOC 2012, and MS COCO data sets [34], relevant experiments verify the detection efficiency and robustness of the model on different data sets and comprehensively evaluate the improved model.

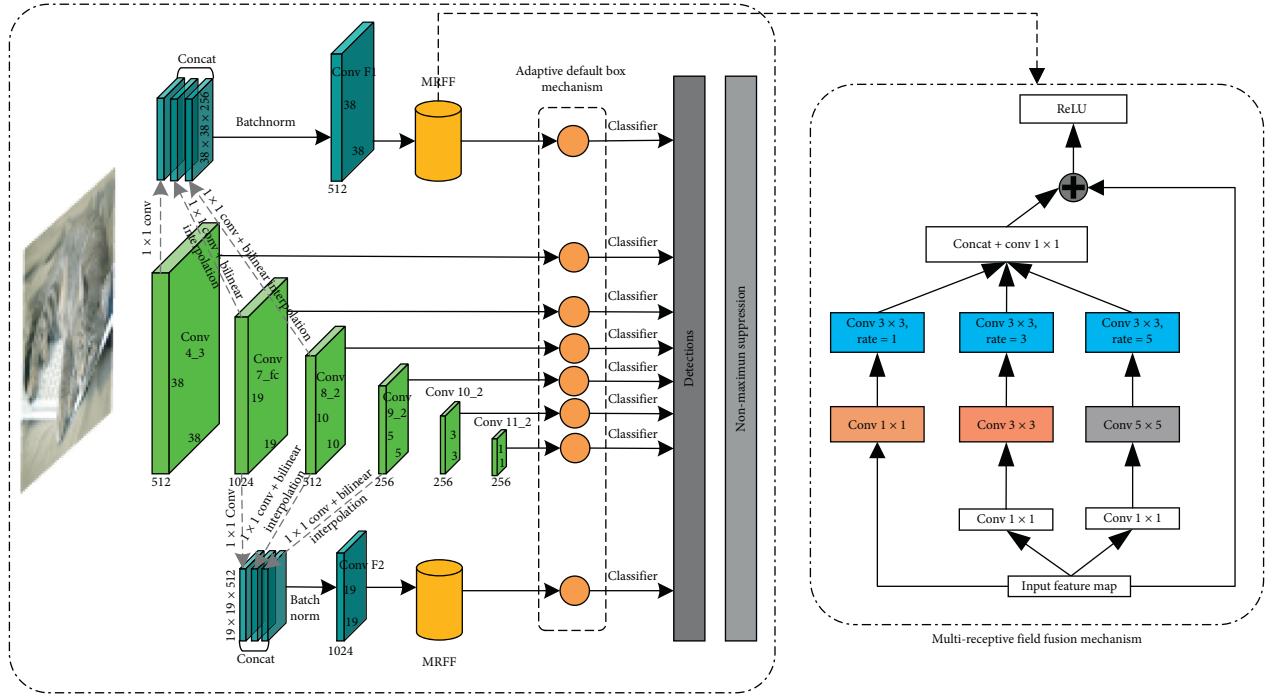

FIGURE 3: Improved SSD model structure.

The Crowd Human data set was released by MEGVII in 2018. The training set and validation set contain about 20,000 images. The data set contains more than 470,000 instances, and there are about 23 human instances in each image on average. At the same time, complex occlusion phenomenon exists in the images.

PASCAL VOC is a classic public data set, which mainly includes VOC 2007 and VOC 2012. This data set provides a complete set of standards for image classification and object detection. The VOC 2007 data set is extended to the VOC 2007 data set, which contains 20 kinds of objects and 11530 images. The related image annotations are complete and of high quality.

MS COCO data set is funded and annotated by Microsoft. It involves multiple computer vision tasks such as object detection, object segmentation, and semantic understanding. It contains about 300,000 data images, more than 2 million instances, and 91 kinds of objects. Compared with other public data sets, the COCO data set has more small objects, more complex object types, and detection scenarios. It can comprehensively evaluate model performance.

**4.2. Data Preprocessing and Model Evaluation Indexes.** In order to fully train the improved model, enhance the generalization of the model, and improve the detection effect of small objects and occlusion objects, the corresponding data preprocessing strategy is formulated. Generally, the object whose number of pixels is less than 1024 in the segmentation mask of the image object region is defined as a small object. Objects with more than 1024 pixels and less than 9216 pixels in the segmentation mask of the image object region are

defined as medium-size objects. It mainly includes two aspects: optical transformation and geometric transformation. Optical transformation mainly includes the adjustment of brightness, contrast, hue, saturation, and channel. The geometric transformation utilizes operations such as random cropping, random expansion, and scaling to achieve image size changes.

The performance of the improved model is measured by average precision (AP), average recall (AR), and frame per second (FPS). As the common evaluation indexes, the AP value reflects the precision and recall rate of the test results. The larger the value is, the better the detection precision of the model will be, and the AR value reflects the recall rate and positioning accuracy of the model. In addition to the detection precision, the FPS value is used to measure the detection speed of the improved algorithm, that is, the number of images the model can process per second.

**4.3. Model Parameters' Setting and Training.** The relevant models are trained and tested on Crowd Human, PASCAL VOC 2012, and MS COCO data sets, respectively, to verify the generalization performance of the improved model on different data sets. In the multitask loss function,  $\beta_1 = 1$  and  $\beta_2 = 0.1$  are set to balance the position loss and shape loss of the default box. The training of the model is based on the stochastic gradient descent algorithm and the "warm-up" strategy is adopted. During the initial five epochs, the learning rate of the model is increased from  $10^{-4}$  to  $4 * 10^{-3}$ . After the "warm-up" phase, the learning rate is changed to  $10^{-4}$  again, and the learning rate is set as  $10^{-5}$  and  $10^{-6}$ , respectively, at the 8th epoch and the 11th epoch. The momentum value during the training process is 0.9, and the

weight attenuation value is 0.005. All experiments are conducted based on GTX 1080 Ti and Titan X GPU environments.

#### 4.4. Influence of Relevant Mechanisms on the Detection Effect.

The improved SSD detection model is based on multiple feature maps for object detection. The deep feature maps with a large receptor field are responsible for the detection of large-scale objects, while the low-level feature maps with a small receptor field are responsible for the detection of small objects. By introducing the corresponding fusion mechanisms, the semantic information of low feature layers can be enriched. Accordingly, Conv 4\_3, Conv7\_fc, Conv F1, and Conv F2 are used for the detection of small objects, while the rest of the detection layers are used for the detection of larger objects. In addition, the ADB mechanism is added to the improved SSD model to improve the positioning precision of the model, avoid manually setting default box hyperparameters, and improve the imbalance of positive and negative samples. Based on different data sets, the experiment explored the influence of relevant mechanisms on the detection effect, and the experimental results are shown in Table 1.

Based on different data sets, Table 1 explores the influence of relevant mechanisms on the detection results of Conv 4\_3, Conv7\_fc, Conv F1, and Conv F2 layers. For Conv4\_3 layer, ADB mechanism was added to the improved algorithm, and the AP values of Crowd Human, PASCAL VOC 2012, and MS COCO data sets reached 92.1%, 72.6%, and 45.3%, respectively. AR value can be up to 81.6%, 61.4%, and 36.1%; compared with the traditional SSD algorithm, the average precision value and the average recall rate are greatly improved. In addition, it can be seen that the detection effect of Conv7\_fc has also been significantly improved.

In order to enhance the detection effect of small objects in dense scenes, additional small object detection layers Conv F1 and Conv F2 are added in the improved algorithm. The relevant detection layers use FLF, MRFF, and ADB generation mechanism to strengthen the semantic information

of the low detection layers. In the case of applying FLF and MR, the average detection precision of the Conv F1 detection layer on the three data sets can reach 87.5%, 68.3%, and 41.2%, respectively. Compared with the detection effect of the Conv4\_3 layer in the traditional SSD algorithm, the algorithm precision is improved. After the introduction of the ADB mechanism, the average detection precision and average recall rate of the algorithm are greatly improved. The experiment shows that the improved network has stronger characterization ability, better detection effect, and higher object positioning precision. Figure 4 shows the influence of relevant mechanisms on the detection effect. With the introduction of ADB, FLF, and MR, the low detection layers of the improved algorithm can extract richer feature information and detect more small objects compared with the original algorithm.

4.5. Comparison of Relevant Models. Based on the PASCAL VOC2012 test set, we compared the detection effects of Faster RCNN, YOLO V2, SSD, DSSD, RSSD, and our SSD algorithms. The training of the algorithm involved VOC 2012 and MS COCO training sets. The basic network included VGGNet, ResNet-101 [35], and Darknet-19. Taking FPS, mAP, and mAR [36] as evaluation criteria, the experimental comparison results of the six models are shown in Table 2.

By analyzing the experimental data in Table 2, our SSD300 has improved its average precision and average recall rate compared with Faster RCNN, YOLOv2, SSD300, DSSD321, and RSSD300 algorithms. The detection precision of our SSD300<sub>-s0</sub> model can reach 73.2% without pre-training, which is 3.6% higher than that of SSD300<sub>-s0</sub>. When the model training is combined with the MS COCO data set, the detection accuracy of our SSD300<sub>+coco</sub> reaches 83.4%, which is 2.2% higher than SSD300<sub>+coco</sub>. In addition, the average recall rate of our SSD300<sub>+coco</sub> is 74.1%, which is about 2.5% higher than SSD300<sub>+coco</sub>. This verifies the effectiveness of ADB and other relevant mechanisms, improves the imbalance of positive and negative samples in traditional SSD algorithms, and improves the detection effect of objects in dense scenes.

FIGURE 4: Influence of the relevant mechanism on small object detection layers. (a) Conv4\_3: SSD, (b) Conv4\_3: SSD + ADB, and (c) Conv F1: SSD + FLF + MR + ADB.

TABLE 2: Results based on the PASCAL VOC 2012 test set.

| Algorithm                    | Training set    | Pretraining | Basic network | FPS | GPU     | Input image            | mAP (%) | mAR (%) |
|------------------------------|-----------------|-------------|---------------|-----|---------|------------------------|---------|---------|
| Faster RCNN [18]             | VOC 2012        | Yes         | VGGNet        | 9   | Titan X | $\sim 600 \times 1000$ | 73.2    | 61.3    |

| SSD300 <sub>-so</sub> [26]   | VOC 2012        | No          | VGGNet        | 56  | 1080 Ti | $300 \times 300$       | 69.6    | 58.2    |
| SSD300 [26]                  | VOC 2012        | Yes         | VGGNet        | 56  | 1080 Ti | $300 \times 300$       | 77.2    | 68.3    |
| SSD300 <sub>+coco</sub> [26] | VOC 2012 + COCO | Yes         | VGGNet        | 56  | 1080 Ti | $300 \times 300$       | 81.2    | 71.6    |
| SSD512 [22]                  | VOC 2012        | Yes         | VGGNet        | 38  | 1080 Ti | $512 \times 512$       | 78.5    | 69.4    |
| SSD512 <sub>+coco</sub> [26] | VOC 2012 + COCO | Yes         | VGGNet        | 38  | 1080 Ti | $512 \times 512$       | 83.2    | 72.5    |
| DSSD321 [27]                 | VOC 2012        | Yes         | ResNet-101    | 12  | 1080 Ti | $321 \times 321$       | 78.6    | 69.7    |
| DSSD513 [27]                 | VOC 2012        | Yes         | ResNet-101    | 7   | 1080 Ti | $513 \times 513$       | 81.5    | 72.4    |
| RSSD300 [28]                 | VOC 2012        | Yes         | VGGNet        | 41  | 1080 Ti | $300 \times 300$       | 78.5    | 68.9    |
| RSSD512 [28]                 | VOC 2012        | Yes         | VGGNet        | 23  | 1080 Ti | $512 \times 512$       | 80.8    | 71.2    |
| Our SSD300 <sub>-so</sub>    | VOC 2012        | No          | VGGNet        | 47  | 1080 Ti | $300 \times 300$       | 73.2    | 62.4    |
| Our SSD300                   | VOC 2012        | Yes         | VGGNet        | 47  | 1080 Ti | $300 \times 300$       | 79.8    | 71.2    |
| Our SSD300 <sub>+coco</sub>  | VOC 2012 + COCO | Yes         | VGGNet        | 47  | 1080 Ti | $300 \times 300$       | 83.4    | 74.1    |
| Our SSD512                   | VOC 2012        | Yes         | VGGNet        | 30  | 1080 Ti | $512 \times 512$       | 82.4    | 73.6    |
| Our SSD512 <sub>+coco</sub>  | VOC 2012 + COCO | Yes         | VGGNet        | 30  | 1080 Ti | $512 \times 512$       | 85.6    | 75.9    |

Due to the introduction of ADB and other modules, some detection time is lost. Compared with the original SSD300, the real-time detection performance of the improved algorithm is reduced, but it is enough to meet the requirements of real-time detection. Compared with RSSD300, DSSD321, and other improved algorithms, our SSD300 not only improves the average detection precision

and average recall rate but also has obvious advantages in real-time detection.

In order to further verify the generalization of the improved algorithm on different data sets, a series of AP values and AR values of the relevant models were fully explored based on the MS COCO data set. The relevant experimental results are shown in Tables 3 and 4.

TABLE 3: AP results based on the MS COCO test set.

| Algorithm        | Training set     | Basic network | Pretraining | AP <sub>IoU</sub> (%)  |                   |                    | AP <sub>Area</sub> (%) |                 |                 |

| DSSD321 [27] | COCO trainval35k | ResNet-101    | Yes         | 30.5                         | 35.1            | 38.9             | 12.7                   | 42              | 62.6            |
| DSSD513 [27] | COCO trainval35k | ResNet-101    | Yes         | 33.9                         | 42.5            | 45.8             | 21.8                   | 49.1            | 66.4            |
| RSSD300 [28] | COCO trainval35k | VGGNet        | Yes         | 30.2                         | 34.6            | 38.2             | 12.1                   | 41.2            | 61.8            |
| RSSD512 [28] | COCO trainval35k | VGGNet        | Yes         | 33.4                         | 41.8            | 44.8             | 20.9                   | 48.4            | 66.1            |
| Our SSD300   | COCO trainval35k | VGGNet        | Yes         | 32.4                         | 36.8            | 40.2             | 14.2                   | 43.8            | 64.3            |
| Our SSD512   | COCO trainval35k | VGGNet        | Yes         | 36.2                         | 44.2            | 47.2             | 23.6                   | 51.3            | 68.3            |

According to the experimental data in Tables 3 and 4, compared with Faster RCNN, YOLO V2, SSD, DSSD, and RSSD algorithms, our SSD still has good detection performance on MS COCO data set. In the detection of small objects, AP<sub>S</sub> and AR<sub>S</sub> of our SSD512 can reach 14.3% and 23.6%, respectively. Compared with the original SSD algorithm, the average detection precision and average recall rate of small objects have been improved by about 3.4% and 7.1%, respectively. In addition, the other evaluation indicators also have different degrees of improvement. The improved algorithm achieves ideal detection results on both MS COCO and PASCAL VOC data sets. On the one hand, the improved SSD algorithm has good generalization. On the other hand, it also directly shows the effectiveness of the algorithm improvement.

## 5. Conclusion

In view of the defects of the traditional SSD detection algorithm, such as the poor detection effect of small objects and the default box generation depending on manual settings, this paper proposes an improved multiobject detection algorithm, which effectively improves the object detection effect in complex scenes. The improved algorithm mainly involves the following contributions: on the one hand, the introduction of feature fusion and multireceptive field fusion mechanism enhances the characterization ability of the low feature layers and improves the detection effect of small objects. On the other hand, through the adaptive default box

mechanism, the steps of setting default box hyperparameters are avoided, the generation of negative sample box is reduced, and the imbalance of positive and negative samples is improved. Under the requirement of real-time detection, the improved algorithm greatly improves the average precision and recall rate of object detection in complex scenes.

## Data Availability

The image data supporting this algorithm research is from previously reported studies and datasets. These prior studies and datasets are cited at relevant places within the text as references [22–24, 29, 30].

## Conflicts of Interest

The authors declare that they have no conflicts of interest in this work.

## Authors' Contributions

All authors contributed equally to this manuscript.

At present, the classification of the hyperspectral image (HSI) based on the deep convolutional network has made great progress. Due to the high dimensionality of spectral features, limited samples of ground truth, and high nonlinearity of hyperspectral data, effective classification of HSI based on deep convolutional neural networks is still difficult. This paper proposes a novel deep convolutional network structure, namely, a hybrid depth-separable residual network, for HSI classification, called HDSRN. The HDSRN model organically combines 3D CNN, 2D CNN, multiresidual network ROR, and depth-separable convolutions to extract deeper abstract features. On the one hand, due to the addition of multiresidual structures and skip connections, this model can alleviate the problem of over fitting, help the backpropagation of gradients, and extract features more fully. On the other hand, the depth-separable convolutions are used to learn the spatial feature, which reduces the computational cost and alleviates the decline in accuracy. Extensive experiments on the popular HSI benchmark datasets show that the performance of the proposed network is better than that of the existing prevalent methods.

## 1. Introduction

HSI has been widely used in environmental monitoring [1], mineral exploration [2], agricultural remote sensing [3], vegetation ecology [4], ocean remote sensing [5], and other earth observation tasks. In these applications, because HSI exhibits mixed land cover categories, resulting in high intraclass variability and interclass similarity, it is a huge challenge for any classification model. In order to improve the performance of HSI classification, traditional machine learning methods integrate spectral features and spatial features to achieve effective feature extraction such as random forest [6], SVM and its variants [7, 8], sparse self-representation [9], and artificial neural network [10]. However, these methods only extract surface features such as edges and textures of HSI, which will reduce the feature representation ability of hyperspectral images.

Deep learning [11, 12] method has been widely used in image processing, especially image classification [13] and

target recognition [14]. It can actively learn to extract features, with little manual intervention, and automatically find effective features. The deep model can also extract high-level abstract features by adding hierarchical abstractions, which are usually more robust to nonlinear processing. The basic network frameworks for deep learning include unsupervised neural networks [15], convolutional neural networks [16], cyclic neural networks [17], and recursive neural networks [18]. Among them, convolutional neural networks (CNNs) are classic models. This model is based on big data and deep network structures. It extracts rich deep features from the original hyperspectral data, ensuring the integrity of spatial and spectral information and avoiding the initiative and randomness of human feature extraction, and it can achieve better classification results than other deep learning models. In addition, the deep convolutional networks AlexNet [19], VGG [20], GoogleNet [21], ResNet [14], etc., perform well, which fully demonstrates the fact that convolutional neural networks are a good strategy for image classification.

In recent years, the classification of HSI based on the deep convolutional network has also made great progress. HSI is 3D data, which include 2D spatial information and 1D spectral information [22]. The classification of HSI based on CNN mainly uses 2D CNN or 3D CNN for hierarchical feature extraction. Chen et al. proposed to use 3D convolution to get spatial-spectral depth features [23]. A 3D CNN was designed by Li for spectral space classification [24]. Subsequently, Yang et al. proposed a 3D recurrent CNN [25]. Song et al. designed a deep feature fusion network to solve the hyperspectral classification problem [26], Fang et al. proposed a deep hash neural network [27], and Gong et al. introduced statistical metric methods for HSI spectral-spatial classification [28]. Zhong et al. designed the SSRN structure and introduced identity mapping residual blocks for spectral-spatial feature learning [22]. Liu et al. used 3D CNN and residual connection to construct a 12-layer deep network ( Res-3D CNN ) [29]. Lee and Kwon adopted the residual connection to make the network deeper and used 11 convolution kernels to learn the hierarchical features [30]. Recently, Roy et al. designed a concise model (HybridSN) [31] that combined 3D CNN and 2D CNN to extract spectral features, and by comparing with the most advanced models in the past, the classification effect is more excellent. Cao and Guo further introduced hybrid dilated convolutions (HDC) and the residual block based on SSRN and proposed a new end-to-end hybrid expansion residual deep convolutional network [32]. Wu et al. designed the 3D ResNeXt structure using feature fusion and label smoothing strategies [33].

It can be clearly seen from the above literature that only using 2D CNN for HSI classification cannot extract a good distinguishing feature map from the spectral dimension, and spectral information will be lost. Using only 3D CNN to extract features can enhance the accuracy, but the complexity will grow, and the performance is worse, when dealing with classes with similar textures in many spectral bands. The main reason for the above situation is that HSI is a 3D data image, with spatial dimensions and spectral dimensions. Using only 2D CNN cannot extract feature images with good discriminating ability from the spectral dimension. Similarly, deep 3D CNN complicates the model and greatly increases the amount of calculation. Moreover, many classes with similar textures, using 3D CNN alone, seem to be even worse.

In order to solve the above shortcomings, our model combines 3D CNN and 2D CNN that can fully extract spectral and spatial feature maps and overcome the shortcomings of single 2D CNN and 3D CNN. In addition, deep networks are difficult to train and are prone to problems such as overfitting, gradient disappearance, and gradient explosion. Therefore, it is natural to introduce the residual network in the model [34, 35] because the residual network can be improved by adding layers. With the depth of the network increasing, the operation costs in the model will also increase. Replacing the traditional 2D convolution with deep separable convolutions [36] can solve the problem of parameter and operation costs and further avoid overfitting. In this study, a new network is proposed by constructing a hybrid deep separable residual network. Firstly, the

framework designs a 3D residual module ROR to extract spatial-spectral mixing features. Subsequently, the feature information is converted from 3D data to a 2D feature map. Finally, the 2D depth-separable convolutions extract spatial features. Depth-separable convolution can enhance the feature learning ability of HSI and reduce the computational complexity. The multiresidual network ROR [37] in the network can enhance the learning ability. In addition, skip connections can extract spatial-spectral mixing features more effectively. The major contributions of this paper are listed as follows:

- (1) A hybrid depth-separable convolution residual network is proposed to enhance the feature learning ability of HSI. In this network, spatial-spectrum 3D CNN and spatial 2D CNN are combined into the model, which can better study deep-level spatial-spectral features.
- (2) We embed multiresidual network ROR in the 3D convolutional layer and the 2D convolutional layer that can greatly decrease the number of parameters, thereby simplifying the network structure and promoting the extraction of deep features.
- (3) In the 2D processing part, the use of deep separable convolutional layers reduces the number of parameters and avoids overfitting.

The rest of the article is organized as follows: in Section 2, we introduce the proposed framework. In Section 3, the HSI set and network configuration are explained, with experimental results and analyses. The conclusions and future directions are given in Section 4.

## 2. Methodology

*2.1. Proposed Model.* The HSI data can be regarded as a 3D cube, where the width of the cube is defined as  $W$ , the height is  $H$ , the spectral band is  $D$ , and the original input of hyperspectral data can be expressed as  $R^{W \times H \times D}$ . Each pixel contains  $D$  spectral measurements and forms a one-hot label vector  $C = (c_1, c_2, \dots, c_n) \in R^{1 \times 1 \times n}$ , where  $n$  represents the land cover categories. We design a HDSRN structure for HSI classification, including six parts, namely, PCA dimensionality reduction, 3D spectral and spatial mixed feature learning process, 3D to 2D deformed part, 2D learning process, average pooling layer, and FC layer. In Figure 1, the HDSRN classification framework is described in detail using the Indian Pines dataset as an example, where  $W = H = 145$  and  $D = 200$ .

In the traditional 2D convolution operation, convolution is applied to the spatial dimension, and the 2D feature map is obtained. However, the HSI is 3D data, and it is necessary to capture the spectral feature; 2D CNN cannot process spectral information. The 3D CNN kernel can simultaneously extract spectral and spatial features, but it increases the computational complexity. In addition, when classifying a large number of features with similar textures on the spectral band, the performance is poor. In order to overcome the shortcomings of 2D CNN and 3D CNN and make full

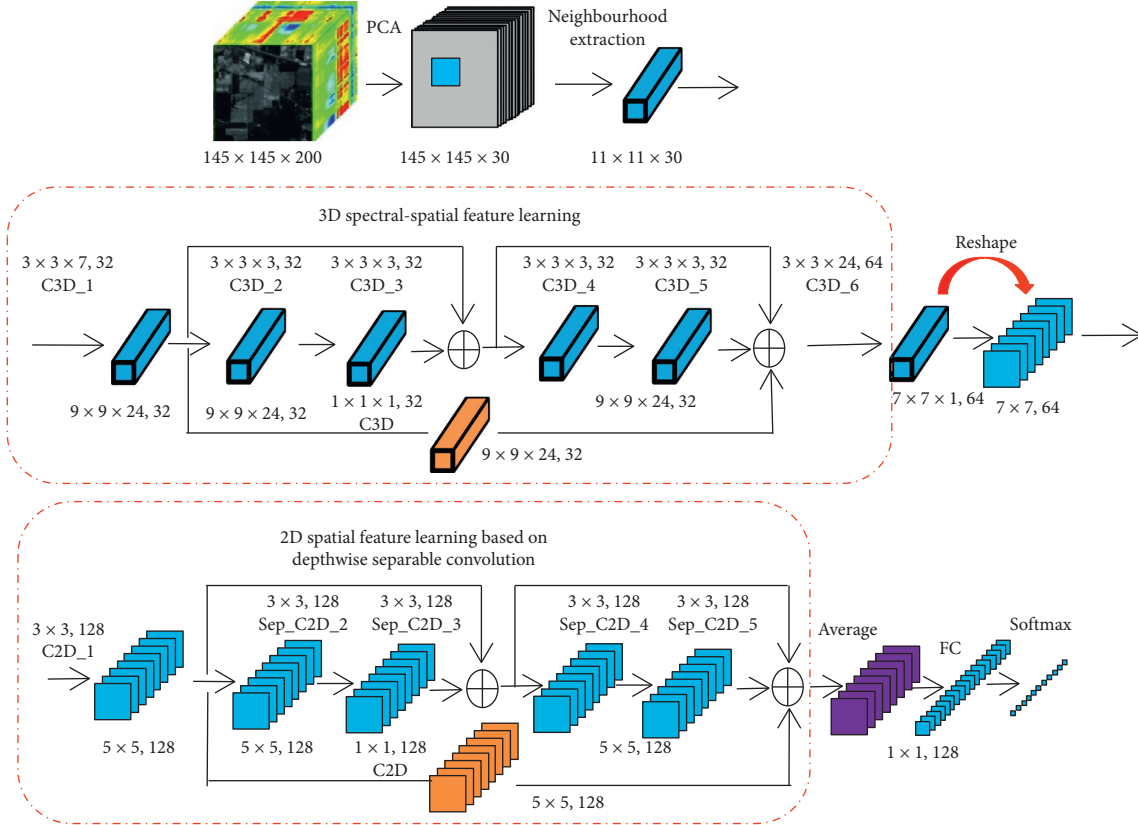

FIGURE 1: The HDSRN classification framework.

use of the automatic feature learning capabilities of 2D and 3D, the model uses a hybrid convolutional neural network framework to combine 3D CNN and 2D CNN into the model. The 3D spatial-spectral feature extraction part consists of two 3D convolutional layers and a set of multi-residual network ROR. The 2D spatial feature is composed of a 2D convolutional layer and a set of multi-residual network ROR. The reshape and average pooling modules are used to adjust the data size to meet the requirements of the next layer. The FC layer and the softmax layer are used to classify HSI.

## 2.2. PCA Dimension Reduction and Data Preprocessing.

In order to remove spectral redundancy, based on the lightweight design, we use PCA to reduce the dimensionality of the original hyperspectral data, retaining relatively few principal components. In Figure 1, PCA decreases the spectral band from  $D$  to  $B$ , and  $B=30$ , while the spatial dimension remains unchanged. In this case, the hyperspectral data are represented as  $R^{W \times H \times B}$ . The HSI image has large size and many bands, and direct processing requires high hardware and memory requirements. Therefore, before image classification and processing, we first divide the HSI image into small pieces. The hyperspectral image is divided into small overlapping 3D patches, expressed as  $R^{S \times S \times B}$ . The height and the width are both  $S$ , and the spectral band is  $B$ . The true value labels are decided by the label of the center pixel. The size of the patches cannot be too small because

being too small will result in a small receiving field and cannot fully extract image features. But, if the patches are too large, the amount of calculation will be large, and the training time and the test time will become longer. Through the comparative experiment in Section 3.2, we find that the classification effect is better when the  $S$  value is 11.

## 2.3. 3D Spectral Space Feature Learning.

HSI data have the characteristics of a spectral-spatial 3D structure. Based on this feature, we construct a 3D convolution network suitable for HSI to extract spatial-spectral features. The 3D convolution operation [38] is achieved by convolving a 3D convolution kernel with 3D data. The input layer is a 3D image, which is composed of a spatial dimension and a spectral dimension. The 3D convolution kernel performs convolution operations on the two dimensions of the input 3D image and obtains a 3D feature map. The 3D convolution formula is as follows:

$$v_{i,j}^{x,y,z} = f \left( \sum_m \sum_{b=0}^{B_i-1} \sum_{h=0}^{H_i-1} \sum_{w=0}^{W_i-1} k_{i,j,m}^{b,h,w} v_{(i-1),m}^{(x+h),(y+w),(z+b)} + b_{i,j} \right), \quad (1)$$

where  $v_{(i-1),m}^{(x+h),(y+w),(z+b)}$  is the value at the position  $(x+h, y+w, z+b)$  of the  $m^{\text{th}}$  feature map output from the  $i-1$  layer,  $k_{i,j,m}^{b,h,w}$  is the value of the  $j^{\text{th}}$  convolution kernel of the  $i^{\text{th}}$  layer at the position  $(b, h, w)$ ,  $B_i$ ,  $H_i$ , and  $W_i$  are the kernel sizes along the spectral and spatial dimensions, respectively,

$(b, h, w)$  is the index of the convolution kernel,  $(x, y, z)$  is the index of the feature map,  $(x, y)$  is the spatial dimension value,  $z$  is the spectral dimension value,  $b_{i,j}$  is the deviation of the  $j^{\text{th}}$  feature map on the  $i^{\text{th}}$  neuron, and  $f$  is the activation function. In the hyperspectral classification task based on 3D convolution, we set the input data to  $W \times H \times B$ ,  $C_1$ , the size of the convolution kernel, is  $k_1 \times k_2 \times k_3$ , and the number of convolution kernels is  $p$ . If there is no padding and the step size is 1 in the convolution operation, the feature map size generated by 3D convolution is  $(W - k_1 + 1) \times (H - k_2 + 1) \times (B - k_3 + 1)$ ,  $p$ . The number of weight parameters of the 3D convolutional layer is  $p \times k_1 \times k_2 \times k_3 \times C_1$ .

Figure 2 is the 3D spatial-spectral feature learning framework. This part is composed of two 3D convolutional layers and a set of multiresidual network ROR. The input data of the network are  $11 \times 11 \times 30$ , the size of the convolution kernel of the first layer is  $3 \times 3 \times 7$ , and the output is 32 feature maps of  $9 \times 9 \times 24$  size. The second layer is a multiresidual network ROR, which uses 3D identity residual blocks to connect to deepen the network, avoiding weak signal loss and excessive fitting, which is conducive to improving efficiency and extracting better deep abstract features without introducing additional parameters. This part uses padding to ensure that the size of the output feature map is the same as the input size. In addition, the outermost skip connection realizes the fusion of feature data by summing the corresponding pixels. Skip connection alleviates the problem of gradient disappearance, contributes to gradient backpropagation, and can more fully extract features. On each convolutional layer connected by the residual block, we use 32 convolution kernels. The size of each kernel is  $3 \times 3 \times 3$ , from which we can get rich spectral and spatial features.

**2.4. 3D to 2D Deformation.** The 2D convolution operation is started, and spatial feature extraction is performed, after the 3D convolution operation. The network outputs 64 feature map data with a size of  $7 \times 7 \times 1$ . In order to learn the output features in the later 2D space, we reshape the 3D features into 64 2D feature maps of size  $7 \times 7$ , as shown in Figure 3. After the reshaping operation, only the 2D spatial features need to be studied, which reduces the parameters and the operation cost compared with 3D convolution.

**2.5. 2D Spatial Feature Learning Based on Depth-Separable Convolution.** Convolutional layer is the core part of CNN to extract deep-level features. The main functional unit of the convolutional layer is a 2D convolution kernel, which acts on the input data of the previous layer to extract features and enhances the model's nonlinear feature extraction capability by adding an activation function, which is beneficial to the extraction of complex deep features. The 2D convolution is shown in the following equation:

$$v_{i,j}^{x,y} v_{(i-1),m}^{(x+h),(y+w)} = f \left( \sum_m \sum_{h=0}^{H_i-1} \sum_{w=0}^{W_i-1} k_{i,j,m}^{h,w} v_{(i-1),m}^{(x+h),(y+w)} + b_{i,j} \right), \quad (2)$$

where  $v_{(i-1),m}^{(x+h),(y+w)}$  is the value at the position  $(x+h, y+w)$  of the  $m^{\text{th}}$  feature map output from the  $i-1$  layer,  $k_{i,j,m}^{h,w}$  is the value of the  $j^{\text{th}}$  convolution kernel of the  $i^{\text{th}}$  layer at the position  $(h, w)$ ,  $B_i$  and  $H_i$  are the kernel sizes along the spatial dimensions,  $(h, w)$  is the index of the convolution kernel,  $(x, y)$  is the index of the feature map,  $b_{i,j}$  is the deviation of the  $j^{\text{th}}$  feature map on the  $i^{\text{th}}$  neuron, and  $f(\cdot)$  is the activation function. In the hyperspectral classification task based on 2D convolution, we set the input data to  $W \times H$ ,  $C_1$ , the size of the convolution kernel is  $k_1 \times k_2$ , and the number of convolution kernels is  $p$ . Through the 2D convolution operation, the current layer can learn local features from the previous layer, and the size of the convolution kernel determines the size of the local space. Continuous convolutional layers can extract deeper and deeper features that are increasingly abstract. Continuous convolutional layer can extract deeper and more abstract features.

Unlike accustomed 2D convolution, depth-separable convolution performs a spatial convolution while keeping the channels independent, and then deep convolution is performed. The depth-separable convolution not only lessens the number of parameters and calculations in the network, but also speeds up the network training speed and reduces the odds of overfitting in HSI classification, as shown in Figure 4.

In general, the input image using convolution operation has the same length and width. Assuming that the input image size is  $H \times H$  and the channel is  $D_1$ , that is, the depth of the image,  $D_2$  convolution kernel size  $h \times h$  convolution operation is used. The specific steps are as follows.

The first step is the deep convolution operation, which uses  $D_1$  convolution kernels of size  $h \times h$  to perform the convolution operation. Each convolution kernel only convolves one channel of the input layer. If no padding is used and the step size is one, the mapping size obtained each time is shown in the following equation:

$$S_M = (H - h + 1)^2, \quad (3)$$

where  $H$  is the length and width of the input image and  $h$  is the convolution kernel size.

These maps are stacked together to create an image, and the size of the image is shown in the following equation:

$$S_h = (H - h + 1)^2 D_1, \quad (4)$$

where  $D_1$  represents the number of channels. Finally, an output image of size  $S_h$  is obtained, and the depth of the image remains the same as the original.

The second step is to expand the depth convolution operation. We use  $D_1$  convolution kernels of size  $1 \times 1$  to perform the operation. Each convolution kernel is convolved with the input image of size  $S_h$  to obtain a size of  $S_M$  mapping. After  $D_2$  times  $1 \times 1$  convolution, the output image can be obtained. The size of the output image is shown in the following equation:

$$I_o = (H - h + 1)^2 D_2. \quad (5)$$

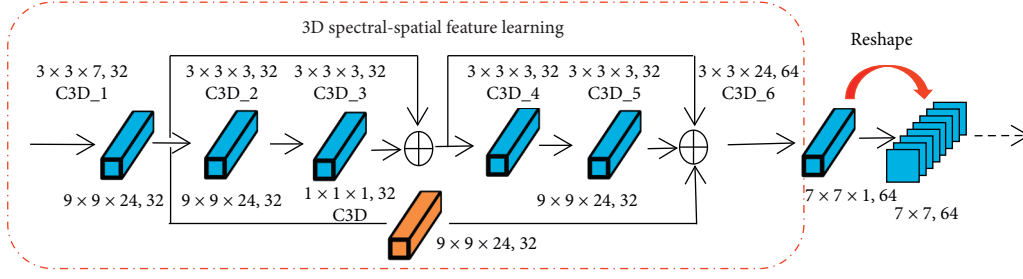

FIGURE 2: 3D spectral-spatial feature learning.

FIGURE 3: Framework of 3D to 2D deformable.

FIGURE 4: Depth-separable convolution.

The depth-separable convolution converts an input layer of  $H \times H \times D_1$  into an output layer of  $I_o$ .

We compare the number of parameters used in the two methods. The number of traditional 2D convolution operation parameters is shown in the following equation:

$$P_t = D_1 h^2 D_2. \quad (6)$$

The number of depth-separable convolution parameters is shown in the following equation:

$$P_d = D_1 h^2 + D_1 D_2, \quad (7)$$

where  $D_1 h^2$  represents the number of operation parameters in the first step and  $D_1 D_2$  is the number of parameters in the second step.

The ratio of the depth-separable convolution and the traditional 2D convolution parameter is shown in equation (8). It can be found that the use of deep separable convolution can greatly reduce the number of parameters and improve operational efficiency:

$$R_p = \frac{1}{D_2} + \frac{1}{h^2}. \quad (8)$$

Figure 5 is a spatial feature learning framework based on depth-separable convolution. This part consists of a

convolutional layer and a set of multiresidual network ROR. In Sep\_C2D\_2, Sep\_C2D\_3, Sep\_C2D\_4, and Sep\_C2D\_5, the depth-separable convolution replaces the traditional 2D convolution operation, which greatly reduces the number of parameters and the operation cost. The input data of the network are 64 feature maps with a size of  $7 \times 7$ . Firstly, this part of the network uses 128 convolution kernels of size  $3 \times 3$  to realize convolution operations on the input data. Secondly, it uses identity residual blocks to connect and deepen the network to extract better deep abstract features. We use padding to keep the size of the output feature map unchanged from the input size. Similarly, the outermost skip connection realizes the fusion of feature data. On each convolutional layer connected by the residual block, we use 128 convolution kernels, and each kernel size is  $3 \times 3$ . Finally, through the average pooling layer, the 128 output feature maps are converted into 128 special maps with a size of  $1 \times 1$ .

**2.6. Residual Network.** In deep learning, the shallow network cannot significantly enhance the classification effect of the network, and the deep network can better learn abstract features [11, 14]. But, the deeper the network, the more obvious the phenomenon of gradient disappearing, and the

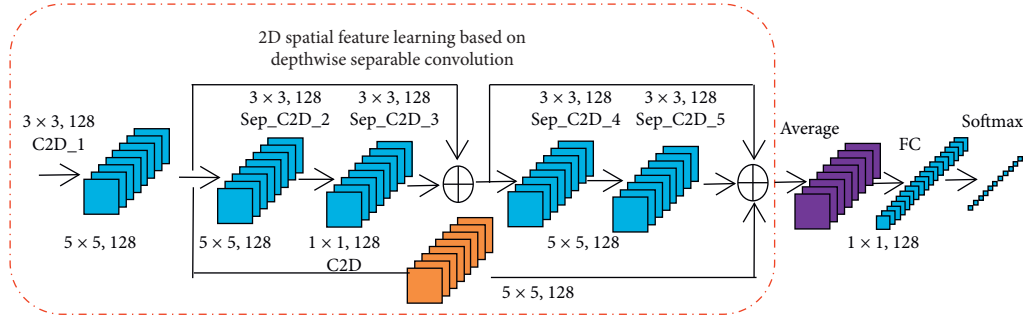

FIGURE 5: 2D spatial feature learning based on depth-separable convolution.

training effect of the network will not be very good. The proposed classification model uses residual connection to deepen the network to solve the gradient dispersion. In addition, the use of residual connections does not introduce additional parameters. According to whether the input and output sizes are the same, ResNet [14] divides the residual connection into identical residual connection and non-identity residual connection, as shown in Figure 6. In the identity residual connection, the input data are  $X$ , and the identity connection is used to inject  $X$  directly into the downstream of the network. The dimension of the output data has not changed, as shown in Figure 6(a). In the nonidentity residual connection, the size of the input data and the output data does not match. A convolutional layer is added to the shortcut path to adjust the input data  $x$  to a suitable size to match the data size of the main path, as shown in Figure 6(b). He et al. [14] show that the identity residual connection can effectively solve network degradation.

Due to the high spectral resolution and high spatial correlation of HSI, we design two consecutive identical residual blocks in the proposed HDSRN model, as shown in Figure 7. In this structure, the gradient in the upper layer can quickly propagate back to the lower layer, thereby facilitating and standardizing the model training process. In addition, we added a skip connection to fuse feature data at the outermost layer of two consecutive identical residual blocks. Skip connection can alleviate the problem of gradient disappearance, help the backpropagation of the gradient, and more fully extract features.

### 3. Experimental Results and Discussion

In this section, we first select three popular HSI benchmark datasets for our experiment and describe evaluation indices and experimental settings. Then, we discuss the impact of input spatial dimensions and proportions of training samples on classification performance. Finally, we compare the HDSRN model with the existing state-of-the-art methods, such as SVM-RBF [39], 2D CNN [40], 3D CNN [24], SSRN [22], and HybridSN [31].

**3.1. Datasets.** We use Indian Pines (IN), University of Pavia (UP), and Salinas Scene (SA) datasets [39] to verify the model.

IN dataset [41, 42] was collected by AVIRIS sensors in northwestern Indiana. The spatial resolution is about 20m, and the image has a  $145 \times 145$  spatial dimension and 224 spectral bands. Among them, 24 spectral bands covering the water absorption area are discarded, so it becomes 3D data of size  $145 \times 145 \times 200$ . The data have 21,025 pixels in total, and the characteristic pixels are 10,249 pixels. The planting area is all agricultural crops with a total of 16 categories.

UP dataset [41, 42] was collected by ROSIS sensors in Pavia University. The spatial resolution is 1.3 m, the image has a  $610 \times 340$  spatial dimension and 103 spectral bands, and its wavelength range is between 430 and 860 nm. The UP dataset contains a total of 2,207,400 pixels, and the feature pixels are only 42,776 and contains 9 categories.

SA dataset [41, 42] was collected by the AVIRIS sensors in Salinas Valley, California, USA. The spatial resolution is 3.7 m, and the image has a  $512 \times 217$  spatial dimension and 224 spectral bands. 20 spectral bands covering the water absorption area are discarded, so it becomes 3D data of size  $512 \times 512 \times 204$ . The SA dataset included a total of 111104 pixels, 56975 pixels are background pixels, and the feature pixels are 54129 pixels with a total of 16 categories.

**3.2. Evaluation Indices.** In this paper, we use the confusion matrix to represent the classification accuracy of HSI. Confusion matrix is an indicator to judge the results of the classification model and is used to judge the quality of the classifier. The judgment indexes customarily used are overall accuracy (OA), average accuracy (AA), and kappa coefficient (kappa).

OA refers to the ratio of the number of correctly classified samples to the overall number of samples, as shown in the following equation:

$$OA = \frac{\sum_{i=1}^n M_{ii}}{N}, \quad (9)$$

where  $N$  is the overall number of samples,  $M_{ii}$  is the diagonal element of the corresponding confusion matrix, and  $n$  is the number of categories.

AA is the average value of the classification accuracy of each category, and its calculation process is shown in the following equation:

FIGURE 6: The residual connections: (a) identity connection; (b) nonidentity connection.

FIGURE 7: Spectral-spatial residual network.

$$AA = \frac{\sum_{i=1}^n \left( M_{ii} / \sum_{j=1}^n M_{ij} \right)}{n} \quad (10)$$

Kappa coefficient is an important indicator to measure classification performance, and its calculation process is shown in the following equation:

$$\text{kappa} = \frac{N \sum_{i=1}^n M_{ii} - \sum_{i=1}^n (M_{i+} + M_{+i})}{N^2 - \sum_{i=1}^n (M_{i+} + M_{+i})} \quad (11)$$

where  $M_{i+}$  is the sum of the  $i^{\text{th}}$  row in the confusion matrix and  $M_{+i}$  represents the sum of the  $i^{\text{th}}$  column in the confusion matrix.

**3.3. Experimental Settings.** We studied the impact of the sample ratio and the input space size on classification performance. For specific experimental details, see Section 3.3. In the end, the most suitable space size we chose is  $11 \times 11$ . For the fairness of comparison, we collected the same spatial dimensions  $11 \times 11$  in the input 3D patches of different datasets. Taking the Indian Pines dataset as an example, the detailed network parameter settings of the model proposed in this paper are shown in Table 1. We applied the Adam algorithm and chose the optimal learning rate of 0.001. The experimental hardware platform is i5-7500 CPU and GTX960 GPU. For these three datasets, in order to get more accurate statistical results, each experiment was repeated 5 times, and the average value of the classification indicators was used as the final result.

**3.4. Experimental Parameter Discussion.** The ratio of training samples and the input space size are two important factors that affect the performance of HSI classification. We use a series of comparative experiments to determine the training sample ratio and the size of the input space. When the training sample ratios of the datasets IN, UP, and SA are 20%, 10%, and 10%, respectively, the classification performance is optimal. Through the experiment in Section 3.4.2, the classification performance is the best when the input space size is  $11 \times 11$ .

**3.4.1. The Impact of the Training Dataset Proportion.** In order to select the appropriate training sample ratio for the dataset, we conducted a comparative experiment with different training sample ratios. The proportions of the training samples we selected are 2%, 5%, 10%, 15%, and 20%. The same spatial dimension is extracted for different datasets. For example, the spatial dimension of IN is  $11 \times 11 \times 30$ , the spatial dimension of UP is  $11 \times 11 \times 15$ , and the spatial dimension of SA is  $11 \times 11 \times 15$ . Each experiment was repeated 5 times, and the average value of the classification indicators was used as observation objects. The changes in OA, AA, and kappa values at different ratios are shown in Table 2. It can be found that as the ratio of input training samples increases, the accuracy gradually improves. When the proportion of training samples in the three datasets reaches 20%, the classification accuracy exceeds 99%, especially the accuracy of the SA dataset is close to 100%. Figure 8 is a classification accuracy chart of three datasets with different training sample proportions. We can clearly see that when the training set is between 2% and 15%, the accuracy is significantly improved. When our training set reaches 15%, the accuracy began to grow slowly. The training sample ratio reaches 20%, and the classification accuracy improves to 99.6%. For the IN dataset, a 20% training sample ratio is enough to train the network. It can be clearly seen from Figures 8(b) and 8(c) that when the training set is between 2% and 10%, the classification accuracy increases significantly. As the training set reaches 10%, the increasing rate of accuracy starts to slow down. The UP classification accuracy reaches 99.73%, and the SA reaches 99.98%. For UP and SA datasets, 10% of the training samples are selected to train the network.

TABLE 1: The architecture of the proposed network.

| Layer           | Output                   | Convolution kernel size | Convolution kernel number |
|-----------------|--------------------------|-------------------------|---------------------------|
| Input           | 11, 11, 30, 1            |                         |                           |

3.4.2. *The Effect of Space Size.* In the deep convolutional neural network, the larger the size of the input image, the larger the number of operation parameters and the higher the computational complexity. In addition, if the size of the

input image is too small, the receiving field will be too small to obtain a good classification result. In our experiment, we tried 5 different spatial input sizes, namely,  $5 \times 5$ ,  $7 \times 7$ ,  $9 \times 9$ ,  $11 \times 11$ , and  $13 \times 13$ , to evaluate the influence of the network

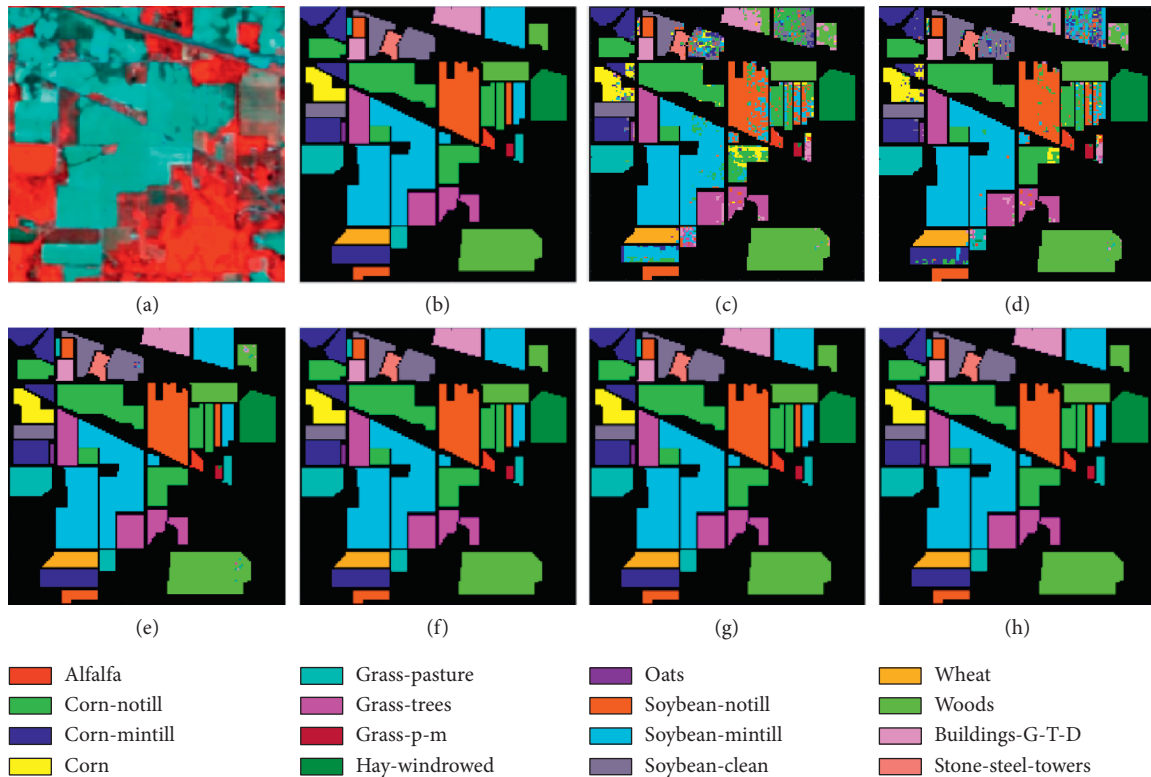

FIGURE 12: Classification results of the models in comparison with the UP dataset. (a) False color image, (b) ground truth, and (c)-(h) predicted classification maps for SVM-RBF, 2D CNN, 3D CNN, SSRN, HybridSN, and proposed HDSRN.

input size. For the IN, UP, and SA datasets, the training dataset ratios are 20%, 10%, and 10%, each experiment was repeated 5 times, and the average value of the classification indicators was used as the observation object. Table 3 and Figure 9 show the changes in OA, AA, and kappa in the IN, UP, and SA datasets under different spatial sizes. Figure 9(a) shows that as the size of the input space increases, the classification accuracy of the IN dataset begins to change

slowly after  $11 \times 11$ . When the space input size is  $13 \times 13$ , there is a slight downward trend. Figure 9(b) and Figure 9(c) show that as the size of the input space gradually increases, the classification accuracy of UP and SA datasets is significantly improved, and when the space input size reaches  $11 \times 11$ , it starts to change slowly.

Table 4 and Figure 10 show the changes in training time and test time under different spatial sizes. We can see from

FIGURE 13: Classification maps for the IN dataset. (a) False color image, (b) ground truth, and (c)-(h) predicted classification maps for SVM-RBF, 2D CNN, 3D CNN, SSRN, HybridSN, and proposed HDSRN.

Figure 10 that as the size of the input space increases, the number of calculation parameters also gradually increases, and the training time and test time both increase sharply, resulting in a significant jump in the calculation cost. Through the analysis of the effect of the above space size on the proposed model, we find that using a space size of  $11 \times 11$  is the most suitable for our model. Therefore, the input space size we chose in the comparison experiment is  $11 \times 11$ . At this time, the accuracy of the three datasets is 99.72% (IN), 99.86% (UP), and 99.98% (SA).

**3.4.3. The Effect of Residual Networks.** We conducted a comparative experiment with different combinations of residual blocks. We tested the combination of 3D residual blocks and 2D residual blocks of 1+1, 1+2, 2+1, 2+2, 2+3, 3+2, and 3+3 and gave each group's accuracy, as shown in Table 5. Figure 11 is a comparison bar chart of the

classification results. We can find that the classification effect of the three datasets is the best, when the combination is 2+2. In addition, we can also find from Figure 11 that the accuracy has not continued to improve, but has decreased, as the number of residual blocks increases. The first reason may be limited training samples, and the second reason may be that a deeper network increases the complexity of feature extraction.

**3.4.4. The Effect of Depth-Separable Convolution.** We conducted a comparative experiment to test the impact of depth-separable convolution. The traditional 2D convolution is replaced by the depth-separable convolution to form a comparison model A. The other settings were consistent with HDSRN. The training sample ratios of the IN, UP, and SA datasets are 20%, 10%, and 10%. The same spatial dimension is extracted for different datasets. For example, the

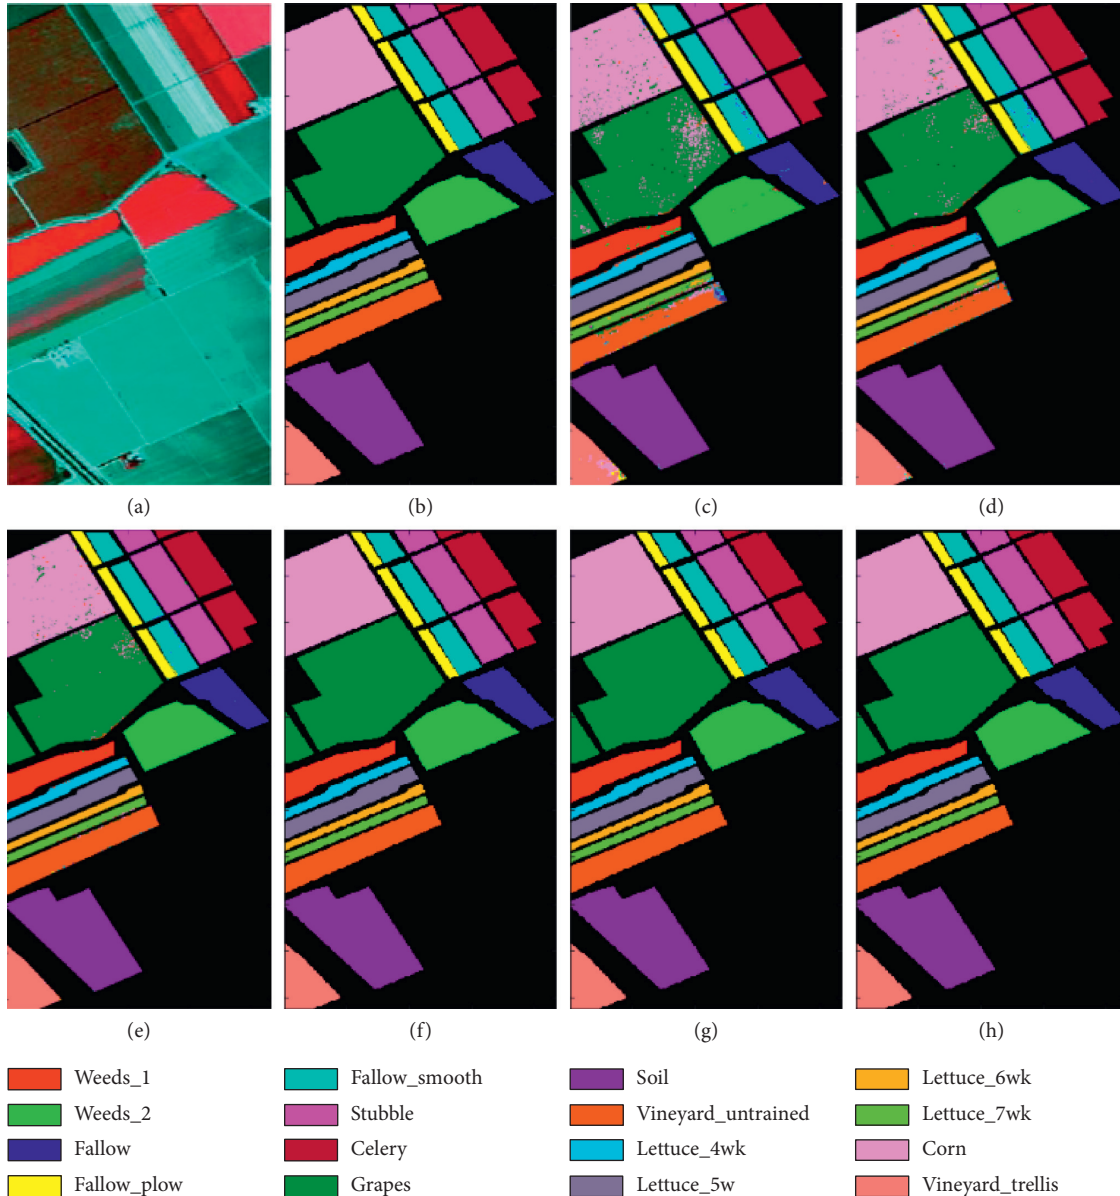

FIGURE 14: Classification maps for the SA dataset. (a) False color image, (b) ground truth, and (c)-(h) classification maps for SVM-RBF, 2D CNN, 3D CNN, SSRN, HybridSN, and proposed HDSRN.

spatial dimension of IN is  $11 \times 11 \times 30$ , the spatial dimension of UP is  $11 \times 11 \times 15$ , and the spatial dimension of SA is  $11 \times 11 \times 15$ . For three datasets, we conducted 5 experiments. Table 6 shows the comparison between traditional 2D convolution and depth-separable convolution in parameters, sample training time, testing time, and overall classification accuracy. We can find that the depth-separable convolution reduces the number of parameters and operation time, avoids overfitting, and improves the performance of HSI classification.

**3.4.5. The Effect of Skip Connections.** The HDSRN framework included a skip layer. In order to test the effect of skip connection, we designed a framework without skip connection as model B and conducted related comparative

experiments on three datasets. We can see from Table 7 that the outermost skip connection can improve the classification accuracy of HSI because skip connection alleviates the problem of gradient disappearance, helps gradients propagate backward, and can extract features more fully.

**3.5. The Comparative Experiment with Popular Methods.** So as to evaluate the HSI classification capability of HDSRN, we compared the model with the popular methods, such as SVM-RBF [37], 2D CNN [38], 3D CNN [24], SSRN [22], and HybridSN [31]. We used some public codes to train and test the data, which can be accessed online at <https://github.com/eecn/Hyperspectral-Classification> and <https://github.com/gokriznastic/HybridSN>. For the fairness of the experiment, through the comparative experiment in Section 3.4,

we set the input space to the same size. The input sizes of IN, UP, and SA datasets are  $11 \times 11 \times 30$ ,  $11 \times 11 \times 15$ , and  $11 \times 11 \times 15$ , respectively. The training data ratios of IN, UP, and SA datasets are 20%, 10%, and 10%, respectively. We conducted 5 repeated trials with the mean classification metrics as final results.

Tables 8-10 show the comparison of experiments using different methods. We can see that the HDSRN method performs well, and the classification effect on the three datasets is better than other methods. One possible reason is that the proposed network model is based on the spatial spectrum 3D CNN and 2D CNN hierarchical framework, and they are complementary. This design method helps to capture more contextual information. Another possible reason is that the multiresidual network ROR is embedded in the proposed model, which can extract deeper abstract features. The last reason is that the depth-separable convolution reduces the computational cost and avoids overfitting.

From the analysis of Tables 8-10, we can see that in the IN dataset, the classification accuracy of HDSRN is about 0.5% higher than SSRN and about 0.4% higher than HybridSN. In the UP and SA datasets, the classification accuracy of HDSRN is also significantly improved. We can also find that the accuracy of network classification that only focuses on spectral or spatial features is usually less than 97%. Therefore, the classification method based on the combination of spectrum and spatial features is significantly better than the traditional method. In the IN dataset, HDSRN obtained significantly better classification results than SSRN and HybridSN, in the classification of categories 2, 5, 9, and 16. In addition, because there are fewer training samples for classes 1, 7, 9, and 16, the classification accuracy of these types of features is unstable and significantly lower than other categories, which has a greater impact on the overall classification accuracy. However, HDSRN can still classify these categories, and the classification accuracy is higher than 97%.

Figures 12-14 are the visualization of the classification by the HDSRN model and the comparison network. These maps include false color images, ground truth, and visualization images of different comparison methods. We can see that SVM-RBF has the worst visual effect among these models. The generated visual image is relatively rough, the classification accuracy is low, and the noise is obvious. This may be due to the fact that traditional methods cannot effectively extract spatial-spectral features, resulting in unsatisfactory classification results. The second is 2D CNN, and the classification effect is relatively poor. This may be because 2D CNN is unable to extract a good identification feature map from the spectral dimension, and a lot of spectral information is lost. The visual images of 3D CNN are relatively smooth. The visual images of SSRN, HybridSN, and HDSRN are smoother. However, SSRN has misclassified noise in categories 7 and 9 of the UP dataset. Compared with other methods, HDSRN has a higher classification accuracy. In addition, the classification map provided by HDSRN is the most accurate, and the edge contours of features are clearer than other methods.

## 4. Conclusions

In this paper, we propose a hybrid separable convolutional residual model for HSI classification. The model integrates spatial-spectral residual blocks, spatially separable convolutional residual blocks, and the outermost skip connections. The spatial-spectral 3D feature and the spatial 2D feature can be continuously extracted. Concretely, the HDSRN model can extract spectral feature information and spatial feature information, and these feature information is complementary. Additionally, we embed a multilevel residual network ROR in the model to learn spectral and spatial features, which improves the network optimization and learning capabilities. Finally, in spatial feature learning, we use separable convolution to extract valuable features, reducing the number of parameters and computing time and alleviating the decline in accuracy. The comparative experimental results on the IN, UP, and SA benchmark datasets verify the superiority of the HDSRN method. The focus of future work will be to use transfer learning methods to further solve the HSI classification problem.

As one of the most important communication tools for human beings, English pronunciation not only conveys literal information but also conveys emotion through the change of tone. Based on the standard particle filtering algorithm, an improved auxiliary traceless particle filtering algorithm is proposed. In importance sampling, based on the latest observation information, the unscented Kalman filter method is used to calculate each particle estimate to improve the accuracy of particle nonlinear transformation estimation; during the resampling process, auxiliary factors are introduced to modify the particle weights to enrich the diversity of particles and weaken particle degradation. The improved particle filter algorithm was used for online parameter identification and compared with the standard particle filter algorithm, extended Kalman particle filter algorithm, and traceless particle filter algorithm for parameter identification accuracy and calculation efficiency. The topic model is used to extract the semantic space vector representation of English phonetic text and to sequentially predict the emotional information of different scales at the chapter level, paragraph level, and sentence level. The system has reasonable recognition ability for general speech, and the improved particle filter algorithm evaluation method is further used to optimize the defect of the English speech rationality and high recognition error rate. Related experiments have verified the effectiveness of the method.

## 1. Introduction

English speech rationality recognition is the product of the combination of emotion computing and speech synthesis. With the help of the concept of emotion computing, the relationship between emotion and speech is analyzed from the speech signal carrying the known emotional state, and these emotional features are applied to the speech synthesis process. In order to obtain natural and friendly synthesized speech with rich tone changes, which can simulate human emotions, current speech synthesis technology usually refers to text-to-speech conversion technology, which mainly solves how to convert text information into audible sound information. English speech interaction is a natural and convenient way for humans to communicate with machines in the future. Research on speech recognition is enough to promote this technology to serve humans faster and better.

Whether it is from the perspective of technology accumulation or data collection, the current period is a favorable period for studying speech recognition technology.

Particle filter algorithm [1, 2] is an online nonlinear identification algorithm based on Bayesian estimation and Monte Carlo method. Its essence is to approximate the state probability density function by finding a set of random samples propagating in the state space. A discrete sample is used to simulate a continuous function, and the sample mean is used to replace the integral operation, thereby obtaining the process of minimum variance distribution of the state. The particle filtering algorithm theoretically has higher recognition accuracy than the extended Kalman filter algorithm. The authors of [3, 4] improved the traditional particle filter algorithm and used the latest observation information in the importance sampling process to more accurately approximate the posterior probability density

function. The authors of [5, 6] proposed a resampling algorithm to solve the problem of particle degradation. The authors of [7–9] use particle filtering algorithm to solve the damage identification problem of structural systems. Research shows that, compared with EKF algorithm, particle filtering has higher structural model parameter recognition accuracy under non-Gaussian noise conditions. The authors of [10–12] use a hybrid Gaussian particle filter to predict and analyze the posterior distribution parameters and monitor values of the monitoring information state variables in one step forward. At present, the research and application of particle filters in civil engineering are still very limited. How to further improve the sampling accuracy of particle filter algorithms and weaken particles is still the key issue to improve the accuracy of the algorithm. The existing methods for synthesizing emotional speech mainly include three categories: waveform stitching, speech conversion, and statistical parameter synthesis. The waveform stitching method collects voices of different emotion types by recording a large-scale emotional corpus and extracts corresponding speech fragments from the corresponding emotional corpus during synthesis and obtains voices that retain the original recorded tone through stitching [13–15]. The voice conversion method analyzes the change of acoustic parameters of voices of different emotion types relative to neutral voices and adjusts and converts presynthesized neutral voices to obtain new emotional voices [16, 17]. Statistical parameter synthesis is based on statistical models such as Hidden Markov Models. It performs parametric characterization and acoustic modeling of speech with different emotions. Based on this, it performs acoustic prediction of emotional speech and synthesizes speech with different emotions [18–20]. At present, the three methods have their own advantages and disadvantages. The emotional speech that is properly combined by the waveform stitching method is better than other methods. However, the types of emotions that can be synthesized are limited by the existing emotion types of the emotional corpus. The cost of large-scale database building is high; English speech rationality optimization conversion method relies on the study of emotional acoustic feature analysis [21–23]. Due to the diversity and complexity of emotional performance, only some specific emotional states and directional cues were associated with changes in acoustic parameters: Statistical parameter synthesis methods can automatically build a new synthesis system in a short period of time, basically without human intervention, and require less data compared to waveform stitching methods and synthetic emotion types. It is more flexible than the previous two methods, but the spectrum and prosody model generated by HMM is too smooth, which makes the details of the spectrum and prosody model lost, affecting the naturalness of the English speech sound optimization and recognition. With the tremendous achievements of neural networks in many fields, many scholars have begun to study their applications in the field of speech recognition. A variety of models such as deep neural networks, convolutional neural networks, and recurrent neural networks have been introduced and achieved good results [24–26]. The system based on the state output of the deep neural network has a certain decrease in error rate compared

to the convolutional neural network, which proves the modeling ability of the neural network method in the field of English speech rationality optimization recognition [27, 28]. However, the method for optimizing the rationality of English speech based on deep learning requires a large amount of training data to ensure its accuracy. Compared with the traditional method, it also requires a larger amount of calculation, which also limits its application in practice to a certain extent.

Under the guidance of the English speech rationality optimization recognition process, a network structure is built. Using the annotation data of the speech sentiment database and the text features obtained based on semantic analysis, a deep learning model is trained to realize the prediction of the optimal recognition of the speech sound from reading text to English speech. The pronunciation description is used as the final result output of the prediction model to guide the generation of subsequent acoustic parameters. The model comprehensively considers the influence of the context environment of different scale units at the chapter level, paragraph level, and sentence level, as well as the interaction between the various links in the process of optimizing the recognition of English sound rationality, forming a multilayer-nested composite network to support structural construction. First, an improved auxiliary traceless particle filtering algorithm is established based on the standard particle filtering algorithm, and the algorithm implementation steps are given. Then, the online parameter identification for the single-degree-of-freedom model is carried out and compared with the identification results of the traditional particle filter algorithm to verify the accuracy and calculation efficiency of the improved algorithm. Finally, the pseudostatic test of the seismic isolation support verifies the effectiveness of the improved auxiliary traceless particle filter algorithm for online identification of model parameters. The rest of this paper is organized as follows. Section 2 discusses optimal recognition modeling of English speech rationality, and optimized recognition model of English sound rationality based on improved particle filter algorithm is designed in Section 3. Experimental verification is discussed in Section 4. Section 5 concludes the paper with summary and future research directions.

## 2. Optimal Recognition Modeling of English Speech Rationality

At present, English speech rationality optimization recognition technology is facing huge development opportunities. First, with the development of devices with high computing power, more complex algorithms and models become possible; second, with the help of massive data on the Internet, it becomes easier to have corpus resources in real scenes, making the trained models more reasonable; finally, the rise and popularity of applications such as smart homes, car systems, and mobile devices make voice, a convenient human-computer interaction, more important. The optimal recognition of English speech rationality can be divided into four main parts, namely, data preprocessing and feature extraction, language model, acoustic model, and decoder, as shown in Figure 1.

The data preprocessing part is performed before the identification and decoding, including the signal pre-emphasis, framing, windowing, and other operations [29]. Research has found that the energy of speech is mainly in the low frequency range, which may lead to an excessive signal-to-noise ratio in the high frequency range. Preemphasis can enhance the high frequency band of speech to make its characteristics more prominent. English speech is a non-stationary time-varying signal, but it has a short-term stationary characteristic when the duration is short, so its signal processing needs to be performed after framing. By framing the signal, each frame can be regarded as a smooth signal. Generally speaking, the duration of each frame is between 10 and 30 ms and there will be overlap between frames. After framing, it will cause discontinuity at the beginning and end of each frame. Windowing is to highlight the signal in the middle and make it continuous. The window function usually chooses the Hamming window.

Feature extraction is mainly to extract some information that can reflect the commonality from the signal. When different speakers speak the same paragraph of text, the pronunciation will be different due to the difference in vocal organs and speaking habits. Feature extraction is to remove these characteristics. The feature used by the system in this paper is the MFCC feature, which is one of the commonly used features in the field of speech recognition.

The purpose of English speech rationality optimization recognition is to convert speech into text. After the system receives a piece of audio, it can find the most reasonable sequence of words to represent the information contained in this piece of audio. We define the speech signal as  $T$  and the text sequence as  $M$ ; then the optimization and recognition of English sound rationality need to be solved:

$$M = \arg \max P(M | T). \quad (1)$$

That is, on the premise of knowing the voice  $T$ , find the most likely text sequence  $M$ . According to the Bayesian formula, we can change the above formula to

$$M = \arg \max \frac{P(T | M)P(M)}{P(T)}, \quad (2)$$

For a particular piece of audio  $T$ ,  $P$  is fixed and therefore does not need to be considered in the optimization process. The above formula is the core formula of speech recognition, which can be seen as a combination of two parts, the language model  $P(M)$  and the acoustic model  $P(T | M)$ ; the language model represents a certain sequence of text  $M$  in language habits rationality.

The main function of the decoder is to use the trained language model and acoustic model to build a decoding network, search in the network, and finally find the optimal path that can explain the input speech and give the recognition result. The decoder can search through a given input feature sequence and finally find and use the decoding algorithm to best interpret the input audio text sequence for the search composed of the language model and the acoustic model.

Feature selection is a link that has a significant impact on the optimization of the recognition efficiency of English

speech. Deciding which acoustic features to use will largely affect the recognition rate of the system. The acoustic features commonly used in the optimization and recognition of English speech rationality include perceptual linear prediction, linear prediction coefficients, and Mel-frequency cepstral coefficients, and cepstral features are commonly used Mel-frequency cepstral coefficients. The Mel-frequency is the cepstral parameter extracted from the frequency domain of the scale. It has a high degree of similarity to the human auditory characteristics. Mel-frequency cepstral coefficient can perfectly combine the frequency selection characteristics of ear-to-sound and speech signal processing technology. It has strong robustness and noise resistance. It is one of the most effective features in the field of English speech sound optimization recognition.

The extraction process of English speech rationality optimization recognition features is shown in Figure 2.

Before extracting the English speech rationality optimization recognition feature for the audio signal, we need to perform relevant preprocessing operations on the data. The power of the voice signal will be very small when the frequency is large. The main energy is distributed in the low frequency band. This may cause the signal-to-noise ratio of the high frequency band to be too large. Pre-emphasis can enhance the high-frequency signal of the voice. Speech is a nonstationary signal, but it is stationary for a short period of time. The framing and windowing operations are to take advantage of this short-term stationarity to divide the long-term nonstationary signal into multiple frames of shorter stationary signals. Generally speaking, the length of each frame of speech is between 10 and 30 ms, and there is overlap between the frames, which can ensure the continuity of the signal. The window function used in this article is the Hamming window, which can be expressed as

$$M(n) = \begin{cases} 0.5 - 0.48 \cos \frac{2\pi n}{M-1}, & 0 \leq n \leq M \\ 0, & \text{OTHER.} \end{cases} \quad (3)$$

After preprocessing the English speech signal, we use fast Fourier transform to transform the obtained short-term signal  $p(1)$  into time frequency and calculate the short-term energy spectrum  $h(1)$ . Then we use the filter  $c(1)$  to process the short-term energy spectrum, followed by using the filter to process the short-term energy spectrum; the formula can be expressed as

$$M(j) = \begin{cases} \frac{j - p(1)}{c(1) - p(1)}, \\ \frac{h(1) - j}{j(1) - c(1)}. \end{cases} \quad (4)$$

Then, we make logarithmic changes to the output of the filter bank and finally through the discrete cosine transform to obtain the English speech rationality optimization recognition feature coefficients.

### 3. Optimized Recognition Model of English Sound Rationality Based on Improved Particle Filter Algorithm

3.1. Reasonable Optimization of Identification Parameters. The improved particle filter algorithm inherits the principle of the particle filter algorithm and is a complete nonlinear estimator that can identify arbitrary nonlinear model parameters. The improved particle filter algorithm model is a representative strong nonlinear model used to simulate the restoring force characteristics of structures and members. In this paper, the single-degree-of-freedom improved particle filter algorithm model is taken as the object, and a specific implementation method of applying the algorithm to online identification of nonlinear model

parameters is given to verify the algorithm recognition accuracy.

Combined with structural motion equation, particle filter algorithm model was improved.

Set the model parameter of the improved particle filter algorithm to the actual value of  $k_0 = 40 \text{ kN/m}$ ,  $n = 1.1 \text{ t}$ ; load the model with displacement control, input displacement excitation, and select the ground motion displacement record measured by the seismic station; the peak displacement is adjusted to 10 cm, as shown in Figure 3, vertical. The coordinates are displacement. Using the fourth-order numerical integration method to calculate the resilience of the improved particle filter algorithm model system, the integration step length is 0.01 s, and the integration number of steps is 4000 steps.

FIGURE 3: Displacement loading time history curve.

$z$  is the process noise;  $k$  is the actual loading speed;  $n$  is the number of times; the system state equation is

$$y = f(y, y') = \begin{bmatrix} y_1 \\ y_2 \\ \dots \\ y_n \end{bmatrix} - \begin{bmatrix} z \\ k \\ \dots \\ n \end{bmatrix}. \quad (5)$$

**3.2. Stepped Resampling Improvements.** In order to solve the problems of sample degradation and reduced estimation accuracy caused by resampling, this paper proposes a particle selection scheme based on the bias-corrected exponential weighted average algorithm and then effectively uses the remaining large-weight particles to complete the replication and new number addition ensure the final particles meets the initial total.

Aiming at the problem that standard resampling directly removes small particles and reduces the filtering performance, the following particle screening strategy is designed: (1) Calculate the weight of particles and arrange them in ascending order. (2) Use the EWA optimization algorithm based on deviation correction to calculate the sorted particle set. The average distribution curve of the expression is:

$$\gamma_i = \frac{\varepsilon \gamma_{i-1} + (1 - \varepsilon) \omega_t^i}{1 - \varepsilon^i}. \quad (6)$$

In the previous equation,  $\gamma_i, \gamma_{i-1}$  is the average weight of the first  $i, i-1$  particles,  $\varepsilon$  is the overshoot parameter,  $\omega_t^i$  is the weight of the  $i$ -th particle, and  $1 - \varepsilon^i$  is the deviation correction term. (3) Calculate the average value of the  $\gamma_i$  curve and judge the particle weight  $\gamma$  with the size of  $\omega_t^i$ ; if  $\omega_t^i \geq \gamma$ , the particle is left and then is discarded. The exponentially weighted average optimization algorithm takes into account the fact that large-weight particles are the decisive factor that affects the estimation accuracy, and the introduction of deviation correction items reduces the previous calculation errors, improves the accuracy of particle screening, and also ensures the effectiveness of replication and new particles.

The process of optimizing the recognition of English speech rationality is divided into two parts: the training stage and the formal stage. The training stage first selects 10

articles for independent labeling, and then several labelers compare the results and discuss the labeling rules. The three annotation results are summarized and integrated into the final annotation result of each document by the introduction method in the next section. The agreement rate of the three labeling results in different scales is shown in Table 1. It can be seen from the table that the labeling agreement rates of the three scales are similar, and the chapter-level agreement rate is slightly higher than the other two levels; the agreement rate between two people is better than that of the three people, but the common agreement rate is also close to 80%, reaching a usable level.

**3.3. English Speech Rationality Optimization Keyword Recognition Model.** Let the English speech rationality optimization keyword recognition system have the rejection function; a feasible method is to use the junk speech model to improve the decoding network. In the training phase, each phoneme model is trained with the corpus of the corresponding phoneme, and the junk speech model uses all corpus for training, so it can be considered that it represents the human voice model rather than a specific phoneme. All voices have a certain matching ability.

Real time is an important feature of human-machine voice interaction. Whether the system can recognize the voice in time will play a vital role in the promotion of user experience and applications. The main time-consuming of the keyword speech recognition system is the decoding efficiency of English speech, so how to improve the efficiency of the decoding algorithm is the key to improving the performance of the system. The Viterbi decoding algorithm needs to search all possible states of the entire decoding network every frame. The token-passing decoding algorithm we mentioned is a specific implementation of the Viterbi decoding algorithm, which has the characteristics of simple search process implementation, thereby reducing the decoding time and improving system performance. However, the token transfer algorithm also cannot avoid the shortcomings of the whole network search. All tokens of the decoding network in each frame need to be transferred between all possible states. When the number of system states increases, the decoding time will also be large, in addition to an increase in amplitude.

The token-passing decoding algorithm searches through the entire network to ensure that the best state path is found. After obtaining the voice characteristics of each frame, all tokens in the decoding network will jump, although this can guarantee that each path can be searched, but it also limits the performance of the algorithm. Performing a network-wide search will consume a lot of computing resources on some paths with very low probability. In fact, these paths have a long distance from the token value at the beginning due to their low matching with the speech to be recognized. Lower than other tokens, the probability of these paths gaining an advantage in subsequent competition is very low, so these tokens can be discarded earlier to prevent their passing down, thereby reducing the consumption of computing resources and improving algorithm performance.

TABLE 1: Statistics of the coincidence rate of the labeling results.

|                 | A&B    | A&C    | B&C    | A&B&C  |
|-----------------|--------|--------|--------|--------|
| Chapter level   | 0.8264 | 0.843  | 0.8525 | 0.7821 |
| Paragraph level | 0.8275 | 0.8392 | 0.8483 | 0.7798 |
| Sentence level  | 0.8267 | 0.8378 | 0.8468 | 0.7788 |
| All             | 0.8269 | 0.8389 | 0.848  | 0.7795 |

“A,” “B,” and “C” represent the three labeling personnel.

In the specific implementation, the maximum number of tokens should be set reasonably according to the complexity of the network. If the maximum number of tokens is set too large, the system performance will cause many paths to be discarded per frame. The improvement is very limited. However, the maximum number of tokens is set too small to include the best path, which leads to a reduction in the accuracy of system identification. Therefore, when setting the maximum number of tokens, the performance and accuracy should be taken into consideration.

#### 4. Experimental Verification

In order to verify that the algorithm in this paper has good filtering performance, MATLAB simulation software is used to compare and analyze the number of particles with 50, 100, and 150 based on the univariate dynamic change filter model. Based on the improved particle filter algorithm, unified particle filter algorithm, scheduling particle filter algorithm, and particle filter algorithm, the English speech rationality optimization keyword recognition model’s online parameter recognition results obtained by four algorithms are compared, as shown in Figure 4. It can be seen that the four algorithms for  $k_0$  and  $n_2$  parameters have the same recognition effect, basically converging to the true value, and the convergence speeds are roughly similar. Among them, the recognition value obtained by the improved particle filter algorithm is the best. The improved particle filter algorithm has higher nonlinear transformation accuracy in importance sampling, enriches the diversity of particles during the resampling process, and effectively weakens the degradation of particles. The performance of the algorithm determines the pros and cons of the recognition result of the calculation example, which is of universal significance. Therefore, when the actual value is of the keyword recognition model parameters for English sound rationality optimization in the calculation example changes, under the same conditions, the recognition results of the four algorithms will still have similar rules.

The particle filter algorithm and its improved scheduling particle filter algorithm and the unified particle filter algorithm and the improved particle filter algorithm are essentially random parameter identification algorithms. The four algorithms are all based on the Monte Carlo random sampling method. Therefore, even under the same condition of initial parameter values, the parameter identification values obtained by each algorithm in each simulation are different; that is, the parameter identification results are random. In order to test the randomness of the recognition results of the algorithm, four independent filtering

algorithms were used for 10 independent simulations. The statistical recognition results compared and analyzed the recognition accuracy and convergence of different algorithms, which was more convincing. In the 10 independent simulations in this example, the initial parameters of the system English sound rationality optimization recognition model and the initial parameters of the algorithm are the same. The randomness mainly comes from the randomness of the particles produced by the algorithm. The relationship between the root mean square error of the four algorithms’ parameter identification values and the number of simulations is shown in Figure 5. The abscissa in the figure is the number of simulations.

It can be seen from Figure 5 that the overall error of the parameter identification of the improved particle filter algorithm is significantly lower than that of the particle filter algorithm, the scheduling particle filter algorithm, and the unified particle filter algorithm, and the error fluctuation range is significantly reduced. It can be seen that the improved particle filtering algorithm uses the latest observation information to modify the particles and at the same time increases the particle diversity by introducing auxiliary factors. Therefore, the improved particle filter algorithm is significantly higher than the recognition accuracy of the particle filter algorithm, scheduling particle filter algorithm, and unified particle filter algorithm.

As shown in Figure 6, the root mean square error mean and relative error mean of the online independent parameter identification value was calculated under independent simulations. It can be clearly seen that the mean value of the root mean square error and the relative error of the parameter identification value of the improved particle filtering algorithm proposed in this paper are smaller than those of the particle filtering algorithm as a whole. The root mean square error of the four sets of parameter identification values obtained by the improved particle filter algorithm is overall lower than those of the particle filter algorithm, scheduling particle filter algorithm, and unified particle filter algorithm. The error is reduced by 76%, 38%, and 23%, respectively, and, in the improved particle filter algorithm, the relative errors of the obtained four sets of parameter identification values as a whole are reduced by 22%, 16%, and 14% compared to the particle filter algorithm, scheduling particle filter algorithm, and unified particle filter algorithm. It can be seen that the average root mean square error and the average relative error of the four sets of parameter identification values in 10 simulations indicate that the accuracy of the improved particle filtering algorithm is higher than that of the other three algorithms. It should be noted that the algorithm needs to pay more time for calculation while achieving higher parameter recognition accuracy.

When we only use the improved English speech rationality of the particle filtering algorithm to optimize the keyword recognition modeling model for token-passing decoding, because there is no adjustable parameter, the equal error rate cannot be measured, and the false rejection rate of the system measured by the test set is only 1.24%, but the false alarm rate is as high as 76.05%, which shows that the system with only the improved particle filter algorithm

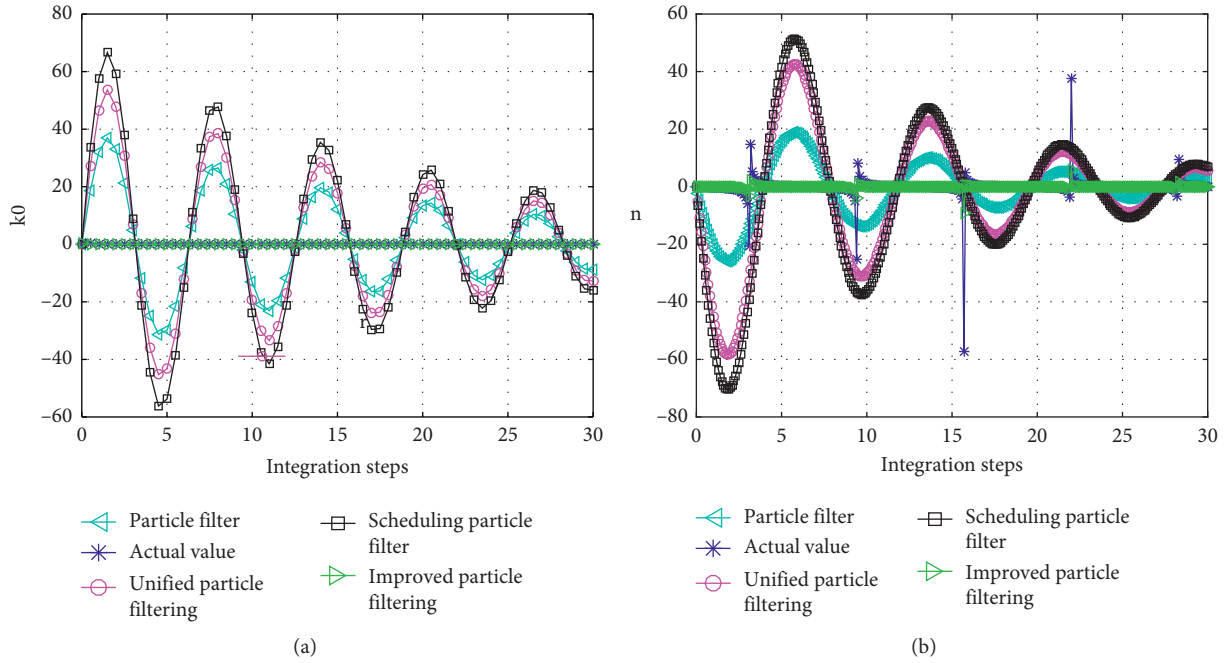

FIGURE 4: English speech rationality optimization keyword recognition value. (a)  $k_0$ . (b)  $n$ .

FIGURE 5: Root mean square error of model parameter identification value. (a)  $k_0$ . (b)  $n$ .

model is very weak for nonkeyword speech recognition, and it is difficult to apply it in practice. We use the verification set to adjust the parameters and use the test set to test the results and finally measured the equal error rate of several different systems. The results are shown in Table 2.

In this paper, the improved particle filtering algorithm proposed in this paper optimizes the stability of English speech keyword optimization modeling, which indicates whether the optimal token on the decoding path can maintain a stable advantage in the competition during the

decoding process. If the decoding path is the correct keyword path, then it should be able to stay ahead of the competition by constantly accumulating advantages. If the decoding path is wrong, the optimal token on this path will not be compared to other paths, and there is a big difference.

As shown in Figure 7, when the voice to be recognized is a keyword, the optimal token on the decoding path of each frame can stably maintain an advantage in the competition, and this advantage will increase as the number of decoded frames increases.

In this paper, the visibility modeling strategy of the deep neural network in the middle layer can effectively integrate prior knowledge into the network structure, thereby improving the performance of the network; optimization measures such as feature dimension balance adjustment and sample balance adjustment can solve the network learning process to a certain extent. The fusion problem between different types of features solve sample sparseness

## 5. Conclusion

In this paper, by introducing an improved particle filtering algorithm, the English speech rationality optimization recognition model enables the system to reject nonkeyword speech, which can be more widely used in actual scenarios. In order to improve the recognition accuracy and rejection ability of the speech keyword recognition system and make the application of the system more mature, on the basis of studying the principle of decoding algorithm, the data generated by the token transfer process in the preliminary experiment is analyzed, and finally two methods of consistency and stability were proposed and used to evaluate and correct the system identification results; and related experiments were set up to test the feasibility of the proposed method. The improved English speech rationality optimization recognition model with improved particle filter algorithm has high positioning accuracy and good stability, and its effectiveness is verified through experimental verification.

In natural language, the phenomenon of polysemy is widespread, which makes it very difficult for machines to process natural language. Word sense disambiguation is a key issue in the field of natural language processing. This paper introduces the more common statistical learning methods used in the field of word sense disambiguation. Using the naive Bayesian machine learning method and the feature vector set extracted and constructed by the Dice coefficient method, a semantic word disambiguation model based on semantics is realized. The results of comparative experiments show that the proposed method is better compared with known systems. This paper proposes a method for disambiguation of word segmentation in professional fields based on unsupervised learning. This method does not rely on professional domain knowledge and training corpus and only uses the frequency, mutual information, and boundary entropy information of the string in the test corpus to solve the problem of word segmentation ambiguity. The experimental results show that these three evaluation standards can solve the problem of word segmentation ambiguity in professional fields and improve the effect of word segmentation. Among them, the segmentation result using mutual information is the best, and the performance is stable.

## 1. Introduction

Word sense disambiguation is to determine the most exact semantics of a polymorphic word according to its context and locale [1]. Chinese is the most spoken language in the world, and it is difficult to avoid the problem of polysemy. According to statistics, ambiguous words account for about 14% of the total vocabulary of the Chinese dictionary, and these ambiguous words are often commonly used words [2]. Statistics on the authoritative Chinese disambiguation corpus show that these ambiguous words are used very frequently, about 42% [3]. The universality of ambiguous word distribution makes word sense disambiguation an important link in many applications related to natural language processing, such as machine translation, information extraction, and content analysis [4, 5].

The earliest Chinese word segmentation method was a word segmentation method based on “lookup dictionary”

[6]. The idea of this method is to read the entire Chinese sentence and then mark all the words in the dictionary separately. When encountering a compound word (such as Peking University), the longest word match is found. The string is split into individual words. This word segmentation method is not efficient, but its proposal lays the foundation for Chinese automatic word segmentation technology [7]. Relevant scholars have theorized the Chinese word segmentation method and proposed the “minimum number of words” segmentation theory; that is, each sentence should be segmented with the least number of words [8]. This word segmentation method is an improvement on the “word dictionary” word segmentation method, which has promoted the development of Chinese word segmentation technology. Researchers believe that, for computers to reach the level of natural language processing by humans, computers must be able to automatically disambiguate ambiguous words in a specific context and choose the most precise

meaning [9–11]. Although the word sense disambiguation system was only a subsystem in the machine translation system at that time, the context window and semantic consistency proposed by it were still the basis for the current research on word sense disambiguation. Among them, the context in which ambiguous words are located is an important condition that affects the accuracy of word sense disambiguation [12]. After that, with increasing attention to word sense disambiguation, more and more experts and scholars have proposed more solutions to word sense disambiguation [13, 14]. With the deepening of research, due to the lack of relevant resources and calculation methods at that time, scholars realized that word sense disambiguation was a very complicated problem and it was difficult to overcome [15]. Bar-Hillel pointed out that word sense disambiguation was impossible to achieve with the technical conditions at the time and was theoretically not feasible [16]. The method of automatically expanding WordNet uses a lot of semantic relationships from Wikipedia resources to expand WordNet. First, it establishes a mapping between Wikipedia pages and WordNet and then converts the pages into WordNet. Test results show that this method improves baseline and can use more disambiguation information to achieve higher disambiguation goals [17]. With the continuous updating of technology and continuous improvement of machine performance, techniques such as machine learning and corpus are used in word sense disambiguation. During this period, supervised, semisupervised, and unsupervised word sense disambiguation techniques have been fully developed. Relevant scholars have proposed a completely unsupervised method based on the topic word frequency estimation model [18]. This method can be applied to any part of the speech manuscript without the need for a hierarchical corpus or parallel text. The library is highly portable. Furthermore, the effectiveness of the method on the main semantic learning and semantic distribution acquisition tasks is proved. Relevant scholars have studied a new and effective fuzzy classification system and applied this system to word sense disambiguation [19, 20]. The system iteratively adjusts the weights of fuzzy rules and adjusts the classifier by adding weights to the rules [21]. Compared with other classification systems, this classification system has achieved good results. The advantage of the unsupervised word segmentation method is that it does not rely on dictionaries and training corpus and does not require training. It can be used for unregistered word discovery without word formation rules. The disadvantage is that this kind of method cannot find low-frequency words, the upper limit of the word segmentation effect is about 0.85, and the word segmentation effect cannot meet the practical application. In practical applications, the unsupervised word segmentation method is generally not used alone. This type of word segmentation method can be used for common word discovery, new words discovery, and other issues and assist in improving the word segmentation effect of existing dictionaries and training corpus word segmentation methods.

For word sense disambiguation, these classification models cannot be simply used, and corresponding improvements should be made on the basis of the original

models. This paper uses the sliding word window to extract the semantic-related features of words in the word window and constructs a Bayesian word sense disambiguation model based on semantics to perform the word sense disambiguation experiment. The Bayesian word sense disambiguation classifier based on semantic information is constructed using three different vector sets in feature extraction. The new method is used to verify the word sense disambiguation performance. This paper proposes to use unsupervised learning to solve the problem of word segmentation ambiguity in professional fields. The frequency of the strings in the test corpus, the mutual information of the strings, the boundary entropy of the strings, and the boundary entropy of the single words are used as the evaluation criteria to resolve the ambiguity problem. Experiments show that these three evaluation standards can solve the problem of word segmentation ambiguity in professional fields to varying degrees. The rest of this paper is organized as follows. Section 2 studies the semantic-based disambiguation model of machine translation. Section 3 analyzes the method of disambiguation of word segmentation in unsupervised professional fields. Section 4 summarizes the full text and points out future research directions.

## 2. Semantic-Based Disambiguation Model for Machine Translation

### 2.1. Machine Translation System

*2.1.1. Language Model.* The language model treats sentences as strings, and the probability that each word in the sentence appears as a character in the sentence is random. For a given string  $w_1, \dots, w_n$ , the probability of its occurrence can be expressed as

$$P(W) = \prod_{k=0}^{n-1} P(w_k | w_1, w_2, \dots, w_{k-1}). \quad (1)$$

$N$ -grams are generally used in language models to calculate the probability of an entire string. The probability that the  $N$ th word appears in the  $N$ -gram model is only related to the first  $N-2$  words; that is,

$$P(w_n | w_1^{n-1}) = P(w_n | w_{n-N+2}^{n-2}). \quad (2)$$

Linguistic studies have shown that the emergence of the current word is strongly dependent on many of the words before it [22]. Language models provide a way to calculate the probability of a string appearing. The disadvantage is that a large-scale corpus is needed to determine the parameters of the model.

*2.1.2. Translation Model.* In order to construct a translation model for a phrase machine translation system, we first need to calculate the phrase translation probability and dictionary probability. The phrase translation probability indicates the probability that a phrase on the source language side is translated into a phrase on the target language side. To obtain these two probabilities, four operations need to be performed on the parallel aligned bilingual corpus: word

alignment, word score, phrase extraction, and phrase score. A schematic diagram of a network bilingual information processing system for machine translation is shown in Figure 1.

According to the probability score calculation of the translated sentence, the longer the sentence, the smaller the probability. So when translating, decoders for phrase machine translation tend to choose shorter sentences. Therefore, longer target sentences need to be compensated. The length penalty model calculates the number of words in the translation as a penalty value and adds it to the model, which can be expressed as

$$\Pr(e) = \exp(I). \quad (3)$$

In the formula,  $I$  represents the number of translated words. The word punishment model can choose the length of the translation.

**2.2. Word Sense Disambiguation Method Based on Statistical Learning.** The Bayesian method is implemented using probability calculations. It is inferred from the probability that an event has happened in the past. The Bayesian method is applied to the word sense disambiguation problem as follows:

$$P(S_i | \text{Context}) = \frac{P(S_i)P(\text{Context} | S_i)}{\sum_{j=1}^m P(S_j)P(\text{Context} | S_j)}, \quad i = 1, 2, 3, \dots, m. \quad (4)$$

Word sense disambiguation based on Bayesian method is to judge the classification of word meaning based on the size of the posterior probability. Among them, Context is the context in which the ambiguous word  $w$  is located. Context is composed of word units on both sides of  $w$ , which provide necessary guidance information for the disambiguation process. The ambiguous word  $w$  has  $m$  semantic categories  $S_1, S_2, \dots, S_m$ . In Context, its true semantic category is  $S_j$ .  $P(X)$  is the probability that  $X$  will occur. In the Context, if the probability of the ambiguous word  $w$  taking the semantic category  $S_j$  is greater than any other semantic category  $S_i$  ( $j \neq i$ ), then the semantic category of the word  $w$  should be determined as  $S_j$ . The Bayesian method has the following two commonly used classifications in practical applications.

**2.2.1. Multivariate Bayes Based on Berle Effort.** First, we find the feature vector  $F = (t_1, \dots, t_m)$  through feature selection, where  $t_i$  is the label of each feature. For the dichotomy, this method deduplicates the corpus sample  $d$  to obtain the label set  $X = (x_1, \dots, x_m)$ , where  $x_i$  is the categorical variable value, which is 0 or 1 for the dichotomous case. According to the results of  $m$  Bernoulli experiments, the disambiguation corpus belongs to the category  $C$ :

$$P(t | c) = \frac{(M_{t,c} + 1)}{(M_c + 2)}. \quad (5)$$

To prevent the denominator from being zero, we use Laplace's method for smoothing.  $M_{t,c}$  is the number of texts that belong to category  $c$  and feature  $t_i$ , and  $M_c$  is the number of texts that belong to category  $c$ .

In order to prevent the result from underflowing, logarithmic processing is generally applied to the probability value in the application. Word sense disambiguation classification criterion is  $T=0$ ; it judges an ambiguity word classification.

**2.2.2. Polynomial Bayes Based on Boolean Attributes.** Polynomial Bayesian method based on Boolean attribute is similar to polynomial Bayesian method based on word frequency. The attribute value in Boolean attribute is Boolean type. However, when the feature is  $x_i = 0$ , the feature term is not added to the calculation of the conditional probability. At this time,

$$P(\bar{X} | C) = \prod_{i=0}^{m-1} p(t_i | C)^{x_i}. \quad (6)$$

And the Laplacian smoothing method is different.

**2.3. Establishment of Word Sense Disambiguation Model.** Most machine learning methods have been applied to the field of word sense disambiguation, which can be divided into discriminative models and generative models according to different model learning methods. In terms of accuracy and efficiency of disambiguation, the Bayesian model has a good balance, and the good robustness of the Bayesian model is also a key point for many word sense disambiguation models to use the model. The English combination ambiguity resolution framework is shown in Figure 2.

According to the characteristics of Chinese word sense disambiguation, this paper uses the sliding word window method to open the word window according to the position of the target ambiguous word, uses the Dice coefficient method to obtain the semantic information of the feature words in the word window as the disambiguation feature, and constructs a feature vector set. The feature vector set is applied to the Bayesian model to obtain a semantic sense disambiguation model based on semantic knowledge.

In the language environment where the ambiguous word is located, the final interpretation of the ambiguous word is determined based on the maximization of the posterior probability, if

$$P(S_j | \text{Context}) \geq P(S_i | \text{Context}), \quad (i = 1, 2, \dots, m). \quad (7)$$

The semantics of the ambiguous word  $w$  is  $S_j$ . Among them, Context is the context in which the ambiguous word  $w$  is located. Generally, Context is composed of word units on both sides of  $w$ , which provide necessary guidance information for the disambiguation process. The ambiguous word  $w$  has  $m$  semantic categories  $S_1, S_2, \dots, S_m$ . In Context, its true semantic category is  $S_j$ .  $P(X)$  is the probability of  $X$  appearing. In the context, if the probability of the ambiguous

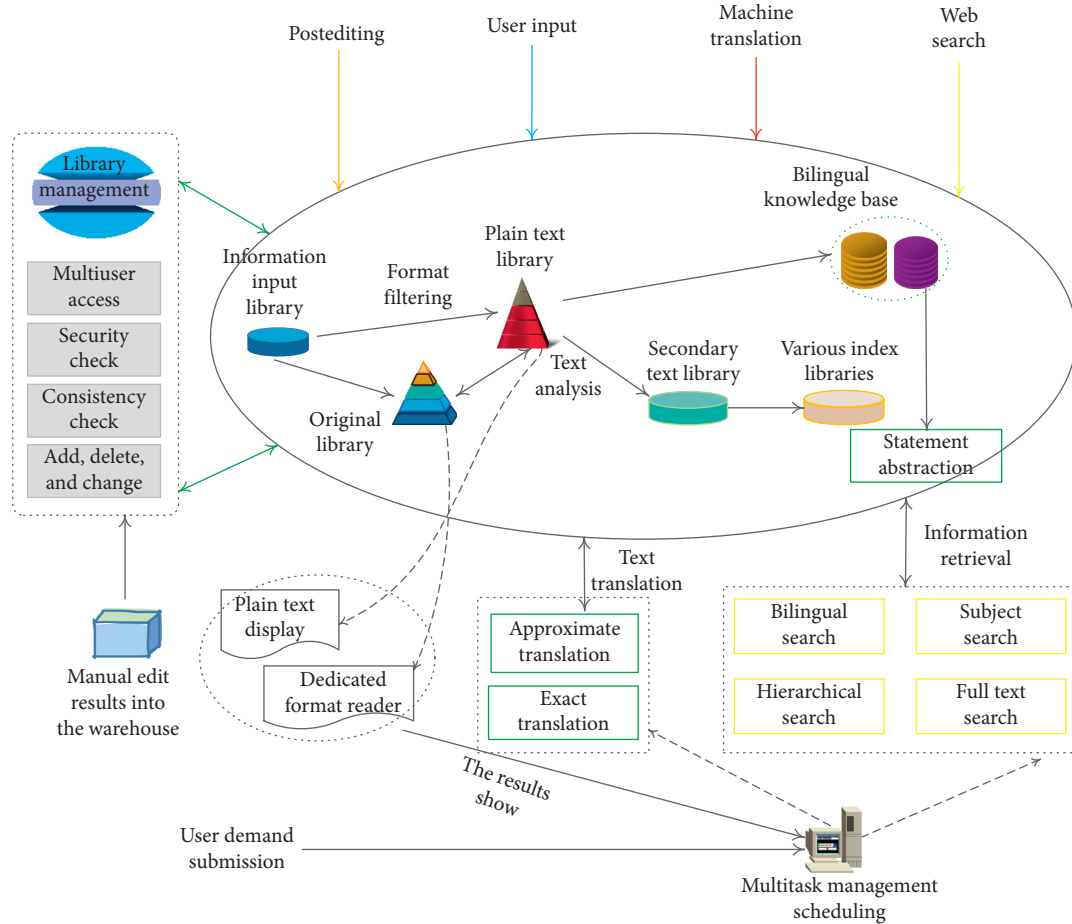

FIGURE 1: Network bilingual information processing system for machine translation.

word  $w$  taking the semantic category  $S_j$  is greater than any other semantic category  $S_i$  ( $j \neq i$ ), the semantic category of the word  $w$  should be determined as  $S_j$ . Bayesian decisions have the smallest probability of error. For the ambiguous word  $w$ , it has  $m$  semantics  $S_1, S_2, \dots, S_m$ , and the context disambiguation features are FL and FR, respectively. Among them, FL and FR are semantic class codes. The semantic code of "Synonym Cilin" is divided into three layers: FL = fl1fl2fl3; FR = fr1fr2fr3.

The process of word sense disambiguation based on semantic knowledge is as follows:

- (1) We analyze the corpus to obtain sentence information, segmentation information, and part-of-speech information.
- (2) We use the sliding word window method to find the position of the target ambiguous word and use it as the center to open the word window on both sides to obtain the word window segmentation.
- (3) We use "Synonyms Word Forest" as a semantic dictionary to obtain the semantic code set of word segmentation in the word window.
- (4) We use the Dice coefficient method to determine the word segmentation code. The feature vector set is constructed by three different feature extraction

methods: first-level semantic code, three-level semantic code, and morphological information.

- (5) We construct a word sense disambiguation model based on semantic knowledge by using the feature vector set extracted from the training corpus.
- (6) We disambiguate the test corpus by constructing a good word sense disambiguation model. Three different tests are performed on different feature vector sets.

**2.4. Construction and Analysis of Numerical Simulation Experiments.** We select 10 more polysemous words for comparison. These words include dichotomous vocabulary and multiple vocabularies. We made statistics on their various data, and the data situation is shown in Figure 3.

We obtain the experimental corpus and preprocess the corpus. The preprocessing part mainly includes analyzing the corpus and locating the target ambiguous words. The sliding word window method is used to obtain the lexical information set near the target ambiguous words. The feature processing part mainly includes acquiring the semantic knowledge set and determining the semantic knowledge by the Dice coefficient method. Semantic codes can be divided into three categories: large, medium, and small.

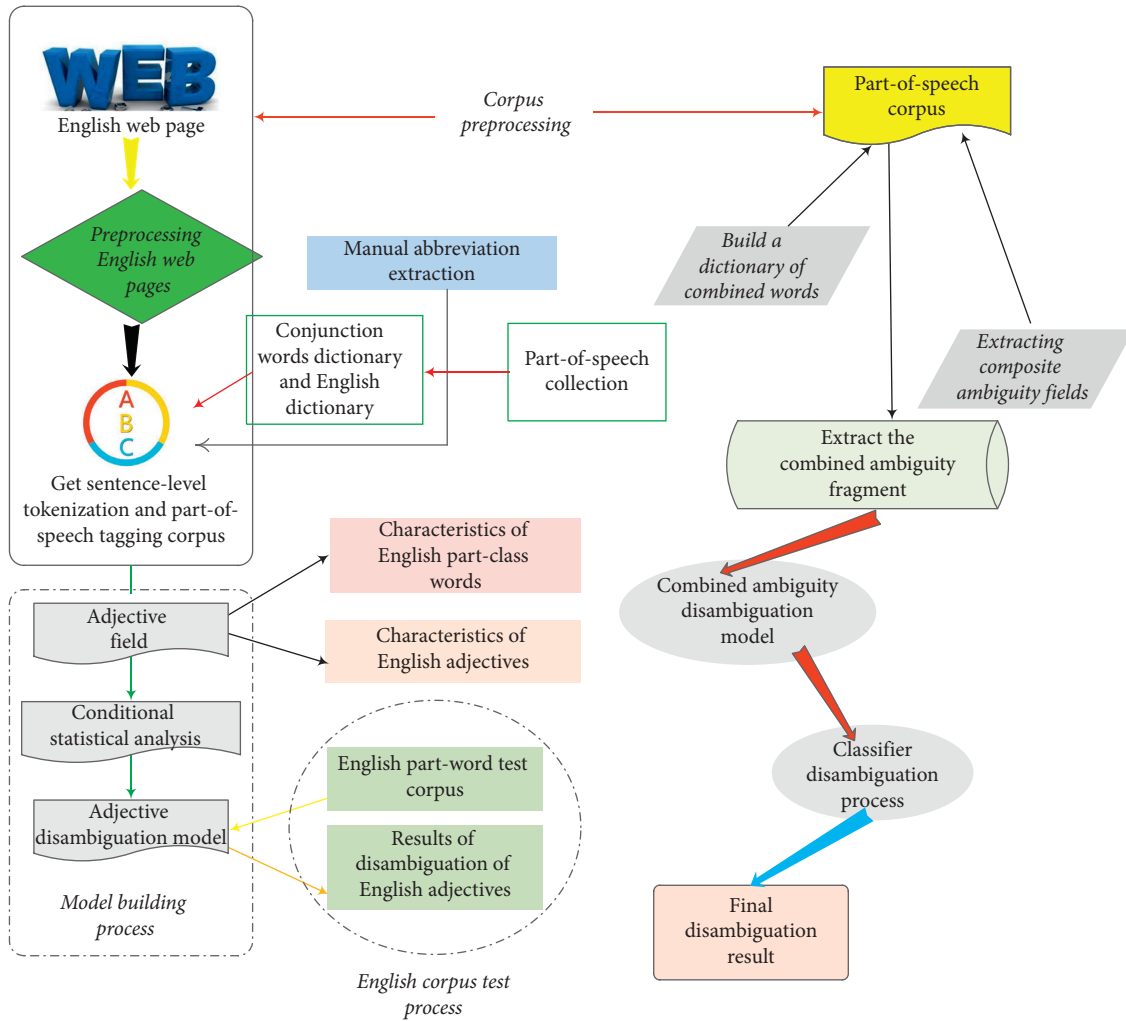

FIGURE 2: English combination ambiguity resolution framework.

FIGURE 3: Detailed corpus statistics.

The word meaning encoding extraction method obtains four semantic class codes. The first-level encoding extraction method obtains three first-level semantic codes, which are “D, H, and J.” Although “Synonym Cilin” has a more precise five-layer structure, which is the “Synonym Cilin” expansion board, this version of the semantic dictionary is different from the purpose of “Synonym Cilin” at first, but it is closer to the definition dictionary. If the extended version is used for implementation, the three-layer structure code of the word is almost the same as the word form information of the word, which results in no essential difference between the two feature vector sets.

From the above coding set, the most probable semantic knowledge information in the target word window is calculated and obtained according to the Dice coefficient method. Using three different feature extraction methods, three different semantic knowledge information feature vector sets are formed, and a semantic-based disambiguation model is constructed. Finally, the test corpus is used to perform experiments in the disambiguation model, and the accuracy of the models formed by three different feature extraction methods is recorded for the final comparison.

In the experimental stage, in order to measure the impact of training corpus and test corpus distribution on word sense disambiguation, relevant statistics were performed on the training data set. In a given corpus, the number of occurrences of each corpus is counted, and the results are shown in Figure 4.

It can be seen from Figure 4 that the interpretation of each vocabulary of the training corpus is about three times that of the test corpus. This corpus division is also in line with the simple cross-validation in statistical learning. In order to compare the results of the word sense disambiguation method proposed in this paper, we test the efficiency of the method through comparative experiments. Figure 5 lists the disambiguation accuracy of the two different methods.

### 3. Unsupervised Professional Field Segmentation Ambiguity Resolution Method

*3.1. Analysis of Word Segmentation Ambiguity in Professional Field.* The words that cause the ambiguity of the professional domain corpus and the general domain corpus are mainly short words. In the Fish corpus, two-word words accounted for 79%, and three-word words accounted for 13%; in the Bird corpus, two-word words accounted for 81%, and three-word words stood for 14%. Compared with the general field segmentation ambiguity, the composition of professional field segmentation ambiguity is slightly more complicated. In the professional domain corpus, not only ordinary words and ordinary words but also ordinary words and domain words cause segmentation ambiguity. For example, the term “neutralization” (neutralization reaction, the exchange of acids and bases with each other, and the reaction of salt and water) is often used in chemistry. In common sentences, “remaining in the measuring cup and the test strip” is often used.

The professional field lacks labeled training corpus and professional field knowledge, cannot count  $N$ -gram grammatical information, and cannot quickly generate professional field word segmentation ambiguity resolution rules; the professional field words and common words in different sentences cannot be generalized. Based on the above reasons, the general Chinese word segmentation ambiguity resolution method is not suitable for solving the problem of word segmentation ambiguity in professional fields.

Chinese word segmentation mainly includes two types of word segmentation ambiguity: cover ambiguity and overlap ambiguity. Statistical analysis of the number and phenomenon of the two types of ambiguities in the corpus shows that the number of coverage ambiguities is small and the number of overlap ambiguities is large.

Based on the vocabulary, the method of “FMM + back word” can be used to find the overlapped ambiguities that may exist in the test corpus. A set of overlapping strings owned by an overlapping type cut is called an overlapping string chain, and its number is called a chain length. For example, “Secondary” consists of two words overlapping “Second” and “Secondary.” The set of overlapping strings is {“time”}, and the chain length of the overlapping field is 1. In

FIGURE 4: Corpus distribution.

FIGURE 5: Comparison of word sense disambiguation results.

TABLE 1: MOAS chain length statistics.

|              | Fish corpus |      |      |      |      | Bird corpus |      |      |      |      |
|--------------|-------------|------|------|------|------|-------------|------|------|------|------|
| Chain length | 1           | 2    | 3    | 4    | 5    | 1           | 2    | 3    | 4    | 5    |
| Number       | 741         | 269  | 8    | 3    | 2    | 1189        | 422  | 40   | 4    | 2    |
| Share        | 0.73        | 0.26 | 0.01 | 0.02 | 0.01 | 0.72        | 0.25 | 0.02 | 0.02 | 0.01 |

the “molecule,” “combination,” “synthesis,” “component,” and “molecule” all form words, and the chain length of the overlapping field is 3.

Using the word fallback method, based on the Fish vocabulary and Bird vocabulary, we find possible overlap ambiguities in all test corpora and obtain MOAS (Maximal Overlapping Ambiguity String). We classify MOAS in Fish and Bird corpus according to chain length. The statistical results of MOAS chain length are shown in Table 1.

3.2. *Unsupervised Professional Field Segmentation Ambiguity Resolution Method.* Some methods in unsupervised word segmentation are often used to determine the likelihood of a string forming a word in the current corpus. Mutual information can be used to quantitatively estimate the binding force between two Chinese characters. The larger the mutual information, the higher the closeness of the combination of the two Chinese characters; the smaller the mutual information, the lower the tightness of the combination. The calculation formula is

$$\text{mi}(x, y) = \log_2 p(x, y) - \log_2 p(x) - \log_2 p(y). \quad (8)$$

Mutual information can only express the combining power of two Chinese characters. When it encounters a word composed of three or more multicharacters, it cannot express it. Based on mutual information, this paper changes the multiword mutual information. When a word is composed of multiple words, the mutual information of two adjacent words is calculated first, and then the average value is taken. The extended mutual information is

$$\text{mi}'(x_{1,\dots,n}) = (n-1)^{-1} \sum_{i=1}^n \text{mi}(x_i, x_{i+1}). \quad (9)$$

Boundary entropy is also one of the important methods to measure whether a string is a word often used in unsupervised word segmentation. The formula is

$$h(x_{i,\dots,j}) = - \sum_{x \in V} \log p(x | x_{i,\dots,j}) p(x | x_{i,\dots,j}), \quad (10)$$

when  $x$  is  $x_{i-1}$ ,  $x$  is the set of left-adjacent words, and  $h(x_{i,\dots,j})$  is called the left-handed conditional entropy and when  $x$  is  $x_{j+1}$ ,  $x$  is the set of right-adjacent words, and  $h(x_{i,\dots,j})$  is the right-handed conditional entropy. The greater the left and right entropy of a string, the more likely it is a word.

String boundary entropy can disambiguate segmentation in two ways. The first is to judge the possibility of string formation. The second is to judge the degree of separation between words. When judging the possibility of forming a string of words, the left entropy and right entropy of each string in the test corpus are statistically calculated, and the average value of the left entropy and right entropy of each word is taken as a measure. When the string  $abc$  has two splitting methods,  $ab/c$  and  $a/bc$ , the string boundary entropy used by the strings  $ab$  and  $bc$  is

$$\begin{aligned} h_{\text{avg}}(ab) &= 0.5[hr(ab) + hl(ab)], \\ h_{\text{avg}}(bc) &= 0.5[hr(bc) + hl(bc)]. \end{aligned} \quad (11)$$

To determine the degree of separation between strings, we use the following formula:

$$h_{\text{separate}}(x_{i,\dots,j}y_{i,\dots,j}) = 0.5[hr(x_{i,\dots,j}) + hl(y_{i,\dots,j})]. \quad (12)$$

When the string  $abc$  has two splitting methods,  $ab/c$  and  $a/bc$ , the degree of separation between  $ab$  and  $c$  can be expressed as

$$h_{\text{separate}}\left(\frac{ab}{c}\right) = hl(c) + hr(ab). \quad (13)$$

The degree of separation between  $a$  and  $bc$  can be expressed as

$$h_{\text{separate}}\left(\frac{a}{bc}\right) = hl(bc) + hr(a). \quad (14)$$

Boundary entropy can be used not only to judge the possibility of forming a string of multiple words but also to judge the possibility of a single word becoming a “single word.”

In the general field segmentation, the more frequently a word in the training corpus becomes a single word, the more likely it is that the word will become a single word in the test corpus. In the string  $abc$  with a length of 3, whether it is split into  $ab/c$  or  $a/bc$ , you can determine who has  $a$  and a word more frequently in the training corpus; if  $a$  is more frequent than a single word  $c$ , the segmentation result is  $ab/c$ . There is no training corpus for word segmentation in professional fields, and it is impossible to count the probability of single words. When encountering a string  $abc$  with a length of 3, you can use  $\text{havg}$  to determine which word in the test corpus is more likely to become a single word.

### 3.3. Numerical Simulation Experiment

3.3.1. *Experimental Corpus and Settings.* The test corpus in the experiment is the corpus of fish and birds in the Bio-volume of China Encyclopedia. The participle answer of the corpus is marked with Peking University participle standard.

The choice of experimental corpus follows two basic principles: First, it only observes the ambiguity of the segmentation in the domain and eliminates the interference of the OOV (Out of Vocabulary) problem on the effect of the segmentation. All words needed for the test corpus are added to the vocabulary. The second is the maximum possible simulation of actual application. For this experiment, large-scale vocabularies, common domain vocabularies, and network vocabularies are added to the experimental vocabulary.

Taking string frequency judgment as an example, the experiment considers two cases:

- (1) MOAS consists of three characters  $abc$ , which can be divided into  $ab/c$  and  $a/bc$ . If  $\text{Freq}(ab) > \text{Freq}(bc)$ , it is divided into  $ab/c$ .
- (2) MOAS is more than 3 characters, such as  $abcd$ ; if there are two forms of  $abcd$  and  $ab/cd$ , when  $\text{Freq}(abc) > \text{Freq}(cd)$ , it is divided into  $abcd$ ; when  $\text{Freq}(cd) > \text{Freq}(abc)$ , you need to consider again. After dividing  $cd$  into words,  $ab$  is still a word in the dictionary. If  $ab$  does not form a word,  $abcd$  is still used; if  $ab$  is formed, it is  $ab/cd$ .

When mutual information is used as the evaluation criterion, the experimental procedure is the same as the frequency of the character string, and  $\text{Freq}$  is changed to  $\text{mi}$ . When taking the possibility of forming a string boundary entropy as the evaluation criterion, the experimental steps are the same as the string frequency experiments, and  $\text{Freq}$  is changed to  $\text{havg}$ .

TABLE 2: Treatment of 10 experiments.

| Experiment number | Processing situation  |
|-------------------|---|
| 1                 | Baseline segmentation results without any ambiguity   |
| 2                 | Baseline segmentation results without any ambiguity   |
| 3                 | Freqword first uses the vocabulary to segment the test corpus, then counts the word frequency information in the test corpus after segmentation, and finally uses the new statistical word frequency information to segment the test corpus |
| 4                 | Freq only uses string frequency to process ambiguous segmentation results   |
| 5                 | Freq + zi_havg uses a single-word boundary entropy judgment when MOAS consists of 3 characters, and more than 3 characters use Freq judgment  |
| 6                 | mi uses only mutual information   |
| 7                 | mi_zi + havg uses single-word boundary entropy when MOAS is composed of 3 characters, and mutual information is used for more than 3 characters   |
| 8                 | word_havg segmentation results use string boundary entropy to determine the likelihood of word formation  |
| 9                 | word_hseparate uses only string boundary entropy to judge string separation results   |
| 10                | word_havg + zi_havg uses the boundary entropy of a single word when MOAS is composed of 3 characters and uses the boundary entropy of a string to determine more than 3 characters  |

When the separation degree of the string boundary entropy is used as the evaluation standard, the experimental steps are the same as the string frequency experiments, but the evaluation rule is changed to determine hseparate ( $ab/c$ ).

**3.3.2. Experimental Results and Analysis.** In order to analyze only the effect of word segmentation ambiguity, based on the Fish vocabulary and Bird vocabulary without OOV, the FMM word segmentation method was used to test the corpus segmentation of Fish and Bird, respectively. The segmentation result without any ambiguity is used as the baseline of the experiment. The processing conditions corresponding to the 10 experiments are shown in Table 2.

The data in Figures 6 and 7 show that, after only using string frequency to resolve the ambiguity problem, the F1 value of the word segmentation result has been significantly improved, the Fish result has increased by 0.48 percentage points, and the Bird result has increased by nearly 0.9 percentage points. Mutual information and string boundary entropy behave differently on different corpora. Mutual information has the best effect on the Fish corpus, with an increase of nearly 0.8 percentage points; on Bird corpus, the best effect is obtained by mixing the string boundary entropy with the single-word boundary entropy, increasing by 1.2 percentage points. The Fish-based corpus of  $m_i$ -based segmentation surpasses Topline.

The experimental results of word\_hseparate show that using this method to resolve the ambiguity of the word segmentation, the effect of the word segmentation decreases. The reason is that this method is equivalent to a local optimal solution, which results in many erroneous results.

In Bird’s corpus, mixed word boundary entropy is better than single-word entropy. However, the results of the Fish corpus are different. The statistical data of single-word boundary entropy comes from the test corpus. If some words in the test corpus often appear at various positions of the word, the single-word boundary entropy of the word will also be high. For example, the “fish” in the Fish corpus appears very frequently, and the single-word boundary entropy of “fish” is very high, but the possibility of becoming

FIGURE 6: Various word segmentation results of Fish without OOV.

FIGURE 7: Bird’s various word segmentation results without OOV.

a single word is very small. It is generally used as the beginning and end of a word, such as “fish bait” and “fish.” There are many such words in the Fish corpus, and the

FIGURE 8: Various word segmentation results of Fish with OOV.

FIGURE 9: Various word segmentation results of Bird with OOV.

single-word boundary entropy does not improve the Fish corpus. There are fewer such words in birds, and the accuracy of the single-word boundary entropy is higher, which has an effect on the result of word segmentation.

The boundary entropy of the word in the test corpus is subtracted from the boundary entropy of the word in the vocabulary, and the difference obtained by subtraction is the final single-element boundary entropy. The boundary entropy of some words after subtraction is negative. In this experiment, the single-word boundary entropy is only used for comparison, it is not used for other operations, and no other processing is performed on negative boundary entropy.

To further verify the validity of the results, the word segmentation vocabulary was changed. The professional words required by the test corpus are halved randomly, so that 879 OOVs (word types) in Fish cannot be recognized, and 1468 OOVs (word types) in Bird cannot be recognized.

The data in Figures 8 and 9 show that, in the presence of OOV, using string frequency, mutual information, and boundary entropy to process ambiguity, the segmentation results are better than baseline. Fish's best results and Bird's

best results are improved. Among all ambiguity processing methods, the performance of mutual information is the most stable.

## 4. Conclusion

According to the constructed feature vector set and through comparison, this paper chooses a naive Bayesian model with better efficiency and accuracy. A word sense disambiguation classifier is established based on the characteristics of semantic codes. A comparison experiment is performed through three different feature vector sets to analyze the performance of the word sense disambiguation classifier based on semantic information. The experimental results show that the accuracy of disambiguation of Bayesian word sense disambiguation model based on semantics is greatly improved compared with the traditional word sense disambiguation model. The general domain segmentation ambiguity resolution method requires professional knowledge and training corpus and is not suitable for solving the professional domain segmentation ambiguity problem. In this paper, the frequency, mutual information, string boundary entropy, and single-word boundary entropy of the test corpus are used as evaluation criteria to solve the problem of word segmentation ambiguity in professional fields. Experiments show that the three evaluation standards can solve the problem of word segmentation ambiguity in professional fields to varying degrees. Among them, the segmentation words using mutual information have the best results and perform stably. The word segmentation method combined with unsupervised learning in the professional field is simple and easy, and it can effectively reduce the problem of word segmentation ambiguity in the test corpus and improve the word segmentation effect in the professional field. However, natural language processing is increasingly a large-scale corpus. Therefore, how to deal with various types of ambiguity fields and improve the speed of word segmentation needs further study.

With the development of virtual scenes, the degree of simulation and functions of virtual reality have been very complete, providing a new platform and perspective for teaching design. Firstly, the hidden Markov chain model is used to perform emotion recognition on English speech signals. English speech emotion recognition and speech semantic recognition are essentially the same. Hidden Markov style has been widely used in English speech semantic recognition. The experiments of feature extraction and pattern recognition of speech samples prove that Hidden Markovian has higher recognition rate and better recognition effect in speech emotion recognition. Secondly, combining the human pronunciation model and the hearing model, by analyzing the impact of the glottis feature on the human ear hearing-model feature, the research application of the English speech recognition emotion interactive simulation system uses the glottis feature to compensate the human ear, hearing feature is proposed by compensated English speech recognition, and emotion interaction simulation system is used in the English speech emotion experiment, which has obtained a high recognition rate and showed excellent performance.

## 1. Introduction

Situation, virtual situation and instructional design are the starting points of this thesis. The teaching research has been concentrated on the discussion of teaching content and teaching methods, and there is almost no teaching research on the perspective and level of time and space and artistic conception. The research on the situation is also focused on the research of the “situation teaching” or “situation learning” theory and its teaching methods, or the pure situation or concept research is very fragmented, unsystematic, and not combined with educational discussions. In order to deepen the situation-based teaching research, especially the English speech recognition emotion interactive simulation teaching design in virtual reality, it is necessary to study and explore the essence of the situation and virtual situation and significance of teaching, which seems very meaningful.

Usually speech recognition technology includes three parts: preprocessing, feature extraction, and pattern matching [1, 2]. In the preprocessing process, the

prefiltering, pre-emphasis, windowing, and framing of the original voice signal are completed. Feature extraction is one of the key issues of speech recognition technology. In this link, the preprocessed speech will be mapped to the feature space, and the mapping function is the feature extraction algorithm [3, 4]. Another key issue of speech recognition technology is pattern matching, which divides the extracted features into two parts, called training features and test features, respectively. Substitute the training feature into the pattern matching algorithm, train one or several models, and then input the test feature into the trained model to find the model with the highest degree of matching; then, the model is considered to be the representative of the test feature category. The best combination of feature extraction and pattern matching will produce the best recognition effect. Speech synthesis systems are also called text-to-speech conversion systems. As the name implies, they are to convert text into speech [5, 6], which corresponds to speech recognition technology. The purpose of speech synthesis technology is simply to let the computer speak human-like language. In a speech synthesis system, the grammatical

ordering of basic phonemes, that is, the definition of annotated sequences, is the key to synthesizing grammatical rules with high intelligibility [7, 8]. At present, most definitions for labeling sequences are based on the relationship between the current phoneme and the current sentence. If you define the relationship between the front and back sentences and the front and back phonemes and the current phoneme in detail and use these relationships to generate synthesized speech in the synthesis stage, then it is inevitable. It will make the grammatical ordering of phonemes more in line with language habits, resulting in synthetic sentences with higher intelligibility and naturalness [9]. The literature [10, 11] makes a comprehensive and detailed analysis of this theory from the background, knowledge, contextuality of cognition and learning, assumptions, and basic characteristics of contextual learning and contextual cognition. The literature [12, 13] reviews the research of situational cognition and learning theory in the West, summarizes the research history, the meaning, and main content of situational cognition and learning, and points out the future development of the theory direction. The literature [14, 15] conducted many experiments and innovations on Chinese speech emotion recognition. Exploratory experiments on speech emotion recognition include the use of various improved neural network methods, support vector machines, and fuzzy entropy recognition methods. The test results can achieve a recognition rate up to about 75%. The authors in [16, 17] have also conducted fruitful research on feature vector decomposition and fusion of speech emotion signals and feature vector dimensionality reduction, proposed improved classification quadratic functions, and improved Mahalanobis distance and other classification algorithms, and recognized in experimental data the good test performance on the rate. Currently, commonly used speech synthesis methods are parameter synthesis method and waveform stitching synthesis method [18, 19]. The parameter synthesis method is to synthesize speech by adjusting acoustic parameters, which can be simply understood as the reverse process of speech recognition. The parameter synthesis method is relatively mature in theory, but because of the complexity of the algorithm and because the loss of information cannot be effectively compensated, the synthesis effect is not ideal and has a strong machine smell. In the waveform splicing and synthesis system, the basic phonemes are selected from a prerecorded speech database. As long as the database is large enough, it is theoretically possible to splice out any sentences needed [20, 21]. Since the synthesized speech is basic the phonemes are all from the natural original pronunciation of the recorder, so the clarity and naturalness of the synthesized sentences are relatively high. However, it requires high storage capacity and operation speed. In recent years, the HMM-based speech synthesis method has attracted widespread attention. The HMM-based synthesis system can solve the defects of the waveform stitching synthesis method. It models the speech parameters, then uses the sound database data for automatic training, and finally forms a corresponding synthesis system [22]. Emotional speech recognition is an important branch of speech recognition,

which has aroused widespread concern in recent years. Similar to speech recognition, emotional speech recognition can also be divided into three parts: preprocessing, feature extraction, and pattern matching [23, 24]. The difference is that the features here refer specifically to those features that can characterize the emotional state, such as the pitch Rhythm characteristics such as frequency, formant, and short-term average energy. Rhythm feature extraction algorithm is simple, but it is not effective enough for some states with less emotional opposition [25, 26]. Studies [27, 28] in recent years have shown that emotional speech features are no longer a simple combination of the above prosody features. Features based on pronunciation mechanisms are increasingly used in emotional speech recognition and have achieved good results.

The in-depth analysis and discussion of the situation and the virtual situation provide a more in-depth theoretical basis for the development and teaching application of constructivism, provide a more practical plan, and open a new perspective and thinking for the teaching design in virtual reality. First, it introduces in detail the establishment, acquisition, and storage methods of the English speech recognition emotion interaction emotion speech sample library, classifies it according to the requirements of subsequent experiments, and then explains how to affect the preprocessed speech emotion signal. Next, we introduce and compare the main English speech recognition emotion interaction speech emotion feature parameters currently used and how to use the experimental method to obtain the feature parameter fields required in this article. Second is an introduction to the process of speech emotion recognition, including the current major voice emotion recognition methods in the world, comparing their respective characteristics, and then choosing the hidden Markov model method as the voice emotion recognition method in this paper to complete the recognition of virtual human emotion recognition of English speech recognition emotion interactive speech emotion signals. Find the Hidden Markov Model that is most suitable for the purpose of this article, conduct a detailed comparison experiment between discrete Hidden Markov and continuous Hidden Markov Models, draw a comparison of the two advantages and disadvantages, and finally choose continuous Hidden Markov. The model serves as a model for further work.

## 2. Virtual Situation and Emotion Theory of English Speech Recognition

*2.1. Design of English Phonetics Teaching Based on Virtual Situation.* Virtual context provides users with a set of experiences, which is an external experience compared with the internal experiences of people's inner activities (such as joy, anger, sorrow, and joy). Because any external experience may cause people's inner activities, virtual situations can also cause people's inner activities. Therefore, the virtual situation can enable the learner to produce the same or similar inner activities as the real situation. Virtual situation is a phenomenon that can be directly observed and experienced, but it does not have the substantial accessibility as the real

world. Functionally speaking, the experience in the human mind is caused by the virtual situation and the real situation is not direct. When the users in the virtual situation conduct research and reflection, the virtual situation is a possible real reality. Since virtual situations are possible real realities, you can use virtual situations to understand real realities. Here, the virtual situation becomes a virtual intermediary.

The practice of English speech recognition emotional interaction teaching in virtual situations is in line with the constructivist theory and includes four basic attributes of “situation,” “collaboration,” “conversation,” and “meaning construction.” Constructivism believes that personal experience can accelerate the process of knowledge construction and realize the consolidation and externalization of knowledge, and the most convenient virtual situation is the most effective. The virtual situation allows the learner to interact with various existing information, experience different time and space in the learning process, and also be in contact with various parts of the virtual realm. The virtual situation is almost the same as the real situation in terms of simulation degree and function, which also meets the requirements of constructivism that the situation is “highly realistic.” And when participating in the virtual situation, through the avatar mode, it can actively interact with other things and characters, participate in various English speech recognition emotional interactive teaching activities, and conduct collaborative learning to obtain knowledge and achieve the purpose of knowledge construction, as shown in Figure 1.

In virtual situation-based teaching, the learner plays the role of a cognitive subject. Therefore, in virtual situations, English speech recognition is often used for emotional interaction. English speech recognition emotional interaction refers to the support and promotion of learners’ effective learning. Its core is to give full play to the initiative and enthusiasm of students in learning and fully reflect the learner’s cognitive subjective role. Under constructivist thinking, many methods of situation-based teaching have been proposed. Learning in the context of virtual teaching can also draw on these methods. These methods highlight two aspects of collaboration and self-exploration. Constructivists are those who collaborate between teachers and students and between students and students, which is very important for the collection and analysis of data, the formulation and verification of hypotheses, the self-feedback of the learning process, the evaluation of learning results, and the construction of meaning. In the teaching based on the virtual teaching situation, discussion and communication are the main forms of collaboration, but the form of discussion and communication is carried out under the virtual situation. In the process of collaborative learning, teachers first ask questions to arouse students’ “thinking and discussion.” During the discussion, teachers further lead the problems deeper to deepen students’ understanding and at the same time guide students to correct errors and supplement one-sided cognition.

## 2.2. Introduction to the Emotional State of Virtual Situations.

According to the basic sentiment theory, the human emotional state can be divided into several basic types. Let the

emotional state space set  $T = \{t_i | i = 1, 2, \dots, N\}$ , where  $N$  represents the number of emotional states. Use random variables to scroll through emotional states. Let  $Q_i$  be the probability of  $X = t_i$  (take the  $i$ th emotional state) and satisfy

$$\sum_{i=1}^N t_i = 1, \quad 0 \leq t_i \leq 1. \quad (1)$$

In this way, the probability space of emotional states can be expressed as follows:

$$\begin{pmatrix} T \\ Q \end{pmatrix} = \begin{pmatrix} t_1, t_2, \dots, t_N \\ q_1, q_2, \dots, q_N \end{pmatrix}. \quad (2)$$

In English speech emotion speech recognition, some features need to be found, and these features can accurately distinguish different emotional states. This issue involves a variety of disciplines such as psychology, biology, and signal processing. Table 1 compares the results of different acoustic characteristic parameters under six emotional states (“happy,” “angry,” “fear,” “sadness,” “amaze,” and “disgust”).

With the deepening of the research on the classification of English speech emotion interaction, some researchers have proposed a continuous English speech emotion interaction model, which describes emotion in a continuous space, that is, the dimension theory of emotion. Dimension theory regards the conversion process between different emotional states as a continuous linear process in an  $N$ -dimensional space, and the distance between different emotional states in the dimensional space represents the similarity and difference between them. Among the dimensional theory of emotion, the most widely accepted dimensional model is the two-dimensional space of activation evaluation:

- (1) The degree of activation or arousal reflects the active degree of body energy in a certain emotional state
- (2) The degree of evaluation or happiness is based on the separation and activation of positive and negative emotions

Based on the theory of activation evaluation space two-dimensional English speech emotion interaction classification model, as shown in Figure 2, each emotion is distributed at the outer end, and the center of the emotion wheel model is the natural origin, which is a comprehensive. The state of emotion tends to all emotions in the direction, and no emotion is reflected. The closeness of emotions in the same direction determines the intensity of each emotion, and the absolute value of the length of emotion shows the intensity of emotion in this aspect. The emergence of the English speech emotion interaction model introduces the vectorization theory into the classification of emotion models. Any emotion can be represented by a unique vector. According to the vectorization theory, naturally, the amplitude value of the emotion vector is expressed. The intensity of emotion and the angle of the emotion vector show the trend of the type of emotional interaction of English speech in this direction.

Introduce the continuous emotion model from the two-dimensional space to the secondary derived emotional

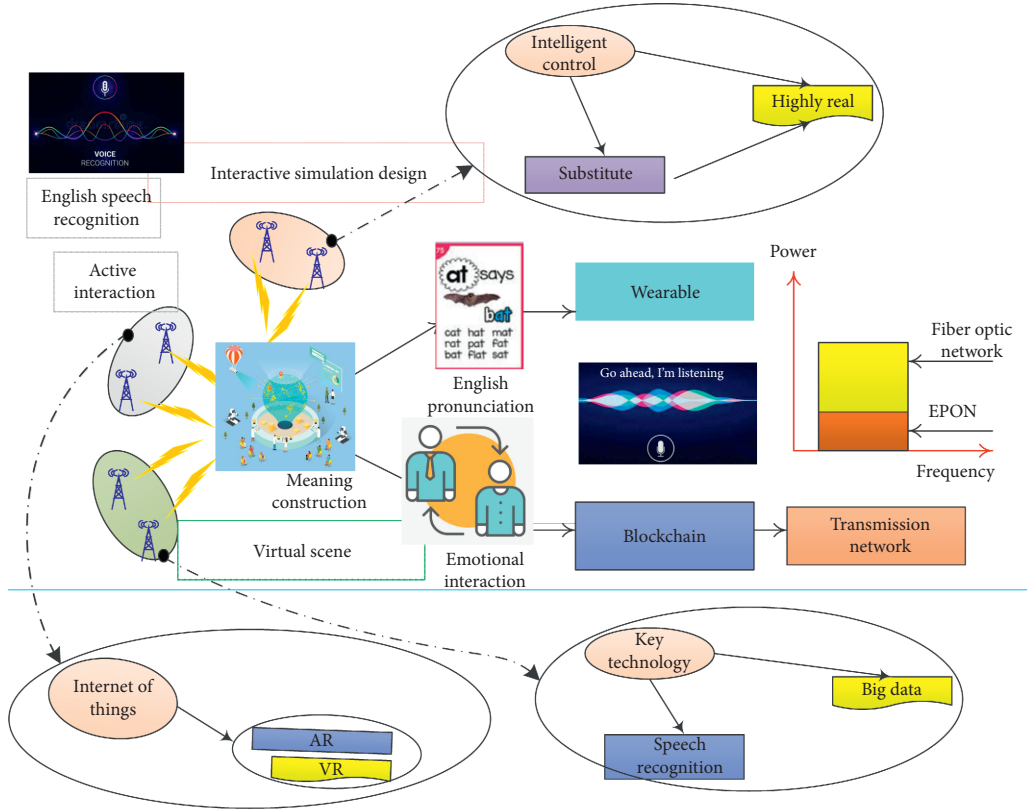

FIGURE 1: English speech recognition emotion interaction mode under virtual scenarios.

TABLE 1: Emotional and speech emotional features.

| Parameter       | Happy     | Pissed off         | Fear              | Sad               | Amazed          | Disgust         |
|-----------------|-----------|--------------------|-------------------|-------------------|-----------------|-----------------|
| Speed of speech | Fast      | Slightly faster    | Quickly           | Slightly slower   | Very fast       | Very fast       |
| Average pitch   | Very high | Very high          | Very high         | Very low          | Very high       | Very low        |
| Pitch range     | Very wide | Very wide          | Slightly narrower | Slightly narrower | Tip up          | Slightly wider  |
| Pitch change    | Smooth    | Mutation at stress | Bend down         | Bend down         | Normal          | Normal          |
| Strength        | Bend up   | High               | Low               | Low               | Irregular sound | Normal          |
| Sound quality   | High      | Breathing          | Resonate          | Resonate          | Accurate        | Irregular sound |
| Sharpness       | Breathing | Chest sound        | Vague             | Vague             | Amazed          | Clear           |

factors, thus introducing the two-dimensional plane space into the three-dimensional space. More importantly, the emotion model in the three-dimensional space combines matrix theory and feature vector. The theory provides the basis of the emotion model for the subsequent vectorized decomposition and fusion of speech emotion feature parameters and the vectorized description of complex emotions in continuous space.

### 3. Research on Emotional Interaction of English Speech Recognition Based on Virtual Situation

**3.1. English Speech Recognition Preprocessing.** In order to convert the continuous analog voice signal into a digital signal for processing and recognition, before extracting the features of the English voice signal, it must go through a series of steps of sampling, digitization, and signal optimization to denoise the voice signal and select recognition

frequency range, high-pass and low-pass filtering, endpoint detection, pre-emphasis, windowing, amplification and control gain, and antialiasing filtering and other voice signal specifications and preparations to facilitate the extraction of voice emotional feature parameters; these tasks are called preprocessing of emotional speech signals.

The English speech signal can be regarded as a non-stationary time-varying signal. Biological research on the principle of sound production by the vocal organs proves that the speed of the state of the vocal organs caused by vibration is much lower than the vibration frequency of the sound. Researchers of emotional signal processing in English speech recognition usually treat emotional signals in English speech recognition as short-term stable signals. In the sound frequency range of 5–50 ms, the spectral characteristics and some physical characteristics of English speech recognition emotion signals are constant. Based on this principle, we have introduced a “windowing” preprocessing method for

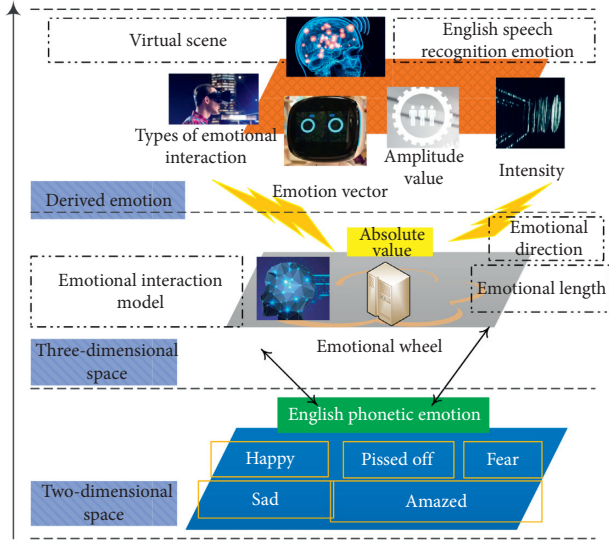

FIGURE 2: English speech emotion interaction classification model.

the English speech recognition emotion signal, combining the short-term processing method of the English speech recognition emotion signal with the processing method and theory of the stable process in a short time slice, and each short-term speech signal segment in a time slice is called an analysis frame. The length of a frame ranges from 10 ms to 30 ms. The “windowing” mentioned by the researchers is a short-term processing method for analyzing frames. The method is the English speech recognition emotion signal in a valid domain which is divided into many short time slices by artificially adding some window functions. The window function of the method of  $w(n)$  to obtain the current frame is to change the sample amplitude outside the divided extraction processing area to zero. The most ideal state of the frequency response of the window function is no side-lobe spectrum leakage, the length is 0, the main-lobe spectrum leakage is close to no, and the length is infinitely narrow. This is only the ideal state that exists in the achieved simulation experiment. The two most commonly used window functions in the rectangular window and Hamming window English speech recognition emotional signal digital processing are

$$w(n) = \begin{cases} 1, & 0 \leq n \leq N-1, \\ 0, & n = \text{else}, \end{cases} \quad (3)$$

$$w(n) = \begin{cases} 0.58 - 0.42 \left( \frac{2\pi n}{N-1} \right), \\ 0, & \text{else}. \end{cases}$$

The characteristic parameters of the speech generated by the linear excitation source filter are mainly reflected in the frequency spectrum structure of speech, in which the formant and pitch frequency are the more commonly used and important characteristic parameters. Formants are one of the most important parameters in speech signal processing.

The difference in the emotional state is reflected in the nervous system to form different degrees of nerve tension, and this difference in tension acts on the vocal muscles, making the same tone. The difference in the degree of muscle tightness is further reflected in the difference in channel frequency. This difference is reflected in the characteristic parameters of the speech signal processing process, which is the formant peak value. A large number of studies have proved that different emotional states will make the position of the formant of the speech signal different. In terms of statistical significance, in order to eliminate the individual differences in formants in the same emotional state on a statistical level, researchers widely use the statistical characteristics of the first three formants peak and bandwidth: average, extreme value, standard deviation, and median, as a research parameter in the process of speech signal processing.

In the extraction of feature parameters of speech signal processing, the linear prediction method based on the all-pole model regards the speech signal  $x(n)$  as a full-pole filter response with  $u(n)$  as the excitation, and from  $u(n)$  to  $x(n)$ , it is expressed as follows:

$$T(z) = \frac{D}{1 - \sum_{i=1}^q b_i z^i} \quad (4)$$

The linear prediction method is used to process the vocal tract model to produce an all-pole model with excellent performance in speech processing research. The practical significance of linear prediction is to decompress the speech signal in the time and frequency domains. The process of deconvolution is to treat the excitation component as the prediction residual  $u(n) = x(n) - \sum_{i=1}^q b_i x(n-1)^i$  and obtain the component of the transfer function  $T(z)$  of the full pole model. The parameter sequence  $[i]$  of this component is further obtained. According to the conclusion that the frequency response characteristic will reach a peak at the resonance peak frequency, the resonance peak is the spectral peak of the frequency response component at this time. By the formula,

$$T(z) = \frac{G}{1 - \sum_{i=1}^q b_i x(n-1)^i} \quad (5)$$

Using the above method, the third formant-related characteristic data in Table 2 below is obtained. From the data in the table, we can think that the third formant has certain distinguishing effects on the four emotions.

For the purpose of feature parameter dimensionality reduction, this paper selects the first 10 numbers from the emotion package of the English speech recognition emotion library for a total of 70 speeches for 7 repetitive trainings, in order to obtain the optimal feature parameter vector combination. In the calculation process, there are two methods for selecting the best feature dimension, one is the cumulative contribution rate method, and the other is to obtain the recognition rate through repeated experiments, and the multiple experiment method of inferring the dimension based on the recognition rate. In the experiment process, only 70 voices were used for dimension reduction

TABLE 2: Statistical parameters related to different emotions of the third formant.

| Third formant frequency | Sad  | Happy | Fear | Pissed off |
|-------------------------|------|-------|------|------------|
| Mean                    | 3048 | 3118  | 3005 | 3067       |
| Maximum                 | 4342 | 4067  | 4098 | 4089       |
| Minimum value           | 2096 | 2106  | 1968 | 2234       |
| Standard deviation      | 356  | 358   | 425  | 354        |
| Median                  | 1908 | 2926  | 2816 | 2945       |

and feature parameter selection, so the method using multiple experiments to find the dimension is more effective. In 7 repeated experiments, the statistical relationship between the average recognition rate and the dimensionality is shown in Figure 3.

As shown in Figure 3, it can be observed that when using feature vector groups with dimensions of 5 to 8, the recognition rate gradually increases; when the dimension exceeds 8, the recognition rate gradually decreases. Using 6 repeated experiments in this paper, the viewpoint of the best vector combination dimension is confirmed so that the conclusion based on the emotional speech library of this article is obtained. The 8-dimensional feature vector group can obtain the best recognition rate. The pitch average, pitch frequency first- and second-order difference, amplitude energy mean, amplitude energy first- and second-order difference, third formant standard deviation, and MFCC standard deviation are eight parameters as speech feature parameters.

### 3.2. English Speech Recognition Based on Virtual Scenarios.

The hidden Markov model is used for emotion recognition. The model characteristics of the double embedded stochastic process characteristics are very consistent with the requirements of emotional state recognition through the emotional feature parameters in speech. The hidden Markov model method is widely used in the field of speech recognition and emotion recognition because of its many statistical advantages as a pattern recognition method; it can be more convenient to train approximate model parameters from a limited number of speech material data. Based on the flexibility of the trained model itself to change materials, optimize the architecture of the cognitive system as the number of training changes and improve the accuracy of the model.

Firstly, a continuous hidden Markov model is used to conduct speech recognition experiments. First, we need to initialize the emotional feature parameters of the speech. The pitch frequency, the first- and second-order difference numbers of the fundamental frequency, the amplitude energy value, the amplitude energy first- and second-order difference values, the first resonance peak, and the eight feature parameters, according to the degree of influence of each feature parameter plus weight value  $w_i$  (where  $\sum_{i=1}^8 w_i = 1$  represents the number of frames) to obtain the eight-dimensional feature vector, are shown below, where  $F_i$  represents the feature vector of each frame and  $i$  represents number of frames:

FIGURE 3: Relationship between average recognition rate and dimension.

$$F_i = \left( w_1 \times F_{0i}, w_2 \times \frac{dF_{0i}}{dt}, \dots, w_8 \times F_{1i} \right). \quad (6)$$

The iterative estimation algorithm is used to train the model of speech emotion parameters. The training results of this method are related to the initial value of the parameter (not the initial value of the system). Sometimes, due to the selection of training parameters, two types of situations will occur: the first type, the model cannot converge; in the second category, the converged solution is not the global optimal solution. In order to avoid and solve these two types of situations, we can use the piecewise K-means algorithm to make the training parameters converge better globally optimal solution:

- (1) The input training voice feature parameters are segmented at equal intervals according to the number of states of the HMM model (that is, the number of classifications of the emotion model), and then the feature parameter set in each segment is used as a specific training set to train a certain Emotional state, calculating the initial parameters of the model.
- (2) According to the incoming parameters, the pre-processed voice signal data is divided into the most likely state sequence.
- (3) Use the K-means segmentation algorithm to iteratively re-evaluate the  $B$  in the initial parameters to obtain the intermediate result, that is, collect all the training data of the five emotional states obtained in step (2) to obtain  $B'$ ; if it has been knowing that a model is divided into mixed Gaussian density functions with  $M$  mixed numbers, the K-means clustering algorithm is used to classify all training parameter sets with a state equal to 1 into  $M$  classes and the covariance matrix and mean value of each class. The vector is the center point of the class as the standard point for classification, and finally the mean

estimate  $M$  and variance estimate  $E$  of the  $M$  Gaussian components are regarded as the vector mean and co-square matrix of each type of feature vector set and each Gaussian component. The mixed weight value is as follows:

$$\vartheta_{jm} = \frac{\text{Number of voice frames in state } j \text{ in class } m}{\text{Number of voice frames in } j \text{ state}}. \quad (7)$$

- (4) Substitute the  $\lambda$  obtained in the previous step into the parameter iterative re-estimation method as its initial value re-estimation model, and the re-estimation results in the new model parameter  $\lambda'$ .
- (5) Find the difference between  $\lambda$  and  $\lambda'$ , see if the difference is less than the preset threshold, and see if the template converges; if it does not converge, enter  $\lambda'$  as the new initial parameter and return to step (2). Go to step (6).
- (6) Output the model parameter  $\lambda'$ , that is,  $\lambda'$  is the final model parameter estimation result.

#### 4. Experimental Verification

The selected English speech emotion recognition categories are sad, happy, fear, angry, and neutral. For these five emotional states, 162 groups of speech are selected for each emotion. A total of 810 groups of speech form a training speech database; divided into four times, the model is trained according to the model training volume of 210 groups, 410 groups, 610 groups, and 810 groups. The remaining 190 sets of corpus materials in the 1000 sets are used as the recognition set for the experiment, and the following two sets of tables are obtained.

As can be seen from Table 3, among the 200 groups of unfamiliar emotion speech recognition results, the recognition rate of angry emotion is the highest, reaching 81.2%, the recognition rate of sad emotion is the lowest, reaching 75.4%, and the other three emotions are happy, neutral, and fearful, whose recognition rates are 79.5%, 76.8%, and 77.8%, respectively, and the average recognition rate was 78.122%. Further analysis of the table also shows that the three emotions of sadness, fear, and neutrality are more easily confused in the recognition process. It is speculated that this situation is closely related to the emotional feature parameter domain of these three emotions.

As shown in Table 4, 190 sets of long-term speech and 190 sets of short-term speech were used to perform recognition experiments under 210, 410, 610, and 810 training amounts, respectively. The recognition rate results shown in the table below are obtained.

As shown in Table 4, the following conclusions are drawn. With 200 groups of untrained unfamiliar voices, the recognition rates are 52.53%, 61.96%, 72.49%, and 78.32% under the training volume of 210, 410, 610, and 810 groups, respectively. With the improvement of the training volume, the recognition performance of the resulting model is significantly improved. The recognition ability of the unfamiliar speech shows an upward trend as shown in Figure 4

TABLE 3: Emotion recognition results under 810 training amounts.

| Emotion type | Sad | Happy | Pissed off | Fear | Neutral | Recognition rate |
|--------------|-----|-------|------------|------|---------|------------------|
| Sad          | 115 | 4     | 3          | 20   | 18      | 75.4             |
| Happy        | 5   | 121   | 15         | 13   | 6       | 79.5             |
| Pissed off   | 8   | 12    | 124        | 12   | 4       | 81.2             |
| Fear         | 16  | 11    | 7          | 117  | 9       | 76.8             |
| Neutral      | 14  | 3     | 4          | 20   | 119     | 77.8             |

TABLE 4: Recognition rate of 190 strange recognition corpora in different situations.

| Training volume                        | voice length | 210    | 410    | 610    | 810    |
|--|--------------|--------|--------|--------|--------|
| Long-term voice (3–6 seconds interval) |              | 52.53% | 61.96% | 72.49% | 78.32% |
| Short-term voice (2 seconds)           |              | 53.56% | 65.79% | 84.59% | 89.87% |

below. We can see that although increasing the training volume can recognize the performance, training in 610, the improvement rate of the recognition accuracy rate between the amount of training and the 810 groups of training is not as fast as the stage of 210 groups to 10 groups. Conclusion: increasing the amount of training can improve the accuracy of recognition. The accuracy improvement curve is infinitely close to the extreme value, and there is a bottleneck value in the system recognition rate.

The experimental recognition results of the 210 long-term speech recognition set under the 810 training set are shown in Table 5:

With the increase in training volume, the recognition performance of the resulting model has improved to a certain extent, but the overall recognition performance of the model for long-term speech in this paper is poor; while the model has a significantly higher recognition rate for short-term speech. The recognition rate curve of long-term speech and short-term speech under different training amounts is shown in Figure 5:

As shown in Figure 6, the above five characteristics include not only classic characteristics reflecting the auditory characteristics of the human ear but also recently proposed characteristics reflecting the nonlinear characteristics of the glottis. Through these five characteristics of the recognition experiment of the English emotional speech database and the  $n$  emotional speech database, the comparison of the experimental results' data can directly prove that the English emotional speech database is a more effective emotional speech database, which can be used for future emotional speech research.

As shown in Figure 7, from the perspective of sentiment classification, the performance of LPCC, MFCC, and LPMCC features has changed. In a single speech database experiment, the "neutral" emotion recognition rate is the highest, "happy" is the second, and "angry" is the lowest.

Test in the same training corpus and rule set, observe the changes in the mark recall rate, and mark the accuracy rate. The results are shown in Figure 8.

FIGURE 4: Recognition rate of 210 groups of strange voices under different training volumes.

TABLE 5: 210 long-term speech recognition results in the 810 training set.

| Emotion type             | Sad | Happy | Pissed off | Fear | Neutral | Unknown error | Recognition rate (%) |
|--------------------------|-----|-------|------------|------|---------|---------------|----------------------|
| Sad                      | 94  | 9     | 4          | 24   | 23      | 12            | 57.5                 |
| Happy                    | 5   | 103   | 18         | 18   | 6       | 12            | 63.2                 |
| Pissed off               | 11  | 24    | 103        | 18   | 6       | 5             | 63                   |
| Fear                     | 22  | 15    | 14         | 98   | 12      | 8             | 60.5                 |
| Neutral                  | 30  | 11    | 9          | 19   | 88      | 4             | 55.8                 |
| Average recognition rate |     |       |            |      |         |               | 59.995%              |

FIGURE 5: Long-term and short-term speech results under different training sets.

It can be seen from Figure 8 that when  $\lambda_1$  takes 0, its LR value is relatively small, and the result is not ideal. Therefore, comprehensive consideration of the rule information and structure co-occurrence information

is indeed very good for improving the accuracy of analysis great help. It can also be seen from the figure that when  $\lambda_2 = 2.5$ , the corresponding LP value is relatively high.

FIGURE 6: Comparison of recognition rates of different features in different languages.

FIGURE 7: Comparison of recognition rates of different features under different emotions.

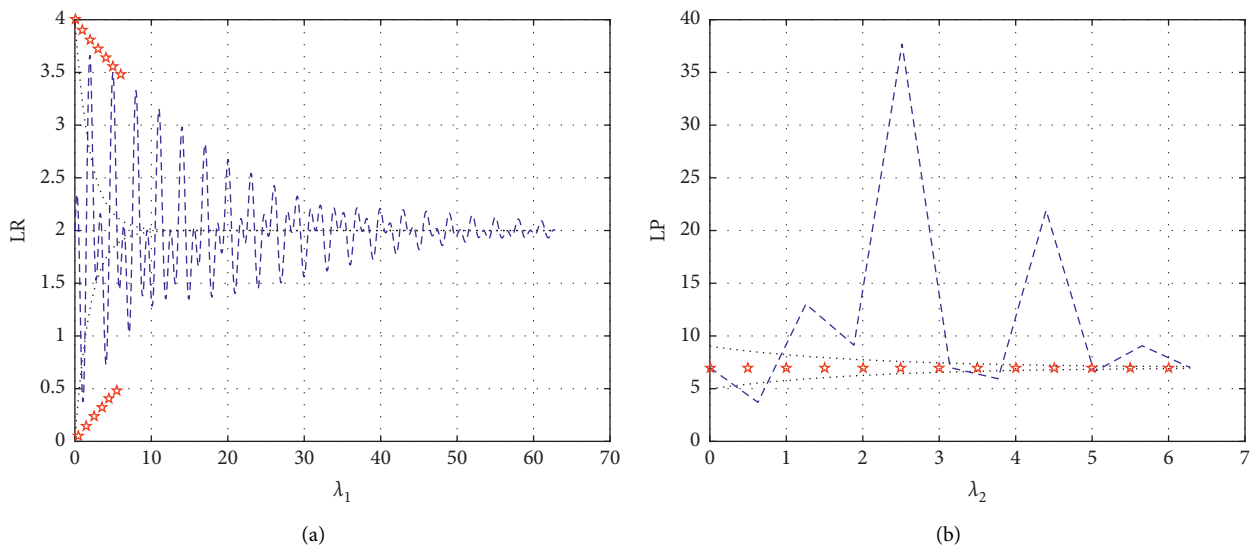

FIGURE 8: Variation of different  $\lambda_1, \lambda_2$  values on the results: (a) the left is LR and (b) the right is the LP change curve.

## 5. Conclusion

This paper synthesizes the research results of pattern recognition and uses 1000 voices of the voice database to train the English voice emotional interaction model in virtual scenarios. Through multiple sets of comparative experiments, the feasibility of the recognition system is verified, and the noise is tested for antijamming capability and robustness. The research work of virtual scene construction adopts the currently popular three-dimensional modeling and three-dimensional virtual reality. Through experiments, the ability of emotional virtual people to recognize and feedback English speech emotion signals in virtual situations is verified. Emotional computing is a highly integrated field of research and technology. By combining computational science, psychology, and cognitive science, we will study the emotional characteristics of human-computer interaction and design a human-computer interaction environment with emotional feedback. It is possible to realize human-machine emotion. With the updating of educational teaching concepts and the advancement of science and technology, there have also been changes in the method of presenting situations. The use of various technical means to present virtual teaching situations has attracted more and more attention from the education community. Therefore, English speech emotional interaction design based on virtual situations will also receive more and more attention.

According to the randomness of the spatial distribution and shape of the internal cells of closed-cell foam aluminum and based on the Voronoi algorithm, we use ABAQUS to model the random polyhedrons of pore cells firstly. Then, the algorithm of generating aluminum foam with random pore size and random wall thickness is written by Python and Fortran, and the mesh model of random polyhedral particles and random wall thickness was established by the algorithm read in by TrueGrid software. Finally, the mesh model is imported into the LS-DYNA software to remove the random polyhedron part of the pore cell. Compared with the results of scanning electron microscopy and antiknock test, the morphology and properties of the model are close to those of the real aluminum foam material, and the coincidence degree is more than 91.4%. By means of numerical simulation, the mechanism of the wall deformation, destruction of closed-cell aluminum foams, and the rapid attenuation of explosion stress wave after the interference of reflection and transmission of bubbles were studied and revealed. It is found that aluminum foam deformation can be divided into four areas: collapse area, fracture area, plastic deformation area, and elastic deformation region. Therefore, the explosion resistance is directly related to the cell wall thickness and bubble size, and there is an optimal porosity rule for aluminum foam antiknock performance.

## 1. Introduction

Closed-cell aluminum foams are a kind of porous metal material, which is composed of thousands of random 3D polyhedral pores embedded in continuous aluminum or aluminum alloy matrix. Compared with other composites, closed-cell aluminum foam has the characteristics of lightweight, high strength, and dual physical properties of function and structure. Because of its unique mesostructural characteristics, the material can have long and almost constant platform stress in compression, which is very beneficial for energy absorption [1, 2]. Therefore, aluminum foams are being increasingly used in energy-absorbing structures [3–11]. It has been widely used in the field of explosion and impact protection. Goel et al. [12] studied the effect of closed-cell aluminum foam on the shock wave passing through the impact tube, and it is found that the existence of aluminum foam interlayer has a great influence

on the reflected wave. According to the research of Shen et al. [13], they carried out the explosion loading experiment on the aluminum foam sandwich plate which was bent outwards and found that compared with the plane aluminum foam sandwich plate, this structure changed the incident angle of detonation wave and the deformation mechanism of the panel. Its antiknock ability was better than the latter. Jing et al. [14–16] introduced experimental studies on antiknock performance of circular arc foam metal composite panels, and the deformation and failure characteristics of such composite plates subjected to blast loading are analyzed.

As we all know, the local failure and deformation of aluminum foam are very serious under the condition of a strong dynamic load. It is difficult to obtain the local mesofailure mode and the failure process (mode) of deformation, collapse, and fracture in the experimental study. Some studies have shown that the mechanical properties of

aluminum foam materials show obvious multiscale characteristics [17]. At the mesolevel, the mechanical behaviors of the aluminum foam cell wall, such as plastic deformation, buckling, and fracture, have a great influence on the macro-mechanical properties. Therefore, scholars at home and abroad have established a large number of numerical models and carried out a variety of research methods [18–23].

At present, there are three main methods to study the mesoscopic model of porous metal materials. The first method adopts repeating unit cell (RUC). The macro-mechanical properties and deformation characteristics of aluminum foam structure are simulated by regularly repeating the predesigned representative unit. The choice of representative units is more diversified. Gibson and Ashby [24] proposed a cubic structure model for closed-cell foam materials. It assumes that the cell structure is a simple and repeated arrangement of cubes, the edge length, edge wall, and wall thickness of each cube are the same, and the elastic modulus and yield strength expression of the foam material are given by this model. In order to more realistically simulate the cell structure of actual aluminum foam, the basic unit shape of this representative model has also been gradually improved. Representative models of closed-cell aluminum foam have successively developed such ideal models as the Kalman model (tetrahedral model) [20, 25, 26], octahedral model [27], more complex cube to pyramid model [28], cube to sphere model [28, 29], all of which use uniform pores, cell walls, and prisms. The main drawback of this method is that it cannot reflect the randomness of the microstructure of aluminum foam. The second type of method considers the randomness of the microstructure of aluminum foam on this basis and generates a cell structure to simulate the pore structure of aluminum foam by certain rules. Many scholars [19, 31, 32] proposed a three-dimensional Voronoi algorithm technology to establish foam three-dimensional mesoscopic model of aluminum. This model can reflect the mesomechanical properties of aluminum foam more realistically, and it has great significance for the study of its energy dissipation mechanism and deformation mode. However, most of the hole walls use shell elements, and their thickness is the same at any position, which is obviously not consistent with the experimental observation results. The third type of method is to perform three-dimensional reconstruction based on the CT scan image of the material to obtain the mesofinite element model [3], which can truly restore the mesoscopic structural characteristics of aluminum foam. However, the number of finite element model elements obtained by this method is huge, and the calculation cost is far more than the previous two methods. In order to more realistically simulate the deformation and failure process of aluminum foam under external load, it is necessary to establish a cell wall model of aluminum foam in line with the actual situation to study the mechanical properties of aluminum foam. Fang et al. [33, 34] used a three-dimensional random polyhedron model algorithm to simulate foam metal materials. The pores were simulated using three-dimensional random convex polyhedrons. At the same time, a random control algorithm for wall thickness was proposed to achieve random distribution

of pores and wall thickness but also increased the calculation of the amount. It is difficult to increase the porosity by a large margin, and there is no real explosive simulation.

In this paper, on the basis of the Voronoi algorithm, the process of random pore size and cell wall thickness is realized by self-programming. A closed-cell aluminum foams modeling method based on a three-dimensional mesomodel is proposed. This method greatly improves the calculation efficiency and shortens the calculation time. At the same time, the sandwich structure of the aluminum foam is designed, and the correctness of the three-dimensional micromodel of aluminum foam is verified by experiments. On the basis of the established finite element model of real structure, the deformation mode, energy absorption effect, and attenuation mechanism of explosion shock wave of aluminum foam sandwich structure were studied, and the wave attenuation law of aluminum foam to explosion loads with different porosities was obtained. These experimental results can provide a theoretical basis for the design of the weight reduction device.

## 2. Mesoscopic Model Setup

The microstructure of closed-cell foam aluminum has a large number of randomly distributed closed cells. In this chapter, we consider the cells in the foam, give the generation algorithm of the closed-cell foam aluminum three-dimensional model, and establish the three-dimensional mesoscopic model of the aluminum foam. The algorithm consists of three steps. The first is the generation of random polyhedron particles. The pores of aluminum foam are regarded as random polyhedral particles. Based on the Voronoi algorithm, ABAQUS is used to model the random polyhedrons and extract their geometric features. The second is to comprehensively use the Python language and Fortran language to write a three-dimensional random aluminum pore size and random wall thickness foam aluminum generation algorithm, so that the aluminum foam cell wall thickness is random, through the TrueGrid software reading algorithm, the establishment of random polyhedron particles, and random wall thickness grid model. The third is to import the mesh model into the LS-DYNA software, random polyhedron particle part of pore cell is removed, generate a foam aluminum model, and then build an explosion model of the foam aluminum sandwich panel.

*2.1. Describe the Randomness of Pore Size and Cell Wall Thickness.* The closed-cell foam metal is composed of a large number of randomly distributed closed cells and cell walls. The pore size is generally 0.5–4 mm, and the cell wall thickness is about 0.05–2 mm. The cell pore size and cell wall thickness are randomly distributed. Metal foams exhibit typical heterogeneity derived from the microstructure of the cell wall.

In this paper, the foam aluminum model algorithm is based on the Voronoi algorithm, using the Python language and Fortran language comprehensively. According to the

mesostructure characteristics of aluminum foam, the modeling method of complex polyhedron is partially improved to Voronoi algorithm. Consider randomness. It not only realizes the randomness of the pore size of the aluminum foam but also realizes the randomness of the wall thickness, so it is a more realistic mesoscopic model of the aluminum foam. The generation of cell walls and particles is shown in Figure 1:

According to the Voronoi algorithm, the discrete data points are reasonably connected to construct a Delaunay triangle network, and then the vertical bisectors of the line segments of two adjacent points are connected to form a Tyson polygon [34], as shown in the figure. Each vertex of the Tyson polygon is the circumscribed circle center of the adjacent triangle. The Tyson polygon is regarded as the pores of two-dimensional aluminum foam. By adjusting the number of polygons, the polygonal pore diameter is controlled within 1–3 mm, and the average pore diameter is 2 mm. Using the Python language and Fortran language comprehensively, a random algorithm of random cell wall thickness is written to obtain the cell wall as shown in Figure 1(b), and the size of the pore size is finely adjusted by the cell wall thickness. At this point, the geometric model of the two-dimensional aluminum foam and the cell wall is generated. After the algorithm is improved, it can be programmed with shorter sentences, which is highly executable, shortens the modeling running time, and generates models quickly.

Then, the two-dimensional model is extended to the three-dimensional cube domain, random polyhedrons are generated in the cubes of arbitrary shape and structure as shown in Figure 2, random thickness is given to any geometric surface by random algorithm, then the random thickness of the cell wall the value range is 0.03~0.4 mm, and the random function of the cell wall is as follows:

$$T_d = T_{\max} - (T_{\max} - T_{\min}) \times \zeta_{\text{random}}, \quad (1)$$

where  $T_d$  is the cell wall thickness,  $T_{\min}$  and  $T_{\max}$  are the minimum and maximum cell wall thickness,  $\zeta_{\text{random}}$  is the random distribution function of the cell wall thickness, and the value range is 0~1. A suitable foam cell mesoscopic model should take into account the randomness of non-uniformity, pore size, and cell wall thickness.  $T_{\min}$  and  $T_{\max}$  were taken as 0.03 and 0.4 mm, respectively, until the cell wall thickness satisfies 0.03~0.4 mm to stop the regeneration of random polyhedron and finally get the three-dimensional polyhedron geometric model of Figure 2(b). Compared with other algorithms, this algorithm can effectively shorten the modeling time and improve the calculation efficiency and ensure the randomness of the cell wall and pore size.

**2.2. Generation of Grid.** Use TrueGrid software to read in the random pores and random cell wall foam aluminum algorithm, extract geometric features, and use the mapping grid method to build a grid model of random polyhedral particles and random wall thickness. Aiming at the characteristics of the pore delivery area of the closed-cell foam aluminum mesomodel, a structured grid is divided, and the

characteristic size of the unit is determined according to the pore diameter and wall thickness. In order to take into account both the computational efficiency and the accuracy of the simulation, this paper takes the feature size of the cell as the grid size is set to 0.2 mm. The regular cell distribution characteristics ensure the calculation efficiency of the subsequent material judgment and are conducive to programming. A spatial eight-node hexahedral unit is used to divide the overall delivery area into a uniform grid to obtain a regular initial grid structure. A fine and uniform grid improves computational efficiency while ensuring accuracy. First build a cube model that surrounds the cylinder, as shown in Figure 3(a); then fill the extracted geometric features in Figure 3(a) to get Figure 3(b); according to the position of the grid in the sample, determine the material properties of the grid; when all nodes of the element are located in a random polyhedron, the material property is set to pore; otherwise, it is defined as aluminum material. Then perform cylindrical cutting to delete the aluminum foam model outside the cylinder, and the remaining part is shown in Figure 3(c); and then propose removing the particle model part and obtaining the mesh model of the foam aluminum as shown in Figure 3(d), the output grid file, the three-dimensional view of aluminum foam is shown in Figure 3(e). To facilitate the observation of the internal structure of aluminum foam, a quarter model is intercepted, as shown in Figure 3(f).

**2.3. Modeling of Aluminum Foam Sandwich Structure.** Use TrueGrid software to establish the air grid model and fill the air grid with explosives and the explosive and the air grid share nodes; use SCDM software to establish the geometric model of the sleeve, cover plate, and bottom plate; divide and export the  $K$  files of all fluid and solid grids; assemble the grids in the LS-PrePost software together with the  $K$  files of the aluminum foam; and finally obtain the model and  $K$  file of the aluminum foam sandwich structure. The quarter model and dimensions are shown in Figure 4. The size of the air domain is 0.82 m × 0.42 m × 0.4 mm, the radius of the explosive is 0.043 m, the thickness of the cover plate is 0.01 m, and the thickness of the bottom plate is 0.02 m.

Add a nonreflective boundary condition on the outer surface of the air layer, the bottom of the bottom plate is set as a fixed boundary, the cover plate and the bottom plate are bound and connected, \*CONTACT\_TIED\_SURFACE\_TO\_SURFACE, the cover plate and the aluminum foam, and the aluminum foam and the bottom plate take automatic surface-to-surface contact \*CONTACT\_AUTOMATIC\_SURFACE\_TO\_SURFACE.

In order to accurately analyze the nonlinear behavior of the foam aluminum sandwich panel under strong dynamic load, the system bottom plate, sleeve, bracket, and end cover are Q235 steel. The above materials and foam aluminum are all used in the PLASTIC KINEMATIC material model of LS-DYNA. The metal materials were numerically simulated. The calculation parameters of metal materials are shown in Table 1.

The air uses the \*MAT\_NULL material model, and the equation of state is described using \*EOS\_LINEAR\_

FIGURE 3: Continued.

FIGURE 3: Finite element model generation of aluminum foam.

TABLE 1: Metal material parameters.

| Metallic material  | $Q$ (kg/m <sup>3</sup> ) | $E$ (GPa) | $I$   | SIGY (MPa) | ETAN (GPa) |
|--------------------|--------------------------|-----------|-------|------------|------------|
| Q235 steel [35]    | 7830                     | 210       | 0.274 | 235        | 6.1        |
| Aluminum foam [33] | 2730                     | 70        | 0.34  | 185        | 4.62       |

POLYNOMIAL. The expression of the equation of state is as follows:

$$p = C_0 + C_1\mu + C_2\mu^2 + C_3\mu^3 + (C_4 + C_5\mu + C_6\mu^2)E,$$

$$\mu = \frac{1}{V} - 1 = \frac{\rho}{\rho_0} - 1, \quad (2)$$

$$C_4 = C_5 = \gamma - 1.$$

Considering air as a gas in an ideal state, the coefficients of the polynomial equation  $C_0 = C_1 = C_2 = C_3 = C_6 = 0$ . The variable coefficient  $\gamma$  is often set to 1.4, so  $C_4 = C_5 = 0.4$ .  $E_0$ ,  $\rho_0$ , and  $V_0$  which are the initial energy density, initial density, and initial relative volume parameter values are 1.29 g·cm<sup>-3</sup>, 0.25 MPa, and 1.0. The parameters are shown in Table 2.

The high-energy combustion explosives use \*MAT\_HIGH\_EXPLOSIVE\_BURN material model, and the equation of state uses \*EOS\_JWL to represent the pressure of the explosive product. The expression of the equation of state is as follows:

$$p = A \left( 1 - \frac{\omega}{R_1 V} \right) e^{-R_1 V} + B \left( 1 - \frac{\omega}{R_2 V} \right) e^{-R_2 V} + \frac{\omega E}{V}, \quad (3)$$

TABLE 2: Air material parameters [22].

| -0.1        | 0     | 0     | 0     | 0.4   | 0.4   | 0     | 1.225                       |

where  $E$  and  $V$  are energy density and relative volume, respectively, and the initial values should be assigned to  $E_0$ ;  $V_0$ ,  $A$ ,  $B$ , and  $E_0$  are pressure units; and  $R_1$ ,  $R_2$ , OMEG, and  $V_0$  are dimensionless. The specific material parameters are shown in Table 3.

And use the ALE algorithm to solve \*CONTROL\_ALE, the explosive and air form an Euler multimatter group (\*ALE\_MULTI-MATERIAL\_GROUP), and the fluid domain and solid domain are set by fluid-solid coupling (\*CONSTRAINED\_LAGRANGE\_IN\_SOLID). Finally submit ANSYS/LS-DYNA for solution.

In the geometric nonlinear analysis of explosion impact, the material often deforms greatly. In order to better fit the changing shape of the aluminum foam cell wall under real conditions, the material erosion method is often used to deal with the distorted unit. When the stress or strain reaches the erosion failure condition, we consider this element to fail and remove it from the model. The failure criterion of

FIGURE 4: Sandwich plate model.

aluminum foam adopts the maximum strain failure criterion. According to the research results, the maximum failure strain of aluminum foam in this paper is 0.37 [37].

### 3. Validation

**3.1. Strain Results Verification.** The antiexplosion performance of the foam aluminum sandwich board was studied. All tests were conducted in the structure in Figure 5. Figure 5 is the sandwich test device. The cover plate and the bottom plate are Q235 steel with a radius of 70 mm, the thickness of the cover plate is 10 mm, and the bottom plate thickness is 20 mm. The size of aluminum foam is  $\Phi 78$  mm  $\times$  H78 mm, and the porosity of aluminum foam is 80%, 85%, and 90%. Each explosion impact test uses the same loading conditions; choose 520 g TNT suspended 250 mm above the center of the cover. The shock wave generated after the charge explodes acts on the cover plate and transmits and compresses the aluminum foam through the cover plate.

Set three strain measurement points on the bottom surface of the bottom plate. Strain gauge S1 is located at the center of the bottom surface of the bottom plate. Strain gauges S2 and S3 are any points on the circle 4.9 cm and 7.7 cm away from the measurement point of S1. The deformation of the bottom plate at 4.9 cm and 7.7 cm from the measuring point of the center S1 can explore the relationship between the distance and the precursor wave of the explosion. The arrangement of strain gauges is shown in Figure 6.

FIGURE 5: Sandwich plate antiexplosion test device.

As shown in Figure 7, the strain response time-history curve test results of the bottom plate under three porosities are shown. It can be seen from the figure that the strain waveform of the bottom plate under the three porosities has similar regular characteristics, and the strain reaches the maximum value in the first cycle of the response, and the duration of the first response cycle is about 2.5 ms. After the first cycle, the deformation of the bottom plate gradually decreases; the peak strain value from the S1 to S3 points decreases with the increase of the propagation distance. With the increase of porosity, the maximum peak value of the strain at each measurement point has increased. The increase of strain of 80%–85% is lower than 85%–90%, indicating that the porosity increases to a certain level, due to the explosion load. The fluid-solid coupling effect with the sandwich structure is enhanced, and the energy absorption effect of the aluminum foam is increased, resulting in increased strain.

Figure 8 shows the simulation results of the maximum effective strain time-history curve at each measuring point on the bottom surface of the bottom plate under three porosities. From the figure, the simulation results of the strain time-history curve are consistent with the test results. Under the three porosities, the time interval for the wave head to reach each aluminum foam plate increases slowly. The wave speed of the elastic precursor decreases with the increase of the propagation distance. The strain value at the S1 measuring point is the largest, and the vertical distance from the burst center increases. Largely, the strain value of the measuring points of S2 and S3 keeps decreasing, and the waveforms of the three measuring points are similar to S1. As the porosity increases, the strain value at each measuring point increases, indicating that as the porosity increases, the aluminum foam effectively shares the explosive load and plays the role of antiexplosion and wave elimination, which reduces the deformation of the bottom plate. Further research on the design of explosive vessels provides a theoretical basis.

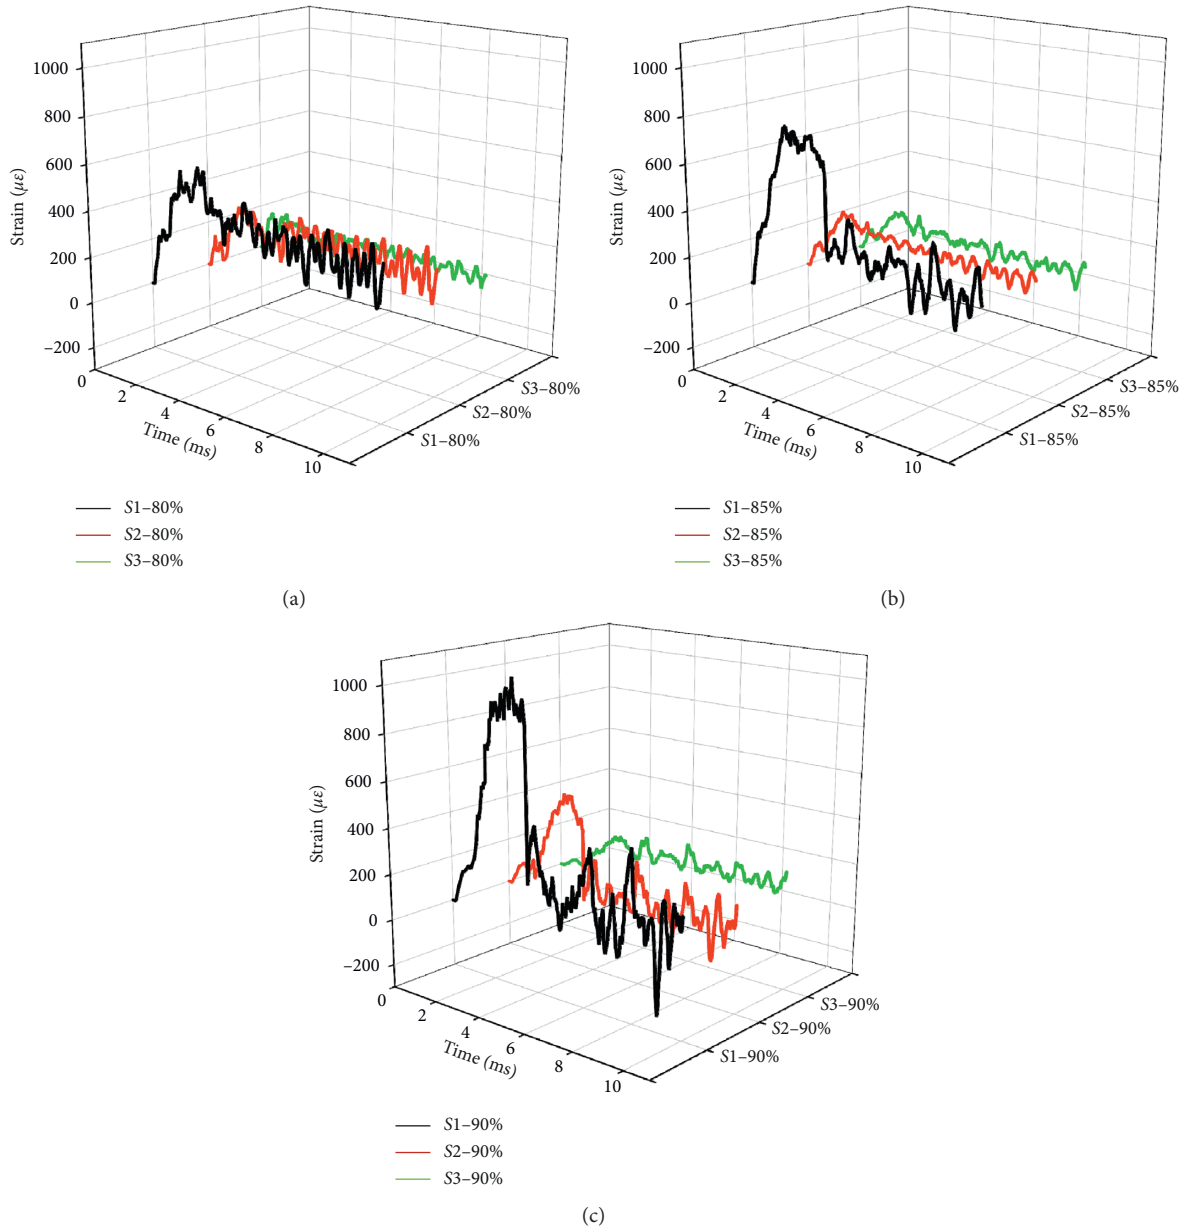

FIGURE 8: Strain time-history curve of each measuring point under different porosity under simulation. (a) 80%. (b) 85%. (c) 90%.

Figure 9 is a comparison chart of the numerical simulation results and test results of the peak strain values of the three groups of porosity aluminum foam under the explosive shock wave of the charge. In order to quantitatively describe the difference between the test and the numerical simulation, the numerical simulation results of the strain at each measuring point of the bottom plate are taken as the  $x$ -axis, and the test results are taken as the  $y$ -axis, and Figure 9 is drawn. The line with a slope of 1 in the figure indicates that the numerical simulation results are completely consistent with the test results. When the test point falls below the straight line, it means that the measured strain given by the numerical simulation is greater than the test value; when the test point falls above the straight line, it indicates that the peak value of strain at each measuring point calculated by

numerical simulation is smaller than the test value. It can be intuitively seen from Figure 9 that the test points basically fall between the solid line with a slope of 1 and the broken line with a slope of 0.90 and 1.1, and the error is within 10%. The numerical simulation results of the strain values at different measuring points under different porosities are in good agreement with the experimental results, indicating that the simulation results are good and verify the correctness of the three-dimensional mesoscopic model of aluminum foam.

*3.2. Comparison of Structural Forms.* Figure 10 is the internal structure of aluminum foam, Figure 10(a) is the macrostructure of aluminum foam in its natural state, Figure 10(b) is the morphology of 85% aluminum foam after electron

FIGURE 9: Comparison graph of numerical simulation and test results.

FIGURE 10: The real structure and numerical simulation structure of aluminum foam.

microscopy, and Figure 10(c) is a three-dimensional mesomodel, modeling 85% porosity aluminum foam structure. In order to verify the reliability of the structural form of the model, three slices were taken in the established three-dimensional mesomodel, the number of cell units and air units were counted, and the porosity of each slice was calculated and compared with the porosity of real aluminum foam. For comparison, the results are shown in Figure 11. It can be seen from the figure that the porosity of different slices in the

model is in good agreement with the real aluminum foam structure, with a maximum difference of 4.42%. The comprehensive strain comparison finally concluded that the agreement between the numerical simulation and the test can reach more than 91.4%. It shows that the established model can accurately express the mesoscopic structural characteristics of aluminum foam, and the modeling results are reliable. It can be observed that the structure with greater porosity has thicker cell walls.

FIGURE 11: Comparison of different sections of the model with the real structure.

## 4. Analysis of Mesoresults

**4.1. Analysis of Aluminum Foam Movement Process under Blast Loading.** This section explores the movement of an aluminum foam sandwich panel with a porosity of 80% under explosive load.

In the first stage, the explosive center detonated until the shock wave reached the cover and began to compress the aluminum foam. As shown in Figure 12, at 0 ms, the explosive performs a single-point center detonation, and the shock wave front starts to expand outwards with the sphere as the center and reaches the cover plate at a certain time between 0.07 ms and 0.08 ms. At a certain speed, the aluminum foam is compressed downward, as shown in the pressure cloud diagram of the aluminum foam on the right side of Figure 12.

Figure 13 shows the process of compressing aluminum foam after the plane spherical wave reaches the cover. At 0.08 ms, the stress wave starts to propagate in the aluminum foam. At 0.09 ms, the stress wave has propagated to the bottom of the aluminum foam and transmitted the stress wave to the bottom plate, and the bottom plate has undergone a stress change. Subsequently, the foamed aluminum experienced significant plastic strain, and the cell walls began to deform and break down. At 0.429 ms, the deformation of the hole wall reached saturation, and the hole wall collapsed and destroyed. At 1.4 ms, the foam aluminum stops deforming, and the entire compression process of the aluminum foam is initially completed.

In order to explore the antiexplosion and wave attenuation capabilities of aluminum foam, we have quantitatively analyzed the attenuation effect of the stress wave strength of the aluminum foam sandwich structure through the three-dimensional mesoscopic model of the aluminum foam, taking the first layer of aluminum foam at different porosities. The average stress of the element is taken as  $\sigma_1$ , and the stress value of the foam aluminum introduced into the cover plate is obtained. The average stress of the uppermost unit of the bottom plate is taken as  $\sigma_2$ , and the stress value of the bottom plate after the explosion wave passes through the aluminum foam is obtained. The distribution of stress waves in the sandwich structure is shown in Figure 14. In the initial stage, stress concentration occurs in local weak areas, the cell walls are in an elastic state, and the stress level rises rapidly with strain. Intuitively, the stress value of 80% porosity aluminum foam in Figure 14(a) reaches 184.34 MPa at 0.4 ms, and the stress wave intensity at the bottom of the bottom plate after passing the aluminum foam is 2.45 MPa.

It can be seen that the blast shock wave decays up to 98.67% after passing through the foamed aluminum. As shown in Figure 14(b), when the porosity of the aluminum foam upper layer is 85%, the stress value reaches 147.35 MPa at 0.384 ms, and the stress wave intensity at the bottom of the bottom plate after passing the aluminum foam is 1.61 MPa. It can be seen that the blast shock wave attenuation is as high as 98.91% after passing through the aluminum foam. As shown in Figure 14(c), when the porosity of the aluminum foam upper layer is 90%, the stress value reaches 86.03 MPa at 0.149 ms, and the stress wave strength at the bottom of the bottom plate after passing the aluminum foam is 4.09 MPa. It can be seen that the explosion shock wave attenuation is as high as 95.25% after passing through the aluminum foam.

It can be concluded that as the porosity increases, the stress value of the cover plate transmitted to the aluminum foam decreases significantly, but the stress value of the bottom plate increases first as the porosity decreases.

The relationship between the foam aluminum with different porosities and the wave elimination rate is shown. As shown in Figure 15, the wave elimination ability of aluminum foam does not increase with the increase of porosity, but there is an extreme value. Probably between 83% and 84% porosity, before reaching the threshold, its antiknocking ability will increase with the increase of porosity, but after reaching the threshold, its antiknocking ability will decrease with the increase of porosity.

**4.2. Mechanism Analysis.** Figure 16 shows the effective plastic strain of the foam aluminum cell wall under the blast load. It can be seen that, at 80% porosity, the deformation is concentrated in local weak areas, and the cell walls are in an elastic state. When the porosity becomes 85%, the cell wall breaks. The cell wall deformation indicates that plastic strain consumes a lot of energy under dynamic load. As the deformation further increases, the local plastic deformation of the unit increases rapidly, and the stress reaches the bearing capacity and breaks, resulting in the generation of some weak surfaces and the formation of a single failure penetration area. As the porosity increases, the aluminum foam has stress concentration, the cell wall collapses, the plastic strain of the aluminum foam cell wall mainly occurs in the upper region, and the lower part of the aluminum foam collapses and compacts.

To explore the mechanism, we conducted an electron microscopy scan of the aluminum foam to explore its microscopic properties. Figure 17(a) shows the typical failure

FIGURE 12: Explosion shock wave reaches the cover plate and begins to compress the aluminum foam.

FIGURE 13: Cloud image of foam aluminum compression process.

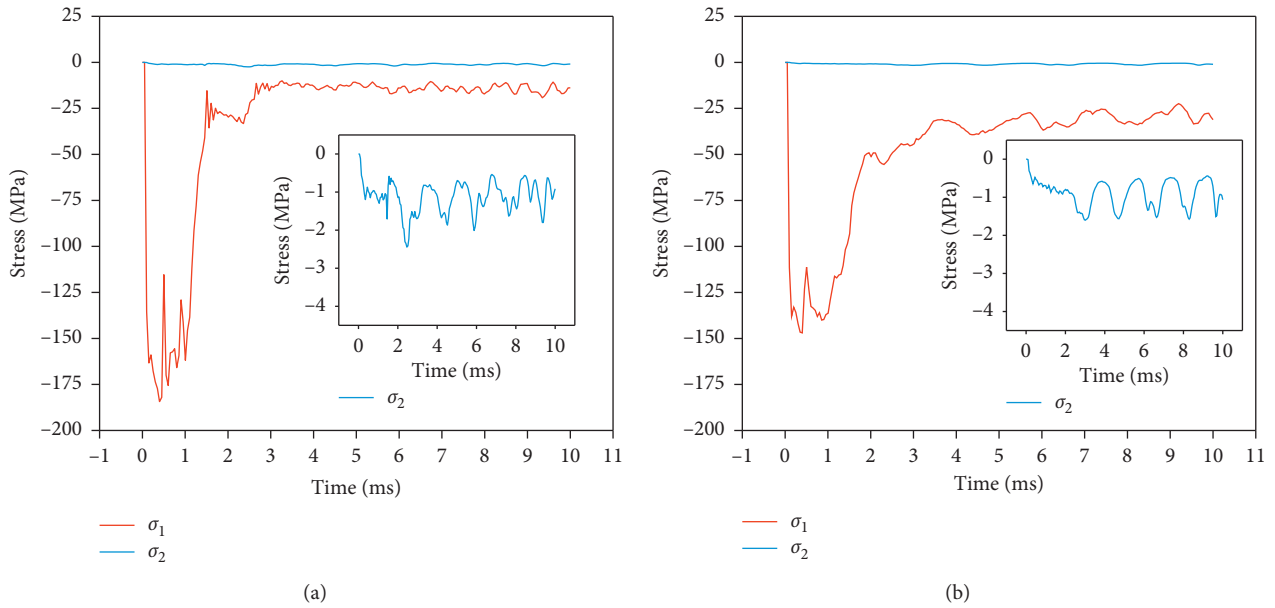

FIGURE 14: Continued.

FIGURE 15: Wave elimination rate curve of aluminum foam under different porosity.

mode of aluminum foam after 85% of the sandwich structure is subjected to explosion impact. According to the results of electron microscope scanning (SEM) experiments (b-e), the microscopic morphological changes of the cells and cell walls of aluminum foam were demonstrated. Figure 16(b) shows the original state of the aluminum foam cell wall. Under the blast load, both the cover and the panel in the sandwich structure undergo large plastic deformation, and the obvious “X”-shaped failure zone appears in the aluminum foam material. According to the scanning electron microscopy results, the deformation of aluminum foam can be divided into four areas: area I, elastic deformation area, the cell structure has not changed significantly as shown in Figure 17(b); area II, the cell wall has undergone significant plastic deformation as shown in Figure 17(c); area III, the cell wall breaks and the structure is destroyed as shown in Figure 17(d); area IV, the cell wall begins to collapse and is gradually compacted as shown in Figure 17(e).

Figure 18 shows the microscopic morphology of aluminum foam under different porosity after explosion. To

ensure the single variability, the center position of aluminum foam under different porosity was selected for electron microscopy scanning. It can be seen from the figure that, with the increase of porosity, the complete pores in the aluminum foam decrease; when the porosity is 85%, the collapse of the pores in the aluminum foam is obvious, the complete pores are almost absent, and the pores are compressed. At% porosity, no complete pores can be seen inside the foam aluminum, and the degree of pore compression is significantly higher than that of the foam aluminum at 85% porosity. It can be seen that the increase in porosity will change the microstructure of aluminum foam. The greater the porosity, the deeper the degree of pore damage.

When subjected to an impact load, aluminum foam is extremely susceptible to deformation. Because aluminum foam is a porous structure, transmission and reflection occur during the propagation of an explosion wave, so there is more reflection, and a part of energy is well converted into internal energy and kinetic energy. Through the study of the mesoscopic model of aluminum foam cell walls, it is found

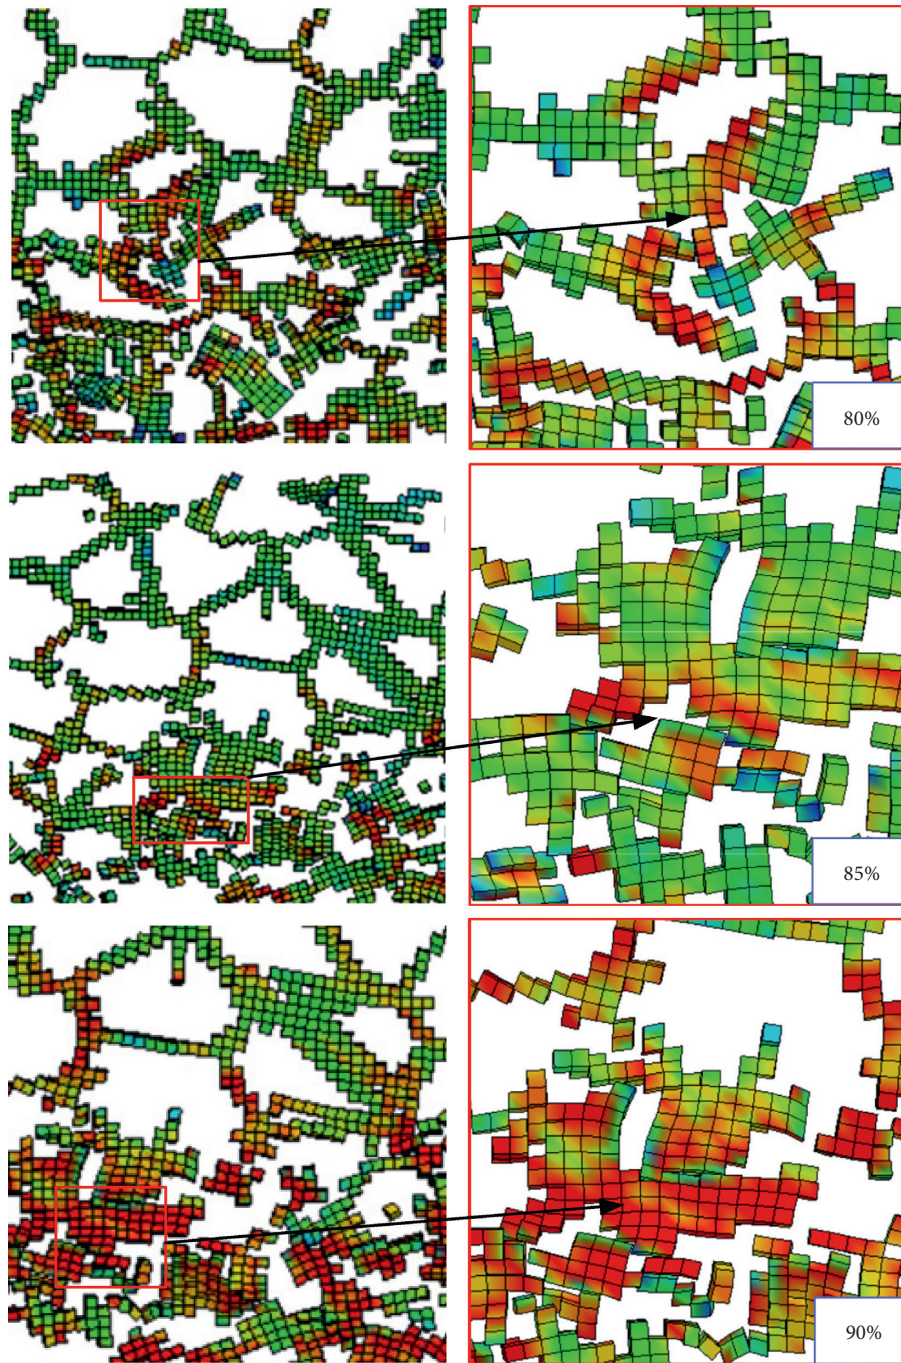

FIGURE 16: Cell wall collapse and rupture.

that the energy absorption of aluminum foam mainly consumes energy through various forms such as crushing, deformation, fracture, and mutual friction of the pore walls of the aluminum foam, so as to achieve the effect of energy absorption. When the porosity is increased to about 85%, the energy absorption effect of aluminum foam is saturated, and the porosity continues to increase so that the aluminum foam is compacted to produce stress enhancement, so the load pressure on the bottom plate increases instead. Under a certain explosion load, the explosion stress wave transmits and propagates through the solid medium of the cell wall or

between the bubbles and the solid. Due to the structural characteristics of random cell generation of aluminum foam, stress waves propagate in the constantly changing solid medium and the interference of reflection and transmission in the bubbles rapidly attenuates. When the stress wave peak is greater than the cell wall strength, deformation and destruction occur. As the propagation distance increases, the stress wave peak decreases and the amount of deformation also weakens until elastic deformation occurs. Therefore, the antiexplosion performance of foamed aluminum is directly related to the cell wall thickness and the size of bubbles.

FIGURE 17: Wave elimination rate curve of aluminum foam under different porosity.

FIGURE 18: Microstructure of aluminum foam under different porosities.

Under a certain load, the contribution of the two to anti-explosion will also change. For example, after the porosity reaches the extreme value of 83%-84%, the deformation energy absorption of the cell wall is more obvious than that of the bubble. The cell wall thickness of 85% aluminum foam is greater than 90%.

## 5. Conclusion

In this paper, the explosive impact test was carried out under the explosive quantity of 520 g and the explosion height of 25 cm. The attenuation law of stress wave in the aluminum foam sandwich plate was studied, and the strain response characteristics of the bottom plate were analyzed. In

addition, a three-dimensional mesomodel for the finite element analysis of aluminum foam is established. On the basis of the three-dimensional micromechanical model, the influence of the micromechanical structure (porosity) of aluminum foam is considered, and the performance of aluminum foam under the blast impact load is studied. The following conclusions can be drawn:

- (1) Based on the Voronoi algorithm, firstly, the 2-random polyhedron model is established by using ABAQUS, and its geometric features are extracted. Then, by using Python language and Fortran language synthetically, the algorithm of generating aluminum foam with random pore size and wall thickness is written, and the grid model is established

by the algorithm read in by TrueGrid software. Finally, the part of the particles is removed to generate the aluminum foam model. Then, the energy absorption mechanism and porosity of the sandwich structure with aluminum foam core are explored under the action of explosion load, and the reliable results can be obtained, which are in good agreement with the test results.

- (2) Through the electron microscope test, it is found that the plastic strain is mainly concentrated in the upper region of aluminum foam under the action of explosion load, and there is an obvious “X” type failure zone in the material of aluminum foam. According to the SEM results, the deformation of aluminum foam is divided into four regions: elastic deformation region, plastic deformation region, cell wall fracture region, and collapse region.
- (3) Through the microscopic simulation of aluminum foam, it is found that the main reasons for aluminum foam antiknock are the deformation and destruction of the cell wall, the propagation of stress wave corresponding to the cell wall, the multiple reflections, and transmission of stress wave corresponding to bubble. Cell wall thickness and bubble size are some of the key parameters of antiknock performance.
- (4) Based on the simulation results, it is found that the porosity has a significant impact on the antiknock ability of aluminum foam, and the porosity has an extreme value of about 83% to 84% for antiknock ability. With the increase of porosity, the strain value of each measuring point of the bottom plate increases, which can absorb more energy, but it increases the energy transfer from the explosion load to the sandwich structure and makes the load amplitude acting on the bottom plate larger.

Equipped with two power sources, the dual-driving powertrain system for pure electric vehicles has a driving mode different from traditional electric vehicles. Under the premise that the structural form of the transmission system remains unchanged, the following transmission schemes can be adopted for double drive electric vehicles according to the demand power: the main and auxiliary electric transmission scheme (two motors are driven separately with dual-motor coupling drive), the transmission scheme in which the two motors always maintain coupling drive, and the speed-regulating type electric transmission scheme (the main motor is always responsible for driving, and the auxiliary motor is responsible for speed regulation). Therefore, a significant difference exists in the design methods of the power transmission system of double drive electric vehicles and existing vehicles. As for such differences, this paper adopts intelligent algorithm to design the parameters of the transmission system and introduces the genetic algorithm into the optimization design of parameters to obtain the optimal vital parameters of the power transmission system based on computer simulation. The prototype car used in this paper is a self-owned brand car; MATLAB/Simulink platform is used to build the vehicle simulation model, which is used for the computer simulation analysis of the vehicle dynamic performance and economy. It can be seen from the analysis result that the system parameters obtained by using the global optimization method proposed in this study can improve the vehicle dynamic performance and economic performance to varying degrees, which proves the efficiency and feasibility of the optimization method.

## 1. Introduction

The rapid development and popularization of pure electric vehicles cannot be realized due to their high price, imperfect charging facilities, and low driving mileage. Although the problems of high cost and incomplete charging facilities have been improved to some extent due to the relevant policies of the government and the electric vehicle technology has also achieved significant development, the critical problem which hinders the development of pure electric vehicles, namely, “how to further improve the vehicle driving mileage,” still exists. The driving mileage depends on

battery technology (to improve battery power density and energy density); also, it is closely related to other factors, such as the configuration, parameter matching, and control method of the power transmission system [1–3]. Therefore, the key to improving the driving mileage and overall performance of pure electric vehicles lie in the efficient transmission system and its design method and the perfect energy control method [4–6].

Professor Zhao adopted genetic algorithm to conduct the optimization design by computer simulation of parameters for the power transmission system of a pure electric vehicle. The dynamic performance index was used as a constraint,

and the weighting coefficient was used to transform the multiobjective optimization of driving mileage and vehicle mass into a single-objective optimization problem. The results were compared with the results obtained by the traditional optimization method. It could be seen from the comparison results that the optimization method could achieve the optimization design in an effective way [7–11]. Professor Zhou adopted two matching optimization methods (minimal kerb mass and global optimization methods) to optimize the power system parameters of the target vehicle and conducted the simulation comparison and verification of the vehicle dynamic performance and economic performance for the optimization matching effects. It could be seen from the results that the global optimization method was a more effective method, which could fully reflect the potential of parameter optimization matching of the power system in improving the vehicle performance [12]. Sornioti et al. and other scholars used the configuration of single-motor pure electric vehicle proposed by them as the basis to carry out the optimal matching calculation of transmission system parameters. They designed the parameters for two-gear transmission and compared them with those of continuously variable transmission vehicles. The results proved that the optimal matching scheme was feasible and effective [13]. Professor Zhu and other scholars adopted the method of orthogonal optimization design based on a cycle condition to carry out the optimizing calculation for the two-speed transmission ratio of pure electric vehicles. Through the simulation results, it could be seen that the dynamic performance could be significantly improved by the transmission system parameters optimized and matched by this method. Still, its economic performance had declined [14]. Professor Kowal and other scholars and Professor Spichartz and other scholars had established the optimization model for the parameter matching of power transmission system of electric vehicles and the control model for the dynamic response property of the power system, which have achieved excellent results [15, 16].

In this research, the new configuration of dual-driving powertrain system for pure electric vehicles is taken as the research goal. Based on the analysis of its working characteristics and working mode, the vehicle performance computer simulation platform is established, and the preliminary matching of power transmission system parameters is completed by computer simulation, to prove whether the initial matching is reasonable; to improve the vehicle performance, the multiobjective optimization function (including the dynamic index and economic index) is determined in this paper, and the genetic algorithm is used to optimize system parameters based on computer simulation.

## 2. Overall Structure and Working Principle of the Dual-Driving Powertrain System for Pure Electric Vehicles

The design goal of this paper is a new configuration of dual-driving powertrain system for pure electric vehicles based on

the planetary gear mechanism power coupling function. The engagement elements such as clutch and brake are used to achieve perfect working mode and the flexible switching between working modes, as shown in Figure 1.

The system consists of the following parts: one set of a single-row planetary gear mechanism, two motors (motor A; motor B), two wet brakes (B1; B2), and a wet clutch C; it outputs power through the planetary gear coupling device. The sun gear  $s$  of the single-row planetary gear mechanism is directly connected to the output shaft of motor B; the gear ring  $r$  is connected to the output shaft of motor A through the transmission gear  $d$ ; the planet carrier  $c$  is connected to the driving axle through gear  $e$  for power output; the gear ring  $r$  can be connected to the sun gear  $s$  through clutch C; the movable part of brake B1 is connected to the box, and the fixed part of brake B1 is fixed to the output shaft of motor A; the gear ring  $c$  can be braked through brake B1. The movable part of brake B2 is connected to the box, the fixed part of brake B2 is fixed to the output shaft of motor B, and the sun gear  $s$  can be braked by brake B2 [17].

The dual-driving powertrain system for pure electric vehicles belongs to the category of multipower source. In addition to being used as a mechanical power source to drive the vehicle, motor A and motor B can also be used as electric power sources, which can operate as a generator during braking. When the parking brake is required, all motors are closed, all brakes operate, and the clutch is disengaged, thus complying with the parking requirements of the vehicle; when the vehicle needs to be kept in neutral, double motors are closed, and then the brake and clutch are all disengaged; during the starting stage of the vehicle and when the vehicle is running at low- and medium-speed and small-load demands, motor A is driven separately, brake B2 operates, the sun gear is locked, and the power of motor A is input through the transmission gear and output through the planet carrier, thus realizing the small-speed ratio deceleration output and complying with the low and medium torque demands of the vehicle; when the vehicle is running at low-speed and large-load demands, motor B is driven separately, brake B1 operates, the transmission gear is locked, thus the gear ring is locked, and the power of motor B is input through the sun gear and then output through the planet carrier, thus realizing the large-speed ratio deceleration output and complying with the large torque demands of the vehicle; when the vehicle is running at high- and medium-speed and medium- and small-load demands, all brakes and clutches are disengaged, the planetary gear mechanism is unlocked, and the planetary mechanism is used to achieve the speed coupling between motor A and motor B, thus jointly driving the vehicle and realizing the continuously variable speed; when the vehicle is running at medium-speed and large-load demands, all brakes are disengaged, the clutch is engaged, the planetary gear mechanism is locked to form a entirety, and the torque coupling between motor A and motor B is realized to jointly drive the vehicle; during vehicle deceleration, the status of both brakes is controlled to determine whether the regenerative braking is performed by motor A or motor B. During the whole mode switching period, the motor can ensure that the sun gear or gear ring is

FIGURE 1: The diagrammatic sketch of dual-drive powertrain for pure electric vehicle.

subject to small resultant moment through zero-speed torque regulation and control. The motor regulation is fully utilized to realize the flexible mode switching, which is convenient for the brake and clutch disengagement or engagement and the reduction of the shift impact.

### 3. Parameter Matching Target and Scheme of Dual-Driving Powertrain System for Pure Electric Vehicles

The parameter design principles for the dual-driving powertrain system for pure electric vehicles are as follows: based on the parameters and the design performance indexes of the given vehicle model and under the premise of complying with the dynamic performance and driving mileage, the key parameters of the selected configuration and the performance indexes of the vehicle model studied in this paper are determined. See Table 1 for the vehicle performance index and vehicle parameters of the prototype vehicle.

After ensuring that the basic dynamic performance and economic performance (driving mileage) are met, this paper takes dynamic performance and economic performance as the dual objectives to carry out parameter optimization design, so as to select the key components of the power transmission system and determine the key characteristic parameters, including the drive system, the power battery system, and the power coupling system.

In this paper, the global optimization scheme is adopted, and the vehicle dynamic performance and energy consumption are taken as the dual optimization objectives. The basic dynamic performance and economic performance and the dynamic coupler characteristics are taken as the constraints. The optimization simulation platform integrating the vehicle numerical model and intelligent optimization algorithm is established. The key characteristic parameters of the power transmission system are used as optimization variables for comprehensive optimization. The key characteristic parameters of the power transmission system are optimized globally, and the optimization scheme is shown in Figure 2. The optimization scheme gives full play to the potential of the parameter matching of the power transmission system in the improvement of the vehicle performance to the greatest extent, as well as the potential of the new configuration of the dual-driving powertrain system for pure electric vehicles in energy saving [18, 19].

The impacts of various driving conditions on optimization effects are fully considered during the whole optimization process. If the optimization is based on a single driving condition, in general, the optimization results represent the optimal solution under that condition. However, if the vehicle is used for other working conditions, its adaptability may become worse and nonoptimal solution may appear. The multicondition parameter optimization method is used in this scheme, which has strong adaptability and fully considers the impacts of the efficiency characteristics of each component on the vehicle performance. In this research, intelligent optimization algorithm and continuous iterative calculation are used. Vehicle numerical model is used as the basis of performance evaluation. The optimization direction is guided, and the optimal parameter solution satisfying the requirements is searched through gradual iterations, thus achieving the global optimization design for the power transmission system parameters [20, 21].

### 4. Global Parameter Optimization of the Dual-Driving Powertrain System for Pure Electric Vehicles Based on Multiple Conditions

The parameters of the dual-driving powertrain system for pure electric vehicles are related to and affect each other. In this paper, the intelligent optimization algorithm is used to coordinate various impacts, and finally the most suitable global solution set is obtained. The parameter optimization design of dual-driving powertrain system for pure electric vehicles mainly includes the following processes: the determination of optimization objective function, the selection of optimization variables, the equation of constraint conditions, and the design of optimization algorithm.

*4.1. Efficiency Analysis of Dual-Driving Powertrain System Optimization and Processing of the Objective Function.* In this paper, the working characteristics of pure electric vehicles and the particularity of evaluation indexes are taken as research objectives; the vehicle dynamic performance and economic performance are considered. The acceleration time and driving mileage of the vehicle are taken as objective functions; the double-objective optimization function of dynamic performance and economic performance is established. The driving mileage of pure electric vehicles is improved to the largest extent on the premise of meeting the dynamic performance demand of the vehicle. In this paper, the acceleration time in 100 km is selected as the goal of dynamic performance optimization, and the driving mileage is selected as the goal of vehicle economic optimization [22].

*4.1.1. Dynamic Performance Objective Function.* The acceleration time in 100 km of the vehicle is shown as follows:  $fd_1$

TABLE 1: The performance indicators and parameter of pure electric vehicle.

|                              | Item  | Indicator  | Unit           |
|------------------------------|---|------------|----------------|
| Maximum speed                | Maximum speed                                 | $\geq 150$ | km/h           |
| Acceleration                 | 0~100 km/h acceleration time                  | $\leq 15$  | s              |
| Capability                   | 0~50 km/h acceleration time                   | $\leq 6$   | s              |
| Climbing ability             | Maximum gradient                              | $\geq 35$  | %              |
|                              | Maximum climbing speed                        | $\geq 15$  | km/h           |
| Endurance capacity           | Pure electric driving range (60 km/h)         | $\geq 150$ | km             |
|                              | Curb weight                                   | 1680       | kg             |
|                              | Windward area                                 | 2.275      | m <sup>2</sup> |
|                              | Drag coefficient                              | 0.3164     | —              |
| Prototype vehicle parameters | Rotation mass conversion coefficient $\delta$ | 1.04       | —              |
|                              | Wheel radius (dynamic)                        | 0.308      | m              |
|                              | Rolling resistance coefficient                | 0.00995    | —              |

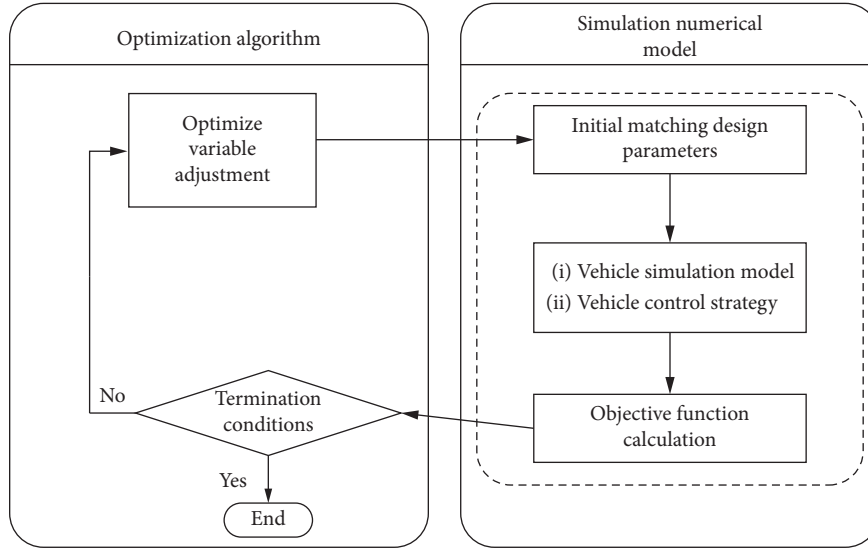

FIGURE 2: Schematic diagram of global optimization scheme.

$$t = \frac{1}{3.6} \int_0^{100} \frac{\delta m}{F_d - (mgf_r + (C_D A v^2 / 21.15))} dv, \quad (1)$$

where  $F_d$  is the maximum driving force of the vehicle.

When the vehicle speed is lower than that corresponding to the rated speed, the motor will achieve constant output at the maximum torque; when the vehicle speed is higher than that corresponding to the rated speed, the motor can achieve constant operation at the maximum power; the output torque is a function of the speed. Therefore, the maximum driving force of the vehicle is a subsection function of the vehicle speed corresponding to the rated speed, as shown in the following equation:

$$F_d = \begin{cases} \frac{3600P_{\text{sys max}}\eta_T}{v_m}, & v \leq v_m, \\ \frac{3600P_{\text{sys max}}\eta_T}{v}, & v > v_m, \end{cases} \quad (2)$$

where  $V_m$  is the vehicle speed corresponding to the rated speed of the drive system motor, in km/h.

Therefore, the dynamic performance objective function is as follows:

$$f_1(x) = t = \frac{\delta m}{3.6} \left( \int_0^{v_m} \frac{dv}{(3600P_{\text{sys max}}\eta_T/v_j) - (mgf_r + (C_D A v^2 / 21.15))} + \frac{1}{3.6} \int_{v_m}^{100} \frac{dv}{(3600P_{\text{sys max}}\eta_T/v) - (mgf_r + (C_D A v^2 / 21.15))} \right), \quad (3)$$

where  $x$  is vector composed of optimization parameters.

**4.1.2. Economic Performance Objective Function.** The average driving mileage of the fully charged vehicle under multiple cycle conditions is taken as the economic performance evaluation index in the paper, and the driving mileage under each working condition is subject to weighted average handling. Through the analysis in [17] it can be found that the driving mileage of the vehicle under single-cycle condition can be expressed by

$$L_i = \frac{Q_b \cdot U_b \cdot \text{DOD}}{1000 \cdot W_{\text{cyclei}}} \cdot s_i, \quad i = 1, 2, \dots, N, \quad (4)$$

where  $Q_b$  is capacity of power battery,  $U_b$  is total rated voltage,  $W_{\text{cyclei}}$  is the energy consumption of the vehicle when it operates under a certain cycle condition,  $S_i$  is driving mileage of vehicle under a certain cycle condition in km, and  $N$  is the number of cycle conditions.

Since the dynamic performance objective function  $f_1(x)$  represents the minimum acceleration time, it is necessary to take the reciprocal of the weighted average driving mileage, thus ensuring that it is consistent with the optimization direction of  $f_1(x)$ . At the same time, the condition weighting coefficient  $\varepsilon_i$  is introduced, which can control the weight of each condition in the process of optimization calculation,  $\sum \varepsilon_i = 1$ . Therefore, the objective function of multicondition economic performance is as follows:

$$f_2(x) = \frac{1}{\bar{L}} = \frac{1}{\sum_{i=1}^N \varepsilon_i L_i}, \quad (5)$$

where  $\bar{L}$  is average driving mileage under multiple working conditions and  $\varepsilon_i$  is working condition weighting coefficient.

**4.1.3. Transformation of Objective Function.** The multi-objective optimization problem is as follows:

$$\begin{cases} F(x) = \min[f_1(x), f_2(x), \dots, f_i(x)], & x \in \Omega, \\ dl \leq x \leq ul, \\ A_j * x = Aeq_j, \\ B_k * x \leq Beq_k. \end{cases} \quad (6)$$

In the process of solving multiobjective optimization problems, the subobjective functions may conflict with each other, and the performance improvement of one objective may reduce the performance of the other. Generally speaking, there is no absolute optimal solution which can achieve the optimization of all subobjective functions. The double-objective optimization (dynamic performance and economic performance) problem of pure electric vehicles is transformed into a single-objective optimization problem in this paper, which helps to obtain the solution and adjust the weight of each objective [23].

To transform the double-objective optimization problem of the vehicle into a single-objective optimization problem, in this paper, the above dynamic performance objective function  $f_1(x)$  and the economic performance objective

function  $f_2(x)$  are weighted and summed up [24], and the new optimization objective function is as follows:

$$f(x) = \delta_1 f_1(x) + \delta_2 f_2(x), \quad (7)$$

where  $\delta_1, \delta_2$  are weighting factor, which is greater than 0.

The weighing factor can be expressed by

$$\delta_j = \delta_{j1} \cdot \delta_{j2}, \quad j = 1, 2, \quad (8)$$

where  $\delta_{j1}$  is the subobjective weighing factor, which is used to characterize the importance of subobjectives in the process of optimization design, which is greater than zero and  $\delta_{11} + \delta_{21} = 1$ ;  $\delta_{j2}$  is a correction weighing factor, which is used to adjust the impacts of the difference in magnitude between subobjectives on the optimization calculation, which may be gradually corrected in the iterative calculation. In general, the reciprocal of the design objective is taken as the initial value. Note that  $\delta_j$  is a real number greater than zero.

**4.2. Selection of Optimization Variables.** The key parameters of the power system closely related to the vehicle performance are selected as optimization variables in this paper, namely, motor A rated power, motor A rated speed, motor B rated power, motor B rated speed, battery capacity, characteristic parameters of planetary gear, final ratio, and transmission ratio of motor A deceleration gear. The optimization variable vectors are as follows:

$$x = [P_{0A}, \omega_{0A}, P_{0B}, \omega_{0B}, Q_b, k, i_0, k_A]. \quad (9)$$

**4.3. Constraint Condition.** When setting the initial value of optimization variables and the boundary conditions of each variable, a variety of factors need to be considered comprehensively, such as the requirements of the basic performance of the vehicle, the cost of the vehicle, and the design experience. For the transmission system parameters, the principle that the components of the same system in mechanical design have similar service life shall be taken into account. In this paper, the boundary conditions of each variable are obtained after considering all influences, as shown in Table 2.

**4.4. Optimization Algorithm.** As the core of optimization calculation, optimization algorithm has a direct impact on the optimization convergence and the reliability of optimization results. Traditional optimization algorithms mainly include gradient method and steepest descent method. Such algorithms need accurate mathematical functions, as well as huge computing resources. As a computational model, genetic algorithm is based on the natural selection theory of Darwin's biological evolution theory and the biological evolution process of Mendel's genetic mechanism. It is composed of three parts (encoding and decoding, individual fitness evaluation, and genetic operation). The calculation model searches for the optimal solution complying with certain conditions by simulating the biological evolution process in nature, which is more suitable for the

TABLE 2: Optimal variable boundary condition.

| Optimization variable                                     | Initial value | Lower limit | Upper limit |
|---|---------------|-------------|-------------|
| Rated power of motor A (kW)                               | 10            | 5           | 36          |
| Rated speed of motor A (r/min)                            | 2800          | 2500        | 4000        |
| Rated power of motor B (kW)                               | 26            | 5           | 36          |
| Rated speed of motor B (r/min)                            | 3200          | 2500        | 4000        |
| Power battery capacity $Q_b$ (Ah)                         | 60            | 50          | 70          |
| Characteristic parameters of planetary gear mechanism $k$ | 3             | 1.5         | 5           |
| Final drive ratio $i_0$                                   | 2.32          | 1           | 7           |
| Motor A reduction gear ratio $k_A$                        | 6             | 1           | 8           |

optimization of iterative calculation [25, 26]. Therefore, genetic algorithm is used for the optimization design in this paper, and the optimization process is shown in Figure 3.

After repeated commissioning, the parameters for genetic algorithm are finally set as follows: the maximum evolution algebra is 80, the population size is 100, the elite number is 10, the proportion of cross offspring is 0.6, and the probability of mutation is 0.01. In addition, the rank sorting and decentralized cross function are adopted. Constrained adaptive mutation is used to achieve good convergence.

The whole optimization model includes the vehicle simulation model based on genetic algorithm toolbox in MATLAB/Simulink platform. Since the focuses of optimization calculation are the dynamic performance and economic performance, there is no need to consider the smoothness in the transient process of mode switching. Therefore, the control strategy based on logic threshold is used as the vehicle control strategy.

## 5. Global Parameter Optimization of the Dual-Drive Powertrain System for Pure Electric Vehicles Based on Multiple Conditions

In this paper, four typical conditions (NEDC, HWFET, WLTC, and CHCQ) are selected for the optimization calculation. NEDC and WLTC are usually used for regulatory testing, including low-speed and low-load condition and high-speed and high-load condition; HWFET represents high-speed and high-load condition and uniform load condition; CHCQ condition can reflect local driving characteristics. In this paper, the simulation optimization process designed above is used for the global optimization calculation of the dual-drive powertrain system for pure electric vehicles. After nearly 50 rounds of iterations, the objective function tends to be constant and the change trend is shown in Figure 4. The optimal fitness optimization variable vectors are as follows:

$$x = [12.13, 2896, 13.86, 2479, 57.71, 2.823, 4.136, 1.482]. \quad (10)$$

In view of the actual situation of the parameter design of the power transmission system, in this paper, some parameters of the dual-drive powertrain system for pure electric vehicles are rounded up, and the parameters before and after optimization are compared in Table 3.

It is found after comparing the data before and after optimization that, compared with the parameters initially

matched, the parameters after the global optimization through genetic algorithm have great changes in the following aspects: the power distribution, rated speed, and gear ratio of transmission system of the two motors. The motor power distribution is adjusted mainly based on the driving condition and the comprehensive efficiency of the driving system. If the weight of the economic target is changed, there will be some changes in the changing amplitude; the maximum speed and the gear ratio of transmission system are mainly based on the dynamic performance index (maximum vehicle speed, etc.). If the weight of dynamic performance target is changed, there will also be corresponding changes in the changing amplitude. There are no significant changes in the rated speed and the capacity of the power battery, only with a small range of changes, but the vehicle curb mass is reduced, which causes certain impacts on the dynamic performance and economic performance.

To verify whether the parameter optimization matching method of the dual-drive powertrain system for pure electric vehicles is effective, the parameters initially matched and parameters after optimization are, respectively, applied to the vehicle performance simulation platform for simulation, and its dynamic performance and economic performance are focuses of the simulation comparison. The changes in the parameters initially matched and parameters after optimization in the four typical conditions SOC are shown in Figure 5. It can be seen that the power battery SOC after optimization at the end of driving conditions is significantly higher than before, with a relatively slow change, indicating that the economic performance of parameters after optimization is significantly improved, and it can achieve more obvious energy-saving effect under high-speed conditions, indicating that the dual-drive powertrain system can improve the efficiency of driving system during high-speed cruise.

In this paper, parameters initially matched and parameters after optimization are calculated for dynamic performance, and Table 4 shows the comparison of simulation results. It can be seen from the table that the maximum vehicle speed has been increased by 9.06%, the acceleration time in 100 km has been shortened by 3.25%, and the maximum gradient has been increased by 6.33%.

In this paper, the parameters initially matched and parameters after optimization are applied to four typical conditions (NEDC, HWFET, WLTC, and CHCQ) to calculate the energy consumption and driving mileage of single cycle. The statistics and comparison of simulation results are

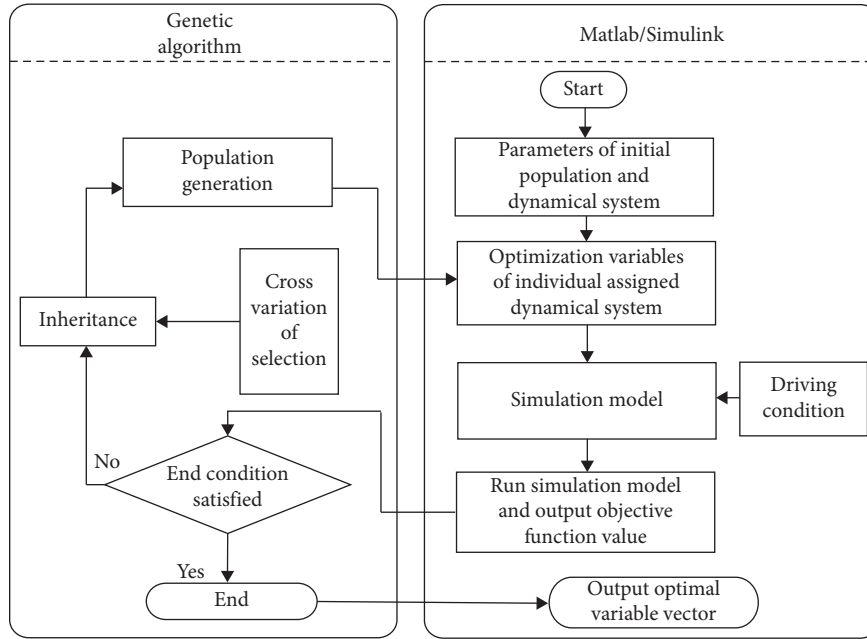

FIGURE 3: Genetic algorithms optimization flowchart.

FIGURE 4: Change trend chart of objective function.

TABLE 3: Comparison of powertrain parameters after optimization.

| Parts         | Item  | Before optimization | After optimization |
|---------------|---|---------------------|--------------------|
| Motor A       | Rated/peak power (kW)                                     | 10/20               | 12/24              |
|               | Rated/maximum speed (r/min)                               | 2800/8000           | 3000/8000          |
|               | Rated/maximum torque (N·m)                                | 34/68               | 38.2/76.4          |
| Motor B       | Rated/peak power (kW)                                     | 26/52               | 24/48              |
|               | Rated/maximum speed (r/min)                               | 3200/8000           | 2500/8000          |
|               | Rated/maximum torque (N·m)                                | 77.5/155            | 91.68/183.36       |
| Powertrain    | Characteristic parameters of planetary gear mechanism $k$ | 3.8                 | 2.823              |
|               | Motor A reduction gear ratio $k_A$                        | 1.8                 | 1.482              |
|               | Final drive ratio $i_0$                                   | 3.5                 | 4.136              |
| Power battery | Rated capacity (Ah)                                       | 60                  | 58                 |

shown in Table 5. It can be seen from the table that the HWFET condition shows the most obvious effect on the economic performance improvement, with an increased range of 9.2%, which once again shows that the efficiency improvement is the most obvious in the high-speed condition. At this moment, the dual-drive powertrain system is operating in the speed-coupling mode. The economic performance simulation results prove the correctness,

feasibility, and obvious energy-saving potential of the energy-saving mechanism of the dual-drive powertrain system above.

## 6. Conclusion

The parameter matching of the power transmission system for pure electric vehicles is the premise and basis for the

follow-up research on control methods. In this paper, with the focus on the parameter matching of the dual-drive powertrain system for pure electric vehicles, the numerical model of the dual-drive powertrain system is analyzed to establish the vehicle performance simulation platform. It can be found through the simulation results that the simulation platform can simulate the working process and performance of the vehicle in an accurate manner, which lays the foundation for the performance simulation of dual-drive powertrain system for pure electric vehicles and follow-up research on control methods, to improve the vehicle performance, a multiobjective optimization function (including dynamic performance and economic performance indexes) is established in this paper, and genetic algorithm is used for the optimization design of system parameters; then the parameters before and after optimization are calculated on the vehicle simulation platform. The calculation results show that both the vehicle dynamic performance and economic performance are improved in different degrees, proving that the optimization method is efficient and feasible.

Fashionable clothing is susceptible to seasonality, fashion popularity, and other factors. The decline in the fashion level for fashion apparel will cause its market value to continuously decrease, reducing market demand and creating a backlog of apparel inventory. Under such a circumstance, the apparel retailer chooses to maintain the fashion of the goods by providing experiential services or enhancing product design capabilities. This paper focuses on the discussions on the issue of whether experience service and design efforts are complements or substitutes. The major objective is to simultaneously determine the experience service investment and the optimal selling price to maximize the total profit. First, a Cobb–Douglas utility function is used to derive a demand function that depends on the price and fashion level. Four kinds of inventory models are further established to obtain optimal pricing and inventory ordering strategies. Second, an algorithm is presented to search for the optimal solutions of the proposed model. Finally, a numerical example is provided to perform a sensitivity analysis of the key parameters and to discuss specific managerial insights. The numerical examples show that both the experiential services and the enhanced fashion design can effectively reduce the apparel company's inventory and increase profits. When the two strategies are combined, they will produce complementary or substitution effects, which depend on the deterioration rate of the fashion level of the apparel. If the deterioration rate is less than a critical value, the interaction of experiential services and design investment has a complementarity effect.

## 1. Introduction

China is a major country in apparel production. With the advent of the era of personalized consumption, consumers are increasingly demanding fashion in apparel. However, since fashion apparel is a typical seasonal product, how to embody product innovation by enhancing the fashion level of the apparel to gain more market competitive advantage has become an urgent problem faced by apparel companies. The life cycle of fashion clothing sales is short, and its fashion level largely depends on the fashion elements contained in the clothing, such as style, pattern, material technology, and decoration accessories. Generally, the higher the fashion level is and the more fashionable the clothing is, the higher the market share of the products is. When new fashion products are launched, they will be favored and sought after by many consumers who prefer fashion. However, as time goes by, consumers' preference for original apparel gradually

decreases, so the fashion level of clothing will gradually decrease with time, and the market value of the apparel is declining. This feature usually makes consumers have different attitudes for fashion at different times. That is, the fashion level of clothing will gradually decay with time, easily causing product backlog. According to a study, the apparel industry is generally threatened by high inventories. In the first half of 2016, 79 textile and apparel listed companies had a total inventory of \$81.366 billion. On the one hand, the apparel retailer is paying more and more attention to providing virtual try-on, tie-in, fashion display, and other experiential services, so as to improve consumers' value on the apparel and, thus, to improve the fashion level of the apparel and stimulate demand [1]. On the other hand, enhancing the fashion design of clothing and continuously meeting the changing needs of the market have gradually become a new requirement for the source design of fashion clothing. Therefore, experience and design do not exist in

isolation but are closely related, and they influence each other. The decay of clothing fashion over time has an important impact on consumers' perceived value, clothing demand, and profits of clothing companies. Therefore, how to improve the interactive participation of clothing "experience and design" through experience services and clothing design investment is a very interesting and practical problem.

The existing literature related to fashion apparel mainly focused on the quick-response (QR) and price reduction. As for the research on the QR of fast fashion apparel products, Sen [2] analyzed the American fashion industry and its supply chain, and they believed that the inventory of the quick-response retailers tracked the sales of stores in real time could be kept to the minimum. Choi et al. [3] pointed out that, in the fashion industry, quick-response is a timely and influential business strategy implemented by many international companies such as Zara and H&M. Choi [4] studied the QR expectations of retailers and manufacturers and analyzed the coordination strategies of wholesale pricing and price discount contracts in the quick-response fashion supply chain. Choi [5] studied the impact of the QR plans targeting inventory services on the profits of the apparel retailer, manufacturers, and fashion supply chain systems. Cachon and Swinney [6] analyzed two key features of the fashion supply chain. One is QR production capacity, and the other is enhanced product design capabilities. All of the abovementioned studies focus on the impact of QR on inventory without considering the impact of price changes on clothing inventory during the sales period. Since price reduction promotion is a commonly used method by the apparel retailer, the promotion strategy has received extensive attention from scholars. Cachon and Feldman [7] found that frequent discounts can attract more consumers considering the consumer buying behavior, and the discount strategy is often more effective than the fixed price strategy. Cosgun et al. [8] considered the multitype clothing price reduction optimization problem of the retailer and used approximate dynamic programming algorithms to study the price reduction strategy of each product. Aviv et al. [9] studied that the seller who sells seasonal fashion goods can adopt dynamic pricing and quick inventory replenishment during the sales season to enable consumers to purchase fashion products at a higher price in advance. In view of the short life cycle of fashion products and the high uncertainty of market demand, Choi [10] considered a two-stage inventory strategy and used Bayesian methods to optimize the inventory and pricing strategies of fashion products based on actual demand data in the sales season. However, a few studies have explicitly considered clothing inventory decisions from the perspective of pricing and replenishment cycles.

Fashion clothing is a short life cycle product, and its market value is similar to the characteristics of perishable products [11]. Therefore, the research on inventory management and pricing of perishable products can be referenced for the study of the fashion apparel. Wang et al. [12] considered an inventory optimization model for perishable products whose deterioration rate followed the Weibull

distribution, and the demand depends on the instantaneous inventory level. Sicilia et al. [13] constructed a perishable inventory control model, in which a time-dependent exponential function of demand is considered. Chen et al. [14] constructed a multiperiod joint pricing and inventory control model that does not allow stock shortage. Besides, some scholars studied the inventory and pricing decisions of perishable products from the perspectives of other factors, such as purchase rate, promotional efforts, and preservation investment. Maihami and Karimi [15] analyzed the influence of the repeated purchase rate of perishable products and the speed of product diffusion on the pricing and replenishment decisions of enterprises. Tsao and Sheen [16] considered a joint decision-making on inventory and pricing of perishable products under promotional efforts. Li et al. [17] considered perishable products under the constraints of fresh-keeping investment and service investment and studied the joint pricing, ordering, and fresh-keeping investment decision-making issues of nonimmediate deterioration items. Li et al. [18] studied the stochastic production inventory model of perishable products under the dual influence of price and service level and discussed the optimal joint dynamic pricing, service, and production strategies of enterprises under the influence of external random disturbances on inventory changes.

Unlike perishable goods whose quantity and quality are declining and changing with time, the market value of fashion apparel is declining over time, but the quantity is not. Tsao [19] studied the inventory control of fashion items under the condition of trade credit and partial overstocking. Considering the effects of the fashion level and reserve price on the performance of the apparel retailer, Chen et al. [11] analyzed the optimal pricing and order strategy of the apparel retailer under dynamic and fixed cases. The literatures mentioned above did not consider the impact of experiential services on the fashion level. Chen and Xu [1] studied the optimal pricing and inventory ordering strategy in the case of no discount and discount in the sales period with considering the experiential service. Among the studies mentioned above, the work of Chen and Xu [1] and Chen et al. [11] are closest to our paper. Both studies examine the inventory and pricing decisions of fashion clothes, but they all adopt a formalized demand function, which is a linear combination of price and fashion level. However, this assumption is not in line with the reality. The difference between fashion apparel and perishable goods is that the fashion level of an apparel is a quality attribute of the apparel. Consumers can visually observe its characteristics, which is an important reference for consumers to buy. Although the price of fashion clothing is also the main factor that affects consumers' purchasing behavior, different consumers have different preferences for the price and fashion level, which will lead to the practical problem that the actual demand is difficult to determine. Some scholars have used the utility theory to study the nonlinear demand function [20–24]. For example, Su [20] took product pricing and consumer waiting costs as important factors influencing consumer utility and studied the optimal pricing strategy for retailers facing different categories of consumers. Wang et al.

[21] discussed the effect of changes in quality information asymmetry on the price decisions by using the Cobb–Douglas utility function. However, the utility functions of Su [20] and Wang et al. [21] cannot reflect the characteristics of fashion clothing, that is, the consumer’s utility function is affected by the fashion level of apparel and changes dynamically with time. Besides, the purchase quantity and the disposable income of consumers are also two important influencing factors. In short, this paper comprehensively considers the influence of fashion level, sales price, purchase quantity, and disposable income on inventory decisions.

The existing literature has conducted a lot of research on the management of perishable products, but for the fashion of clothing products, there are few studies combining experiential services and enhanced fashion design. Based on the principle of consumer utility maximization, we derive a time-varying nonlinear demand function, which mainly depends on the price and fashion level and is a nonlinear combination of the two factors. We analyze four potential operating systems—a traditional system (without experiential service and design efforts), experiential service system, design efforts system, and fast fashion systems (with experiential service and design efforts). This paper focuses the discussions on the issue of whether experience service and design efforts are complements or substitutes. The major objective is to simultaneously determine the experience service investment and the optimal selling price to maximize the total profit. It is found that both the experiential services and the enhanced fashion design can effectively reduce the apparel company’s inventory and increase profits. When the two strategies are combined, they will produce complementary or substitution effects, which depend on the deterioration rate of the fashion level of the apparel. If the deterioration rate is less than a critical value, the interaction of experiential services and design investment has a complementarity effect.

The rest of the paper is structured as follows. In Section 2, the symbols and assumptions of the model are described. Section 3 constructs four inventory models. Section 3.1 studies the retailer’s profit model and optimal pricing strategy under the basic scenario (where the apparel retailer neither provides experiential services nor enhances design). Section 3.2 discusses the case where only experiential services are provided to improve the influence of the fashion level on operational decisions; Section 3.3 investigates the situation that an apparel enterprise enhances design efforts to improve the fashion level of an apparel; Section 3.4 examines the combination of providing experiential services and enhancing design innovation and analyzes whether the two strategies are complements or substitutes. Section 4 provides numerical results and sensitivity analysis. Finally, Section 5 provides conclusions.

## 2. Notation and Assumptions

*2.1. Problem Description and Notation.* We first provide a problem description. We model an apparel retailer that sells fashionable clothing products. The demand for

fashionable clothing is determined by the selling price and fashion level of clothing during the selling period. A replenishment problem of a single fashion item is considered. The inventory system evolves as follows:  $Q$  units of items arrive at the inventory system at the beginning of each cycle. The inventory level  $I(t)$  is depicted in Figure 1 and decreases due to consumers’ demand during the replenishment cycle. Fashion apparel provides experiential service to consumers. Also, fashion apparel tries to enhance design efforts to improve the fashion level of the apparel, thus to raise the demand. The selling price and experiential service are the decision variables. We seek to answer the following questions:

- (1) Are experiential service and design efforts complements or substitutes?
- (2) How to make the optimal price and experiential service for the apparel retailer to maximize his total profit during the period?

Thus, we analyze a total of four potential operational systems. A traditional system, which represents that no experiential service or design effort is offered during the sales period, an experiential service system that employs experiential service but maintains the design efforts unchanged, a design efforts system that provides design efforts to improve the fashion level of goods but does not provide the experiential service, and a fast fashion system that employs both experiential service and design efforts.

The notations used in this paper are illustrated in Table 1.

*2.2. Utility Function.* When fashion products are released, they are favored by consumers, but as new products appear over time, consumers’ preference for original fashion clothes decreases, so the fashion level of fashion clothes will gradually decrease over time. This feature usually makes consumers buy clothes at different times to obtain different utilities, that is, the utility of consumers changes dynamically with the fashion level. Referring to the work by Wang et al. [21], a Cobb–Douglas utility function is introduced to characterize the dynamics of the utility as follows:

$$U_t = A \left( \frac{D}{p} \right)^a \omega_t^b + k(Y - pD), \quad (1)$$

where  $U_t$  is the utility of consumers at time  $t$  and  $\omega_t$  is the fashion level of apparel. The parameter  $a$  ( $0 < a < 1$ ) represents the consumers’ preference for the quantities and price of fashion clothes. The parameter  $b$  ( $0 < b < 1$ ) represents the consumers’ preference for the fashion level of the apparel. The notations  $D$ ,  $p$ , and  $Y$  represent the market demand, the selling price, and the consumers’ disposable income, respectively.  $A$  and  $k$  are positive parameters. Considering that the utility of consumers changes with time, at a certain moment, consumers will choose to purchase the optimal quantity under the circumstances of a given price and fashion to maximize their utility.

The maximization of utility provides the necessary condition for the market demand:

FIGURE 1: The apparel inventory level.

TABLE 1: Notations and definitions.

|            |                                 |
|------------|---------------------------------|
| $p$        | Selling price                   |
| $s$        | Experiential service investment |
| $a$        | Price preference coefficient    |
| $b$        | Fashion preference coefficient. |
| $h$        | Holding cost                    |
| $\lambda$  | Coefficient of design efforts   |
| $B$        | Fixed cost                      |
| $C_s$      | Service cost                    |
| $\eta$     | Fashion deterioration rate      |
| $D$        | Demand                          |
| $I$        | Inventory levels                |
| $Y$        | Disposable income               |
| $Q$        | Initial order quantity          |
| $c$        | Order cost per unit             |
| $U$        | Consumer utility                |
| $T$        | Replenishment cycle             |
| $\pi$      | Profit                          |
| $\omega_0$ | Initial fashion level           |
| $\omega_t$ | Fashion level                   |
| $C_\eta$   | Design cost                     |

$$D = \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_t^{(b/1-a)}, \quad (2)$$

where  $D$  is the market demand at time  $t$ . Substituting (2) into the utility equation (1) gives

$$U_t = \frac{k(1-a)}{a} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_t^{(b/1-a)} + kY. \quad (3)$$

Formula (3) shows that the rational consumer always purchases the optimal amount of fashionable clothing within a certain period of time to obtain the instantaneous maximum utility. Under the condition that other conditions remain unchanged, the maximum utility level for consumers to buy fashion clothing at different time points is different.

Next, we discuss the rationality of formula (3). First, we take the first partial derivative of (3) with respect to the price and fashion level, respectively, and we have

$$\frac{\partial U_t}{\partial p} = -2k \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_t^{(b/1-a)} < 0, \quad (4)$$

$$\frac{\partial U_t}{\partial \omega_t} = k \frac{a}{b} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_t^{(a+b/1-a)-1} > 0. \quad (5)$$

From inequalities (4) and (5), it can be observed that the utility function decreases as the sales price increases, but increases as the fashion level increases. The results given above are consistent with common sense in the industrial practice, so the assumption about the utility function of (1) is reasonable.

**2.3. Fashion Function.** It can be noted from Section 2.2 that both the consumers' utility function and the market demand for clothing are affected by the fashion level of the clothing. The complexity of this relationship arises a primitive question: how to characterize the dynamics of the fashion level? Motivated by the method used by Chen and Xu [1], this paper provides a fashion level function to describe the attenuation of the fashion level. The fashion level is given by

$$\omega_t = \omega_0 e^{-\eta t}, \quad (6)$$

where  $\omega_0$  ( $\omega_0 > 0$ ) is the initial fashion level and represents the fashion level of the garments when they were launched.  $\eta$  ( $\eta > 0$ ) is the deterioration rate of fashion level, which means the fashion level  $\omega_t$  decreases with time. We compare the influence of different initial fashion levels on the fashion level function. The fashion level decreases with time; however, the larger  $\omega_0$  is, the greater the remaining fashion level of fashion clothing at the same time. This shows that the initial fashion level has a significant delay effect on the fashion of fashion clothing. In order to meet consumers' personalized demands for fashion apparel products, retailers can provide consumers with experiential services, such as try-on, fashion display, and apparel collocation, to enhance consumers' psychological feelings about apparel fashion, so as to improve the initial fashion level of clothing to a certain extent.

Similarly, the fashion level deterioration rate  $\eta$  also has an effect on the fashion level. The smaller the  $\eta$  is, the slower the fashion level attenuation will be. A large part of the fashion level of an apparel depends on the fashion elements contained in the apparel, such as style, color, design, material technology, and decoration, and these fashion elements determine the size of the deterioration rate  $\eta$  of the fashion level of the apparel. Therefore, if retailers enhance product design and increase investment in the creative design of fashion elements through cooperation with suppliers, then the fashion level of an apparel can be reduced and relatively improved.

Substituting (6) into the demand equation (2) gives

$$D(p, t) = \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_0^{(b/1-a)} e^{(-b\eta/1-a)t}. \quad (7)$$

Formula (7) shows that the demand for clothing depends nonlinearly on the selling price and fashion level.

### 3. The Model

**3.1. The Traditional System.** The traditional system refers to the scenario in which the apparel retailer neither directly provides the experiential service nor indirectly invests in promoting the apparel enterprise to enhance the design during the sales period. Under the traditional scenario, the fashion level function is

$$\omega_t = \omega_0 e^{-\eta t}. \quad (8)$$

Substituting (8) into the (1) and (2), the utility function and the demand function in this section can be expressed as follows:

$$D_1 = \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_t^{(b/1-a)}, \quad (9)$$

$$U_1 = \frac{k(1-a)}{a} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_t^{(b/1-a)} + kY.$$

From Figure 1, we can see that the inventory level  $I(t)$  decreases due to consumers' demand during the time interval  $[0, T]$ . The differential equation that represents the inventory status is given by

$$\frac{dI(t)}{dt} = -D_1 = -p^{-(1+a/1-a)} \left(\frac{Aa}{k}\right)^{(1/1-a)} \omega_0^{(b/1-a)} e^{(-b\eta/1-a)t}, \quad (10)$$

With the condition  $I(T) = 0$ , solving (10) yields

$$I(t) = p^{-(1+a/1-a)} \left(\frac{Aa}{k}\right)^{(1/1-a)} \omega_0^{(b/1-a)} \cdot \left(\frac{1-a}{-b\eta}\right) (e^{(-b\eta/1-a)T} - e^{(-b\eta/1-a)t}). \quad (11)$$

The following notations are defined to simplify the expression of the mathematical model:

$$G_1 = \left(\frac{Aa}{k}\right)^{(1/1-a)} \omega_0^{(b/1-a)} \frac{1-a}{-b\eta} (e^{(-b\eta/1-a)T} - 1),$$

$$G_2 = h \left(\frac{Aa}{k}\right)^{(1/1-a)} \omega_0^{(b/1-a)} \left(\frac{1-a}{-b\eta}\right)^2 \cdot \left(\left(\frac{-b\eta T}{1-a} - 1\right) e^{(-b\eta/1-a)T} + 1\right). \quad (12)$$

The apparel retailer's ordering quantity is given as follows:

$$Q = I(0) = p^{-(1+a/1-a)} G_1. \quad (13)$$

The retailer incurs the following costs in a replenishment period: (i) purchasing cost,

$$C_1 = cQ + B = cp^{-(1+a/1-a)} G_1 + B, \quad (14)$$

where  $c$  is per unit ordering cost and  $A$  is the fixed ordering cost.

(ii) The cumulative inventory-holding cost,

$$H = h \int_0^T I(t) dt = p^{-(1+a/1-a)} G_2, \quad (15)$$

where  $h$  is unit inventory-holding cost per time unit.

In addition, the retailer's sale revenue (SR) equals to the selling price  $p$  times the sum of the demand during the replenishment period, that is,

$$SR = pQ = p^{-(2a/1-a)} G_1. \quad (16)$$

Therefore, total profit (denoted by  $\pi_1(p)$ ) during the time interval  $[0, T]$  is given by

$$\pi_1(p) = \max_{p \geq 0} \{SR - H - C_1\} = (p - c) p^{-(1+a/1-a)} G_1 - p^{-(1+a/1-a)} G_2 - B. \quad (17)$$

$\pi_1(p)$  is a function of  $p$ . Maximization of the formula (17) with respect to  $p$  yields

$$p^{(-2/1-a)+1} \left(\frac{-2a}{1-a}\right) G_1 + p^{(-2/1-a)} \left(\frac{1+a}{1-a}\right) cG_1 + p^{(-2/1-a)} \left(\frac{1+a}{1-a}\right) G_2 = 0. \quad (18)$$

By simplifying formula (17), the optimal pricing can be obtained:

$$p_1^* = \frac{(1+a)(cG_1 + G_2)}{2aG_1}. \quad (19)$$

According to the analysis mentioned above, the following proposition can be obtained.

**Proposition 1.** *When the retailer's pricing  $p$  is the optimal pricing  $p^*$ , the corresponding order quantity  $Q$  is also the optimal order quantity  $Q^*$ .*

*Proof of Proposition: 1* the retailer's optimal order quantity  $Q^*$  satisfies  $(\partial\pi_1(p)/\partial Q) = 0$ ,  $Q$  is a function of  $p$ , and we get  $\partial\pi_1(p)/\partial p = (\partial\pi_1(p)/\partial Q)\partial Q/\partial p$ . If  $p = p^*$ , there is  $\partial\pi_1(p)/\partial p|_{p^*} = 0$ , and then,  $(\partial\pi_1(p)/\partial Q)\partial Q/\partial p = 0$ ,  $\partial Q/\partial p = -(1 + a/b\eta) (Aa/k)^{(1/1-a)} p^{(-2/1-a)} \omega_0^{(b/1-a)} (1 - e^{(-b\eta T/1-a)}) < 0$ . Hence,  $\partial\pi_1(p)/\partial Q|_{Q^*} = 0$ . These steps complete the proof.  $\square$

**3.2. The Experiential Service System.** The experiential service system is based on the traditional system. Specifically, the retailer invests in experiential services, such as try-on, fashion display, and apparel collocation, in order to enhance the consumer's perception of the value of clothing fashion, thereby enhancing the consumer's psychological value. Referring to the research on fresh perishable goods preservation investment in Li et al. [17] and Dye [25], this section considers the effect of experiential service investment on improving the initial fashion level of clothing. We assume that the experiential service investment (denoted by  $s$ ) is a

continuous variable,  $s \in [0, +\infty)$ , which represents the experiential service investment of the apparel retailer in unit time. The more the investment per unit time, the greater the effort of retailers' experiential service in unit time. In order to be consistent with the law of diminishing marginal returns, it is assumed that the effect of service investment on fashion can be expressed as  $(2 - e^{-rs})\omega_0$ , that is, the initial fashion degree increases with the increase of service investment, but the incremental value is smaller and smaller. Hence,  $\lim_{s \rightarrow \infty} (2 - e^{-rs})\omega_0 = 2\omega_0$ , that is, the initial fashion degree ultimately reaches a limit value  $2\omega_0$ . In other words, we assume that the experiential service effort can double the psychological recognition of the initial fashion. Therefore, the fashion level function in an experiential service system is given by

$$\omega(t) = (2 - e^{-rs})\omega_0 e^{-\eta t}. \quad (20)$$

Experiential service means that the apparel retailer incurs the extra cost. The experiential service cost is assumed as follows:

$$C_s = \tau s^2 \int_0^T D dt, \quad (21)$$

where the positive parameter  $\tau$  is the cost coefficient of the experiential service effort. By substituting formula (20) into (1) and (2), the demand function and consumer utility function in the case of providing experiential services are obtained as follows:

$$\begin{aligned} D_2 &= \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_0^{(b/1-a)} (2 - e^{-rs})^{(b/1-a)} e^{-(b\eta/1-a)t}, \\ U_2 &= \frac{k(1-a)}{a} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_0^{(b/1-a)} \\ &\quad \cdot (2 - e^{-rs})^{(b/1-a)} e^{-(b\eta/1-a)t} + kY. \end{aligned} \quad (22)$$

According to  $(\partial U_2 / \partial s) > 0$ , the abovementioned consumer utility increases with the experiential efforts provided by the apparel retailer. Similar to that in Section 3.1, within a single cycle  $t \in [0, T]$ , we can obtain the inventory level  $I(t)$ , order quantity  $Q$ , sales revenue  $SR$ , inventory cost  $H$ , order cost  $C_1$ , and experience effort cost  $C_s$  in the case of providing experiential service:

$$\begin{aligned} I(t) &= p^{-(1+a/1-a)} \left(\frac{Aa}{k}\right)^{(1/1-a)} \omega_0^{(b/1-a)} \left(\frac{1-a}{-b\eta}\right) \\ &\quad \cdot (2 - e^{-rs})^{(b/1-a)} \left(e^{-(b\eta/1-a)T} - e^{-(b\eta/1-a)t}\right), \\ Q &= I_0 = p^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_1, \\ SR &= pQ = p^{-(2a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_1, \\ H &= h \int_0^T I(t) dt = p^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_2, \\ C_1 &= cQ + B = cp^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_1 + B, \\ C_s &= \tau s^2 \left[ \int_0^T D_2(p, s, t) dt \right] = \tau s^2 p^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_1. \end{aligned} \quad (23)$$

Therefore, the total profit (denoted by  $\pi_2(p, s)$ ) during the time interval  $[0, T]$  is given by

$$\begin{aligned} \pi_2(p, s) &= \max_{p \geq 0, s \geq 0} \{SR - H - C_1 - C_s\}, \\ &= (p - c - \tau s^2) p^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_1 \\ &\quad - p^{-(1+a/1-a)} (2 - e^{-rs})^{(b/1-a)} G_2 - B. \end{aligned} \quad (24)$$

The necessary conditions for the retailer to maximize the total profit within a single cycle are

$$\begin{aligned} \frac{\partial \pi_2(p, s)}{\partial p} &= 0, \\ \frac{\partial \pi_2(p, s)}{\partial s} &= 0. \end{aligned} \quad (25)$$

Maximization of formula (24) with respect to  $p$  yields

$$\begin{aligned} \frac{\partial \pi_2(p, s)}{\partial p} &= \left(\frac{1}{1-a}\right) p^{-(2a/1-a)} (2 - e^{-rs})^{(b/1-a)} \\ &\quad \cdot \left\{ [(1+a)(G_2 + (c + \tau s^2)G_1)] - 2aG_1 p \right\} = 0. \end{aligned} \quad (26)$$

By simplifying formula (26), the optimal pricing can be obtained as follows:

$$p_2^* = \frac{(1+a)(G_2 + (c + \tau s^2)G_1)}{2aG_1}. \quad (27)$$

Maximization of the formula (24) with respect to  $s$  yields

$$\begin{aligned} \frac{\partial \pi_2(p, s)}{\partial s} &= p^{-(1+a/1-a)} (2 - e^{-rs})^{1-(b/1-a)} \\ &\quad \cdot \left\{ \left( (p - c - \tau s^2)G_1 - G_2 \right) \frac{b}{1-a} r e^{-rs} \right. \\ &\quad \left. - 2\tau s (2 - e^{-rs})G_1 \right\} = 0. \end{aligned} \quad (28)$$

The optimal experiential service effort level  $s_2^*$  of the fashion apparel retailer satisfies the following equation:

$$bre^{-rs} \left( (p - c - \tau s^2)G_1 - G_2 \right) = 2(1-a)\tau s G_1 (2 - e^{-rs}). \quad (29)$$

Since both the equations (27) and (29) are highly nonlinear, it is difficult to obtain accurate solutions. However, Newton's iterative method can be used to find approximate solutions of equations in the real field, so we use Newton's iterative method to solve the system of simultaneous binary nonlinear equations. The specific algorithm is given in Section 3.4. By solving the model, the optimal pricing and order quantity of the fashion apparel retailer can be obtained in the experiential service system.

**3.3. The Design Innovation System.** In the era of pursuing fashion and individuation, enhancing the design of fashion clothing can improve the fashion level of products, further

making the marginal value increasing the effect of consumers on the valuation of garments. At the same time, strengthening the design of fashion apparel will also affect the supplier's production methods, which will further change the situation of coexistence and shortage of fashion products and ultimately reduce the level of apparel inventory. From the perspective of supply chain collaboration, the retailer can order products from the supplier based on the analysis of consumer purchase history data. Obviously, the initial fashion level of garments plays an important role in the retailer's ordering decision. In order to obtain fashion products with higher fashion levels, clothing retailers can provide clothing manufacturers with product design innovation subsidies, thereby improving the fashion level of clothing and reducing the decay rate of fashion levels. A smaller fashion level deterioration rate means a bigger subsidy which is charged by the manufacturer to the apparel retailer. The design innovation cost  $C_\eta$  is introduced as follows:

$$C_\eta = \lambda(\eta - \eta_1)^2 \int_0^T D dt, \quad (30)$$

where the parameter  $\lambda > 0$  represents the cost coefficient of the design innovation cost.  $\eta$  represents the deterioration rate corresponding to the standard design;  $\eta_1$  is an exogenous variable controlled by the apparel retailer. The smaller the  $\eta_1$  is, the higher the fashion level of clothing is and the more fashionable the apparel is, but the higher the cost of the design subsidy will be.

The fashion level function of the design innovation system is

$$\omega_t = \omega_0 e^{-\eta_1 t}. \quad (31)$$

Substituting (31) into the (1) and (2), the utility function and the demand function in this section can be expressed as follows:

$$D_3 = \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_0^{(b/1-a)} e^{(-b\eta_1/1-a)t},$$

$$U_3 = \frac{k(1-a)}{a} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_0^{(b/1-a)} e^{(-b\eta_1/1-a)t} + kY. \quad (32)$$

Similar to that in Section 3.1, the order quantity is

$$Q_3 = p^{-(1+a/1-a)} G_3. \quad (33)$$

Within a single cycle time  $t \in [0, T]$ , the profit function of the retailer can be obtained as follows:

$$\pi_3(p) = \max_{p \geq 0} \{SR - H - C_1 - C_\eta\},$$

$$= (p - c - \lambda(\eta - \eta_1)^2) p^{-(1+a/1-a)} G_3 - p^{-(1+a/1-a)} G_4 - B, \quad (34)$$

where  $G_3 = (Aa/k)^{(1/1-a)} \omega_0^{(b/1-a)} (1 - a - b\eta_1) (e^{(-b\eta_1/1-a)T} - 1)$  and  $G_4 = h(Aa/k)^{(1/1-a)} \omega_0^{(b/1-a)} (1 - a - b\eta_1)^2 (((-b\eta_1 T / 1 - a) - 1) e^{(-b\eta_1/1-a)T} + 1)$ .

$\pi_3(p)$  is a function of  $p$ . Maximization of the formula (34) with respect to  $p$  yields the optimal pricing:

$$p_3^* = \frac{(1+a)(cG_3 + \lambda(\eta - \eta_1)^2 G_3 + G_4)}{2aG_3}. \quad (35)$$

As can be seen from equation (35),  $p_3^*$  is affected by  $\eta_1$  of the fashion level through the enhanced design input, that is, the optimal price of the apparel retailer is affected by the deterioration rate which is determined by the apparel retailer according to the actual situation of the market.

**3.4. Fast Fashion System.** From the discussion of Sections 3.2 and 3.3, it can be observed that the apparel retailer not only provides experiential services to enhance its initial fashion but also increases design subsidy investment to reduce the consumer's psychological perception of the decay of clothing fashion, both of which can affect the operation decision of the clothing retailer. In this section, we analyze the impact of combining experiential services and design efforts in a fashion system. A fast fashion system employs both experiential services and design efforts.

The total profit of the fast fashion system is denoted by  $\pi_4$ . Specifically, we seek to answer the following question: are experiential services and design efforts complements or substitutes? If they are complements, then investing experiential services in a design innovation system results in a superadditive benefit: the incremental value of a fashion system (the change in profit over a traditional system) is more than the combined incremental value of experiential services and design efforts employed in isolation, i.e.,

$$\pi_4 - \pi_1 > (\pi_2 - \pi_1) + (\pi_3 - \pi_1). \quad (36)$$

Simplifying this expression, experiential service and design efforts are complements if and only if  $\pi_4 - \pi_2 > \pi_3 - \pi_1$ . For notational convenience, let  $\Delta\pi_{42} = \pi_4 - \pi_2$  and  $\Delta\pi_{31} = \pi_3 - \pi_1$ . If  $\Delta\pi_{42} > \Delta\pi_{31}$ , then experiential service and design efforts are complements. If  $\Delta\pi_{42} < \Delta\pi_{31}$ , then experiential service and design efforts are substitutes.

The utility function and the demand function in the fashion system can be expressed as follows:

$$D_4 = \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(1+a/1-a)} \omega_0^{(b/1-a)} (2 - e^{-rs})^{(b/1-a)} e^{-(b\eta_1/1-a)t},$$

$$U_4 = \frac{k(1-a)}{a} \left(\frac{Aa}{k}\right)^{(1/1-a)} p^{-(2a/1-a)} \omega_0^{(b/1-a)} \cdot (2 - e^{-rs})^{(b/1-a)} e^{-(b\eta_1/1-a)t} + kY. \quad (37)$$

Considering the combined effect of experiential service and design efforts, the profit of the retailer is

$$\begin{aligned}
\pi_4(p, s) &= \max_{p \geq 0, s \geq 0} \{SR - H - C_1 - C_\eta - C_s\}, \\
&= (p - c - \tau s^2 - \lambda(\eta - \eta_1)^2) p^{-(1+a/1-a)} \\
&\quad \cdot (2 - e^{-rs})^{(b/1-a)} G_3 - p^{-(1+a/1-a)} \\
&\quad \cdot (2 - e^{-rs})^{(b/1-a)} G_4 - B.
\end{aligned} \tag{38}$$

The necessary conditions for the retailer to maximize the total profit within a single cycle are

$$\begin{aligned}
\frac{\partial \pi_4(p, s)}{\partial p} &= 0, \\
\frac{\partial \pi_4(p, s)}{\partial s} &= 0.
\end{aligned} \tag{39}$$

Maximization of formula (38) with respect to  $p$  yields

$$\begin{aligned}
\frac{\partial \pi_4(p, s)}{\partial p} &= \left( \frac{1}{1-a} \right) p^{-(2a/1-a)} (2 - e^{-rs})^{(b/1-a)} \\
&\quad \cdot \left\{ [(1+a)(G_2 + (c + \tau s^2)G_1)] - 2aG_1 p \right\} = 0.
\end{aligned} \tag{40}$$

By simplifying formula (40), the optimal pricing can be obtained as follows:

$$p_4^* = \frac{(1+a)(G_2 + (c + \tau s^2 + \lambda(\eta - \eta_1)^2)G_1)}{2aG_1}. \tag{41}$$

The optimal experiential service effort level  $s_4^*$  of the fashion apparel retailer satisfies the following equation:

$$\begin{aligned}
bre^{-rs} \left( (p - c - \tau s^2 - \lambda(\eta - \eta_1)^2) G_3 - G_4 \right) \\
= 2(1-a)\tau s (2 - e^{-rs}) G_3.
\end{aligned} \tag{42}$$

Since both the equations (41) and (42) are highly nonlinear, it is difficult to obtain accurate solutions. We use the Newton iteration method to search and solve the design algorithm of (41) and (42).

Step 1: let  $f_1 = \partial_p \pi_4(p, s) = 0$  and  $f_2 = \partial_s \pi_4(p, s) = 0$ , and the abovementioned simultaneous equations are denoted by  $\vec{f}(\vec{x}) = 0$ , where  $\vec{x} = (p, s)^T$ ,  $\vec{f}(\vec{x}) = (f_1, f_2)^T$ . The Jacobian matrix of  $\vec{f}(\vec{x})$  is denoted by  $J(\vec{x})$ .

Step 2: it is assumed that  $\vec{x}^{(i)} = (p^{(i)}, s^{(i)})^T$  is the solution to step  $i$  iteration of  $\vec{f}(\vec{x}) = 0$ ; thus,  $\vec{x}^{(i+1)} = \vec{x}^{(i)} - [J(\vec{x}^{(i)})]^{-1} \vec{f}(\vec{x}^{(i)})$ .

Step 3: it is begun with  $i = 1$  and the initial trial value of  $p^{(i)} = p^1, s^{(i)} = s^1$ .

Step 4:  $\vec{x}^{(i)} = (p^{(i)}, s^{(i)})^T$  and  $\vec{x}^{(i+1)} = (p^{(i+1)}, s^{(i+1)})^T$  are calculated.

Step 5: If  $\max\{|p^i - p^{i+1}|, |s^i - s^{i+1}|\} < 10^{-6}$ , then  $(p^*, s^*)^T = (p^{(i)}, s^{(i)})^T$  is set and proceeded to Step 6. Otherwise,  $i = i + 1$  is set and we go to Step 4.

Step 6: Using this algorithm, we obtain the optimal solution  $(p^*, s^*)$ . We can obtain and  $\pi_4^*(p, t_1)$  using that in (38).

## 4. Numerical Analysis

To illustrate the solution procedure and the results, let us apply the proposed algorithm to solve following numerical example. The results can be obtained by applying the software Matlab2016a. We set  $k = 0.5$ ,  $a = 0.35$ ,  $b = 0.65$ ,  $c = 1.5$ ,  $h = 0.5$ ,  $r = 0.5$ ,  $A = 120$ ,  $\omega_0 = 0.8$ ,  $T = 15$ ,  $Y = 10000$ ,  $\eta = 0.015$ , and  $\tau = 1$ ,  $\lambda = 2$ .

**4.1. Optimal Solutions.** Figure 2 shows that the profit  $\pi_1$  of the retailer is a strictly concave function of the selling price  $p$  in the traditional system. As shown in Figure 2, the global maximum can be obtained at the local maximum point, that is, there exists an optimal sales price. The scenario of the design innovation system is similar to that of the traditional system. As can be seen from Figure 3, the profit function  $\pi_2$  is strictly concave in  $(p, s)$ . Therefore, we ensure that a local maximum is the global maximum. The scenario of the fashion system is similar to that of the experiential system. Hence, we can conclude that the maximum searched by the algorithm could be viewed as the optimal solution of the problem.

**4.2. Impact of the Preference Combinations  $(a, b)$ .** In the case of providing experiential services, in order to better explain the model, we specifically analyze the impact of experiential service efforts and prices on retailer decisions under different combination preferences. From Table 2, it can be observed that when consumers' fashion preference for apparel  $b$  is greater than price preference  $a$ , the retailer should invest more in experiential service efforts to improve the initial fashion of the apparel. At this time, the sales price is gradually increasing. On the contrary, consumers have little preference for clothing fashion, and retailers lack the incentive to invest in service.

**4.3. Impact of the Deterioration Rate  $(\eta)$ .** Next, we will analyze the impact of the fashion level deterioration rate  $\eta_1$  on the retailer's decision-making in the case of enhancing design. Note that  $\eta_1$  is exogenous variables. Here, we adjust the value of  $\eta_1$  such that it varies from 0.007 to 0.015 at a step of 0.001 and keep the values of other parameters unchanged, as shown in Table 3. We can see from Table 4 that when  $\eta_1 = \eta = 0.015$ , the design cost function is  $C_\eta = 0$ . It represents that the apparel retailer did not invest in fashion design, which is equivalent to the traditional system. With decrease in  $\eta_1$ , that is, the increase in fashion design reduces the deterioration rate of the fashion level of an apparel, the price and order quantity are correspondingly enhanced, and the consumer's utility and retailer's profit are also increased. However, when  $\eta_1$  reaches 0.009, the order quantity of the retailer does not decrease, and the profits and consumers' utility reach an inflection point and, then, start to decrease. This is because of the decrease in fashion deterioration rate benefits from the design that enhances fashion. When it is reduced to a certain extent, the cost of the effort to enhance the design rises rapidly, and the retailer shares part of the

design cost through the order volume, thus offsetting part of the sales revenue. Therefore, investment in fashion design needs to be within a certain range. The optimal design investment can reduce the deterioration rate of the fashion level and increase the profit at the same time. However, excessive emphasis on the fashion level will inevitably increase the investment in fashion design and indirectly affect the income of the apparel retailer.

We have analyzed the impact of experiential service investment and design efforts on apparel retailers' operational decisions. Next, we analyze whether experiential

service and design efforts are substituted or complementary. Consider four different scenarios: the basic scenario (the case where the apparel retailer provides neither experiential services nor enhanced design), the experiential service scenario alone, the enhanced design scenario alone, and the experiential service and enhanced design combination due to the retailer's revenue are affected by the fashion level of clothing, so this paper will discuss the impact of the fashion deterioration rate on the optimal profit and, then, analyze whether the experiential services and design efforts are an alternative relationship or a complementary relationship. The sensitivity analysis of the deterioration rate results is shown in Table 4.

Table 4 shows that the profits  $\pi_2^*$ ,  $\pi_3^*$ , and  $\pi_4^*$  are always larger than the profit  $\pi_1^*$  in the traditional system. This result indicates that investing in experiential services alone, product design innovation alone, or implementing both strategies can help apparel retailers increase profits. Besides, the profit  $\pi_4^*$  of the fashion system is larger than the experiential one  $\pi_2^*$  until the deterioration rate of the fashion level reaches a certain threshold  $\hat{\eta}_1 = 0.015$ . In other words, when  $\eta_1$  is small ( $\eta_1 \in (0.01, 0.015)$ ),  $\pi_4^* > \pi_2^*$ , the retailer will further improve profits by offering design efforts on the basis of providing experiential service. Experiential service and promotion efforts are complements. When  $\eta$  is relatively large ( $\eta \in [0.015, 0.02)$ ),  $\pi_4^* < \pi_2^*$ , and this is in contrast to previous policies. Moreover, we conduct a sensitivity analysis of the deterioration rate of the fashion level, which is shown in Figure 4.

As we can see from Figure 4, when  $\eta_1$  is relatively large ( $\pi_4^* < \pi_2^*$ ),  $\Delta\pi_{42} < \Delta\pi_{31}$ . Thus, experiential services and

FIGURE 4: The incremental value of an interactive fashion over experiential services ( $\Delta\pi_{42}$ ) and the incremental value of design efforts over the traditional system ( $\Delta\pi_{31}$ ), plotted as a function of the deterioration rate of fashion level,  $\eta_1$ .

design efforts are substitutes. Moreover, the difference between  $\Delta\pi_{31}$  and  $\Delta\pi_{42}$  is increasing in  $\eta_1$ . When  $\eta_1$  is large (costume designing is relatively poor), the substitution effect is dramatic. This occurs because the larger the deterioration rate  $\eta_1$  is, the faster the fashion level  $\omega(t)$  fading is. If the costume's design is relatively poor, it is difficult for the apparel retailer to improve the fashion level of clothing by providing experiential services. These apparels are very outdated, resulting in backlog. Besides, when  $\eta_1$  is relatively small ( $\pi_4^* > \pi_2^*$ ),  $\Delta\pi_{42} > \Delta\pi_{31}$ . Thus, experiential services and design efforts are complementary. Moreover, the difference between  $\Delta\pi_{31}$  and  $\Delta\pi_{42}$  is decreasing in  $\eta_1$ . When  $\eta_1$  is small (the design of the clothing is very novel), the complementarity effect is dramatic. This occurs because the smaller the deterioration rate  $\eta_1$  is, the slower the fashion level  $\omega(t)$  fading is. If the design of the clothing is very novel, the clothing retailer can enhance the brand by providing experiential services, thereby attracting more consumers to purchase products and obtain more profits.

## 5. Conclusions

The decline in the fashion level of fashion for fashion apparel has caused its market value to continuously decrease, reducing market demand and creating a backlog of clothing inventory. The demand for fashionable clothing is determined by the selling price and fashion degree of clothing during the selling period. Under these backgrounds, the apparel retailer invests in experiential services, such as providing virtual and physical try-on, to improve the fashion level of apparel and, thus, to increase the demand. On the other hand, the fashion apparel adopts a design innovation strategy, that is, the apparel manufacturer improves the innovative design of the apparel according to the requirements of retailers in order to produce an apparel that meets a

certain attenuation criterion. We present a modeling framework that allows us to capture and isolate the key aspects that define a fast fashion system: experiential service and design efforts. By employing this approach, we analyze four potential operating systems—a traditional system (without experiential service and design efforts), experiential service system, design efforts system, and fast fashion systems (with experiential service and design efforts). We characterize the properties of the optimal solution (the selling price and experiential service investment) in each case and propose an iterative algorithm. This paper focuses on discussing the issue of whether experiential service and design efforts are complements or substitutes. We find that when the deterioration rate of the fashion level is relatively small, the incremental value of a fashion system (the change in profit over a traditional system) is more than the combined incremental value of experiential service and design efforts employed in isolation. In other words, the interaction of experiential service and design efforts has a complementarity effect when the design of the clothing is relatively novel.

In the proposed inventory model, the price was assumed as a static variable. As we all know, price strategy, as an important factor in the success of the business of the modern firms, has a significant effect on the consumers' demand. The static price strategy ignores the fashion attribute of fashion apparel, which has been declining over time. In fact, dynamic pricing is a powerful tool to manage the demand of different quality level products. Therefore, according to the time-varying characteristics of fashion clothing, how to implement the time-varying dynamic pricing strategy would be worth exploring in the future. Besides, this paper considers the deterministic situation that we may also consider the stochastic demand in the model. The pricing and experiential service investment policy in the supply chain of fashion items should also be considered. Last but not the least, it would be useful to test our results through qualitative research and case studies.

## Data Availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also form part of an ongoing study.

## Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this study.

Coke is an indispensable and vital flue for blast furnace smelting, during which it plays a key role as a reducing agent, heat source, and support skeleton. Models of prediction of coke quality based on ANN are established to map the functional relationship between quality parameters  $M_b$ ,  $A_d$ ,  $V_{daf}$ ,  $S_{t,d}$ , and caking property ( $X$ ,  $Y$ , and  $G$ ) of mixed coal and quality parameters  $A_d$ ,  $S_{t,d}$ , coke reactivity index (CRI), and coke strength after reaction (CSR) of coke. A regularized network training method based on Sigmoid function is designed considering that redundancy of network structure may lead to the learning of undesired noise, in which weights having little impact on performance and leading to overfitting are removed in terms of computational complexity and training errors. The cascade forward neural network with validation is found to be the most suitable one for coke quality prediction, with errors around 5%, followed by feedforward neural network structure and radial basis neural networks. The cascade forward neural network may play a guiding role during the coke production.

## 1. Introduction

With the growing trend of large-scale blast furnace, smelting effect of blast furnace and its economic and technical indicators are more deeply influenced by the quality and performance of coke [1]. Unfortunately, various types and proportions of mixed coal can lead to different coke quality [2]. In that case, it is of significance to study the relationship between physical and chemical properties of mixed coal and that of coke in controlling the coke quality.

Due to multidimension, being dynamic, incompleteness, and uncertainty, the data of coking test is difficult to collect and handle, and this makes the actual production process still in an unscheduled and irregular state and causes the occurrence of the “rich data and poor knowledge” phenomenon [3]. Rule data mining technology is capable of finding the potential link between historical data, promoting information transmission, digging knowledge from data, and providing decision basis [4]. Numerous researches and experiments have been carried out in response to coke

quality prediction. Alvarez, R et al. predicted the CSR property of coke using the law of addition [5]. Roest et al. used different statistical analysis tools (MLR and PCR) and the ANN technique to solve the same problem [6]. Using the thought of coal blend with petrography, Tao Peisheng guided the coke quality prediction and determination of the coal blending ratio based on coal-rock phase composition and reflectance pattern of single coal while taking into account coal maceral and coke strength, etc. [7]. Although the above studies enrich the theory of coke quality prediction models, rare deep data rule mining is adopted for relevant data [8]. A large number of models predicting coke quality have been proposed up to now, a majority of which are merely based on coal characteristics and limited to the same coal geography origin, but no general applicable prediction formula has been developed up to now [9].

The statistical law of abundant coking testing data indicates the extremely strong nonlinear relationship between the physical and chemical properties of coke and that of mixed coal [10]. A variety of existing artificial coal blending

plans are inefficient and the application of corresponding results is quite poor, which fails to meet the production need of modern enterprises [11]. Fortunately, the adoption of neural network technology can decrease time consumption and reduce economic costs through rule mining of the experimental data and rationally predicting the physical and chemical properties of coke from mixed coal.

The application of data rule mining techniques is here and there right now. It becomes an important mission of interdisciplinary researchers in coking industry and mathematical application fields to guide the data mining process and draw meaningful results using the professional knowledge in coking industry.

## 2. Factors Affecting Coke Quality

In steel industry, coke as a fuel has been used to provide heat for the melting of slag and metal [12]. Coke is also used as a reduction agent to reduce iron ore to elemental iron. Hence, the parameters influencing the coke property are of great importance [5]. Coke production is shown in Figure 1. First of all, the raw materials are collected from the raw material yard to the mixing warehouse, crushed by a crusher, then put into a coke oven for calcination, and finally put into a blast furnace for smelting.

**2.1. Mixed Coal Properties.** The properties of mixed coal play key roles in determining the coke quality. Moisture, ash, volatile, sulfur, and caking property affect it in different degrees. Table 1 shows the range of content of mixed coal corresponding indicators and the impact on coke production.

**2.1.1. Full Moisture ( $M_t$ ).** It is the sum of intrinsic and external moisture in coal. Too much moisture content is bad for processing and transportation; it also deteriorates thermal stability and thermal conductivity when burning, reduces the coke yield, and extends the coking cycle when coking. Hence, it is specified to be below 8% [13].

**2.1.2. Ash ( $A_d$ ).** Ash in coal remains in coke after coking. Too much ash will lead to sudden drop of the cold state strength, the increase of residue in a blast furnace, and finally production reduction. Ash in coke can be guaranteed within the required range only if the ash in mixed coal is controlled, and the ash in coke is generally 1.3-1.4 times that in mixed coal. So the ash of mixed coal in general is controlled between 9% and 10% [1].

**2.1.3. Volatiles ( $V_{daf}$ ).** The metamorphism of coal can be reflected through volatiles. The volatiles can be calculated roughly on a weighted average basis according to the volatile of single coal. The product yield of coking gas and chemical products can be improved by appropriately adding high volatile coal, with the best content being controlled in the range of 24%–30% [14].

**2.1.4. Sulfur Content ( $S_{t,d}$ ).** Sulfur content is the harmful component in coke, most of which is brought into the blast furnace by coke. The sulfur content of pig iron is directly affected by it, and the quality of pig iron is declined. Therefore, the control of sulfur content is indispensable. Related study [15] shows that 60%-70% sulfur content from coal is transferred into coke, the inorganic sulfur in coal is transferred into coke as sulfocompounds, and the remaining part stays in ash in the form of sulfate and sulfide. The coke rate of mixed coal is 70%-80% usually, while the sulfur content in coke is 80%-90% of that in coal [16]. Thus, the sulfur content of the mixed coal should be constrained in the range of 0.6%-0.7%.

**2.1.5. Caking Property.** Caking property refers to the ability of coal forming plastic substance during coking, which serves as a necessary condition in coking process and affects the coking property of mixed coal [17]. It commonly can be reflected by three indexes, X, Y, and G in glial layer. Among them, shrinkage X can be used to estimate whether the final shrinkage of coal can cause difficulty of coke pushing, the maximum thickness of the glial layer Y indicates the amount of liquid produced with the mixed coal, and the bond index G, to a certain extent, reflects the content of the gum. So, the caking property of mixed coal can be measured by the mentioned indicators.

**2.2. Index Assessing the Coke Quality.** Coke provides heat and reducing gas, occupying an important position in the furnace. The hot strength (coke reactivity index CRI and coke strength after reaction CSR) is a main index in quality judgment of coke, and so are ash, sulfur, and volatile [15, 17].

**2.2.1. Ash ( $A_d$ ).** Ash in coke is mainly composed of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and other acidic oxide composition with high melting point. In the blast furnace refining slag discharge requires a lot of solvent to reduce the melting point of the compound [18]. The ash content of the coke all comes from mixed coal. The higher the ash content, the less the carbon content of the coke, the more solvent required, the more slag, and the lower yield [19]. The ash in coke is an inert component, and it will reduce the caking property of mixed coal, increase the coke crack, and reduce the coke mechanical strength. At the same time, the alkali metal oxide in the ash component also catalyzes the  $\text{CO}_2$  reaction of the coke and increases the  $\text{CO}_2$  reaction rate.

**2.2.2. Sulfur Content ( $S_{t,d}$ ).** 80%–85% of sulfur content in coke, as one of indicators affecting coke quality, comes from the mixed coal. It influences the sulfur content in steel from the blast furnace smelting and the design of the blast furnace and destroys the environment severely [20].

**2.2.3. Hot Strength of Coke.** The coke supplies heat and carbon in the blast furnace, serving as a reducing agent for the furnace reaction; its hot strength is a mechanical strength

FIGURE 1: Coke production.

TABLE 1: The range of content of mixed coal corresponding indicators and the impact on coke production.

| Index of mixed coal | Range (%)    | Effect  |
|---------------------|--------------|---|
| $M_t$               | $0 << 8$     | Bad for processing and transportation, deteriorates thermal stability and thermal conductivity when burning, and reduces the coke yield and extends the coking cycle when coking. |
| $A_d$               | $9 << 10$    | Leads to sudden drop of the cold state strength, the increase of residue in a blast furnace, and finally production reduction.  |
| $V_{daf}$           | $24 << 30$   | The product yield of coking gas and chemical products can be improved by appropriately adding high volatile coal.   |
| $S_{t,d}$           | $0.6 << 0.7$ | The sulfur content of pig iron is directly affected by it, and the quality of pig iron is declined.   |

index reflecting the thermal performance [21]. This indicator characterizes the ability to resist crushing and abrasion subjected to thermal stress and mechanical force at specific temperature and atmosphere. The thermal performance is commonly denoted by coke reactivity index (CRI) and coke strength after reaction (CSR). The lower the CSI and the higher the CSR, the better the thermal performance of coke. At the same time, they are the most critical parameters used to evaluate the high temperature performance of coke [22].

### 3. Neural Networks Based on Domain Knowledge

Neural networks are often merely trained and generalized in data-driven mechanisms. However, it helps to speed up the search of approximation and improve the prediction quality if adding priori knowledge (including knowledge such as symmetry, invariance common sense, and so on) of the desired approximation function to networks. Domain knowledge focuses on the investigation of important issues or concepts in the located fields, as well as the interrelationships of them, which can make up for the shortcomings of unclear directivity and unexplainable results.

Based on the current situation that high-quality coking coal resources are relatively scarce, a multicoal source coking method is proposed. Considering that the nonlinear

relationship between parameters of mixed coal and coke determined by the inherent properties of coking environment, process and chemical reaction, cannot be described accurately by functions simply, neural networks are very suitable for coke quality prediction in coking systems, which avoids the function description between system characteristic indexes and dependent variables, gets relationship between input and output according to memory and feature extraction, and has features of generalization, distributed knowledge storage, associative memory, and parallel processing.

#### 3.1. Multilayer Feedforward Backpropagation (FB) Network.

The pretreated samples are randomly presented to the neural network in traditional algorithm, and the output signals of neurons are revealed through forward recursion next [23]:

$$y_q = f(v_q) = f(u_q - \theta_q) = \left( \sum_{j=1}^n w_{qj} x_j - \theta_q \right). \quad (1)$$

The parameters are corrected in the negative gradient direction in terms of the selected error energy function  $\zeta(n) = f(e_j(n))$  after obtaining the error signal  $e_j(n) = d_j(n) - y_j(n)$  from comparing the expected value and the actual output [23].

$$\begin{aligned}
w_{ji}^{(s)}(k+1) &= w_{ji}^{(s)}(k) + \eta^{(s)} \delta_j^{(s)} y_j^{(s-1)}, \\
\delta_j^{(s)} &= \begin{cases} e_j(n) \phi_j'(v_j(n)), & j \text{ is the putput node,} \\ \phi_j'(v_j(n)) \sum_k \delta_k(n) w_{kj}(n), & j \text{ is the hidden node.} \end{cases} \quad (2)
\end{aligned}$$

Another algorithm is investigated owing to the slow convergence of the original one, which can be roughly divided into the following:

- (1) Heuristic improved algorithms, including back-propagation with momentum updates, search convergence method, and bulk update of variable learning rates
- (2) Numerical optimization techniques, including conjugate gradient backpropagation, recursive back-propagation based on least squares, and backpropagation with adaptive activation function

The concepts of sensitive area and its width of Sigmoid function  $f()$  are discussed in literature [24]; each implicit neuron has a corresponding respective sensitive area; directions of neurons depend on that of the hidden node. The hidden nodes interact with each other in the feature space formed by themselves, which affects the training performance of neural network. The input interval of hidden node whose output is within  $(0, a)$  is defined as the  $a$ -level sensitive area  $A_a$  of the node [25]:

$$A_a = \{x \in R^{n \times 1} : 0 < f(x^T w + \theta) < a\}, \quad (3)$$

where  $x$  is the vector inputted into synapse, and its weights are  $x_j, j = 1, 2, \dots, n, x = [x_1, x_2, \dots, x_n]^T$ .  $x_j$  is connected to the neuron  $q$  through the weight of synapses  $w_{qj}$ ; the nonlinear activation function  $f()$  is able to regulate the amplitude of outputs and enhance abilities of classification, function approximation, anti-noise jamming, and so on;  $\theta$  is the threshold to reduce the cumulative input of the activation function.

The width of  $A_a$  is defined as [25]

$$G_a = P_a - P_0 = \frac{\ln(a/(1-a))}{\|w\|}, \quad (4)$$

where  $P_a$  and  $P_0$  represent the equivalent hyper-surface when outputs  $f(x^T w + \theta)$  of hidden nodes are  $a$  and  $0$ , respectively, and  $\|w\|$  is the  $L_2$  norm of matrix  $w$  (also known as Euclidean norm).

**3.2. Radial Basis Function (RBF) Network.** The function approximation of the multilayer perceptron is realized by nesting the weighted sums, and the RBF is itself a general approximator following the interpolation theory, and it is delicate and tight in the mathematical point of view. Different from the random approximation of multilayer perceptions, RBF based on radial basis functions includes two stages in solving nonlinear mapping problems: high-dimensional transformation and least squares estimation of input samples. The idea is to map the samples non-linearly to

high-dimensional space where the single weighted sum is performed and eventually outputs results. Its rationality is explained by the configurable Cover theorem. The classical training method is to train the hidden layer by using the K-means clustering algorithm in unsupervised mode and then to calculate the weight vector of the output layer using the recursive least squares method. The method has the characteristics of simple calculation and accelerated convergence. The following calculation is carried out once the samples are given:

- (1) It is assumed that the training set  $\{\varphi(i), d(i)\}_{i=1}^N$  and the number of iterations  $n = 1, 2, \dots, N$  are known already. Initialize  $\hat{w}(0) = 0, p(0) = \lambda^{-1}I$ , where  $\lambda$  is a small positive number.
- (2) For a given encoder  $C$ , minimize the total clustering variance  $\sum_{j=i}^K \sum_{C(i)=j} \|x_i - \hat{\mu}_j\|^2$  according to the clustering mean  $\{\hat{\mu}_j\}_{j=1}^K$ , resulting in the clustering mean  $\{\hat{\mu}_j\}_{j=1}^K$ , and minimize the encoder  $C(i) = \arg \min_{1 \leq j \leq K} \|x(i) - \hat{\mu}_j\|^2$ . Repeat the step until the clustering result remains unchanged.
- (3) Calculate  $\mathbf{p}(n) = \mathbf{p}(n-1) - (\mathbf{p}(n-1)\Phi(n)\Phi^T(n) \mathbf{p}(n-1) / 1 + \Phi^T(n)\mathbf{p}(n-1)\Phi(n))$ , where  $p(n) = R^{-1}(n)$ , and  $R(n)$  is the  $K \times K$  order related function of the hidden units:  $\mathbf{R}(n) = \sum_{i=1}^n \phi(x_i)\phi^T(x_i)$ ,  $\phi(x_i) = [\varphi(x_i, x_1), \varphi(x_i, x_2), \dots, \varphi(x_i, x_k)]^T$ ; among them,  $\varphi(x_i, x_j) = \exp(-(1/2\sigma_j^2)\|x_i - x_j\|^2)$   $j = 1, 2, \dots, K$ .
- (4)  $g(n) = p(n) \cdot \Phi(n)$ .
- (5)  $a(n) = d(n) - \hat{\mathbf{w}}^T(n-1)\Phi(n)$ .
- (6)  $\hat{\mathbf{w}}(n) = \hat{\mathbf{w}}(n-1) + \mathbf{g}(n)a(n)$ : the weight vector of the output layer is obtained.

**3.3. Algorithm to Better the Neural Network Generalization.** The training process of the network can be regarded as the process of constructing the fitting curve. The network is of pretty good generalization when the mapping calculated by it is correct although inputs are beyond the training samples. There appears overfitting phenomenon with redundant network structure in which the extra synapses memorize unexpected characteristics of information. It can be readily seen that the wider the sensitive area defined by (4) is, the stronger the node generalization ability is. In addition, the ideal function is the smoothest function of approximation and mapping functions for a given error, taking up fewer computing resources. And the process of seeking for it is called network pruning. In this section, a regularized network training algorithm based on the sensitive area of Sigmoid function is developed, and the specific process is shown in Figure 2.

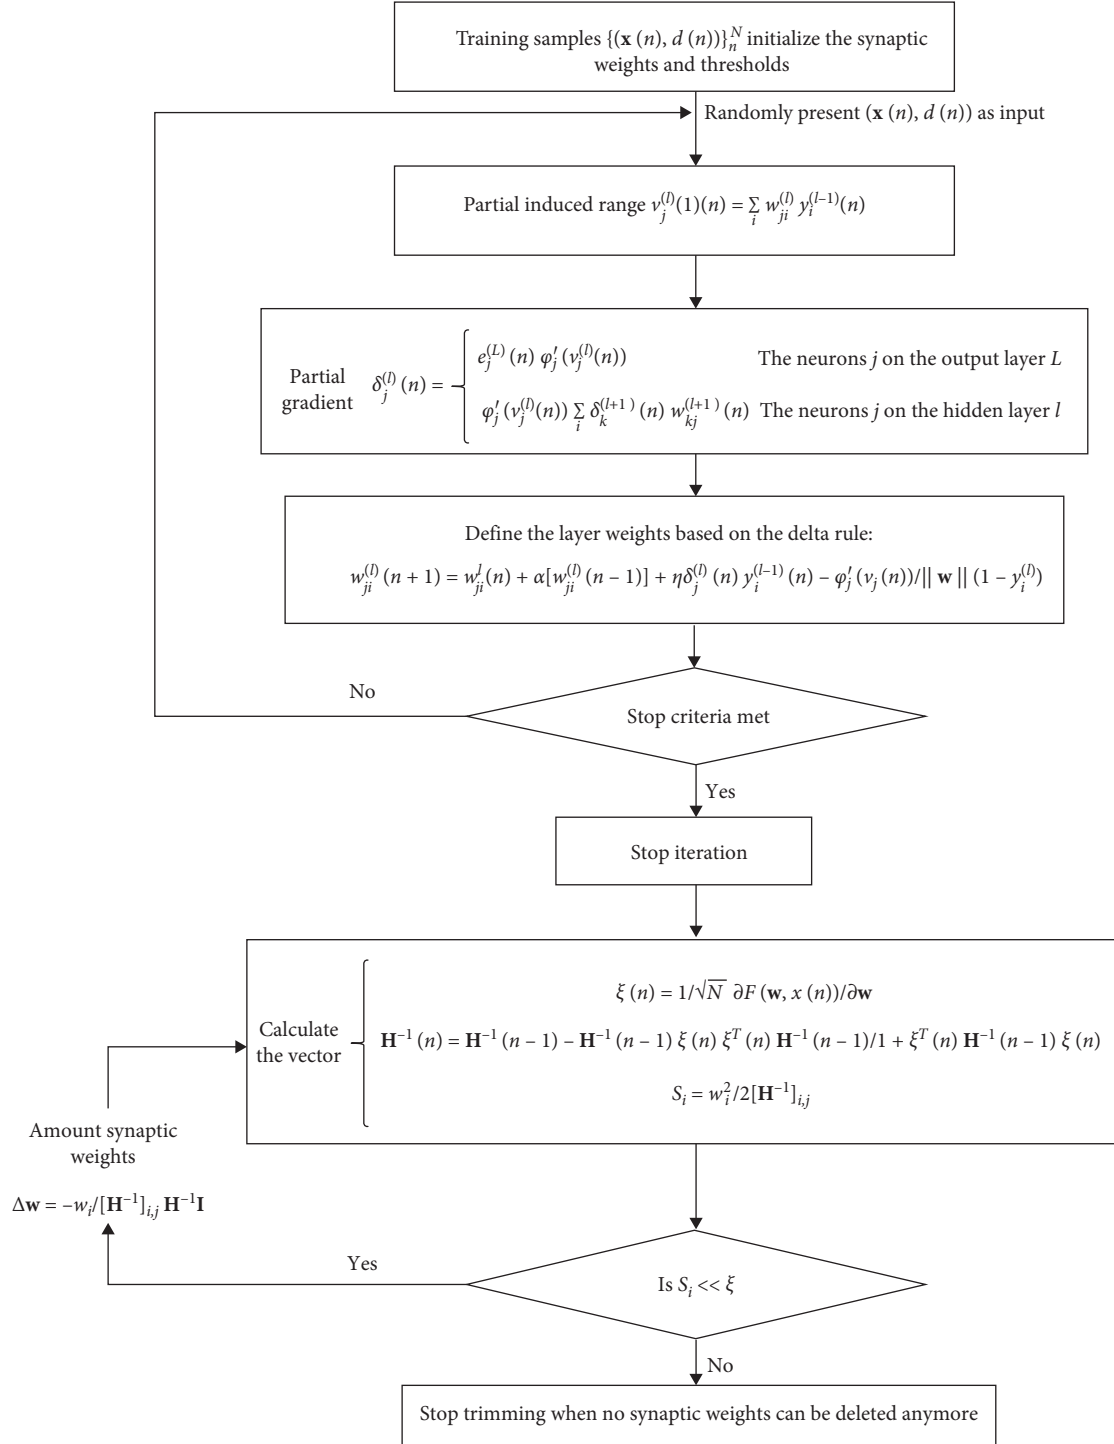

FIGURE 2: The regularized network training algorithm based on the sensitive area of Sigmoid function.

The sensitive area of the activation function proposed in equation (4) is introduced to the mean square error performance function:

$$\varsigma(n) = \frac{1}{2} \sum_{k \in C} e_k^2(n) - G_a(n), \quad (5)$$

where the neuron  $k$  is an output node.

The wider the sensitive area is, the stronger the generalization ability of the node is. The parameters in the parallel network are modified considering the distribution of sensitive areas and the anti-jamming ability of the network. Then excess weights, that is, the weights having little impact on performance and leading to overtraining, are removed in the pruning process using the second-order information of the error function and considering the complexity and the

training error performance. The final parameters then make it possible to minimize the growth of performance functions when removing them away, which are ideal compromises considering complexity and error performance, and they can further enhance generalization capabilities.

The training is actually a fitting process of nonlinear inputs and outputs, and the generalization of network can be seen as the nonlinear interpolation of the verification data. It is said that the network loses the ability to generalize in other samples when overfitting occurs. Numerous hidden units in a cascade network are likely to store too much noise effect. In that case, it is of necessity to use cross-validation.

Check the verification error in the corresponding parameters state under the set viewing cycle, and enter the next cycle if passing the validation. The training error converges along with the increase of training times, while the validation error monotonically decreases and then rises. The network starts to capture the noise information after crossing the minimum point. Hence, the state is regarded as the stopping criterion to reduce the occurrence of overfitting.

## 4. Coke Quality Prediction Model

**4.1. Data Preprocessing.** In general, the direct input of untreated data is not optimal. For example, the finite limit of the logistic activation function is  $(0, 1)$ , but the sample value is tremendous compared with its finite limit, which results in the function being almost saturated and the training being stagnated. In addition, the backpropagation algorithm is similar to the LMS algorithm, of which the calculation time is heavily dependent on the condition number  $\lambda_{\max}/\lambda_{\min}$ . The  $\lambda_{\max}/\lambda_{\min}$  of nonzero mean input is bigger than that of the zero-mean input.

Hence, it is required that mean value of the data on the entire training set is close to 0. The conventional processing is the mean centering and variance regulation. Let the input and output modes  $A \in R^{n \times m}$ ,  $C \in R^{p \times m}$  be arranged by columns, calculate the mean value of the  $n$ -th row of  $A$  and the  $p$ -th row of  $C$ , and subtract this mean value in each row. Calculate the variance of the  $n$ -th row in  $A$  and the  $p$ -th row in  $C$ , and divide the corresponding values in each row. The processing of the input matrix  $A$  and the output pattern matrix  $C$  should be synchronous.

**4.2. Multilayer Feedforward Backpropagation Network.** The parameters of mixed coal are selected as inputs and the coke quality as outputs in the FB model shown in Figure 3; cascade forward network can be used to solve more complex problems and improve the training precision, in which each subsequent layer is connected to the input layer and the adjacent one and the output is directly influenced by the input layer.

The excitation function is used to process the result of the summer, and the nonlinear function is generally used to maximize the efficiency of the network. In this paper, the logsig and tansig functions are used to perform the combination trial and error.

In the cascade forward backpropagation (CF) structure, it can be seen that the accuracy and fit effect that the training method can obtain are better than that of other training functions; hence, it is fixed as the training function in this paper.

The number of hidden nodes depends on the number of training samples, the size of the noise, and rules hidden in data. Commonly, it is best for the number of hidden nodes to be twice the number of input layers. It is illustrated by lots of tests carried out for 12–16 nodes in a single hidden layer that 16 nodes produce the best prediction result.

**4.3. RBF.**  $N$  samples are given in advance and the parameter  $r$  specifies the division between the training set  $\ell'$  and the verification one  $\ell''$ . Then, there are  $(1-r)N$  samples in  $\ell'$  and  $rN$  samples in  $\ell''$ . It is a good choice that the parameter  $r$  remains at a fixed value of 0.2 according to the simulation experiment by Keams; that is, the training set is assigned 80% of the samples and the remaining samples are distributed in the validation set  $\ell''$ .

The number of input nodes depends on the dimension of the input vector  $x$ , written as  $m_0$ .

The hidden layer size  $m_1$  is determined by the number of planned clusters, controlling the network performance and the computational complexity.

The clustering mean  $\hat{\mu}_j$  is obtained via the clustering algorithm and serves as the center of the basis function  $\varphi(x_j)$  which is known as  $x_j$ .

$\sigma = d_{\max}/2K$  is the extended parameter, where  $d_{\max}$  denotes the maximum distance between the centers ensuring that the hidden layer unit is neither too sharp nor too flat.

## 5. Simulation Results and Analysis

800 sets of mixed coal quality parameters and their corresponding coke quality indexes are randomly selected from the 1000 sets of preprocessed data to train FB, CF, and RBF networks, respectively.

**5.1. Results and Analysis of Training Results.** RBF can meet the conditions required by the Cover theorem. The adjustment of weight and threshold is considered by functions newrbe and newrb in constructing the network, so there are no specific training and learning functions for the network. In that case, only the training results of FB and CF networks are compared through error curves in Figures 4 and 5:

As can be seen from the figure, the results of training, verification, and test of the two networks basically remain consistent. Under almost identical iteration number, the performance of cascade forward network reaches 0.01, showing a slightly better behavior than that of the forward network (0.05) with the training time being close, while the prediction errors of both networks are comparatively small on the whole.

**5.2. Results and Analysis of Prediction Results.** The remaining 200 sets of mixed coal quality parameters are

FIGURE 3: The structure of FB network.

FIGURE 4: The training error curve of FB network.

FIGURE 5: The training error curve of CF network.

utilized to predict the coke quality by the above trained networks, and predictions of ash, sulfur, CRI, and CSR are shown in Figures 5–8. Prediction errors of 5% and 10% represent different levels of accuracy required by the business.

The line with the symbol of “◁” in Figures 6–9 denotes the error margin of 10%, The line with the symbol of “▷” in Figures 6–9 denotes the error margin of –10%, the line with the symbol of “△” represents that of 5%, the line with the symbol of “▽” represents that of -5% and the line with the symbol of “○” represents that of 0%. The symbols of “×”, “-,” and “|” show the prediction results of the FB, CF, and RBF networks, respectively.

Only three sets of ash prediction error are more than 10% in the FB, CF, and RBF networks, while the error between 5% and 10% exists in 51, 29, and 48 sets, respectively. There are 13 and 12 sets in the FB and the RBF networks, respectively, while there is one set in the CF network with the prediction error being more than 8%. It can also be illustrated from Figure 6 that the predictive values of CF network are closer to the 0% error margin line as a whole compared to the results of FB and RBF networks. Hence, the conclusion obviously can be drawn that the CF network performs much better than the others in terms of ash prediction.

FIGURE 6: Comparison of prediction errors of  $A_d$ .

FIGURE 8: Comparison of prediction errors of CRI.

FIGURE 7: Comparison of prediction errors of  $S_{r,d}$ .

FIGURE 9: Comparison of prediction errors of CSR.

The prediction errors of sulfur content of three networks are all within 10%, and errors of 54, 17, and 27 sets are beyond 5%, respectively. The forecast of sulfur content is more excellent than that of ash and the RBF is better than BP for prediction. It can also be seen from Figure 7 that the number of the predictive values of CF network outside the 5% error margin line is significantly less than that of FB and RBF networks. The CF network behaves excellently in the completion of sulfur content prediction.

The errors are also controlled within 10% in the three networks as for the CRI index, 29, 10, and 32 sets of samples among them having the errors over 5%. The prediction effect of CRI is much better than that of the former indicators. It is shown that the number of the predictive values of FB and

RBF networks outside the 5% error margin line is significantly greater than that of CF network and a majority of errors of CF are within the 5% error margin line.

The prediction of FB network is not so good for CSR, with 10 sets having errors between 10% and 15%, while there are only 2 sets in two other networks with the same errors. With 62, 19, and 24 sets of errors over 5%, respectively, in the three networks, the overall prediction effect of CRI is worst among the predictions of the four properties. It is shown that most of the predictive values of FB network are distributed between the 5% and 10% error margin line, and the effect is comparatively poor; values of CF network near the yellow line are slightly more than that of RBF. Hence, the CF network is quite suitable for the prediction of the data structure selected in this paper.

It can be concluded in general that the prediction results for the four properties are satisfactory and the prediction accuracy is relatively high, with the best prediction effect for the CRI and the most disappointing predictive result for the CSR. The cascade forward network performs best among the three networks with most errors controlled within 5%, while the forward BP behaves the worst, as its most prediction errors vary from 5% to 10% and even over 10%.

## 6. Conclusions

Three networks for coke quality prediction were proposed based on the forward backpropagation network, the cascade forward backpropagation network, and the radial basis network and the corresponding results were compared, respectively. It is shown that the prediction of the CRI is closest to the actual values with errors within 10% in all three networks, better than that of the CSR with errors between 10% and 15% in 14 sets of samples. The prediction errors for the four properties are all within 15% and it can be said that the three networks all have a relatively high prediction accuracy. When it comes to the network structure, the cascade forward network behaves best with errors mostly controlled within 5%, which acts as an excellent guide during the coke production to some extent. It is the additional connection between each layer and the front ones that ensures the prediction accuracy. The closer the hidden layer is to the output layer, the greater the amount of information of effect on weights adjusting. And the traditional forward network is not suitable here as its most errors are between 5% and 10% and even over 10%. In this way, it is concluded that the cascade forward network matches the data structure selected in this paper.

However, the main budget constraint is computing time for large-scale samples, and the advantage of cascade networks with a large number of internal connections is likely to become no longer obvious; hence, large-scale learning problems need to be further investigated.

In view of the defects of the motors used for flywheel energy storage such as great iron loss in rotation, poor rotor strength, and robustness, a new type of motor called electrically excited homopolar motor is adopted in this paper for flywheel energy storage. Compared to general motors, this motor has the advantages of simple structure, high rotor strength, and low iron loss in rotation. A double closed-loop PI governing system of the new motor was designed, modeled, and simulated with this motor as the controlled object on simulation platform. The simulation result shows that the PI-controlled electrically excited homopolar motor system realized fast speed governing and good system performance, achieved the purpose of quick charge by flywheel energy storage, verified the correctness and effectiveness of the design scheme, and provided data reference and theoretical basis for the practice of future flywheel energy storage experiments.

## 1. Introduction

Today the whole world is confronted with an increasing shortage of energy. Besides, constantly developing new energies, how to utilize existing energies effectively has become a hot spot of people's attention. Energy storage is an important way to achieve efficient utilization of energy [1], so the storage technology of electric energy, as a main form of energy consumed today, has become the most important research subject in the energy field.

In the 21st century, flywheel energy storage, owing to its many advantages including high energy ratio, high power ratio, high efficiency, wide application, no pollution, no noise, easy maintenance, and long service life, is bound to bring about an evolution to energy storage and show the prospect of green energy storage technology [2]. In overseas, the research of flywheel energy storage technology started between 1950s and 1970s when magnetically levitated energy

storage flywheel was created in the form of a series of prototype. At present, international leading companies in the field of flywheel energy storage include US-based Active Power which produces and supplies with UPS and energy storage flywheel developed by Japanese company with HTS magnetic levitation technology, which is mainly used for the trolley bus. As a replacement of traditional energy technology, flywheel energy storage technology is applied to fields such as transportation, energy generation, and aerospace relying on its strong competitiveness. Now, China is relatively backward in this field and still in the fledging period, but is gradually emerging being impacted by the current great upsurge around the world. The Flywheel Energy Storage Laboratory of Tsinghua University was the first institution in China to initiate the research of this technology and developed an energy storage flywheel prototype in 1999, which laid a solid theoretical and experimental basis for our flywheel energy storage technology. In

addition, Beijing University of Aeronautics and Astronautics, Nanjing University of Aeronautics and Astronautics and North China Electric Power University, etc., also completed this technology experiment and obtained their unique patented products.

Flywheel energy storage is a kind of energy-storing device utilizing physical interconversion between electric energy and mechanical energy (kinetic energy). It is mainly composed of auxiliary devices including flywheel, flywheel motor, motor controller, bearings, and vacuum chamber [3]. The flywheel energy storage system completes energy absorption and release by the flywheel motor and its controller, so the flywheel motor is the main part of this device. Systems using different flywheel motors and control types may have different performances. The energy storage flywheel motor and its control system is a complex integrated electromechanical system. As a new type of motor, the homopolar motor has not been widely known yet. Due to its advantages such as simple structure, high-strength rotor, and low iron loss in high-speed rotation, it is especially suitable for energy storage flywheel. By modeling and simulation research of the high-speed control system of electrically-excited homopolar motor [4] as the controlled object, we aim to provide a preliminary theoretical foundation and essential experimental basis for the Research on Topology Optimization and Dynamically Decoupling Nonlinear Control of High-speed Permanent Magnet Homopolar Motor with Solid Rotor by NSF of Inner Mongolia, in order to save the design cost and R&D time.

## 2. Structure and Principle of Homopolar Motor

Electrically-excited homopolar motor, such as general motors, also consists mainly of rotor, stator, and other relevant components, as shown in Figure 1. The differences are the stator and rotor materials and structural design. Due to cost consideration, the rotor bearings choose angular contact ball bearings in order to ensure stable and high-speed operation. Its rotor is made of 40CrNiMoA, adopts high-strength forged solid-steel structure with flywheel-motor integrated design, and is designed with uniformly distributed concaves and convexes [5] and antisymmetric upper and lower ends, as shown in Figure 2. The flywheel-motor integrated design, which enables the rotor to integrate the functions of kinetic energy storage and electromagnetic force output, greatly simplifies the design process, reduces the production cost, and makes the solid-steel rotor; the flywheel has the same level of energy storage density as the composite rotor flywheel. Its stator is composed of two parts, the armature and the exciter; its section view is shown in Figure 3. The motor stator has such characteristics: its armature windings use tinned copper braid which is parallel to rotor length axis and evenly distributed along rotor circumference; currents in adjacent in-phase windings flow to opposite directions; and three-phase current generates space rotating magnetic field; while the salient pole of the rotor induced by electromagnetic force drives the motor to rotate. The motor's parameters are provided in Table 1.

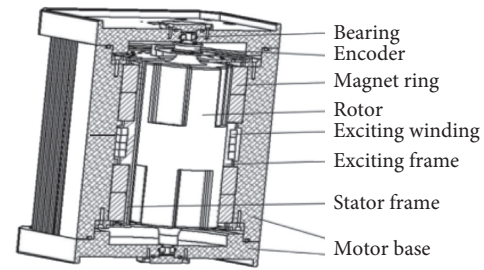

FIGURE 1: Section of motor assembly.

FIGURE 2: Structure of solid rotor.

FIGURE 3: Section of stator.

Running principle of electrically excited homopolar motor; its space magnetic field is generated by the impressed current through the exciting windings around the end circumference. Its magnetic loop is a closed circuit formed by exciting flux flowing from the upper end of the rotor, through the magnet ring and air gap into the lower end. Because the rotor's magnetism is generated by the exciting coil, its magnetic strength is controllable by exciting current. The motor rotates as its rotor's salient pole senses the corresponding space rotating magnetic field, while the required space rotating magnetic field is generated by the variable three-phase current through the rotor. The motor's operational principle is shown in Figures 4 and 5. As stator current flows from A to C, seen from the motor's upper end in Figure 4, A-phase winding current flows

FIGURE 4: Upper stator and rotor of the motor.

FIGURE 5: Lower stator and rotor of the motor.

clockwise; the magnetic field generated by armature winding is inward at S pole and outward at N pole. The upper salient pole (N pole) of the rotor rotates clockwise when induced by this electromagnetic force; similarly and simultaneously, seen from the motor's lower end in Figure 5, the rotor's salient pole (S pole) also rotates clockwise being driven by the magnetic field generated by the current varying counterclockwise in C-phase winding, i.e., the rotating magnetic field produced by variable current in the motor stator acts on the motor rotor and drives the latter to rotate.

### 3. Mathematical Model of Homopolar Motor

As the rotor of the motor in this paper has the characteristics of the salient pole structure, we built and deduced a unified dynamic mathematical model [6, 7] of the motor in the stator's three-phase coordinate system based on the basic electromagnetic relationship. And because the counter electromotive force wave and phase current output by the motor are similar to those by brushless DC motor, this motor's mathematical model is approximate to that of brushless DC motor.

The mathematical model of electrically excited homopolar motor using the motor's own vector in the stator's three-phase coordinate system is shown in Figure 6.

In this figure  $as$ ,  $bs$ , and  $cs$  are the corresponding axes of three-phase stator windings;  $A-A'$ ,  $B-B'$ , and  $C-C'$  are three-phase stator windings; the rotor speed  $\omega_r$  is set as counterclockwise,  $\psi e$  is the flux linkage vector generated by the external electromagnetic, forming an angle of  $\alpha$  with the plane of the stator three-phase coordinate system; and  $\psi e_0$  is the projection of  $\psi e$  in the coordinate system plane, with an angle of  $\theta$  with axis  $as$ .

Without affecting the control performance, simplified analysis shows that three-phase windings of the motor are symmetric, and its stator's voltage state equation is as follows:

$$\begin{bmatrix} u_a \\ u_b \\ u_c \end{bmatrix} = \begin{bmatrix} R_a & 0 & 0 \\ 0 & R_b & 0 \\ 0 & 0 & R_c \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} L_a & L_{ab} & L_{ac} \\ L_{ba} & L_b & L_{bc} \\ L_{ca} & L_{cb} & L_c \end{bmatrix} \frac{d}{dt} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix}. \quad (1)$$

In this equation,  $u_a$ ,  $u_b$ , and  $u_c$  are, respectively, the stator's three-phase terminal voltages (V);  $R_a$ ,  $R_b$ , and  $R_c$  are the resistances ( $\Omega$ ) of the motor's three-phase windings;  $L_{ab}$ ,  $L_{ba}$ ,  $L_{ca}$ ,  $L_{ac}$ ,  $L_{bc}$ , and  $L_{cb}$  are the mutual inductances (H) among the three-phase stator windings;  $L_a$ ,  $L_b$ , and  $L_c$  are the self-inductances (H) of the motor's three-phase windings;  $e_a$ ,  $e_b$ , and  $e_c$  are, respectively, the counterelectromotive forces (V) of the motor's three-phase windings; and  $i_a$ ,  $i_b$ , and  $i_c$  are the three-phase currents (A) of the stator.

Assuming that the three-phase winding is symmetric and the reluctance of rotor does not change as the rotor position shifts.

Namely,  $R = R_a = R_b = R_c$ ,  $M = L_{ab} = L_{ac} = L_{bc} = L_{ba} = L_{ca} = L_{cb}$ , and  $L = L_a = L_b = L_c$ .

In the brushless DC motor, the three-phase winding is symmetric; then,

FIGURE 6: Mathematical model of motor's 3-phase stator.

$$i_a + i_b + i_c = 0, \quad (2)$$

$$Mi_a + Mi_b + Mi_c = 0. \quad (3)$$

Thus, from equation (1), we can deduce

$$\begin{bmatrix} u_a \\ u_b \\ u_c \end{bmatrix} = \begin{bmatrix} R & 0 & 0 \\ 0 & R & 0 \\ 0 & 0 & R \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} L-M & 0 & 0 \\ 0 & L-M & 0 \\ 0 & 0 & L-M \end{bmatrix} \frac{d}{dt} \begin{bmatrix} i_a \\ i_b \\ i_c \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \\ e_c \end{bmatrix}. \quad (4)$$

The flux-linkage equation of the homopolar motor stator in the three-phase coordinate system is as follows:

$$\begin{cases} \psi_A = L_A i_A + M_{AB} i_B + M_{AC} i_C + \psi_e \cos \alpha \cos \theta, \\ \psi_B = L_B i_B + M_{AB} i_A + M_{BC} i_C + \psi_e \cos \alpha \cos \left( \theta + \frac{2}{3} \pi \right), \\ \psi_C = L_C i_C + M_{AC} i_C + M_{BC} i_B + \psi_e \cos \alpha \cos \left( \theta + \frac{4}{3} \pi \right). \end{cases} \quad (5)$$

The equation of the electromagnetic torque generated by the interaction between impressed exciting field and stator current and the motor's motion equation is as follows:

$$T_e = \frac{(e_a i_a + e_b i_b + e_c i_c)}{\omega_r}, \quad (6)$$

$$J \frac{d\omega_r}{dt} = T_e - T_L - B\omega_r. \quad (7)$$

In the equations,  $T_e$  is the motor's electromagnetic torque ( $N \cdot m$ );  $\omega_r$  is the motor's mechanical angular velocity (rad/s);  $J$  is the motor's rotational inertia ( $\text{kg} \cdot \text{m}^2$ );  $T_L$  is the load torque ( $N \cdot m$ ); and  $B$  is the damping coefficient ( $\text{s}^{-1}$ ).

## 4. Control Strategy of Homopolar Motor

Famous scholar Astrom once said [8] "in process control today, more than 95% of the control loops are of PID type." It shows the dominance [9] of the PID controller in the field of process control. The flywheel energy storage motor control system focuses more on the motor's speed regulation time and less on indexes such as control precision. Therefore, PID strategy is used to control the double closed-loop system of the homopolar solid rotor motor and applied in the research on flywheel energy storage.

**4.1. PID Control Strategy.** PID control is the most commonly used control law in the simulation control system. It is a kind of linear controller. Its structure is shown in Figure 7.  $r(t)$  is set input value;  $e(t)$  is control deviation;  $u(t)$  is control variable; and  $y(t)$  is actual output value.

PID control law:

$$u(t) = K_p e(t) + \frac{K_p}{T_i} \int_0^t e(t) dt + K_p T_d \frac{de(t)}{dt}, \quad (8)$$

or

$$u(t) = K_p e(t) + K_i \int_0^t e(t) dt + K_d \frac{de(t)}{dt}. \quad (9)$$

In the form of transfer function,

$$G_s = \frac{U(s)}{E(s)} = K_p + \frac{K_p}{T_i s} + K_p T_d s, \quad (10)$$

or

$$G_s = \frac{U(s)}{E(s)} = K_p + \frac{K_i}{s} + K_d s. \quad (11)$$

In the equations above,  $K_p$  is proportionality coefficient;  $T_i$  is integral time constant;  $T_d$  is differential time constant;  $K_i$  is integral coefficient,  $K_i = (K_p/T_i)$ ; and  $K_d$  is differential coefficient,  $K_d = K_p \times T_d$ .

For the convenience of computer implementation, the discrete method is adopted to convert continuous PID to the corresponding digital PID control algorithm [10, 11]. The expression is as follows:

$$u(k) = K_p e(k) + \frac{K_p T}{T_i} \sum_{j=0}^k e(j) + \frac{K_p T_d}{T} [e(k) - e(k-1)], \quad (12)$$

or

$$u(k) = K_p e(k) + K_i T \sum_{j=0}^k e(j) + \frac{K_d}{T} [e(k) - e(k-1)]. \quad (13)$$

In the equations,  $T$  is sampling period;  $k$  is sampling signal, ( $k = 1, 2, 3, \dots$ );  $e(k)$  is system deviation input value at the  $k$ th time of sampling;  $e(k-1)$  is system deviation input value at the  $(k-1)$ th time of sampling; and  $u(k)$  is control quantity output value at the  $k$ th time of sampling.

Its pulse transfer function is

FIGURE 7: Block diagram of the PID controller.

$$G(z) = \frac{U(z)}{E(z)} = K_p + \frac{K_i T}{1 - z^{-1}} + \frac{K_d}{T} (1 - z^{-1}). \quad (14)$$

Commonly used digital PID control algorithms include the following:

- (1) Full PID control: this kind of control algorithm directly presents the execution point of the actuator (such as motor speed and valve opening), and thus it is named full variable or positional PID control algorithm. It directly calculates based on the defining equations (9) and (10) of PID control law. Its disadvantage is that the output is full variable and always associated with all past states; moreover, it requires accumulation of  $e(k)$  in the calculation, which increases a huge amount of work.
- (2) Incremental PID control [11]: this control algorithm applies where the output is only the increment of the control variable. Where the actuator needs the increment of the controlled variable (such as step motor), incremental PID control algorithm can be deduced from full variable PID control algorithm. The formula is

$$\Delta U(k) = Ae(k) + Be(k-1) + Ce(k-2). \quad (15)$$

In this equation,  $A = K_p + K_i T + (K_d/T)$ ;  $B = K_p - (2K_d/T)$ ; and  $C = (K_d/T)$

Once the sampling period and coefficients  $A$ ,  $B$ , and  $C$  are determined, we can get the increment of the controlled variable by just entering three times of measurement deviations before and after the measurement. It presents the positional variation of the actuator between the two times of sampling. Compared with the positional one, the incremental one requires a much smaller amount of calculation and simple algorithm and is convenient for software programming. Therefore, it is widely used in practical production. Based on the incremental PID control algorithm, the recursion formula of full quantity PID control algorithm can also be deduced:

$$U(k) = U(k-1) + \Delta U(k). \quad (16)$$

The above formula is the digital recursive PID control algorithm widely used in digital control systems today.

Another great advantage of digital PID control is that it allows us to improve PID depending on the object and working condition so that PID control can achieve high-quality control effect in different fields. Commonly used improved digital PID control algorithms [12–15] include

differential forward PID control algorithm, incomplete differential control algorithm, integral clamping PID control algorithm, PID control algorithm with dead zone, and integral separation PID control algorithm.

**4.2. PID Controller Tuning.** We can see from PID control principle diagram 6 that the PID controller is composed of three major control links (proportion, integral, and differential) decided mainly by PID's three parameters which are mutually inseparable, interconnected, and restrictive. Look at the roles of proportion, integral, and differential in terms of overshoot, stability, response, and steady-state precision of the control system [10, 11]:

- (1) Proportional control link: proportionality coefficient  $K_p$  and deviation signal  $e(t)$  together constitute the proportional control link. It is the most basic link and plays a leading role in PID control. Once deviation occurs to the system, this link is immediately activated to reduce deviation. However, proportional control alone cannot eliminate system deviation. There will be a residual error. Larger proportional control coefficient  $K_p$  means stronger control effect, faster system response, and higher stability precision, but a too large  $K_p$  value is easy to cause system overshoot, instability, and oscillation. On the contrary, a too small  $K_p$  will reduce system's stability precision, prolong the transition time for system to reach the set value, slow down its response time, and spoil system static and dynamic characteristics.
- (2) Integral control link: integral coefficient  $K_i$  and the time integral of deviation together constitute the integral control link. Its main function is to eliminate system static error and improve system stability. Larger  $K_i$  means faster speed of eliminating system static error, but a too large  $K_i$  value is easy to lead to overshoot at the beginning of control due to integral saturation. On the contrary, a too small  $K_i$  value will have little effect in eliminating system static error and will also reduce the system's control precision.
- (3) Differential control link: differential coefficient  $K_d$  and the time differential of deviation together constitute the differential control link. It compensates the function of the proportional control link, prevents system overshoot, suppresses oscillation, and maintains system stability. It mainly predicts deviation change in the process of response and reduces it. The  $K_d$  value should not be too large; otherwise, it will suppress the response process in advance, prolong the tuning time, and reduce the system's antiinterference performance.

From the above effects of proportional coefficient  $K_p$ , integral coefficient  $K_i$ , and differential coefficient  $K_d$  on system and the synergy of the three, we can see that they are all critical for system control. The parameters of the PID controller vary with the steady-state condition of the control system. Once the working condition (or the process object's "characteristic") changes, then the optimal value of the

controller parameter changes too. This means controller tuning may be necessary at any time so that the control system and process control object reach the required rapidity, precision, and stability [16]. Commonly used PID parameter tuning methods include the following.

Testing method parameter tuning is also called engineering tuning method. It applies the valuable experience people accumulated in long-term engineering practice to the control system to test directly. This method is simple and easy to grasp. The testing method is to find out characteristic parameters in the response system according to the testing result and work out the controlling parameter with empirical formula.

Attenuation curve methods include 4:1 attenuation curve method and 10:1 attenuation curve method.

Empirical method, also known as trial and error, is a PID parameter tuning method including three steps from proportion to integral and then to differential. Turn the parameters repeatedly according to this sequence until a desired effect is achieved. Here is the procedure. First, tune the value of the proportionality coefficient. Increase it one by one and find one with small overshoot and quick response. Now, observe whether there is a static error. Add the integral coefficient if there is. When tuning the integral coefficient, decrease the set value from large to small and at the same time tune the proportionality coefficient. Observe the system response until the system static error is eliminated. While the eliminating system static error, keep an eye on system overshoot and response time. If the system overshoot is very large or response is slow, add the differential coefficient and tune again until desired control effect is obtained.

## 5. Control System Design and Modeling

Flywheel energy-storage system is composed of three major parts, flywheel rotor, motor/generator, and controller. The controller, as the system command center, directly determines the system's control performance [17]. Therefore, in the process of designing the control system of high-speed homopolar solid rotor motor with energy-storing flywheel, we built a control system simulation model (Figure 8) of electrically excited homopolar motor based on its operation principle and mathematical model with the modular modeling method [18–20] on MATLAB/SIMLINK simulation platform in order to shorten the design cycle and lower the research cost and risk. The control system simulation model of homopolar motor consists of seven subsystems, including homopolar motor, inverter, speed controller PI-W1, current controller PI-current, PWM generator, commutator, and decoder, as well as speed reference  $w_r$ -ref and load module TL.

As energy-storing flywheel requires high motor efficiency, the system of this homopolar motor is designed with double-closed-loop control. The outer one is speed loop. It applies PI control strategy to its speed controller PI-W1 to ensure the system dynamic tracking performance and suppress speed fluctuation. The inner one is the current loop. It applies integral separation PI control strategy to its current controller PI-current to limit the maximum current, makes

the system have enough accelerating torque, and ensures system stability and high-performance operation. Signal from the current controller is sent into the PWM generator which then produces PWM signal with adjustable pulse width. Then, PWM signal, along with rotor position decoder signal, is sent into commutator module which generates Hpwm-Lon mode of pulse modulation waves, according to rotor position decoding (Table 2) and commutation rule (Table 3) to control ordered switching of the inverter's IGBT full bridge circuits. This driving mode is an output mode with high leg PWM modulation and low leg constant live. It can suppress motor torque ripple and improve system dynamic performance [21]. Details of each subsystem are shown in Figures 9–13.

From the six switching states of the homopolar motor upon commutation, we note that the motor's commutation sequence is associated with the rotor position. According to the motor's operational principle, when the motor rotates clockwise, the switching relationship between the rotor position and the switching tube is given in Table 2. The switching tube's conducting state is set to "1", while its breaking state is set to "0".

## 6. Simulation Result and Analysis

Acceleration energy storage is one of the core issues of system control and relates to system's energy storing speed and safety. When energy storing acceleration is controlled, the flywheel motor runs as an electric motor [17]. In this paper, the parameters required by the homopolar motor and controller were set in a homopolar motor control system model which was built on the "simulation model editor" interface on software platform Matlab, see Table 4.

In order to test each performance index of the system after all module parameter settings of the homopolar motor control system and the corresponding program file embeddings were completed, we repeated system running, simulation, and tuning again and again and finally obtained the simulation result and made an necessary analysis of the tuning result and waveform.

In the simulation experiment of tuning the homopolar motor control system, in order to ensure the motor's safe startup and simulate some practical factors in its real environment, the motor started with a load (0.1 N·m) at the initial preset speed of  $n^* = 15000$  r/min. At 0.5 S it added an external load  $TL = 0.4$  N·m and continued to operate. The speed response wave is as shown in Figure 14.

Figure 14 shows that the motor quickly accelerates to 15,000 r/min after the start-up, with a little speed overshoot at the beginning, yet  $\sigma\% < 0.04\%$ , acceleration time  $t_p = 0.137$  S, and transition time  $t_s = 0.23$  s, with very small and negligible static error. At 0.5 S, the motor begins to run with load ( $TL = 0.4$  N·m) and slightly slows but maintains basically at 15,000 r/min. The whole system responds fast and runs steadily. Eventually, the motor speed is basically stable at the set value with little fluctuation.

Other performance indexes of the motor: Figure 15 is the torque wave of the electric motor. At 0.137 S, the torque is basically stable at 2.1 N·m but with notable fluctuation.

FIGURE 14: Speed waveform of PI control of homopolar motor.

When the motor runs with load at 0.5 S, the torque changes to 2.5 N.m. The pulse wave output by the commutator is PWM signal in Hpwm-Lon modulation mode (see Figure 16). Figure 17 is the induction electromotive force of three-phase motor stator. The stator's induction electromotive force is in the form of 180° trapezoidal wave and each corresponding phase of the magnetic flux is also in

trapezoidal waveform, so this system is also known as the speed-governing system of trapezoidal-wave permanent magnet synchronous motor (TPMSM). Figure 18 is the induced current waveform of the three-phase motor stator. The motor current is in 120° rectangular waveform. As the voltage adopts PWM chopper control, the rectangular wave contains a significant harmonic component. Upon the

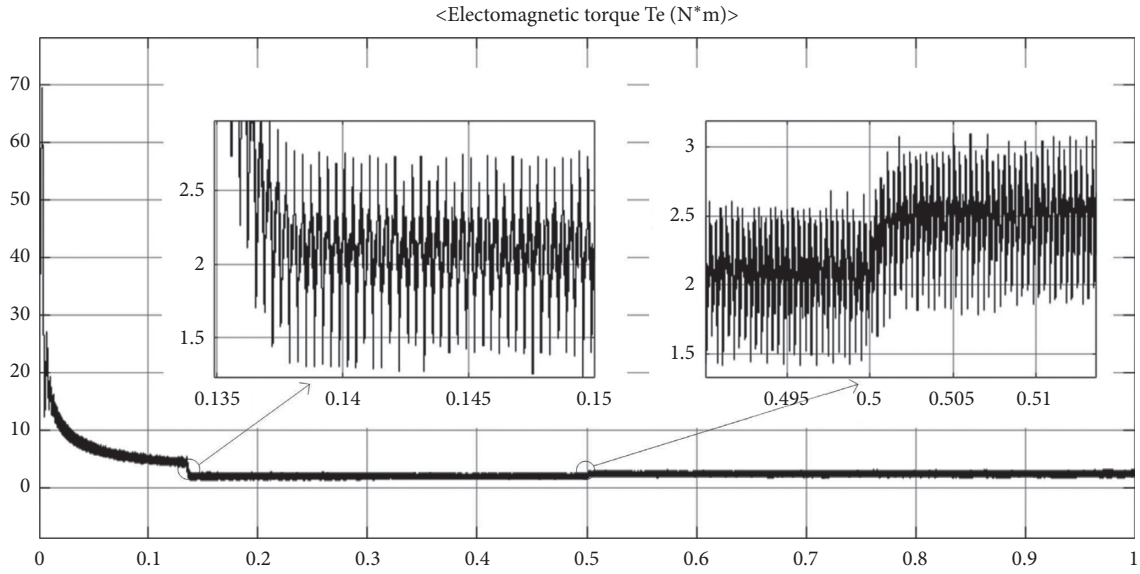

FIGURE 15: Torque waveform of the homopolar motor of PI control.

FIGURE 18: Three-phase-induced current waveform of the homopolar motor of PI control.

loading at 0.5 S, the state of the power switching tube of the PWM modulator changes and causes the current pulse amplitude to vary slightly.

It is thus clear that the simulation result basically coincides with the expected result, which suggests that the control method is feasible. The purpose of this research, however, is only to verify the correctness and feasibility of this control method by simulation and analysis considering the large inertia of flywheel and long acceleration time in the practical control of flywheel motor acceleration. The experiment result and the discussion part of work apply to general parameters and to the parameters used in experiment.

## 7. Conclusion

Flywheel energy storage will be a future direction for the field of energy saving, though traditional flywheel motors have the defects of great iron loss in rotation, poor rotor strength, and robustness. In view of these problems, the electrically excited homopolar motor is adopted for flywheel energy storage in this research for its advantages such as simple structure, high rotor strength, and low iron loss in high-speed rotation. A PI-controlled double closed-loop governing system of the homopolar motor was designed on simulation platform Simulink. And the charging process of the flywheel energy storage is studied in this paper. The simulation result shows that the control system of the electrically excited homopolar motor realized the regulating of motor phase current and torque by modulating PWM duty cycle in Hpwm-Lon mode with a speed-current controller using PID control strategy, realized fast speed governing, showed good static and dynamic performances, and achieved the purpose of quick charge by flywheel energy storage. This research is just a small part of the flywheel energy storage project which will continue the research and verification of the energy storage and discharge process later, use advanced motor intelligent control algorithm to realize homopolar motor's robust control, reduce the switching loss and torque ripple, and further improve the system performance.

For face recognition systems, liveness detection can effectively avoid illegal fraud and improve the safety of face recognition systems. Common face attacks include photo printing and video replay attacks. This paper studied the differences between photos, videos, and real faces in static texture and motion information and proposed a living detection structure based on feature fusion and attention mechanism, Dynamic and Texture Fusion Attention Network (DTFA-Net). We proposed a dynamic information fusion structure of an interchannel attention block to fuse the magnitude and direction of optical flow to extract facial motion features. In addition, for the face detection failure of HOG algorithm under complex illumination, we proposed an improved Gamma image preprocessing algorithm, which effectively improved the face detection ability. We conducted experiments on the CASIA-MFSD and Replay Attack Databases. According to experiments, the DTFA-Net proposed in this paper achieved 6.9% EER on CASIA and 2.2% HTER on Replay Attack that was comparable to other methods.

## 1. Introduction

With the application of face recognition technology in the identification scene such as access security check and face payment, the methods of attack and fraud against face recognition system also appear. Face is obviously a much easier way to steal identity information than biometric features such as iris and fingerprints. Attackers can easily steal images or videos of legitimate users on social networking sites and then launching print or replay attacks on face recognition systems. Some face verification systems use techniques such as face tracking to locate key points on the face, requiring users to complete actions such as blinking, shaking their heads, and reading text aloud and use motion detection to determine whether the current image is a real face. This approach is not suitable for silent detection scenarios. In addition, some researchers use infrared camera,

depth camera, and other sensors to collect different modes of face images to achieve living detection [1–3]. These methods show excellent performance in many scenarios but need to add information acquisition equipment other than camera to face recognition devices, need to invest additional hardware costs, and cannot meet the requirements of some mobile devices. In this paper, we will study the monocular static and silent living detection and achieve the living detection task by analyzing the difference between real face and fake face in image texture, facial structure, action change, and so on.

Real face image is often taken directly by the camera, while attacking face images are collected many times. As shown in Figure 1, false face images may show the texture of the image carrier itself, and the light region with large difference from the real face image is also easy to appear in the false face image. According to this, researchers proposed

many feature descriptors for characterizing the living texture of face and then implemented the classification by training models such as SVM and LDA classifier. In order to characterize the high semantic features of face living body, the deep neural network is applied in the feature extraction process to further enhance the performance of living detection. The features included in the local area of the face can often be used as an important basis for living detection and play a different role, as shown in Figure 2. Based on this, some researchers [4, 5] decomposed faces into different regions to extract features through neural networks and then realize feature splicing.

Most prosthetic faces are difficult to simulate the vital signs of real faces, such as head movement, lip peristalsis, and blinking. At the same time, due to background noise, skin texture, and other factors, the dynamic characteristics of real face in some frequency bands are obviously higher than that of fraudulent face, which provides the basis for distinguishing real face from fraudulent face. The variation in optical flow field is an important basis of this kind of algorithm. However, the dynamic information generated by movement and bending of photo will influence the extraction of life signals. Remote photoplethysmography (rPPG) is another effective noncontact living signal extraction method, which provides a basis for face living detection by observing face images to calculate the changes in blood flow and flow rate [6, 7], but the rPPG method has strict requirements for algorithm application environment.

This work proposed a network that fuses dynamic and texture information to represent face and detect the attacks. Optical flow method is used to calculate the motion change in two adjacent frames of face images. The optical flow generated by the bending and movement of the photo is different from the optical flow generated by the movement of the real face in the direction of displacement. We use a simple convolutional neural network with the same structure to characterize the magnitude and direction of displacement. Then, a feature fusion module is designed for the combination of the above two representations so that, on this basis, facial motion features can be further extracted. In addition, RGB images are used to extract texture information of the face area. By giving a different attention to the parts of the face, we enhance the network's ability to represent living faces.

Face detection algorithms are widely used in living body detection tasks, which can be used to locate faces, thereby eliminating the interference of background information on living body detection. In this paper, for face detection scenes under complex lighting, we propose an improved image preprocessing algorithm combined with local contrast in the face area, which effectively improves the performance of the face detection algorithm.

## 2. Relating Works

*2.1. Texture based.* Living verification is completed by using the difference between real face and replay image in surface texture, 3D structure, image quality, and so on. Boulkenafet et al. [8] analyzed the chroma and brightness difference

between real and false face images, it is based on the color local binary pattern, and the feature histogram of each order image frequency band was extracted as the face texture representation. Finally, the classification was realized by support vector machine, and testing on the Replay Attack Dataset obtained the half error rate; it is 2.9%. Galbally et al. [9] prove that the image quality loss value produced by Gaussian filtering can distinguish the truth effectively with fraudulent face images, designed a quality assessment vector containing 14 indicators, and proposed a live detection method, the method in combination with LDA (linear discriminant analysis), and obtained 15.2% half error rate on the Replay Attack Dataset. However, such methods based on static feature often require the design of specific descriptors for a certain types of attacks, and the robustness is poor under different light conditions and different fraud carriers [10].

*2.2. Dynamic Based.* Some researchers have proposed a face living detection algorithm based on dynamic features by analyzing face motion patterns and show good performance in related datasets [11]. Kim et al. [12] designed a local velocity pattern for the estimation of the speed of light and distinguished the fraud from the real face according to the difference in the diffusion speed between the light on the real face and the fraud carrier surface. A 12.50% half error rate was obtained on the Replay Attack Dataset. Bharadwaj et al. [13] amplify the blink signal which is 0.2–0.5 Hz in the image by the Eulerian motion amplification algorithm, combined with local binary pattern with directional flow histogram (LBP-HOOF) to extract dynamic features as classification basis and obtained error rate which is 1.25% on the Replay Attack Dataset. At the same time, they proved the positive effect of image amplification algorithm on the performance of the algorithm. Freitas et al. [14] learned from the facial expression detection method, extracted feature histograms from the orthogonal plane of time-spatial domain by using LBP-TOP operator, used support vector machine to classify, and got 7.6% half error rate on Replay Attack Dataset. Xiaoguang et al. [15] based on the action information between adjacent frames established a CNN-LSTM network model, used convolutional neural network to extract the texture features of adjacent frame face images, and then input it to the long- and short-term memory structure to learn the time-domain action information in face video.

In addition, some researchers combined different detection equipments or system modules to fuse information on different levels, which effectively increased the accuracy of living detection [1, 16]. Zhang and Wang [17] used Intel RealSense SR300 camera to construct multimodal face image database including RGB image, depth image (depth), and infrared image (IR). The face region was accurately located using face 3D reconstruction network PRNet [18] and mask operation and then based on ResNet 18 classification [19] network to extract and fuse feature of multimodal data which mixed RGB, depth, and IR.

FIGURE 2: Weights visualization of a layer in a depth neural network for real face texture information extraction. Different face regions occupy different weights in living detection task.

### 3. Proposed Method

**3.1. Face Detection in Complex Illumination.** In order to eliminate the interference of background in the process of living information extraction, it is necessary to segment the face area of the image. Traditional detection techniques can be divided into three categories: the face detection based on feature, the face detection based on template, and the face detection based on statistics. This paper uses face front detection API provided by Dlib, which uses gradient direction histogram feature to achieve face detection. The face detection algorithm based on gradient direction histogram can maintain good immutability of image texture and optical deformation and ignore the slight texture and changes in expression.

Histogram of Oriented Gradients (HOGs) is a method used to describe the local texture features of image. The algorithm divides the image into small spaces and calculates the gradient of pixel points in each space. The pixel point gradient calculation is shown in the following equations:

$$G_x(x, y) = I(x + 1, y) - I(x - 1, y), \quad (1)$$

$$G_y(x, y) = I(x, y + 1) - I(x, y - 1), \quad (2)$$

where  $G_x(x, y)$  and  $G_y(x, y)$  are the horizontal gradient and vertical gradient at the  $(x, y)$  of the image, respectively,

and  $I(x, y)$  is the gray value. In reality, local shading or over exposure will affect the extraction of gradient information because the image target will appear in different light environments, as shown in Figure 3. In order to enhance the robustness of the HOG feature descriptor to environmental changes and reduce the noise such as the local shadow of the image, a Gamma correction algorithm is used to preprocess the image to eliminate the interference of partial light.

Traditional Gamma correction method changes the brightness of image by selecting the appropriate  $\gamma$  operator, as follows:

$$O(x, y) = 255 \times \left[ \frac{I(x, y)}{255} \right]^\gamma, \quad (3)$$

where  $I(x, y)$  is the pixel value of the image at the position  $(x, y)$ ,  $O(x, y)$  is the corrected pixel value, and  $\gamma$  is the constant. The traditional method performs image processing at the global level without considering the lightness difference between local and neighborhood pixels. Therefore, Schettini et al. [20] proposed a formula for the value of  $\gamma$  operator:

$$\gamma[x, y] = \partial^{[128 - \text{mask}(x, y)/128]},$$

$$\partial = \begin{cases} \frac{(\ln(\bar{I}/255))}{(\ln(0.5))}, & \bar{I} < 128, \\ 1, & \bar{I} = 128, \\ \frac{(\ln(0.5))}{(\ln(\bar{I}/255))}, & \bar{I} > 128, \end{cases} \quad (4)$$

where mask is an image mask and Gaussian blur can be used in practice. For the more balanced image with bright area and dark area, the average pixel of the image is close to 128, so the calculated  $\alpha$  is close to 1, and the image is hardly changed, which obviously does not meet the actual needs. Considering the local feature of face, this paper introduces

FIGURE 3: HOG feature of shadow on face region under light condition. It is necessary to initialize the face image because the shadow or exposure caused by complex light can affect the face region gradient information.

the local normalization method proposed in [21] to calculate the ratio relation of pixels in the neighborhood and adjust the operator  $\alpha$ :

$$\partial(x, y) = \begin{cases} \frac{(\ln(\bar{I}/255))}{(\ln(0.5))} + \frac{N(x, y)}{(\ln(\bar{I}/255))} \ln(0.5), & \bar{I} < 128, \\ \frac{(\ln(0.5))}{(\ln(\bar{I}/255))} + \frac{N(x, y)}{(\ln(0.5))} \ln\left(\frac{\bar{I}}{255}\right), & \bar{I} \geq 128. \end{cases} \quad (5)$$

Among them, the specific calculation process of local normalized characteristic  $N$  is as follows:

- (1) To calculate the maximum pixel value  $I_m(x, y)$  in the neighborhood  $\varphi(x, y)$  centered on pixel  $(x, y)$ ,

$$I_m(x, y) = \max\{I(i, j) \mid (i, j) \in \varphi(x, y)\}. \quad (6)$$

- (2) To calculate the median value of the  $I_m(x, y)$  of all pixels centered on pixel  $(x, y)$ ,

$$I_{mm}(x, y) = \text{medium}\{I_m(i, j) \mid (i, j) \in \varphi(x, y)\}. \quad (7)$$

- (3) To calculate the maximum value of the  $I_{mm}(x, y)$  of all pixels centered on pixel  $(x, y)$ ,

$$S(x, y) = \max\{I_{mm}(i, j) \mid (i, j) \in \varphi(x, y)\}. \quad (8)$$

- (4) To calculate the ratio of pixels  $(x, y)$  to neighborhood pixels,

$$N(x, y) = \frac{I(x, y)}{S(x, y)}. \quad (9)$$

We use algorithm in [20] and the improved algorithm in this paper to preprocess the portrait 208 photos on YaleB subdatabase that is difficult to be detected by HOG under complex lighting conditions and then detect 196 and 201 faces separately. The result is shown in Figure 4.

**3.2. DTFA-Net Architecture.** In Section 3.2, we mainly introduce the dynamic and texture features fusion attention network DTFA-Net. As shown in Figure 5, the optical flow graph and the texture image are, respectively, subjected to obtain  $256 \times 2$  and  $256 \times 4$  embedding by extracting dynamic feature and texture feature from subnetwork and then fusing the spliced  $256 \times 6$  features through the fully connected layer and living detection. The specific details of the network are described below.

**3.2.1. Dynamic Feature Fusion.** This paper generates the optical flow field change map of adjacent two frames of face video by the optical flow method. The optical flow change in face region is extracted by dynamic feature fusion subnetwork in two dimensions of displacement and size, and the features of the two dimensions are fused by feature fusion block to extract the dynamic information of face region.

(1) *Optical Flow.* Optical flow method is a proposal used to describe the motion information of adjacent frame objects. It reflects the interframe field changes by calculating the motion displacement in the  $x$  and  $y$  directions of the image on the time domain. Defining video midpoint  $P$  located  $(x, y)$  of the image at the  $t$  moment and moving to the place  $(x + dx, y + dy)$ , then when the  $dt$  is close to 0, the two pixel values satisfy the following relationship:

$$I(v) = I(v + d), \quad (10)$$

where  $v = (x, y)$  is the coordinate of the point  $P$  at the time  $t$ ,  $I(v)$  is the gray value of the place  $(x, y)$  at the time  $t$ ,  $d = (dx, dy)$  is the displacement of the point  $P$  during  $dt$ , and  $I(v + d)$  is the gray value of the place  $(x + dx, y + dy)$  at the time  $t + dt$ .

In this paper, the dense optical flow method proposed by Farneback [22] is used to calculate the interframe displacement of face video. The algorithm approximates the pixels of two-frame images by a polynomial expansion transformation. And it based on the assumption that the local optical flow and the image gradient are stable, and the displacement field is deduced in the polynomial expansion coefficient. We transform the displacement  $d = (dx, dy)$  to the extreme coordinate system  $\bar{d} = (\rho, \theta)$  and visualize the optical flow displacement and direction by the HSV model. As shown in Figure 6, the optical flow change image obtained will be used as input of the dynamic feature fusion network.

(2) *Fusion Attention Module.* In the process of dynamic information extraction, we extract, respectively, the motion information contained in the input optical flow change direction feature map and the optical flow change intensity feature map through 5 convolution layers. Because the motion pattern of living human face contains two dimensions of direction and intensity, it is necessary to combine the above representations to further extract the moving features of the face. As a result, we designed a fusion module, as shown in Figure 7.

FIGURE 4: Comparison between [20] and ours. The improved algorithm we proposed performs better than that in [20]. (a) Original images that cannot detect face by HOG; (b) images processed in [20] and the detection result; (c) images processed by ours and the detection result.

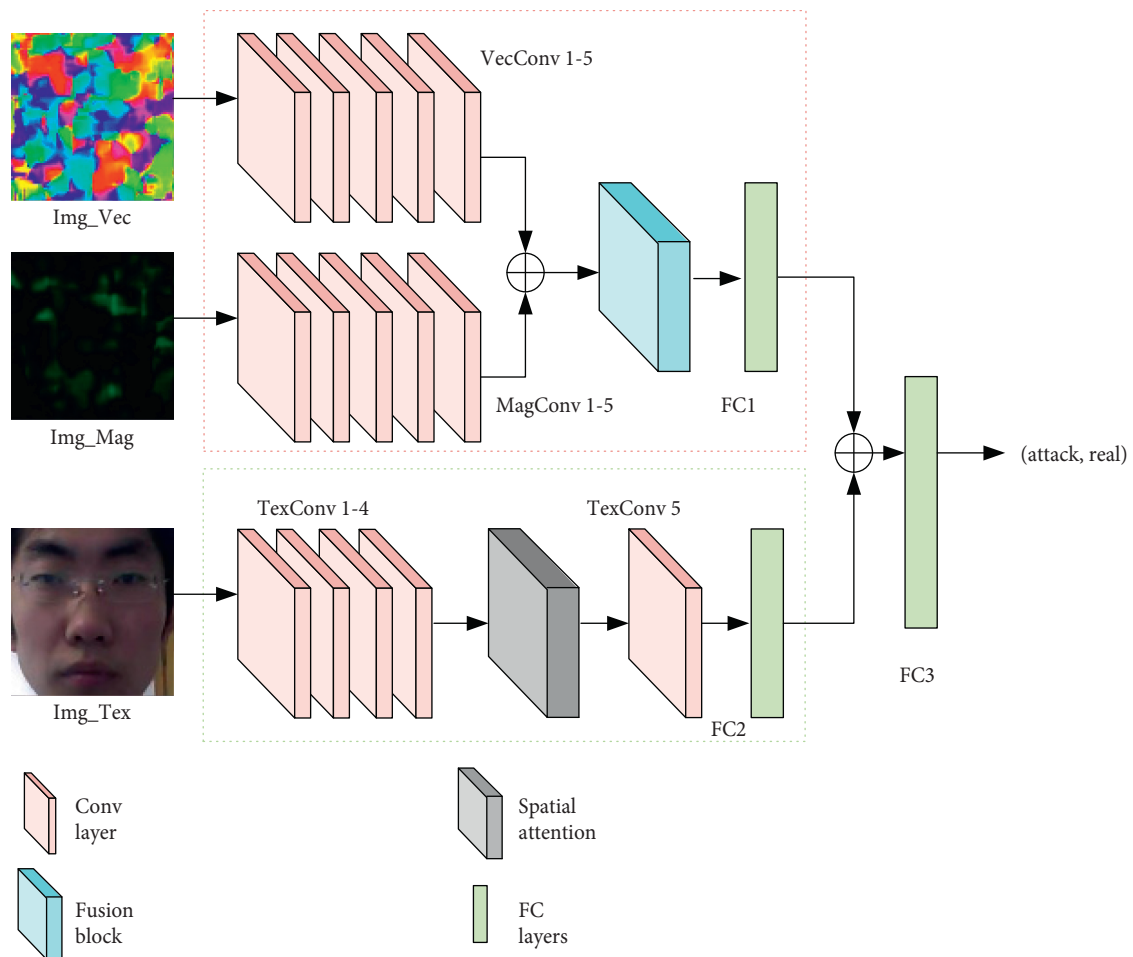

FIGURE 5: The dynamic and texture features fusion attention network (DTFA-Net) architecture. The figure omits the ReLU and pooling layers after the convolution layer, and the id of the convolution is shown on the top. Color code used is as follows: pink = convolution; blue = fusion block; gray = spatial attention; green = fully connected layer.

FIGURE 6: Optical flow visualization of two adjacent face regions: (a) visualization of changes in optical flow direction: hue = direction of optical flow, saturation = 255, and value = 255; (b) optical flow magnitude visualize: hue = 255, saturation = 255, and value = size of optical flow. Among them, the left two are the optical flow changes in the real face, and the right two groups are the optical flow changes in the photo attacks.

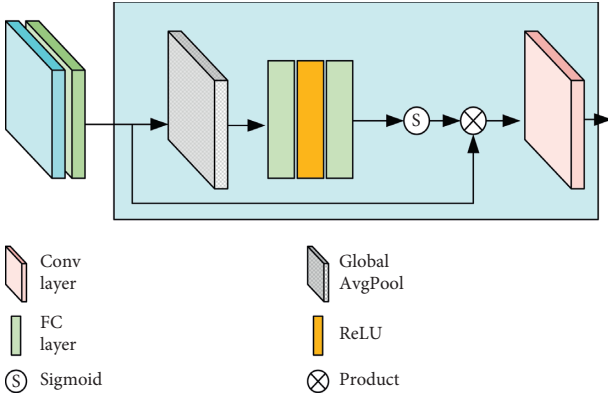

FIGURE 7: Fusion attention module architecture.

To improve the characterization ability of the model, we use the SE structure [23] in the fusion module, which gives different weights for the optical flow intensity, and direction features to strengthen the decision-making ability of some features. First, global pooling of feature graphs is

$$\text{op}_c = \text{AvgPool}(F_{\text{op}}) = \frac{1}{H \times W} \sum_{i=1}^H \sum_{j=1}^W F_{\text{op}}(i, j), \quad (11)$$

where  $F_{\text{op}}(i, j)$  stands for the concatenated features of optical magnitude and angle. Through global average pooling, the dimension of the stitching feature map changes from  $C \times H \times W$  to  $C \times 1 \times 1$ . Secondly, learn the nonlinear functional relationship between each channel through full connection (FC) and activation function (ReLU). Then, use normalization (sigmoid) to get the weight of each channel:

$$\text{op}_a = \sigma(\text{FC}(\delta(\text{FC}(\text{op}_c))))), \quad (12)$$

where  $\sigma$  is the sigmoid function and  $\delta$  is the ReLU function. The two fully connected layers are used to reduce and recovery dimension, respectively, which is helpful to improve the complexity of the function. Finally, we multiply  $F_{\text{op}}$  with  $\text{op}_a$  and pass through a convolution layer to get the fusion features:

$$F_{\text{op}^+} = \text{Conv}(\text{op}_a \otimes F_{\text{op}}). \quad (13)$$

(3) *Network Details.* Dynamic feature extraction subnetwork input image size is  $227 \times 227 \times 3$ , which contains 11 convolution layers, 2 full connected layers, and 6 pooling layers. Tables 1–3 show the specific network parameters of convolution and pooling layers.

3.2.2. *Texture Feature Representation.* In specific, we map the input RGB image to the intermediate feature maps with a dimension of 384 through TexConv1-4 and then pay more attention to some of the regions through the spatial attention mechanism and then input the output of the attention module to TexConv5 and full connection layer FC2 performs feature extraction. The structure of the convolutional layer TexConv1-5 is shown in Table 1, and the structure of the fully connected layer FC2 is shown in Table 4.

(1) *Spatial Attention Block.* After experiments, we found that neural networks often pay special attention to the human eyes, cheeks, mouths, and other areas when extracting living features. Therefore, we added a spatial attention module to the static texture extraction structure and give a different

attention to the features of different face regions. We adopted the CBAM (Figure 8) spatial attention structure proposed in [24]. This module reduces the dimension of the input feature map through the maximum pooling and average pooling layers, splices the two feature maps, and obtains the attention weight of  $1 * H * W$  by the convolution layer and activation function:

$$SA_c = \delta(\text{Conv}(\text{Cat}(\text{AvgPool}(F_t), \text{MaxPool}(F_t)))). \quad (14)$$

Finally, we utilized element-wise product for input  $F_t$  and  $SA_c$ , and the output of the spatial attention block will pass through the next layers, TextConv5 and FC2:

$$F_{t+} = SA_c \otimes F_t. \quad (15)$$

**3.2.3. Feature Fusion.** Through the above two subnetworks, dynamic information and texture information are obtained, respectively. By a series of fully connected layers, dropout layers, and activation functions, we fully fuse the two

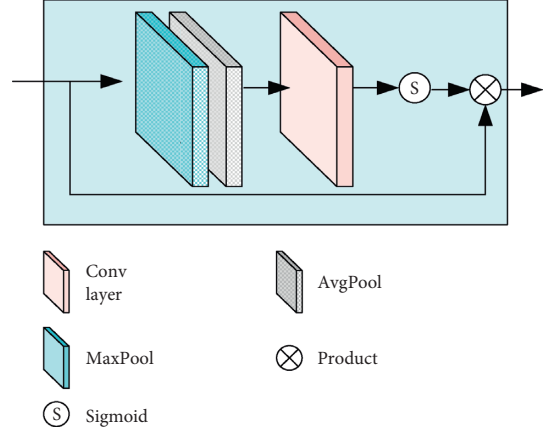

FIGURE 8: Spatial attention block. We introduce this module after the convolution layer of the subnetwork is extracted from the static feature, which gives the difference attention to the local area of the face.

information, learning the nonlinear relationship between the dynamic and static features, and obtain a two-dimensional representation of face in living information for living detection, as shown in Table 4.

## 4. Experiment

**4.1. Dataset.** We use CASIA-MFSD [25] to train and test the model. The dataset contains a total of 600 face videos collected from 50 individuals. Face video of real face, photo attack, and video attack scenes are collected at different resolutions. Among them, photo attack includes photo bending and photo mask. We ignore the different attack ways and divide all the videos into real face and false face. Through the calculation of optical flow field, face region detection and tailoring, etc., get 35428 sets of training images and 64674 sets of test images, as shown in Figure 9. And we also train and test our model on Replay Attack Database.

**4.2. Evaluation.** This experiment uses false acceptance rate (FAR), false rejection rate (FRR), equal error rate (EER), and half total error rate (HTER). The face living detection algorithm is based on these indicators. The FAR refers to the ratio of judging the fake face as the real face; the FRR refers to the ratio of judging the real face as false, and the calculation formulas are shown as follows:

$$FAR = \frac{N_{f_r}}{N_f}, \quad (16)$$

$$FRR = \frac{N_{r_f}}{N_r}, \quad (17)$$

where  $N_{f_r}$  is the number of false face error,  $N_{r_f}$  is the number of real face error,  $N_f$  is the number of false face liveness detection, and  $N_r$  is the number of real face detection. The two classification methods of this experiment are as follows: (1) nearest neighborhood (NN), which corresponds the two-dimensional vector, of which each

FIGURE 9: CASIA-MFSD examples after preprocessing. From left to right: texture image, optical flow magnitude, and optical flow direction. Among them, (a) fake face and (b) real face.

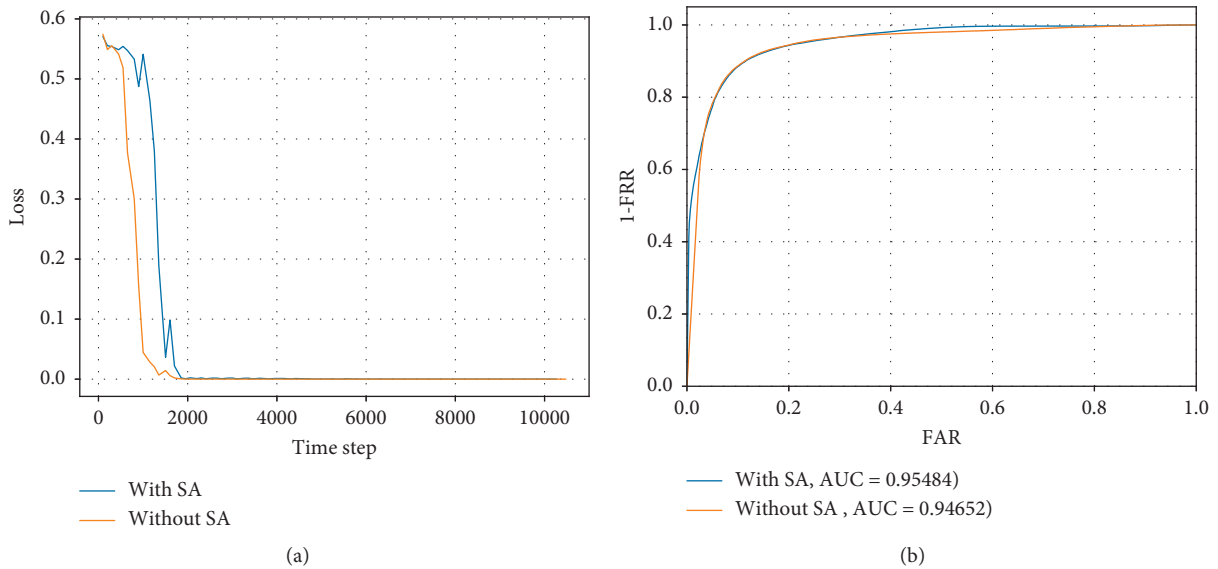

FIGURE 10: Network loss and ROC curve with or without spatial attention module: (a) training loss as time step went by; (b) ROC curve.

dimension value represents the probability of real face or attack face and selects the category which corresponds to the maximum value as the classification result. (2) Thresholding selects a certain threshold to classify the representation result. This method is mainly for model validation and testing. Calculating FAR and FRR at different thresholds can plot the receiver operating characteristic (ROC) curve for measuring the nonequilibrium in the classification problem; the area under the ROC curve (area under curve, AUC) can intuitively show the algorithm classification effect.

**4.3. Implementation Details.** The proposed method is implemented in Pytorch with an inconstant learning rate (e.g.,  $lr = 0.01$  when  $epoch < 5$  and  $lr = 0.001$  when  $epoch \geq 5$ ).

The batch size of the model is 128 with  $num\_worker = 100$ . We initialize our network by using the parameters of AlexNet100. The network is trained with standard SGD for 50 or 100 epochs on Tesla V100 GPU. And we use cross entropy loss, and the input resolution is  $227 \times 227$ .

#### 4.4. Experimental Result

**4.4.1. Ablation of Spatial Attention Module.** We conducted an ablation experiment on the attention module of the texture feature extraction subnetwork and only rely on texture features to perform live detection on the CAISA dataset. We trained the two texture feature extraction networks with or without spatial attention block 50 times,

FIGURE 11: Change in weight heat map before and after spatial attention module: (a) before; (b) after. The spatial attention module pays special attention to some features of the face area.

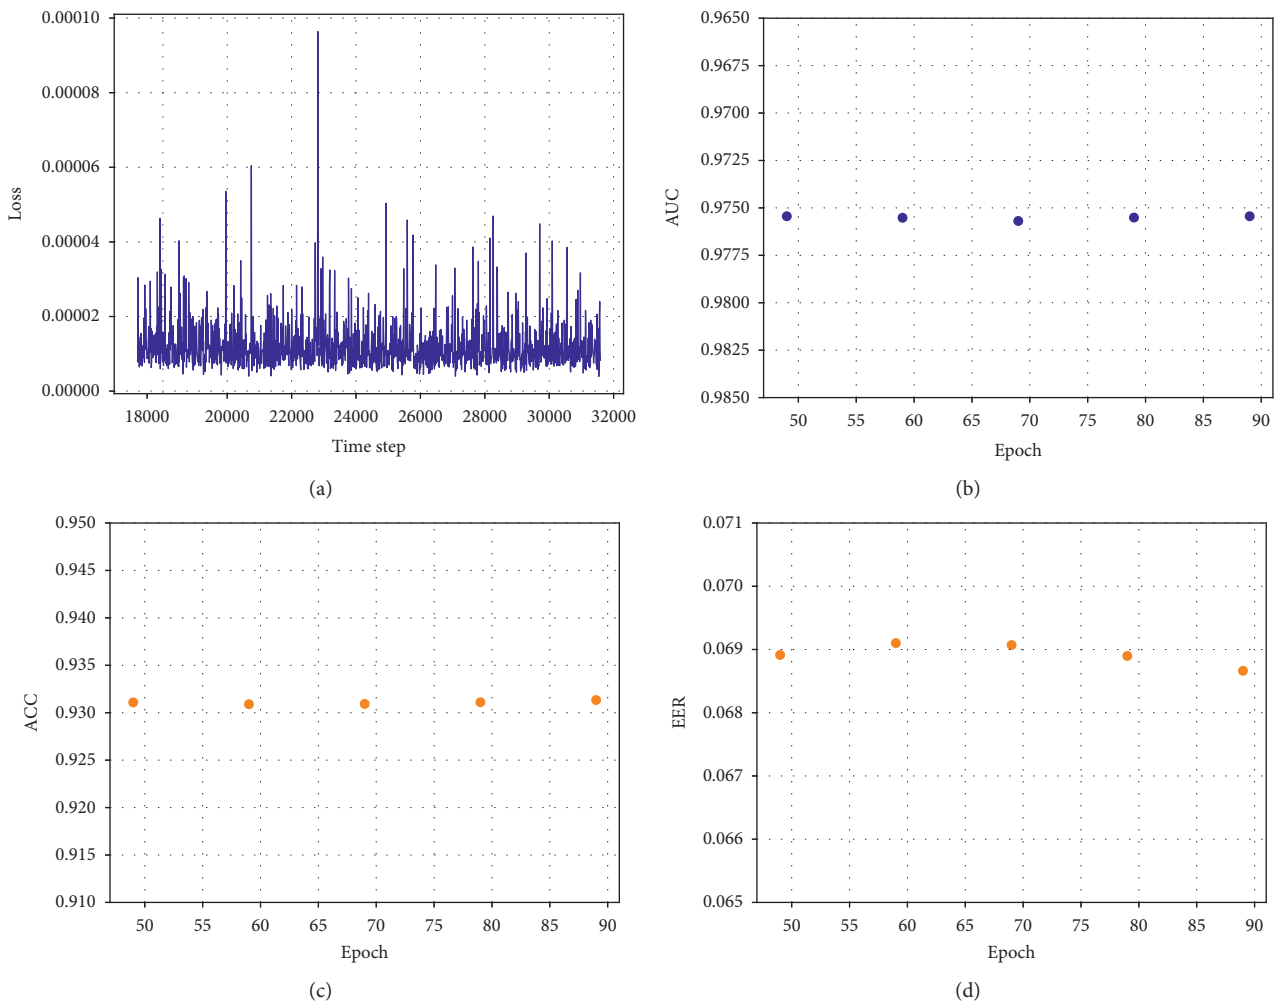

FIGURE 12: DTFA-Net training and evaluation results in Epoch49-89: (a) the loss fluctuations of model training in Epoch49-89; (b) the AUC results of the model in the test set in Epoch49-89; (c) the ACC results of the model in the test set in Epoch49-89; (d) the ERR results of the model in the test set in Epoch49-89.

TABLE 5: Comparison between our proposed method and the other in intradatabase.

| Method          | CASIA-MFSD |  | Replay Attack |          |
|-----------------|------------|--|---------------|----------|
|                 | EER (%)    |  | EER (%)       | HTER (%) |
| LBP [26]        | 18.2       |  | 13.9          | 13.8     |
| IQA [9]         | 32.4       |  | –             | 15.2     |
| CNN [4]         | 7.4        |  | 6.1           | 2.1      |
| LiveNet [27]    | 4.59       |  | –             | 5.74     |
| DTFA-Net (ours) | 6.90       |  | 6.47          | 2.2      |

FIGURE 13: The false and right detection samples. Left: false-negative result; right: true-positive case.

respectively, and verified them on the CASIA test set. Figure 10 shows the training loss process (Epoch0-Epoch29) and the ROC curve in the test set (Epoch50). The experiment shows that, after introducing the attention mechanism, due to the increase in the network structure (in fact, a convolution layer is added), the loss of the model during the training process is slower than that of model without SA in the initial stage of training and there is a large shock. However, as the number of network training iterations increases, the loss tends to be stable, and there is almost no difference between the two cases. After 50 cycles of training, the model with SA achieved  $AUC = 95.4\%$  on the test set, which is higher than model without SA.

Visualize the input and output results of our spatial attention mechanism module, as shown in Figure 11. It shows that SA pays more attention to local areas in the face image, such as the mouth and eyes. This point shows the consistency of the prior knowledge as assumed by the traditional image feature description method.

We first do not use SA to train the DTFA network to a certain degree and then add the SA structure to train 100 times so that the spatial attention module can better learn face area information and accelerate model convergence. Figure 12 shows the training and test results of DTFA-Net on the CASIA dataset. When the number of training iterations of the model reaches the interval of 49–89,  $EER = 0.069$  and  $AUC = 0.975 \pm 0.0001$ , reaching a stable state.

Table 5 provides a comparison between the results of our proposed approach and those of the other methods in both

intradatabase evaluation. Our model result is comparable to the state-of-the-art methods.

*4.5. Samples.* Figure 13 shows several samples of the failure and right detection of real faces. Through analysis, we found that the illumination in RGB images may be the main cause of wrong classification.

## 5. Conclusion

This paper analyzed the photo and video replay attacks of face spoofing and built an attention network structure that integrated dynamic-texture features and designed a dynamic information fusion module that extracted features from texture images based on the spatial attention mechanism. At the same time, an improved gamma image optimization algorithm was proposed for preprocessing of image in face detection tasks under multiple illuminations.

In smart cities and factories, robotic applications require high accuracy and security, which depends on precise inverse dynamics modeling. However, the physical modeling methods cannot include the nondeterministic factors of the manipulator, such as flexibility, joint clearance, and friction. In this paper, the Semiparametric Deep Learning (SDL) method is proposed to model robot inverse dynamics. SDL is a type of deep learning framework, designed for optimal inference, combining the Rigid Body Dynamics (RBD) model and Nonparametric Deep Learning (NDL) model. The SDL model takes advantage of the global characteristics of classic RBD and the powerful fitting capabilities of the deep learning approach. Moreover, the parametric and nonparametric parts of the SDL model can be optimized at the same time instead of being optimized separately. The proposed method is validated using experiments, performed on a UR5 robotic platform. The results show that the performance of SDL model is better than that of RBD model and NDL model. SDL can always provide relatively accurate joint torque prediction, even when the RBD or NDL model is not accurate.

## 1. Introduction

Smart cities and factories contain “intelligent” things that can autonomously and collaboratively enhance the quality of living and working conditions, save human lives, and act as a sustainable resource ecosystem. To implement these advanced collaborative technologies, such as drones, robots, artificial intelligence, and Internet of Things, it is required to increase the “intelligence” of smart cities and factories, by improving the connectivity, energy efficiency, and quality of services [1]. There have been many excellent application cases, such as [2–4]. Particularly, intelligent robotic platforms are a technology, increasingly used, in smart cities and factories, where the constantly changing applications scenarios also place higher demands in robot control. Specifically, in motion control systems, there is a time delay in the transmission of feedback information, making smooth

motion impossible to achieve by feedback control alone. Therefore, feedforward control becomes particularly important. In robotics, feedforward control usually refers to model-based control, involving the dynamics of the robotic platform. The accuracy of such dynamical models is critical to the development of control laws that are compliant, energy efficient, and safe [5].

There are two major approaches for modeling robot dynamics: parametric and nonparametric. Parametric approaches rely on parameterized Newtonian physics models of the robot dynamics. Common methods for physics-based dynamics modeling can be found in the literature. These methods require the mechanical parameters of the rigid bodies, composing the robot, to be identified [6–9] and then employed in model-based control and state estimation schemes [10]. The advantage of these models is that they represent a global and unique relationship between the joint

trajectory  $(q, \dot{q}, \ddot{q})$  and the torques  $\tau_{\text{RBD}}$ . This type of inverse dynamics model can be computed efficiently and employed in real time. Thus, a great deal of prior knowledge is acquired, without the need of data. For example, it is well known that robots are subject to gravitational forces, viscous forces, and joint constraints, making it wasteful to have to go through a laborious data-gathering and machine learning process, to discover these well-known constraints. The disadvantage of parametric models is that they are only crude idealizations of the actual system dynamics, such as rigidity of links or a simple analytical form of friction, which may not be accurate in real systems. In the case of traditional industrial robots, these unmodeled dynamics can often be ignored. However, for modern robotic platforms, these omissions and simplifications result in significant control inefficiencies.

Alternatively, the model can be obtained from experimental data, using machine learning techniques, resulting in a nonparametric model. Nonparametric methods, based on algorithms such as Support Vector Regression (SVR) [11–13], Neural Network (NN) [14–16], Local Weighted Projection Regression (LWPR) [17–19], Independent Joint Learning (IJL) [20–22], or Gaussian Processes Regression (GPR) [23–27], can model dynamics by extrapolating the input-output relationship directly from the available data. If a suitable kernel function or learning architecture is selected, then the nonparametric model is a universal approximator which can account for the dynamics factors, not considered by the parametric model. Therefore, nonparametric methods can be more flexible to use and are powerful in capturing higher order nonlinearities, resulting in faster model approximation and higher learning accuracy. When learning inverse dynamics, the nonparametric methods will approximate a function describing the relationship  $q, \dot{q}, \ddot{q} \rightarrow \tau$ , including all nonlinearities encoded by the sampled data.

Nonparametric methods attempt to learn the model from scratch and, thus, do not make use of any knowledge available from analytical robotics. Nevertheless, nonparametric learning methods also exhibit several drawbacks. First, very large amounts of data are necessary for obtaining a sufficiently accurate model and predictions on the entire input space [28]. Second, since nonparametric models rely on local neighborhood training data to make predictions, they do not generalize well to unexplored state regions, where little or no training data are available. Covering the entire state space becomes exponentially harder, as the complexity and number of degrees of freedom in the robot system increase. Thus, if only small and relatively poor data sets are available, nonparametric models will not be able to generalize well for unknown data. Third, it is indeed wasteful to have to go through a laborious data-gathering and machine learning process to discover such well-known prior knowledge as Rigid Body Dynamics.

Thus, it appears quite desirable to combine the benefits of parametric and nonparametric approaches to improve on the aforementioned issues. However, doing so, in an efficient way, is not trivial. A reasonable approach would be to first fit a parametric model and then fit a nonparametric model to

the errors made by the parametric model. Nguyen-Tuong et al. [29] present a learning technique which combines prior knowledge about the physical structure of the mechanical system and learning from available data using Gaussian Process Regression (GPR) [30]. Similar approaches are presented in [20] and [31]. In [32], an incremental semiparametric robot dynamics learning scheme, based on Locally Weighted Projection Regression (LWPR), initialized using a linearized parametric model, is presented [33]. However, this approach uses a fixed parametric model that is not updated, as new data become available. Moreover, LWPR has been shown to underperform with respect to other methods (e.g., [34]). These semiparametric methods, as described above, could not benefit from simultaneous optimization of parametric and nonparametric models. Instead, the nonparametric model is applied, after parametric identification, which may result in a suboptimal model. In addition, as far as it can be known, there is no semiparametric method based on deep learning methods.

Deep learning is a new approach in machine learning, which has been widely applied in smart cities and factories [35]. Deep learning has turned out to be very good at discovering intricate structures in high-dimensional data and is therefore applicable to many domains of science, business, and government. Since it requires very little engineering by hand, it can easily take advantage of increased amount of available computation resources and data [36]. In this work, a method that is based on deep learning and semiparametric approach is presented. The method is formalized in the framework of what is called Semiparametric Deep Learning (SDL), designed for optimal inference using combinations of parametric RBD and Nonparametric Deep Learning models. Key properties of this method are (1) appropriate deep learning frame for a semiparametric approach and (2) features that can be optimized simultaneously for parametric and nonparametric models. The proposed method is validated using experiments performed on a UR5 robot. The article is organized as follows. In Section 2, a complete description of the proposed Semiparametric Deep Learning framework is introduced. Section 3 presents the validation of the proposed method on the UR5 robotic platform. Finally, Section 4 summarizes the content of the presented work.

## 2. Methodology

The parametric modeling method and NDL, as the basis of the SDL method, have been elaborated in previous research publications [37, 38]. Therefore, this section only briefly reviews the above two methods, while it analyzes the SDL modeling method, proposed in this paper.

*2.1. Parametric Robot Dynamics Model.* It is well known that the robot dynamics can be modeled according to the following [39]:

$$\tau(q, \dot{q}, \ddot{q}) = M(q)\ddot{q} + C(q, \dot{q}) + G(q) + \varepsilon(q, \dot{q}, \ddot{q}), \quad (1)$$

in which  $q, \dot{q}, \ddot{q} \in \mathbb{R}^{m \times 1}$  are joint positions, velocities, and accelerations of the robot, respectively,  $\tau \in \mathbb{R}^{m \times 1}$  denotes the joint torques,  $M(q)$  is the generalized inertia matrix of the robot,  $C(q, \dot{q})$  are the Coriolis and centripetal forces, and  $G(q)$  is gravity. As shown in equation (1), the robot dynamics equation contains Rigid Body Dynamics (RBD) model:

$$\tau_{\text{RBD}} = M(q)\ddot{q} + C(q, \dot{q}) + G(q). \quad (2)$$

The model errors  $\varepsilon(q, \dot{q}, \ddot{q})$  are caused by unmodeled dynamics (e.g., hydraulic tubes, actuator dynamics, and flexibility and dynamics of the cable drives), ideal-joint assumptions (e.g., no friction and clearance), and inaccuracies in the RBD model parameters. The RBD model of a manipulator is well known to be linear regarding the parameters  $\beta$  [39], i.e.,

$$\tau_{\text{RBD}} = \varphi(q, \dot{q}, \ddot{q})\beta, \quad (3)$$

in which  $\varphi$  is a matrix containing nonlinear functions of joint angles, velocities, and accelerations, often called basis functions. Modeling the robot dynamics, using the RBD model in equation (3), requires the identification of the dynamics parameters  $\beta$ . For the 6 Degree-of-Freedom (DoF) UR5 robot, for example, 60 dynamics parameters are to be identified (for each DoF, there are 10 parameters that could ideally be obtained directly from the CAD data).

## 2.2. Nonparametric Deep Learning Model

**2.2.1. NDL Formulation.** The inverse dynamic model, in model-based control, is described as the mapping from joint positions, velocities, and accelerations to torques, as shown in equation (1). The aim of nonparametric learning model is to predict the torque value of the  $i^{\text{th}}$  joint,  $\tau_i \in \mathbb{R}$ , as the response of the query point at  $(q, \dot{q}, \ddot{q}) \in \mathbb{R}^{3m \times 1}$ , by using the given  $n$  training data,  $\{q[j], \dot{q}[j], \ddot{q}[j], \tau_i[j]\}_{j=1}^n$ , in which  $q[j], \dot{q}[j], \ddot{q}[j] \in \mathbb{R}^{m \times 1}$  and  $\tau_i[j] \in \mathbb{R}$ . Since the problem can be considered as a supervised learning problem, any supervised learning technique can be employed for the learning process, as shown in

$$\tau(q, \dot{q}, \ddot{q}) \sim \mathcal{DL}(q, \dot{q}, \ddot{q}). \quad (4)$$

Deep learning methods are representation-learning methods with multiple levels of representation, obtained by composing simple but nonlinear modules, each transforming the representation at one level (starting with the raw input) into a representation at a higher, slightly more abstract level. With the composition of enough such transformations, very complex robotic dynamics functions can be learned [36, 40]. Therefore, the application cases of deep learning are too numerous, such as [41–45].

The sequential nature of manipulator inverse dynamics suggests that, to predict the joint torque, it is important to model the relationship among sequential data points [39]. RNNs, a type of deep learning network, can be seen as very deep feedforward network, where all the layers share the same weights. Although their main purpose is to determine long-term dependencies, theoretical and empirical evidence

shows that it is difficult to learn to store information for very long time [46]. LSTM networks have subsequently proved to be more effective than conventional RNNs, especially when there are several layers at each time step [48], enabling an entire speech recognition system that goes all the way from acoustics to the sequence of characters in the transcription. LSTM networks or related forms of gated units are also currently used for the encoder and decoder networks, performing very well in machine translation [47–49]. Moreover, studies presented in [38] and [50] confirmed the validity of applying LSTM to the prediction of manipulator inverse dynamics. Therefore, in this section, the LSTM network is proposed as the nonparametric learning technique for modeling the inverse dynamics of manipulator.

**2.2.2. NDL Model Architecture.** In this paper, the proposed architecture of the Nonparametric Deep Learning network has one input layer, one LSTM layer, one full-connected layer, one dropout layer, and one output layer, as shown in Figure 1. Only 1 LSTM layer is used here, because it has been verified in our previous studies that, with the same number of neurons, the fewer the layers, the better the prediction performance [38].

The input layer has 18 neurons (manipulator's 6 joint positions, 6 velocities, and 6 accelerations, as shown in Figure 2).

The state activation functions of LSTM cells are set to "tanh," while the gate activation functions are set to "sigmoid." The input weights are initialized according to the Glorot initializer. The forget gate bias is initially set to 1 and the remaining biases are set to 0. The training algorithm adopts back-propagation through time.

## 2.3. Proposed Semiparametric Deep Learning (SDL) Model.

In this section, the proposed semiparametric model, based on deep learning and RBD, is described in detail. The method is formalized in the framework of the so-called Semiparametric Deep Learning (SDL), which can be used to predict the joint torque of a robotic arm more accurately. First, formulation of SDL is introduced in Section 2.3.1, while the specific model architecture of SDL is described in Section 2.3.2.

**2.3.1. SDL Formulation.** Using the Nonparametric Deep Learning (DL) framework, the robot dynamics can be modeled by  $\tau \sim \mathcal{DL}(q, \dot{q}, \ddot{q})$ , in which  $q, \dot{q}, \ddot{q}$  is the input and  $\tau$  is the output of the Deep Learning Model. Consequently, the DL model does not make use of any prior knowledge, which allows reproducing arbitrary functions. One way to include the RBD model, as shown in equation (5), is to set the  $\tau_{\text{RBD}}$  as input to the DL model. This approach is equivalent to a semiparametric model:

$$\begin{aligned} \tau(q, \dot{q}, \ddot{q}) &\sim \mathcal{SDL}(q, \dot{q}, \ddot{q}) \sim \mathcal{DL}(\tau_{\text{RBD}}, q, \dot{q}, \ddot{q}) \\ &\sim \mathcal{DL}(\varphi(q, \dot{q}, \ddot{q})\beta, q, \dot{q}, \ddot{q}). \end{aligned} \quad (5)$$

The resulting dynamics model, as described in equation (5), is a semiparametric frame which consists of a parametric

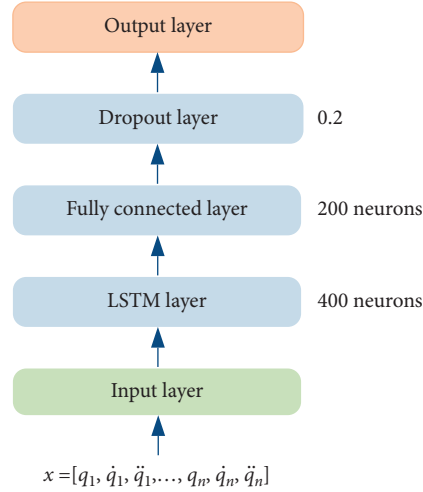

FIGURE 1: Proposed deep learning architecture.

FIGURE 2: Inverse dynamics learning architecture of manipulator with 21 input data sets.

part, i.e., the RBD model. When comparing equation (5) to the robot dynamics in equation (1), it becomes evident that the main purpose of the nonparametric term is absorbing the unmodeled dynamics  $\varepsilon(q, \dot{q}, \ddot{q})$ . In order to approximate the unmodeled dynamics with an appropriate DL, a model can be used, such as DNN or LSTM. Key properties of this semiparametric learning method are (1) employment of appropriate deep learning frame as nonparametric part and (2) features that can be optimized simultaneously for parametric and nonparametric model; i.e., the value of  $\tau_{\text{RBD}}$  will also be updated by weight changes as the learning process evolves.

If the RBD model perfectly describes the robot dynamics, the error  $\varepsilon(q, \dot{q}, \ddot{q})$  in equation (1) will disappear and the prediction will depend only on the RBD part; i.e., it is very easy to train deep learning networks. Equation (5) also shows that if the query point is far away from the training data, the resulting torque prediction will mainly depend on the RBD part. This property is important, as the complete state space can never be completely included using finite (and possibly small) training data sets. If the robot moves to the regions of the state space, not considered by the sampled data (i.e., the learned nonparametric models may not

generalize well in these state space regions), the torque prediction will rely on the parametric RBD part.

**2.3.2. SDL Model Architecture.** The effectiveness of the NDL model has been verified in previous work presented in [40]. The SDL model proposed in this article adds an RBD term to the NDL architecture. Its specific model architecture is shown in Figure 3. The input of the SDL architecture is still  $[q, \dot{q}, \ddot{q}]$ . However, unlike NDL, the input passes through the RBD term, forming the new input vector  $[\tau_{\text{RBD}}, q, \dot{q}, \ddot{q}]$ . Next, the new input vector enters the LSTM hidden layer. The advantage of this architecture is that the parametric and nonparametric parts can be optimized simultaneously; i.e., the weight of  $\tau_{\text{RBD}}$  in the feature vector will also be updated during network training. The grid search method is used to optimize the hyperparameters of the SDL model.

### 3. Evaluation

The proposed SDL method will be verified on a collaborative robot UR5, while the torque prediction results will be compared to the ones provided by NDL methods. The prediction performance for training and for generating

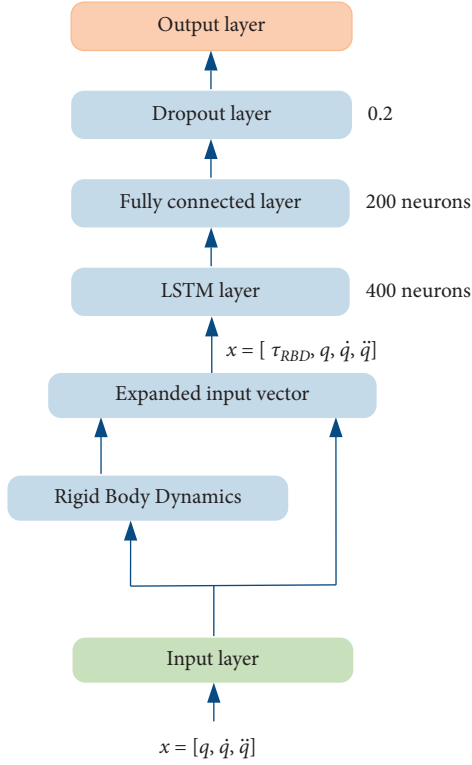

FIGURE 3: Proposed deep learning architecture.

predictions in rhythmic motor tasks is evaluated. The joint angles, the joint velocities, the joint accelerations, and the joint torques are recorded using a GUI (Graphical User Interface), i.e., PolyScope, making it easy to program the robot to move the tool along a desired trajectory path.

**3.1. Experimental Setup.** UR5 is a 6-DoF collaboration robot with extruded aluminum tubes and joints. It has six rotary joints, and its structure is shown in Figure 4. The UR5 robot has a joint rotation range of  $[-2\pi, 2\pi]$  (rads) and a joint acceleration range of  $[0, \pi]$  (rads/s<sup>2</sup>). The UR5 robot is very popular in the robot research field.

According to the robot rotation angle and installation restrictions, the robot workspace is selected to be a hemisphere with an approximate radius of 850 mm above the installation plane. The range of joints motion is shown in Table 1. In order to best approximate the actual working situation of the robot, within the selected robot workspace, 1000 points are randomly selected. According to the actual use requirements of the robot, the joint running speed range is  $[0.8-2]$  rads/s, while the acceleration range is  $[1-1.8]$  rads/s.

The robot is ordered to run in a rhythmic way, according to the set trajectory. The joint position, speed, and servo motor current data, along the robot trajectory, is delivered from the robot controller at a frequency of 100 Hz. Since the UR5 robot is not equipped with a torque sensor, the measured torque is obtained indirectly through the motor current, at each joint. The relationship between torque and current is as follows [51]:

FIGURE 4: UR5 robot structure.

$$\tau_i = N_i k_i I_i, \quad (6)$$

in which  $N_i$  is the gear ratio,  $N_i = 101, i = 1, \dots, 6$ ;  $k_i$  motor constant,  $k_i = 0.125 \text{ Nm/A}, i = 1, \dots, 3$ ,  $k_i = 0.0922 \text{ Nm/A}, i = 4, \dots, 6$ ; and  $I_i$  is the motor current (A).

During the actual operation, the robot is affected by noise, making the sampling data fluctuate. In that case, there will be large fluctuations and ripples in the actual measured current, which seriously affects the accuracy of the torque prediction. The average data method can increase the signal-to-noise ratio of the data [52], reduce the influence of noise, and improve the prediction accuracy. The average joint position  $\bar{q}$  can be expressed as follows:

$$\bar{q}(k) = \frac{1}{M} \sum_{m=1}^M q_m(k), \quad (7)$$

in which  $M$  is the number of running trajectories,  $q_m(k)$  is the  $k$ -th sampling point of one running trajectory, and  $\bar{q}(k)$  is the position after  $M$  times of averaging. The same method is used to deal with speed and current. The zero-phase low-pass Butterworth filter (forward and reverse IIR Butterworth filters) with a cutoff low-pass frequency of 1 Hz is used to process the averaged position and velocity  $(\bar{q}, \dot{\bar{q}})$ . Acceleration is obtained by the central difference method [53]. Data processing is important for the accuracy of parameter identification, making the above processing very appropriate, as it avoids large deviations in identification.

A total of 1,000 groups (a total of 108,008) of valid samples were obtained. According to the ratio of 80% to 20%, they were divided into training and testing sets, serving in  $K$ -fold cross-validation. In addition, the test data is ensured to be sufficiently different from the training data, highlighting the generalization ability of the learned models. The above sample set is used to train and test the NDL model and SDL model, respectively, while it also analyzes and compares the prediction performance.

TABLE 1: Rotation angle range of each joint in the selected robot workspace.

| Joint #               | Joint 1     | Joint 2   | Joint 3     | Joint 4   | Joint 5     | Joint 6     |
|-----------------------|-------------|-----------|-------------|-----------|-------------|-------------|

All input and output data are normalized to match the consistency of the learning model. After the prediction of inverse dynamics, the real value is restored. The normalized equation is as follows:

$$x_n = \frac{x_r - x_{\min}}{x_{\max} - x_{\min}}, \quad (8)$$

in which  $x_n$  represents the normalized value;  $x_r$  denotes the real value; and  $x_{\min}$  and  $x_{\max}$  are the minimum and maximum real values, respectively.

The performance of manipulator inverse dynamics predictions is evaluated using Root Mean Square Error (RMSE), which is defined as follows:

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (p_i - y_i)^2}, \quad (9)$$

in which  $p_i$  and  $y_i$  represent the  $i$ -th predicted value and real value, respectively, and  $N$  is the total number of the data sets.

## 4. Results

The training and prediction in this paper were performed with MATLAB 2019a, using an ordinary personal computer. Computer hardware has a high influence on training time. In this work, the models are trained on a CPU with a clock speed of 2.7 GHz. The structure and hyperparameters of the NDL and SDL models were initially set according to previous work, while the final settings were determined based on the fivefold cross-validation method.

The prediction results of the RBD, NDL, and SDL models are listed in Table 2. The data in the table shows the RMSE of the RBD, NDL, and SDL models, on different robot axes and under different cross situations. Based on Table 2, the following conclusions apply:

- (1) The results of “cross average” (Figure 5) indicate that the prediction accuracy of SDL is generally more accurate than the one of NDL and NDL is generally more accurate than RBD. Also, the prediction accuracy of the SDL model for the first 3 axes of the robot is significantly improved.
- (2) The results of “all axes” (Figure 6) indicate that the prediction accuracy of the NDL model is sometimes better than the one of the RBD model (cross 3, 4, 5), while sometimes it is worse (cross 1, 2). However, the NDL model is better than the RBD model (mean) in general, while the prediction accuracy of the SDL model is always better than in the case of the other two models.
- (3) All the data in Table 2 shows that the semiparametric models are able to combine the strengths of both models, i.e., the parametric RBD model and the Nonparametric Deep Learning model. The prediction accuracy of the SDL model is always better than that of the RBD and NDL models.

RMSE is not sufficient to fully represent the performance of torque prediction, because the range of torque variation for each joint of the robot varies greatly. Therefore, the ratio of cross average RMSE to the range of measured torque values was used to further analyze the predictive

FIGURE 5: Cross average prediction results.

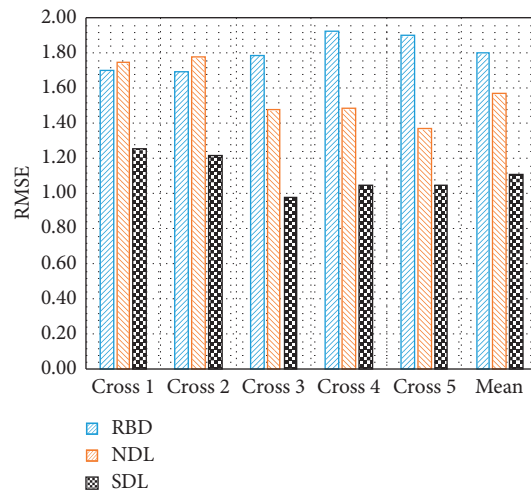

FIGURE 6: All axes prediction results.

TABLE 3: Comparative analysis of prediction performance of different joint forces.

|                          |     | Axis 1  | Axis 2  | Axis 3  | Axis 4 | Axis 5 | Axis 6 |

|                          | NDL | 2.2387  | 2.4535  | 1.7682  | 0.3891 | 0.4455 | 0.4190 |
|                          | SDL | 1.5679  | 1.7430  | 1.1861  | 0.3400 | 0.4210 | 0.3872 |
| Range of measured torque |     | 42.1816 | 98.1207 | 49.3103 | 5.7766 | 4.4944 | 6.6976 |
| Ratio                    | RBD | 0.0599  | 0.0262  | 0.0473  | 0.1126 | 0.1357 | 0.0649 |
|                          | NDL | 0.0531  | 0.0250  | 0.0359  | 0.0674 | 0.0991 | 0.0626 |
|                          | SDL | 0.0372  | 0.0178  | 0.0241  | 0.0589 | 0.0937 | 0.0578 |

performance of different joints. As shown in Table 3, the torque prediction performance of the first three (elbow) joints is better than that of the last three (wrist) joints.

Part of the measured values of each joint torque, RBD predicted value, NDL predicted value, and SDL predicted value are all plotted in Figure 7. Figures 7(a)–7(f) are the predicted moments of axis 1 to axis 6, respectively; Figures 7(g)–7(l) are the predicted errors of moments of axis

1 to axis 6, respectively; the purple curve represents the measured torque value, the blue represents the calculated torque value using RBD method, the red represents the DL predicted torque value, and the yellow represents the SDL predicted torque value. Figure 7 shows that the SDL model combines the advantages of the RBD model and the NDL model. For example, as shown by the red dashed box in Figure 7, when the torque prediction error of the RBD is

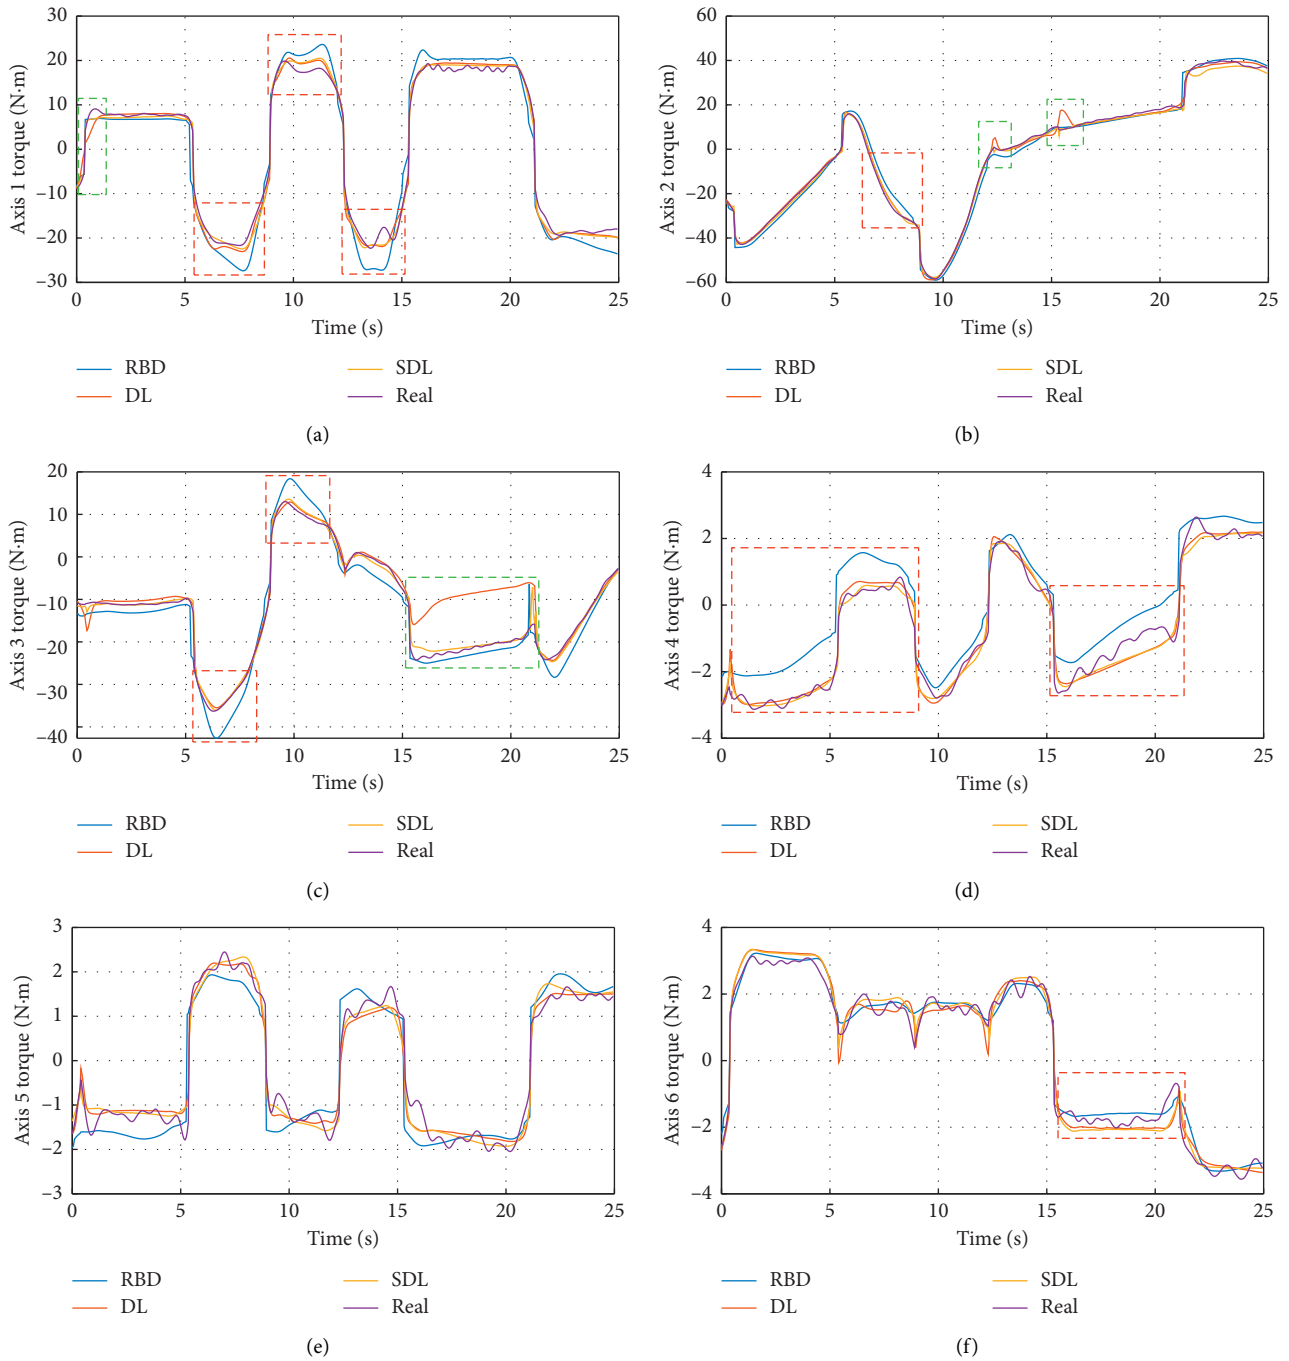

FIGURE 7: Continued.

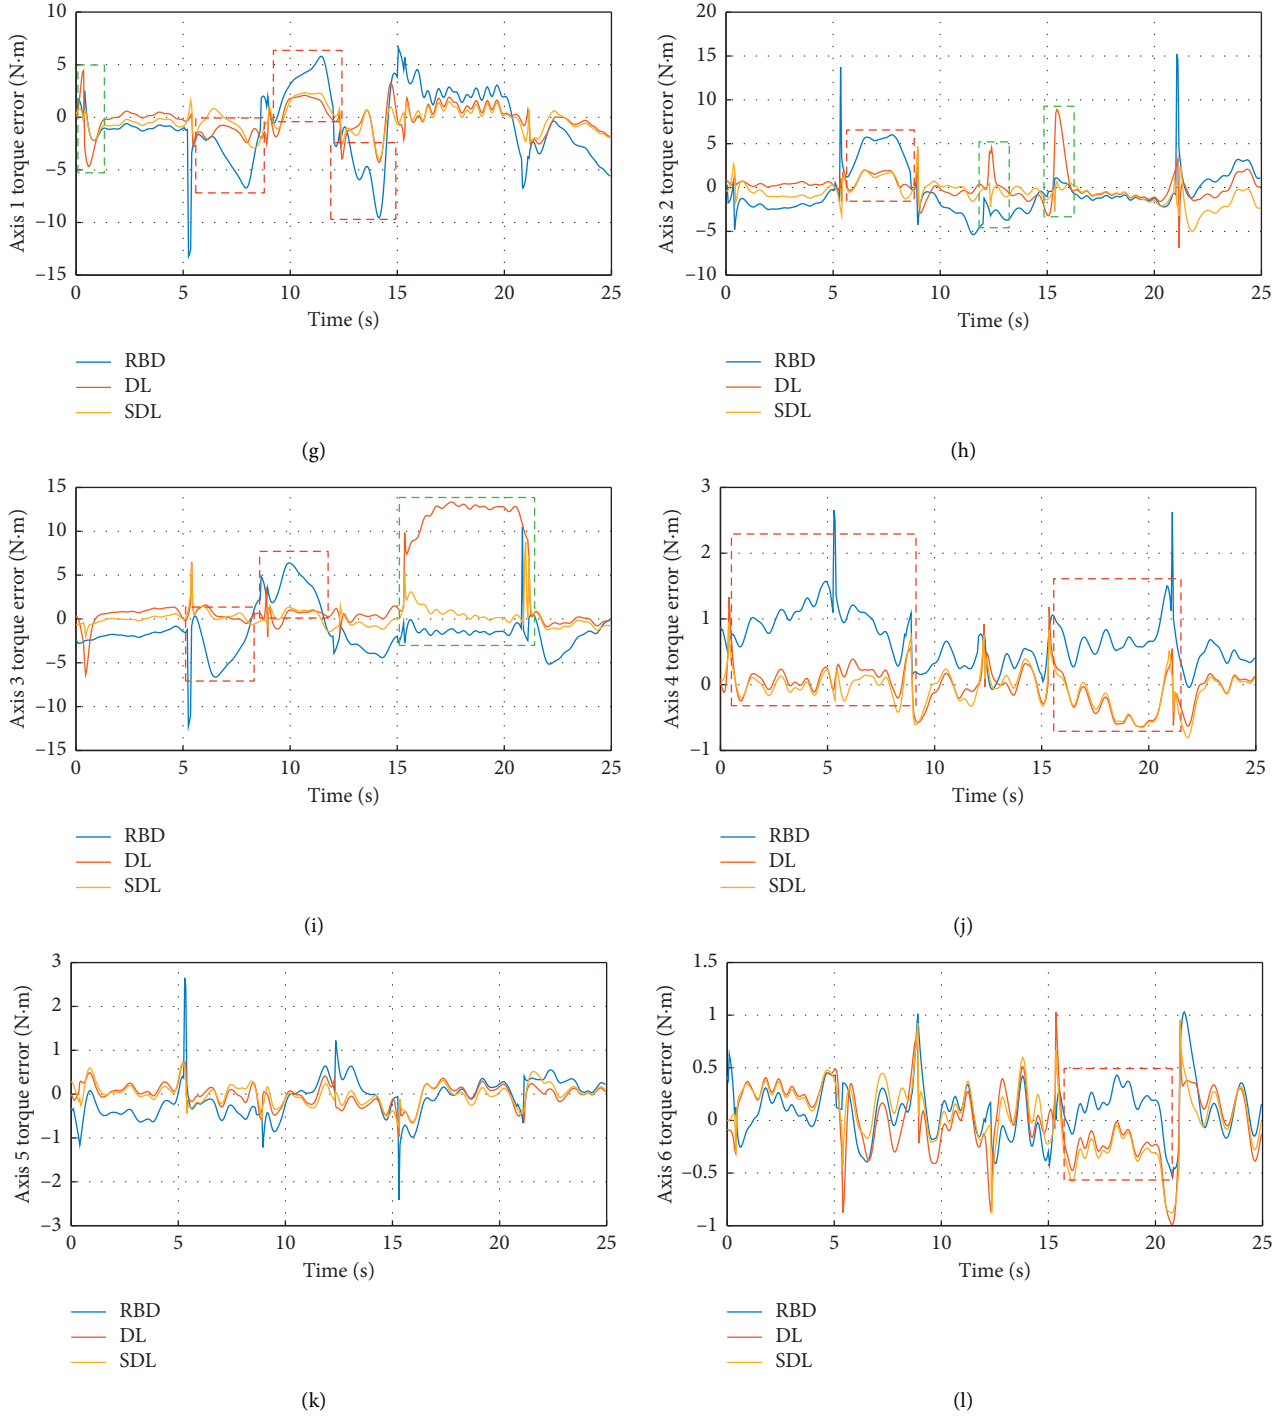

FIGURE 7: Joint torque prediction comparison curves. (a) Axis 1 torque. (g) Axis 1 torque error. (b) Axis 2 torque. (h) Axis 2 torque error. (c) Axis 3 torque. (i) Axis 3 torque error. large, the nonparametric part works, which greatly improves the prediction accuracy of the SDL model. As another example, shown by the green dotted box in Figure 7, when the learned nonparametric models do not generalize well to the state space regions, the torque prediction will rely on the parametric RBD part.

## 5. Conclusion

In this work, Semiparametric Deep Learning (SDL) method is proposed to model robot inverse dynamics, for smart city and industrial applications. The SDL model takes advantage of the global characteristics of classic RBD and the powerful

fitting capabilities of deep learning methods. Moreover, SDL model can be optimized simultaneously for the parametric and nonparametric model, instead of separate optimizations. The results on the UR5 robot show that the SDL models provide higher accuracy and better generalization, compared to RBD and NDL. The essence of the SDL model is to fully utilize the a priori information encoded in the parameterized model, overcome the limitations of the NDL method, and always show good learning performance. As far as future work is concerned, the flexible factors in dynamics will be considered as addition to the SDL model, in order to improve the accuracy prediction performance.

With the change of the network communication environment in vehicular ad hoc networks (VANETs) of a smart city, vehicles may encounter security threats such as eavesdropping, positioning, and tracking, so appropriate anonymity protection is required. Based on the certificateless cryptosystem and group signature ideas, this paper proposes a certificateless group signature anonymous authentication scheme for the VANETs of a smart city. In this scheme, it can implement the process of adding, signing, verifying, and revoking group members only by simple multiplication of the elliptic curve and synchronization factor technology, which shortens the length of the signature and improves the efficiency of the signature. From the proofs of correctness and security, we know that it does not only have anonymity and traceability of the group signature scheme but also has unforgeability and forward security. According to the performance verification, this scheme has lower calculation overhead and higher authentication efficiency.

## 1. Introduction

Vehicular ad hoc networks (VANETs) [1] of a smart city, as a typical application of the Internet of Things technology, enable real-time traffic information interaction between vehicles and vehicles and between vehicles and the infrastructure. And, it has played a positive role in reducing traffic accidents and has been widely developed in the field of intelligent transportation. With the continuous change of the network environment, a variety of information security and privacy leakage issues have also emerged, seriously threatening the personal safety and personal privacy of vehicle users. Therefore, it is necessary to provide corresponding security policies, which can effectively protect the communication security and personal privacy of vehicle users while providing fast services for vehicle users.

At present, anonymous authentication technologies in VANETs mainly include PKI-based authentication, identity-based authentication, and group signature-based

authentication. In the early days, the public key infrastructure- (PKI-) based public key certificate scheme proposed by Raya and Hubaux [1] in 2007 was mainly used. This scheme requires a large number of public-private key pairings and related certificates to be stored in the vehicles. By occupying a large amount of storage space, it increases communication and computational overheads and causes certificate management problems. Shim [2] proposed an identity-based batch authentication scheme. The scheme uses a pseudonym to represent vehicle identity information and uses a pseudonym replacement strategy for each message signature to achieve message traceability. However, in this scheme, PKG knows the private keys of all users, so it is inevitable that the key escrow problem will occur.

In 1991, Chaum and Heyst [3] first proposed the concept of the group signature. It allows group members to sign anonymously on behalf of the group. The group administrator is responsible for the creation and distribution of group member keys. The group members use group member

certificates to sign on messages. The group public key is used to verify its authenticity. The verifier can only verify that the signer is from a member of the group but cannot determine the identity of specific members in the group, thereby protecting the group members' identity. In addition, the group administrator can open the signature and reveal the true identity of the signing members to resolve the dispute. But, it is computationally infeasible to distinguish whether two different group signatures come from the same signer. Therefore, the group signature technology has been widely used, and it has been gradually introduced into the anonymous authentication scheme in VANETs [4–7]. Shao et al. [5] proposed a threshold anonymous authentication protocol capable of implementing batch authentication based on the group signature. Zheng et al. [6] introduced a lightweight group signature technology, which made the group public key and signature length fixed and did not depend on the number of group members. Zhao [7] proposed a revocable group signature scheme based on the Chinese remainder theorem in VANETs. When members join and revoke, they only need to regenerate a new group public key without changing the key pairings of other members, improving the efficiency of member joining and revoking. However, in these schemes, each member needs to generate a corresponding group member certificate, which will increase storage overhead and computational overhead.

In 2003, Al-Riyami and Paterson [8] first proposed a certificateless cryptosystem. In the system, a part of the user key is provided by the key generation center and the rest is generated by the user to form the user key, which ensures that the key generation center does not know all the user's private keys, and it solves the problem of certificate management in traditional public key cryptosystems and key escrow in identity-based cryptosystems. Based on the group signature technology, Chen et al. [9] and Li et al. [10] proposed different certificateless group signature schemes. At the same time, certificateless group signature schemes applied to VANETs have also been proposed [11–17], which has also become a hotspot in the security of VANETs. Zhang et al. [12] and Chen et al. [14] used bilinear pairings to study the application of the certificateless group signature in VANETs, avoiding the problem of key escrow, without the need for certificate management, effectively reducing the system storage load.

However, the current certificateless group signature schemes are implemented with the help of bilinear pairing operations, which increases the overhead of the system operation. Therefore, this paper proposes a certificateless group signature scheme based on elliptic curves, which uses elliptic curves instead of bilinear pairings for operations. This scheme not only inherits the security and anonymity of group signature schemes but also greatly reduces the computational overhead. In particular, the introduction of the synchronization factor technology in this scheme makes it unnecessary to modify the public key information of the group administrator when the members in the group change. Only the group synchronization factor and group members' synchronization factor are calculated and

modified, which greatly reduces the calculation steps when group members join and revoke.

## 2. Preliminaries

*2.1. System Model.* In the general mode, the system model of VANETs consists of fixed RSUs (road side units) at the road side, mobile OBUs (on-board units) equipped in vehicles, and a TA (trusted authority), as shown in Figure 1.

OBUs access the VANETs through the road side deployment infrastructure RSUs and periodically broadcast their own vehicle information to other vehicles, including safety information such as the location, speed, direction, acceleration, road conditions, traffic events, and time stamps, so that other OBUs can quickly obtain useful information on the road. RSUs can broadcast and receive some signature information in the group and provide various services for the OBUs. And, when needed, they reveal the real identification of some illegal vehicles and broadcast the identification information of revoked vehicles. RSUs have their own storage space and computing capabilities. The TA, as a third-party trusted agency in this scheme, saves the real identity information of OBUs and RSUs and generates public and private key pairings of OBUs and RSUs for identification in VANETs.

*2.2. Elliptic Curve.* The elliptic curve is an encryption algorithm in the current public key encryption system, and it is also the encryption algorithm that can provide the highest encryption strength for data. The encryption strength corresponding to the encryption calculation using the 160-bit key length is equivalent to the encryption length corresponding to the RSA algorithm using the 1024-bit key length in the public key encryption system. However, the elliptic curve has the characteristics of fewer calculation parameters, shorter key length, and faster operating speed. Therefore, it is appropriate to apply the elliptic curve encryption algorithm to the VANETs with limited computing capacity, storage space, and transmission bandwidth.

*Definition 1* (elliptic curve definition). This scheme uses a 160-bit elliptical encryption algorithm. Assume that  $q$  is a large prime number and  $F_q$  is a finite field of the module  $q$ . An elliptic curve over a finite field  $F_q$  can be defined as:  $E: y^2 \equiv x^3 + ax + b \pmod{q}$ , where  $a, b, x,$  and  $y \in F_q$  and  $\Delta = 4a^3 + 27b^2 \neq 0$ .

*Definition 2* (addition of elliptic curves). Assume that the point of an elliptic curve  $P = (x_1, y_1) \in E$ ,  $-P = (x_1, -y_1)$  is the negative point of  $P$ ,  $Q = (x_2, y_2) \in E$ ,  $Q \neq -P$ , the line  $l$  passes through  $P$  and  $Q$ , and it intersects the elliptic curve at a point  $R' = (x_3, -y_3)$ , The symmetrical point about the  $x$ -axis with  $R'$  is  $R = (x_3, y_3)$  and  $R = P + Q$ . The addition cyclic group of the prime order  $q$  on the elliptic curve  $E$  is  $G_q = \{(x, y): a, b, x, y \in F_q, (x, y) \in F_q, (a, b)\}$  where  $G$  is a generator on the elliptic curve  $E$  and the scalar multiplication operation on the elliptic curve is  $kP = P + P + P + \dots + P(k, k \in Z_q^*)$ .

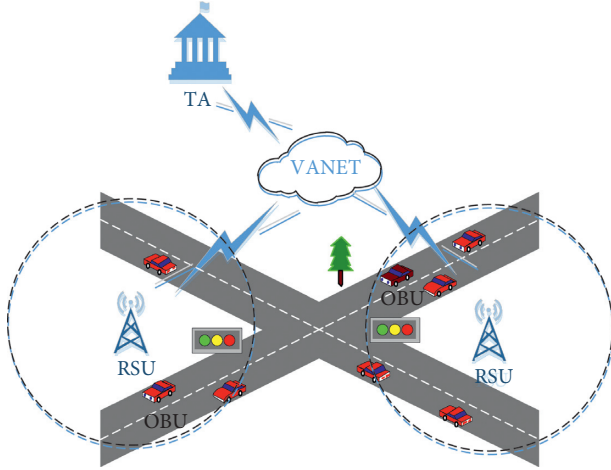

FIGURE 1: The system model of VANETs.

*Definition 3* (elliptic curve discrete logarithm problem (ECDLP)). There are two points  $P_1$  and  $P_2$  on the elliptic curve  $E$  on the finite field  $F_q$  and there exists  $k \in Z_q^*$ , such that  $P_1 = kP_2$ ; it is feasible to calculate  $P_1$  from  $k$  and  $P_2$ , but it is not advisable to calculate  $k$  from  $P_1$  and  $P_2$ .

### 3. Establishment of an Anonymous Authentication Scheme Based on Certificateless Group Signature

*Design Idea.* In this paper, the certificateless design idea is integrated into the scheme based on the group signature, which simplifies the member joining process and can resist public key replacement attacks. During the member joining process, the member  $A$  uses the private key to sign  $SK_A$ , obtains the identity signature information  $h_A$ , and sends  $(ID_A \| Y_A \| h_A \| v_A \| b_A)$  to RSU and RSU obtains  $A$ 's public key from TA to verify the identity information sent by  $A$ . It not only proves the legitimacy of  $A$  but also avoids public key replacement attacks. In addition, in the process of generating the group member certificate, the vehicle user needs to verify the identity of the group administrator RSU before accepting the member certificate to enhance the credibility of the certificate.

The certificateless group signature anonymous authentication scheme includes system initialization, public and private key generation for group administrators and group members, group member joining, signature generation, signature verification, member revocation, and opening signature. The specific work is as follows:

- (1) *System Initialization.* TA chooses the system parameters and generates the master key and its own public key, and public key information is made public.
- (2) *Public and Private Key Generation for Group Administrators and Group Members.* TA generates relevant public and private keys for administrators RSU and vehicle users OBU. The

administrator generates an initial group synchronization factor  $T$ .

- (3) *Member Joining.* The new member  $A$  joins according to the group joining method and generates a self-synchronization factor and updates the group synchronization factor.
- (4) *Signature Generation.* Group member  $A$  signs the message  $M$  based on the signature algorithm.
- (5) *Signature Verification.* In VANETs, the verifier verifies the message signature through making information and signature information public and confirms that the signed message is signed and issued by a member of the group.
- (6) *Member Revocation.* When a member in the group leaves the group for some reason, RSU recalculates the synchronization factor  $T'$  in the group according to the identity information of the member  $A$  which left the group and sends the new synchronization factor  $T'$  and related information of  $A$ 's synchronization factor to other members  $B$  in the group, which updates their synchronization factor to  $T_B$  according to the information.
- (7) *Opening Signature.* When  $A$  finds that the message signature sent by the group member vehicle user is false information or a dispute occurs between the group members, the signature is calculated by opening the signature to reveal the identity of the user.

### 4. Proposed Scheme

*4.1. Initialization.* Based on the selected security parameter  $k$ , TA generates two large prime numbers  $p$  and  $q$ , such that  $q|p-1$ . Choose the generator  $P$  on the cyclic group  $G$  on the elliptic curve of the order  $q$ . Then, choose two collision-free hash functions:  $H: \{0, 1\}^* \rightarrow Z_q^*$  and  $H_1: \{0, 1\}^* \times G \rightarrow Z_q^*$ . TA chooses a random parameter  $z \in Z_q^*$  as the system master key and calculates  $P_z = zP$  as the public key. TA makes system parameters  $\text{params} = \{p, q, G, P, P_z, H, H_1\}$  public and secretly saves the system master key  $z$ .

#### 4.2. Public and Private Key Generation

- (1) In this scheme, RSU acts as a group manager to manage vehicle members in the group. Assume that the identity information of the group manager RSU is  $ID_{RSU}$ , then RSU randomly chooses  $x_{RSU} \in Z_q^*$ , calculates  $P_{RSU} = x_{RSU}P$ , and sends  $P(ID_{RSU}, P_{RSU})$  to TA; TA randomly chooses  $r_{RSU} \in Z_q^*$ , calculates  $R_{RSU} = r_{RSU}P$  and  $S_{RSU} = r_{RSU} + zH_1(ID_{RSU} \| P_{RSU} \| R_{RSU})$ , and sends  $(R_{RSU}, s_{RSU})$  to RSU secretly, where  $R_{RSU}$  is a partial public key of RSU and  $s_{RSU}$  is a partial private key of RSU; RSU receives the information, verifies whether  $s_{RSU}P = R_{RSU} + P_zH_1(ID_{RSU} \| P_{RSU} \| R_{RSU})$  is established, and judges the validity of the partial private key  $s_{RSU}$ . At this time, RSU gets a complete private key pairing  $SK_{RSU} = (x_{RSU}, s_{RSU})$  and a complete public key

pairing  $PK_{RSU} = (x_{RSU}P, s_{RSU}P) = (P_{RSU}, S_{RSU})$ . TA saves the corresponding information  $(ID_{RSU}, P_{RSU}, S_{RSU}, s_{RSU})$  of RSU and saves the public key to the public list.

- (2) Assume that the identity information of the user  $OBU_A$  is  $ID_A$ . Through the above process, the private key pairing  $SK_A = (x_A, s_A)$  and the public key pairing  $PK_A = (P_A, S_A)$  of the user  $OBU_A$  are generated, and the public key  $PK_A$  is made public. The hash function  $H_1$  is used to generate a part of the private key.
- (3) The group manager RSU randomly chooses  $e \in Z_q^*$  and calculates  $T_0 = eP$  as the initial group synchronization factor of the group, and the engaged synchronization factor is  $T$ .

#### 4.3. Joining

- (1) When the user  $OBU_A$  wants to join the group,  $OBU_A$  randomly chooses  $y_A \in Z_q^*$  and  $b_A \in Z_q^*$  and calculates  $Y_A = y_AP$ ,  $h_A = H(ID_A \| PK_A \| Y_A \| b_A)$ , and  $v_A = y_A - h_A \cdot SK_A$ . The user  $OBU_A$  sends  $(ID_A \| Y_A \| h_A \| v_A \| b_A)$  to RSU.
- (2) RSU sends  $ID_A$  to TA, obtains  $OBU_A$ 's public key  $PK_A$ , verifies that whether  $Y_A = v_AP + h_A PK_A = Y_A$  is established, and generates a certificate for  $OBU_A$  if it holds.
- (3) RSU randomly chooses  $e_A \in Z_q^*$ , calculates  $E_A = Y_A + e_AP = (e_A + y_A)P$ ,  $h_{RSU} = H(E_A \| PK_{RSU} \| T)$ , and  $s_{RSU} = e_A + SK_{RSU} \cdot h_{RSU}$ , sends  $(E_A, h_{RSU}, s_{RSU}, T)$  to  $OBU_A$ , and stores  $(ID_A, PK_A, Y_A, b_A, E_A, E_AP, e_A, h_A, s_A)$  into the group member information list.
- (4)  $OBU_A$  verifies RSU's public key  $PK_{RSU}$  and calculates that whether  $E_A = (s_{RSU} + y_A)P - h_{RSU} PK_{RSU} = E_A$  is established. If it holds, the user  $OBU_A$  joins the group and generates the group member certificate as  $(ID_A, PK_{RSU}, Y_A, E_A, b_A, T)$ .
- (5) RSU sends  $(T, b_A)$  to other members in the group, and member  $OBU_B$  updates their synchronization factor  $T_B$ . Assuming that  $OBU_B$ 's certificate is  $(ID_B, PK_{RSU}, Y_B, E_B, b_B, T_B)$ ,  $OBU_B$  calculates a new synchronization factor as  $T_B' = T + T_B(b_B - b_B)$ , and  $OBU_B$ 's new certificate is  $(ID_B, PK_{RSU}, Y_B, E_B, b_B, T_B')$ .
- (6) RSU updates the synchronization factor as  $T' = T \cdot (b_A + x_{RSU})$ .

**4.4. Other Steps.** The remaining four steps in the scheme are, in order, signature generation, signature verification, member revocation, and signature opening.

**4.4.1. Signature Generation.** Assume that the group member  $OBU_A$  generates a signature on message  $M$ , calculates  $C_1 = E_AP + T_A PK_{RSU}$  and  $C_2 = T_AP$ ,  $C_3 = b_A E_A$ , randomly chooses  $r_1, r_2, r_3, r_4 \in Z_q^*$ , and calculates

$$d_1 = r_1 C_1 - r_2 PK_{RSU}, \quad d_2 = r_1 C_2 + r_3 S_{RSU}, \quad d_3 = r_3 P, \\ d_4 = r_3 PK_{RSU} + r_4 P, \quad c = H(PK_{RSU} \| M \| C_1 \| C_2 \| C_3 \| d_1 \| d_2 \| d_3 \| d_4), \\ s_1 = r_1 - cb_A, \quad s_2 = r_2 - cb_A T_A, \quad s_3 = r_3 - cT_A, \quad \text{and} \\ s_4 = r_4 - cE_A; \quad \text{the output signature is } RM = (c, s_1, s_2, s_3, s_4, C_1, C_2, C_3).$$

**4.4.2. Signature Verification.** The verifier calculates  $d_1' = s_1 C_1 - s_2 PK_{RSU} + c PC_3$ ,  $d_2' = s_1 C_2 + s_3 S_{RSU} + c TP$ ,  $d_3' = s_3 P + c C_2$ ,  $d_4' = c C_1 + s_4 P + s_3 PK_{RSU}$ , and  $c' = H(PK_{RSU} \| m \| C_1 \| C_2 \| C_3 \| d_1' \| d_2' \| d_3' \| d_4')$  based on  $(c, s_1, s_2, s_3, s_4, C_1, C_2, C_3)$ . If the equation  $c' = c$  holds, the verification passes.

**4.4.3. Member Revocation.** To revoke the user  $OBU_A$ , RSU calculates a new synchronization factor  $T' = T \cdot (b_A + x_{RSU})^{-1}$  based on  $(T, b_A)$ . Then, RSU sends  $(T', b_A)$  to other members in the group  $OBU_B$ , and  $OBU_B$  updates their synchronization factor  $T_B$  to  $T_B'$ , where  $T_B' = (T_B - T') \cdot (b_A - b_B)^{-1}$ .

**4.4.4. Signature Opening.** When RSU finds that the message signature sent by the group member vehicle user is false information or a dispute occurs between the group members, it calculates  $E_AP = C_1 - C_2 SK_{RSU}$  based on the signed message  $RM = (c, s_1, s_2, s_3, s_4, C_1, C_2, C_3)$  and the group manager's private key  $SK_{RSU} = (x_{RSU}, s_{RSU})$  and then finds the corresponding identity of the group member.

## 5. Anonymous Scheme Analysis

### 5.1. Correctness Analysis

**5.1.1. Correctness of Key Distribution.** After the group manager RSU receives  $(R_{RSU}, s_{RSU})$ , it verifies whether  $s_{RSU}P = R_{RSU} + P_z H_1(ID_{RSU} \| P_{RSU} \| R_{RSU})$  is established. Since  $s_{RSU}P = r_{RSU}P + zPH_1(ID_{RSU} \| P_{RSU} \| R_{RSU}) = R_{RSU} + P_z H_1(ID_{RSU} \| P_{RSU} \| R_{RSU})$ , the verification result is consistent with the result of the signature generation algorithm, so the signature scheme satisfies the correctness.

Similarly, after the user  $OBU_A$  receives  $OBU_A$ , it verifies whether  $s_AP = R_A + P_z H_1(ID_A \| P_A \| R_A)$  is established. Since  $s_AP = r_AP + zPH_1(ID_A \| P_A \| R_A) = R_A + P_z H_1(ID_A \| P_A \| R_A)$ , the signature scheme satisfies the correctness.

**5.1.2. Correctness of Signature in Joining.** After RSU receives the signature information  $(ID_A \| Y_A \| h_A \| v_A \| b_A)$  from the user  $OBU_A$ , if  $(h_A, v_A)$  is a legitimate signature, the equation  $Y_A = v_AP + h_A PK_A = y_AP - h_A SK_A P + h_A PK_A = Y_A$  holds, and then RSU calculates  $h_A' = H(ID_A \| PK_A \| Y_A \| b_A)$  based on  $Y_A$  and gets  $h_A' = h_A$ . And so, the  $r_4 P - cE_AP + r_3 PK_{RSU}$  signature is valid, that is, the identity of the user  $OBU_A$  is valid.

Similarly, when  $OBU_A$  receives the message  $(E_A, h_{RSU}, s_{RSU}, T)$  sent by RSU and calculates  $E_A = (s_{RSU} + y_A)P - h_{RSU} PK_{RSU}$  based on RSU's public key  $PK_{RSU}$  and

$s_{RSU} = e_A + SK_{RSU} \cdot h_{RSU}$ , then the equation  $E'_A = E_A$  holds. And so, the signature is valid.

**5.1.3. Correctness of Group Signature.** If  $(c, s_1, s_2, s_3, s_4, C_1, C_2, C_3)$  is a legitimate signature, the verifier calculates  $d'_1 = s_1 C_1 - s_2 PK_{RSU} + c PC_3 = r_1 C_1 - cb_A E_A P - cb_A T_A PK_{RSU} - r_2 PK_{RSU} + cb_A T_A PK_{RSU} + cb_A E_A P = r_1 C_1 - r_2 PK_{RSU} = d_1$ ,  $d'_2 = s_1 C_2 + s_3 S_{RSU} + c TP = r_1 C_2 - cb_A T_A P + r_3 S_{RSU} - c T_A S_{RSU} + c TP = r_1 C_2 + r_3 S_{RSU} = d_2$ ,  $d'_3 = s_3 P + c C_2 = r_3 P - c T_A P + c T_A P = r_3 P = d_3$ , and  $d'_4 = c C_1 + s_4 P + s_3 PK_{RSU} = c E_A P + c T_A PK_{RSU} + r_4 P - c E_A P + r_3 PK_{RSU} - c T_A PK_{RSU} = r_3 PK_{RSU} + r_4 P = d_4$ , based on  $TP = T_A (b_A + x_{RSU})P = T_A b_A P + T_A S_{RSU}$  and gets  $c t = c$  from the existing public information, so the signature verification algorithm is correct.

**5.2. Unforgeability.** Unforgeability means that the group certificate of the members in the group is unforgeable.

In this scheme, RSU's private key pairing is  $SK_{RSU} = (x_{RSU}, s_{RSU})$ , where  $s_{RSU} = r_{RSU} + z H_1(ID_{RSU} \| P_{RSU} \| R_{RSU})$ ; the group certificate for the group member  $OBU_A$  is  $(ID_A, PK_{RSU}, Y_A, E_A, b_A, T_A)$ , where  $E_A = Y_A + e_A P = (e_A + y_A)P$ ,  $Y_A = y_A P$ , and the synchronization factor of the group  $T$  and the synchronization factor of the group member  $OBU_A$  have the following relationship:  $T = T_A (b_A + x_{RSU})$ .  $y_A, b_A, x_{RSU}$ , and  $e_A$  are private to group members  $OBU_A$  and RSU, respectively, so no single party can complete the group member certificate creation independently. Therefore, the group certificate is unforgeable.

**5.3. Forward Security.** When group member  $OBU_A$  joins the group, the group synchronization factor  $T$  is updated as follows:  $T' = T \cdot (b_A + x_{RSU})$ , based on  $b_A$  provided by  $OBU_A$ , and the synchronization factors of other members  $OBU_B$  in the group are updated as follows:  $T'_B = T + T_B (b_B - b_B)$ ; when the group member  $OBU_A$  is revoked, the group synchronization factor  $T$  is updated as follows:  $T' = T \cdot (b_A + x_{RSU})^{-1}$ , and the synchronization factors of other members  $OBU_B$  in the group are updated as follows:  $T'_B = (T_B - T) \cdot (b_A - b_B)^{-1}$ . It can be seen that the signature in the verification phase and the synchronization factor used in the verification phase will be updated synchronously according to the membership addition and revocation. After the update, the previous signature verification equation will not be established, so the forward security can be guaranteed.

**5.4. Performance Analysis.** In this section, performance analysis will be performed in terms of communication costs and calculation costs. For this scheme, the communication cost needs to consider the length of the group manager's public key and the length of the group member's signature. In the calculation aspect, the cost of joining the group, the cost of revoking the group, the cost of computing the signature, and the cost of verifying the signature are considered. Compared with other group signature schemes, some

performance analysis comparisons are made as given in Table 1, where  $N$  represents the number of current group members and the number of joined and revoked members each time is set to 1.

In this scheme, the length of the group manager's public key and the length of the group member's signature information are not directly related to the number of members in the group and are constant.

In this scheme, when joining and revoking, the synchronization factor of each user needs to be updated, so the cost of joining and revoking is  $O(N)$ .

In this scheme, the efficiency of the calculation cost of the information signature and the verification cost of the signature information are both constant, and the number of group members does not affect the time spent on signature and verification.

For this scheme, the performance analysis mainly considers the cost of group membership joining and revocation, the cost of information signature, and the cost of verifying signature information.

According to the literature [15], we choose a hardware platform consisting of Intel I7-6700 and Windows7 with 8G processor memory. By performing elliptic curve/bilinear pairing simulation experiments multiple times and taking the average value of the results, the operation execution schedule can be obtained as shown in Table 2. The comparison of this paper's average execution time of simulation operations is shown in Figure 2.

Considering the overall performance of the scheme, we will focus on analyzing the time overhead in the signature generation and signature verification process. This scheme is compared with the existing schemes [14, 15]. In the signature generation phase, scalar multiplication of bilinear pairs is mainly used in the scheme [14, 15]. The overall multiplication operation is less than this scheme, but the length of a single multiplication operation is longer than the elliptic curve multiplication and modular multiplication operations used in this scheme, and the overall time overhead is greater than the time overhead of this scheme; moreover, in the signature generation, the calculation of  $2T_{EC\_MUL} + 2T_{MUL}$  is a fixed calculation, and it does not need to participate in each calculation process, which can further reduce the calculation cost of group members when performing signature generation. In the signature verification phase, the time-consuming bilinear operation in the scheme [14, 15] increases the time overhead, and the signature verification process of this scheme is not much different from the signature generation calculation overheads, as shown in Table 3. The comparison of signature generation and signature verification overhead for the three schemes is shown in Figure 3.

In the process of the group member joining, since the group members and the group management need to verify the identity of each other, the group members need to perform four elliptic curve multiplication operations and two hash comparisons. During the joining and revocation stages of group members, the group management broadcasts the synchronization coefficients of new members, and the members within the group update their respective

synchronization factors. Without modifying the group public key, the calculation costs caused by changes in the members of the group will be spent, allocating sales to members in the group and reducing the calculation requirements for group management.

## 6. Conclusion

Aiming at the problem of low authentication efficiency in the anonymous authentication scheme in VANETs, this paper proposes a certificateless elliptic curve anonymous authentication scheme. Though based on a certificateless signature scheme, this scheme does not have to consider certificate maintenance and key escrow issues. It also uses elliptic curves to perform calculations on the basis of certificatelessness and introduces synchronization factor technology to further improve computing efficiency of group members when joining, revoking, and signing. The analysis of the scheme shows that the proposed scheme can not only ensure the anonymity and traceability of the group signature scheme but also ensure unforgeability and forward security under the premise of correctness. The partial key generation scheme adopted in this scheme effectively ensures the security of user keys, and there is no need to save too much certificate information in the system, and the calculation and storage overhead is low. Therefore, it is very suitable for OBUs and RSUs with very limited computing and storage space in the VANETs.

With the continuous advancement of technology, the amount of information and knowledge disseminated on the Internet every day has been developing several times. At the same time, a large amount of bilingual data has also been produced in the real world. These data are undoubtedly a great asset for statistical machine translation research. Based on the dual-sentence quality corpus screening, two corpus screening strategies are proposed first, based on the double-sentence pair length ratio method and the word-based alignment information method. The innovation of these two methods is that no additional linguistic resources such as bilingual dictionary and syntactic analyzer are needed as auxiliary. No manual intervention is required, and the poor quality sentence pairs can be automatically selected and can be applied to any language pair. Secondly, a domain adaptive method based on massive corpus is proposed. The method based on massive corpus utilizes massive corpus mechanism to carry out multidomain automatic model migration. In this domain, each domain learns the intradomain model independently, and different domains share the same general model. Through the method of massive corpus, these models can be combined and adjusted to make the model learning more accurate. Finally, the adaptive method of massive corpus filtering and statistical machine translation based on cloud platform is verified. Experiments show that both methods have good effects and can effectively improve the translation quality of statistical machines.

## 1. Introduction

Currently, corpus-based translation system relies on large-scale bilingual parallel corpus, uses the translation model to estimate the probability, and selects the final translation result based on the translation probability. The advantage of the corpus-based translation method over the rule-based translation method is that it does not require much human and material participation in the construction of the model. The researchers themselves do not need to master the level of linguistic experts in the mastery of the two languages. The threshold is not so high, which allows more interested scholars and researchers to invest in it. Depending on the specific translation strategy, corpus-based machine translation can be divided into statistical-based machine

translation and instance-based machine translation. The statistical-based method is the mainstream method of current machine translation.

The early stages of statistical machine translation development use only some coarse-grained features, such as bidirectional phrase translation probabilities [1–3], bidirectional lexical translation probabilities [4], vocabulary length penalties [5], phrase lengths, punishment [6], language model [7], and sequence model [8–10]. Many systems use only these 10–20 features to complete the translation process and use the minimum error rate training (MERT) method [11–13] to perform feature weight adjustment. With the development of statistical translation models and the widespread use of massive data, researchers have found that the use of fine-grained

features [14] can further improve the accuracy of the translation system. However, the use of a large number of fine-grained features poses a great challenge to the adjustment of feature weights. The traditional MERT method can only adjust the weights of dozens of features but cannot do anything for a translation system with thousands of features. References [15–17] proposed a training algorithm based on max-violation perceptron and forced decoding [18], which can be used to translate the system by using all bilingual training data, large-scale discriminative training, and support for tens of millions of sparse features. Compared to the MERT and PRO methods, this approach can bring very significant performance improvements [19, 20] and further maximizes the use of perceptual machine training methods. The hierarchical phrase translation system has also achieved good results. The traditional statistical machine translation domain adaptive method usually migrates the model for a single domain. For example, the training data is news corpus, and the test data is network corpus. However, most practically in the application scenario, it is necessary to perform model migration on multiple domains at the same time. For example, for online translation services, the user’s input is usually text from various fields, which requires the statistical machine translation model to process automatically according to the actual input. The field adaptive research of deep learning translation is still relatively few, and the existing work has not given a clear domain label. However, the actual translation of scientific and technological literature often faces multiple professional fields, and the use of existing knowledge to organize information, such as the keywords of the paper, the scientific and technological word system, and other knowledge to obtain more clear semantic tags, helps to divide the corpus more finely.

In view of this, this paper mainly studies the multidomain adaptive method of statistical machine translation based on massive corpus under the cloud computing platform. Firstly, two corpus screening strategies are proposed, based on the double-sentence pair length ratio method and the word alignment information based method. The innovation of these two methods is that no additional linguistic resources such as bilingual dictionary and syntactic analyzer are needed as auxiliary. No manual intervention is required, and the poor quality sentence pairs can be automatically selected, and can be applied to any language pair. Secondly, a domain adaptive method based on massive corpus is proposed. The method based on massive corpus utilizes massive corpus mechanism to carry out multidomain automatic model migration. In this domain, each domain learns the intradomain model independently, and different domains share the same general model. Through the method of massive corpus, these models can be combined and adjusted to make the model learning more accurate. Finally, the adaptive method of massive corpus filtering and statistical machine translation based on cloud platform is verified. Experiments show that both methods have good effects and can effectively improve the translation quality of statistical machines.

## 2. Massive Corpus Screening Strategy under Cloud Computing Platform

*2.1. Cloud Computing Platform Framework.* The Hadoop Distributed File System (HDFS) can be deployed on a large number of inexpensive machines to store up terabytes and petabytes of data in a highly fault-tolerant and reliable manner. It combines well with the MapReduce model to provide high-throughput data access. The structure of DFS is shown in Figure 1.

As can be seen in Figure 1, an HDFS cluster that consists with a NameNode and multiple DataNodes was discussed. The metadata and the DataNode are actual data. The application accesses the NameNode to get the metadata of the file, and the actual I/O operation is directly interacting with the DataNode. The NameNode is the primary control server responsible for managing the file system namespace and coordinating application access to files, recording any changes to the namespace or changes to their properties. The DataNode is responsible for storage management on the physical node where the file is located. The feature of HDFS is that the data is “write once, read many times.” The files of HDFS are generally divided into different data blocks according to a certain size, and each data block is dispersed into different DataNodes as much as possible. In addition to completing the namespace operation of the file system, the NameNode also determines the mapping of the data block to the DataNode.

*2.2. Massive Corpus Screening Strategy.* For statistical machine translation systems, the intuitive understanding is that increasing the size of the training data can help improve system performance. Massive data is easier to obtain in today’s information environment than ever before. Scholars have built knowledge bases such as parallel sentence pairs and bilingual dictionaries by crawling bilingual web pages [21]. There are more and more sources of corpora, from multilingual websites, comparable bilingual corpora, human translated text, and more. The scale of building parallel corpora has been large, and it can be used for statistical machine translation system training. Too many errors must affect statistical machine translation systems that rely on data quality. In view of the fact that there is no qualitative change in the current statistical model, it is necessary to acquire the model features by training the corpus. Therefore, in order to train a high-performance statistical machine translation system, it is necessary to process and screen the training data. In this paper, two methods are used to filter the noise sentence pairs in the bilingual parallel corpus: the method based on the sentence pair length ratio and the method based on the alignment information.

*2.2.1. Method Based on Sentence to Length Ratio.* In general, the length of a pair of statements that are translated should be proportional to a certain ratio. However, most parallel corpora contain sentence pairs that do not match the length ratio. These sentence pairs are usually noise in the corpus. Noise phenomena caused by the length ratio include

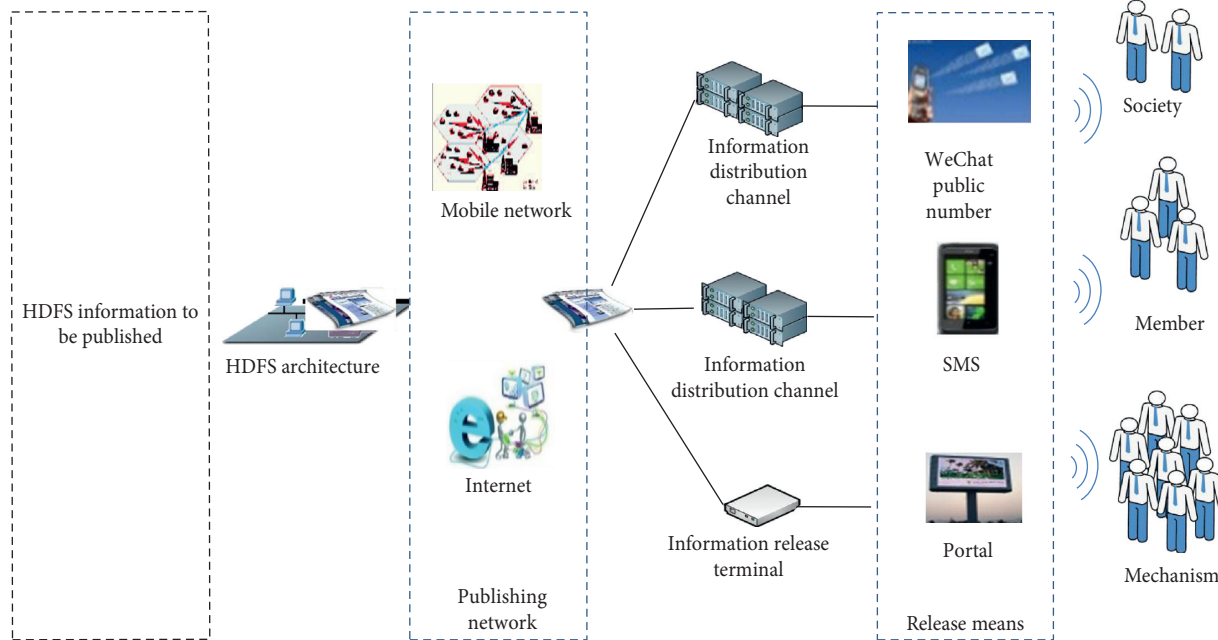

FIGURE 1: HDFS and DFS structure diagram.

monolingual errors, alignment errors, and inclusion of unknown tags (html tags, etc.). These phenomena have been observed, and many noise sentence pairs whose length ratios do not conform to the regularity are found in the experimental corpus. Some examples are listed in Table 1.

In order to remove such pairs of erroneous sentences, we set a length rule that defines the length ratio as

$$LR(f, e) = \frac{|f|}{|e|}, \tag{1}$$

where  $f$  is the source sentence,  $e$  is the target sentence, and  $|f|$  and  $|e|$  are the number of words after the source and target sentences.

The method based on the length ratio is usually based on linguistic knowledge, and the artificially set length is lower than the upper and lower limits. This paper assumes that the noise sentence in the corpus is less than the normal sentence pair; that is to say, there is a continuous range of ratios, which is the majority of the normal sentence pairs in this range. Therefore, the threshold is set according to the statistical distribution characteristics of the length ratio; that is, the sentence pairs whose length is less than the total number are filtered out. This has the advantage that thresholds can be set for different language pairs without the need for specific linguistic knowledge.

**2.2.2. Method Based on Word Alignment.** The word alignment problem is the task of finding the alignment of words in a given two-state pair. It is a key step in statistical machine translation. The word alignment model has been studied for a long time, and people use different methods for bilingual word alignment. Run the IBM model from both directions and merge the results of the two word alignments. In general, the intersection contains relatively reliable

TABLE 1: Noise sentence pair example.

| Sentence example  | Error                                 |
|---|---------------------------------------|
| (of an enterprise, institution, etc.)<br>Shift to another system                        | Sentence level alignment is incorrect |
| Falco jigger &bra; lagger falcon &ket;<br>c & w &bar; c-and-w &bar; country-and-western | Source unknown tag<br>Unknown label   |
| 1. (of a liquid) to settle, 2. clear;<br>transparent                                    | Sentence level alignment is incorrect |
| Take cognizance of  | Incorrect content                     |

alignment points; that is, the alignment point is highly accurate but does not contain all reliable alignment points; and the assembly contains most of the desired alignment points; that is, the recall rate is high but introduces additional errors. A good alignment point is adjacent to other good alignment points. Therefore, the algorithm starts from aligning the intersections. In the expansion step, adjacent alignment points located in the union but not in the intersection are added, and finally points that are not aligned in both directions are added. The pseudocode for this algorithm is given in Table 2.

The position of the two sentences in the corpus is adjacent. The occurrence of this situation is the automatic noise extraction of the parallel sentence to the technology, because it is impossible to judge the correct alignment sentence pair (the correct alignment sentence corresponds to <discountant opinions, discordant opinions>, or <discondant opinions> which is the second sentence in the table). A similar situation has occurred many times in the corpus we use.

Figure 2 shows the alignment matrix of the two sets of sentence pairs. As shown in Figure 2, it shows the results of two unidirectional alignments in English and Chinese, and

TABLE 2: Pseudocode for grow-diag-and-final heuristic word alignment extension.

```

GROW DIAG-AND-FINAL( $e2f$ ):
  neighboring = ((-1, 0), (0, -1), (1, 0), (0, 1),
                (-1, -1), (-1, 1), (1, -1), (1, 1))
  alignment = intersect( $e2f$ ,  $f2e$ );
  GROW-DIAGQ; FINAL( $e2$ ); FINAL( $f2$ );
  GROW DIAL-ANDQ:
    iterate until no new points added
      for English word  $e=0, 1, 2 \dots en$ 
        for Foreign word  $f=0, 1, 2 \dots fh$ 
          if (e aligned with f)
            for each neighboring point( $e$ -new,  $f$ -new):
              if( $e$ -new not aligned or  $f$ -new not aligned)and
                ( $e$ -new,  $f$ -new)in union( $e2f$ ,  $f2e$ )
                add alignment point( $e$ -new,  $f$ -new)
  FINAL(a):
    for English word  $e$ -new = 0, 1, 2 ... en
      for foreign word  $f$ -new = 0 ... fn
        if( $e$ -new not aligned or  $f$ -new not aligned)and
          ( $e$ -new,  $f$ -new)in union( $e2f$ ,  $f2e$ )
        add alignment point( $e$ -new,  $f$ -new)

```

---

the bidirectional alignment matrix on the right is obtained by the grow-diag-and-final algorithm. It can be seen that the intersection of two unidirectional alignments is only a matter of discretion, discordant; that is to say, when the grow-diag-and-final extension is performed, there is only one alignment result that is originally considered reliable. After the expansion, the result of the obvious error alignment is obtained. This error not only affects the alignment quality of itself, but also affects the rule extraction result of the translation system. For example, in the phrase system, the above sentence pairs are extracted from the rules of discriminating, inconsistent. This kind of rule does not play any role in translation decoding; even if the decoder selects the rule, it will only reduce the translation quality. Therefore, similar problems should be avoided as much as to improve the quality of the translation or to reduce the size of the rule set.

To this end, we propose a sentence-pair filtering method based on the grow-diag-and-final extension method. We consider expanding the number of alignment results EC and the number of alignment results of the intersection alignment IC. When the extended alignment result exceeds the intersection alignment result by a certain amount, we think that the alignment result is unreliable. We set the filtering rules based on the word alignment extension and use the following to judge whether the word alignment results are reliable:

$$ER(f, e) = \frac{IC - EC}{UC}. \quad (2)$$

### 3. Statistical Machine Translation Adaptation Based on Massive Corpus

*3.1. Statistical Machine Translation Adaptation.* This section introduces a domain adaptive approach based on massive corpus. The main idea is that the training of our model is

mainly divided into three steps: first, selecting the data in the domain is according to the predefined domain; second, training the domain model and the general model is to construct the statistical machine translation system; third, using massive corpus technology makes joint adjustments to multiple domain systems.

According to the above, the first step in this work is to select the in-domain bilingual control data from all the bilingual training data to train the translation model. Since the monolingual data in a specific field can be obtained in large quantities, we draw on the method of bilingual cross section data selection [22] to obtain bilingual data in the field:

$$[H_{I\text{-src}}(s) - H_{G\text{-src}}(s)] + [H_{I\text{-tgt}}(t) - H_{G\text{-tgt}}(t)]. \quad (3)$$

This bilingual cross-entropy-based criterion tends to choose a sentence pair that is more similar to the data distribution in the domain but different from the general data distribution. Therefore, this method considers that the sentence pair with larger cross-entropy difference should be selected.

In the second step, we use the training data in the selected domain to build a statistical machine translation system based on the hybrid model. Specifically, we adopted the idea of a hybrid model to build  $N$  machine translation systems for  $N$  predefined fields; each of which is a log-linear model. For each system, the optimal translation result  $f$  is given by

$$f = \arg \max_r \{P(f | e)\}. \quad (4)$$

For each machine translation system, two translation models and two language models are included. The translation model of a specific field is trained by the bilingual data selected by the data selection method introduced in the previous section, and the translation model of the general domain is trained using all bilingual data. For the language model, we reuse the language-specific and general-language models of the specific domain trained for data selection in the previous section. Compared to a translation system that does not do domain migration, this system with a hybrid model can better balance the general translation knowledge and domain-specific translation knowledge and can benefit from two aspects.

In the third step, it is necessary to adjust the feature weights in different machine translation systems. The traditional method of arranging is generally directed to a single system. The method described in this section regards translation systems in different fields as related translation tasks, and joints are coordinated under the framework of massive corpus. There are two reasons for using massive corpora:

- (1) The translation system of a specific domain shares the same general domain translation model and language model, and the massive corpus mechanism can make better use of the common translation knowledge of translation tasks in different fields.
- (2) By forcing the general domain translation model and the language model to behave the same in different

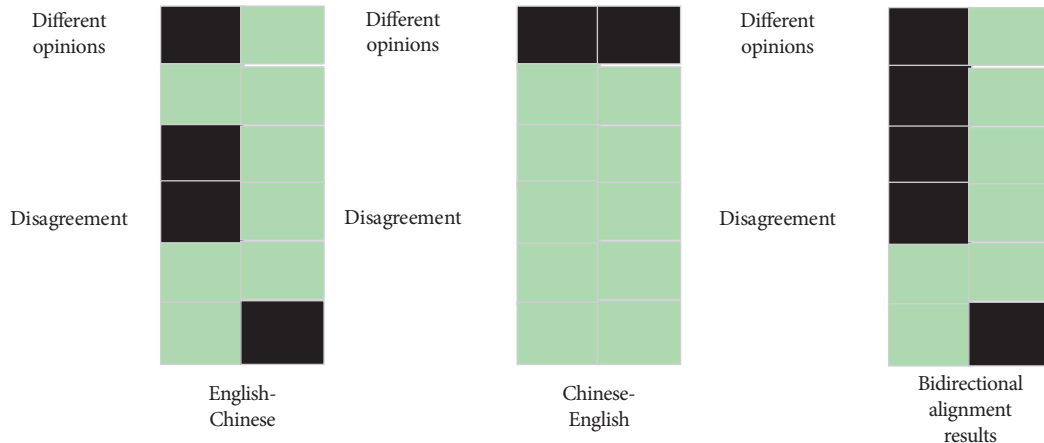

FIGURE 2: Schematic diagram of the alignment matrix of the wrong sentence pair.

fields, massive corpus provides a regularization mechanism to prevent model overfitting. Formally, the objective function of using massive corpus to adjust parameters is represented by the following formula:

$$\min_w \left\{ \sum_{i=1}^N \text{Loss}(E_i, e(F_i, w_i)) \right\}. \quad (5)$$

In order to be able to efficiently coordinate the parameters, we have improved an asynchronous stochastic gradient descent algorithm to optimize and borrowed the idea of pairwise ranking to use the perceptron algorithm to update the feature weights.

$$L(w_i) = -(w_i, v^1 - v^2). \quad (6)$$

We first use the machine translation system to generate the  $N$  best translation result candidates ( $N$ -best), which are reordered and combined into pairs by scoring with smooth sentence level BLEU. Specifically, similar to the asynchronous gradient descent algorithm, we divide the  $N$  best translation result candidates into three parts: the best 10% (high), the middle 80% (middle), and the worst 10% (low). These three parts of the translation result candidates are used for two-two sorting, in which we choose “high one,” “medium one low,” and “high one low” to combine in pairs, but will not select two of the same part Candidate combinations that are paired. The basic idea of constructing a sample in this way is that the algorithm can better have the discriminability of distinguishing between high quality and low quality translation results.

**3.2. Neural Network Deep Fusion Model.** The algorithm based on domain knowledge uses the explicit discrete features of domain knowledge, and the deep labeling algorithm uses the hidden continuous features of deep learning. The sentence domain probability vectors obtained by the two methods are different.

Combining the domain labeling algorithm based on domain knowledge and the domain labeler based on deep learning, a multilayer perceptron based on the top layer is designed as a deep fusion model of the neural network. The architecture is shown in Figure 3. The preprocessing of the sentence to be labeled is mainly word segmentation and garbled filtering. The preprocessed results are input to the knowledge-based domain tagger and deep learning-based domain tagger to obtain the domain knowledge-based probability vector and probability vectors for deep learning. The top-level neural network deep fusion model is a two-layer perceptron, and the hidden layer is two receiving four-dimensional vectors. Neuron, the activation function, is set to the ReLU (Rectified Linear Unit) function.

$$\begin{aligned} y_1 &= \text{ReQ}(W_1 x_1 + b_1), \\ y_2 &= \text{ReQ}(W_2 x_2 + b_2). \end{aligned} \quad (7)$$

The deep mixed neural model obtained through this fusion will well combine explicit and invisible knowledge, merging the advantages of discrete features and continuous features, and make the probability vector and decision category of each sentence more accurate. Thereby, the adaptation problem in the field of machine translation is better improved, and, for the data to be translated in a specific field, a higher quality translation output will be obtained.

## 4. Experiments and Results

**4.1. Massive Corpus Screening Experiment Verification.** The experimental part of this paper runs on a separate server. The specific software and hardware configuration is shown in Table 3. Because Hadoop installation is a stand-alone mode, the comparison and analysis of experimental results focus on the impact of the proposed method on translation quality.

Under the cloud translation platform, bilingual parallel corpora are a wide range of sources, such as translated manuscripts completed by translators, officially published bilingual materials, and automatic extraction of multilingual web pages. The quality of corpus is uneven. Therefore, in order to test whether the method is effective, the training

| Intel (R)-Xeon (R) 11 2.93 Hz | 96       | Ubuntu 12.04.1   |

corpus selected is mostly from the network. It contains 1,937,289 bilingual parallel sentences as a training set, which mixes multiple fields of content. The English language model uses the Xinhua part of LDC2007T07, the test set, and the development set. The test set contains a British news review in cwmt2011, and nist02 to nist08. The data sets are specifically listed in Table 4.

The tools used in the experiment include open source word alignment tool GIZA ten +, open source statistical machine translation system Moses, open source language model training tool irstlm, and Chinese word segmentation tool icclas. The translation model used is the phrase model, and the parameters use the standard settings of Moses.

First, we count the distribution of the length ratio of the English-Chinese sentence in the training set. The result is shown in Figure 4. The ordinate indicates the number of sentence pairs, and the abscissa indicates the ratio of the

TABLE 4: Source of experimental data.

| Corpus type  | Corpus name             | Corpus size             |

|              |                         |                         |
| Test set     | cwmt2011                | 1006 sentence pair      |
|              | nist02                  | 878 sentence pair       |
|              | nist03                  | 919 sentence pair       |
|              | nist04                  | 1788 sentence pair      |
|              | nist05                  | 1082 sentence pair      |
|              | nist06                  | 1664 sentence pair      |
|              | nist08                  | 1357 sentence pair      |
| LDC2007T07   | 9,685,593 sentence pair |                         |

length of the sentence between English and Chinese. We can find the ratio of the length of the sentence to a certain distribution law. When the ratio is 1.0, the sentence number is the most, and there are 297,341 pairs of sentences. The figure shows that the highest point of the ratio (1.0) is also relatively large in number of sentences. This verifies our hypothesis that the length ratios of the two languages conform to the law in a continuous range.

As shown in the above figure, the contrast value of the sentences appearing in the corpus is 0.1–66.0 due to the

FIGURE 4: Statistics of length-to-length ratios of English-Chinese sentences.

influence of noise and domain differences. We use the training corpus used for statistics. The comparison value of %0.06% falls within the range of 0.4–3.8. Even in the range of 0.5–4.5, there is still 90.11% of the sentence pairs. To this end, we screened the corpus training comparison system for the different ratio ranges of more than 90% of the total corpus and compared the BLEU scores of the systems on the test set. As shown in Table 5, the statistical distribution of the percentage of total corpus pairs in different ratio ranges is listed. The first line represents the corpus used, and the remaining lines represent the number of sentence pairs contained in the different ratio ranges and the percentage of the corpus. Table 5 shows the number of sentence pairs retained and the proportion of the total corpus when the ER filters different pairs of sentences. The higher the score of ER, the better the effect of word alignment, and the more reliable we think the result is. Based on the method of word alignment information screening corpus, we consider two cases: use the filtered sentence to align the retraining words and then get the translation model; directly use the filtered sentence pairs and alignment information to train the translation model. In the first case, the filtered noise information may affect the calculation of the word alignment probability during the iterative process of word alignment. Realignment after filtering out may improve the word alignment quality and improve the translation effect. In the second case, we use ER to retain the word alignment that is considered reliable, so reword alignment or different alignment results may occur due to the change of word alignment probability, and there may be unreliable alignment results in these results. The experimental results are shown in Table 6.

It can be seen from the experimental results that the BLEU scores of each test set are improved in both cases. As far as the overall effect is concerned, it is better not to retrain the word alignment. However, in both cases, the improvement effect on the nist03 and nist05 test sets is not very obvious, the effect of reword alignment on nist03 is slightly better than the latter,

TABLE 5: Scores of 8 length ratios on the development set after filtering.

| $t$   | Ratio range | Number of sentences | Percentage (%) |
|-------|-------------|---------------------|----------------|
| 0.000 | 03–2.0      | 1,911,491           | 100            |

| *     | 22.87        | 30.11      | 28.31      | 29.44      | 27.93      | 24.02      | 18.87      |
| >−0.5 | 23.00        | 30.03      | 27.87      | 29.53      | 27.59      | 24.30      | 19.06      |
| >−0.4 | 22.94        | 30.43      | 28.05      | 29.37      | 27.65      | 24.35      | 19.02      |
| >−0.3 | 23.21        | 30.64      | 28.41      | 29.52      | 27.47      | 24.09      | 19.20      |
| >−0.2 | 23.11        | 30.36      | 28.16      | 29.45      | 27.64      | 24.08      | 19.40      |
| >−0.1 | 23.56        | 29.59      | 28.21      | 29.93      | 27.14      | 24.42      | 19.91      |

and the opposite is on nist45. Use ER to determine whether the word alignment is reliable. When ER is lower than the given threshold, we think that the word alignment result of the sentence pair is not reliable overall. We will filter out the sentence pair, that is, the sentence pair. All alignment information is deleted. In fact, in the word alignment result of the sentence pair, there will be some correct word alignment information; that is, the correct word alignment information is also deleted while deleting the error alignment information. Although the wrong information is not useful for translation tasks, the correct information to be deleted may be helpful for translation tasks. Therefore, there is also the possibility of reducing the BLEU score.

As shown in Figure 5, we find an instance from the filtered sentence pair to illustrate. The thick solid line in the figure is the intersection of two aligned directions, the thin solid line is the correct result of the extended alignment, and the dashed line is the wrong result of the extended alignment. The sentence in Figure 4 is correct for itself, but its alignment information is incorrect; only partial alignment is correct, and its ER value is −0.22; it can be seen that there is some correct word alignment information, and this part of information can be extracted. A rule facilitates translation. Because the ER value is lower than the given threshold, all alignment information of the sentence pair is filtered out, but the correct information is also filtered out, so there is a problem of degraded translation quality.

4.2. Adaptive Experimental Verification of Statistical Machine Translation Based on Massive Corpus. We compared the impact of different searched documents and hidden layer lengths on the accuracy of the translation system. The results are shown in Figure 6.

FIGURE 5: Example of incorrect alignment of correct sentence pairs.

FIGURE 6: The effect of different number of retrieved documents and hidden layer length on machine translation accuracy.

As shown in Figure 6, we found that, for most results, the optimal translation accuracy was obtained when the number of retrieved documents was  $N = 10$ . This result confirms that extending the source language input by means of information retrieval is very helpful for determining topic information. It plays an important role in the selection of translation rules. However, in the experiment, when  $N$  is large, for example,  $N = 50$ , the translation performance is drastically lowered. This is because as the number of retrieved documents increases further, the introduction of topic-independent documents into the neural network will be introduced, and irrelevant documents will bring about unrelated real words, thus affecting the performance of neural network learning.

In Figure 7, it can be seen that when  $L$  is small, the translation system is relatively accurate. In fact, in the case of  $L < 600$ , the difference in translation performance is small. However, when  $L = 1000$ , the translation accuracy is worse than other cases. The main reason is that the amount of parameters in the neural network is so large that it cannot be well studied. We know that when  $L = 1000$ , there are  $100000 \times 1000$  parameters between the linear and nonlinear layers of the network. The current training data size is not enough to support this network parameter level training, so the model is likely to fall into the local Optimal and unacceptable topic representation information.

FIGURE 7: The impact of topic-related features on machine translation accuracy.

As shown in Figure 8, we find that the topic similarity feature on the source language side is slightly better for the system than the target language-side similarity feature, and the enhancements that they bring can be accumulated, which means that the neural network based on bilingual data training can help the statistical machine translation system. Translation result candidates perform better disambiguation. Further, based on the similarity feature, the topic sensitivity feature of the translation rule can bring more performance improvement, because the translation rules of specific topics are usually more sensitive, when the similarity is similar. The system tends to choose translation rules for specific topics rather than general translation rules. Finally, we see that our methods perform best when using all topic-related features, with an average of 0.39 BLEU points higher than the LDA-based method.

As shown in Figure 9, we use the method of information retrieval to extend the original input, thus avoiding restrictions on bilingual chapters. We use neural network technology for topic modeling. The algorithm is more practical and has good scalability. Under the deep learning framework, our method directly optimizes the bilingual topic similarity, so that the learned topic representation can be easily integrated into statistical machine translation.

**4.3. Domain Labeling Performance.** The statistics of the data set are used by the domain tagger; 1% is randomly selected as the test data for the domain tagging performance experiment. The training data for training deep learning is selected from the remaining 99% of the size of the data set. At the same time, the domain labeler based on the domain knowledge and the trained deep learning domain labeler are used to label the test data to obtain the category and probability vector, and then the results are simply linearly

FIGURE 8: The impact of different features on the translation system.

FIGURE 9: Topic distribution information of three sentence candidates.

fused. The category with the highest probability in the probability vector is selected as the final judgment category, and this judgment category is used as the statistical basis for the accuracy rate and the recall rate and the  $F-1$  value. Four subexperiments are performed. The results are shown in Table 7. The results show that using only the domain knowledge tagger will cause misjudgment and omissions due to the lack of self-built domain knowledge base feature words, so the score is not high, but the judgment efficiency is high; using only the deep learning domain tagger requires a lot of the training data belonging to mining tacit knowledge

and continuous features, but training is slow and does not combine prior knowledge; simple linear fusion models linearize the probability vectors of the first two and so on.

Proportional weighting combines explicit and tacit knowledge but this simple fusion is difficult to improve most of the misjudgments and missed judgments and has not been greatly improved; the final neural network deep fusion model is deepened through multilayer neural networks. The integration, giving full play to the advantages of the two, greatly reduced the phenomenon of misjudgment and omission and significantly improved.

TABLE 7: Effect of each labeling method on labeling performance.

|           | Domain knowledge | Deep learning | Simple linear fusion model | Deep fusion model |
|-----------|------------------|---------------|----------------------------|-------------------|
| Accuracy  | 0.85             | 0.9185        | 0.898                      | 0.947             |
| Recall    | 0.76             | 0.95          | 0.886                      | 0.9345            |
| F-1 value | 0.7633           | 0.9531        | 0.8936                     | 0.942             |

## 5. Conclusion

When the training corpus is small, some pairs of training sentences related to the test text may be filtered out, which will affect the quality of the translation. But when the training data is large enough, such problems will hardly occur. In addition to learning the domain model independently for each domain, different domains share the same general model. Through the method of massive corpus, these models can be combined to make the model learning more accurate. The experimental results show that this method can significantly improve the translation accuracy of multiple fields in large-scale machine translation tasks. In addition, the performance of this joint tuning method is better than independent model migration. At the same time, this result can be easily applied to the online translation system, training different models for a pre-determined number of fields, determining the domain according to the input source language text, and selecting the corresponding domain model or general model for translation. The experimental results also show that when there is no such problem, the method of this paper can effectively improve the translation quality of the statistical machine translation system.

The work that needs to be improved in this study is as follows. (1) Consider in the field that the adaptive mechanism is placed in the architecture of human neural machine translation. Calculate different domain vectors, improve the attention mechanism, and make the domain adaptive. (2) How to integrate deep learning methods and prior knowledge to improve the system's performance will be researched in every area of natural language processing in the future. Later, we will try different ways in neural machine translation Chinese and Canadian prior knowledge in the field to improve translation quality for different fields. How to integrate deep learning methods and prior knowledge to improve the performance of the system will be a problem that needs to be studied in the future. After that, we will try to add a priori knowledge in the field of neural machine translation in different ways to improve the translation quality for different fields.

## Data Availability

The data used to support the findings of this study are included within the article.

Short-term traffic flow has the characteristics of complex, changeable, strong timeliness, and so on. So the traditional prediction algorithm is difficult to meet its high real-time and accuracy requirements. In this paper, a multiscale and high-precision LSTM-GASVR short-term traffic flow prediction algorithm is proposed. This method uses 15 min traffic flow data of the first 16 sections as input and completes the data preprocessing operation through reconstruction, normalization, and rising dimension by working day factor; establishing the prediction model based on the long- and short-term memory network (LSTM) and inverse normalization; and proposing the GA-SVR model to optimize the prediction results, so as to realize the real-time high-precision prediction of traffic flow. The prediction experiment is carried out according to the charge data of a toll station in Xi'an, Shaanxi Province, from May 2018 to May 2019. The comparison and analysis of various algorithms show that the prediction algorithm proposed in this paper is 20% higher than the LSTM, GRU, CNN, SAE, ARIMA, and SVR, and the  $R^2$  can reach 0.982, the *explanatory variance* is 0.982, and the MAPE is 0.118. The proposed traffic flow prediction algorithm provides strong support for traffic managers to judge the state of the road network to control traffic and guide traffic flow.

## 1. Introduction

High-precision and short-term traffic flow forecast shows the future trend of traffic development [1]. For intelligent traffic management, road network planning provides future traffic flow data [2]. It is not only helpful to alleviate traffic congestion, but also important for autonomous vehicles [3]. Traffic flow prediction refers to forecast traffic flow in the next period based on several historical traffic flow data [4]. A prediction one to several hours ahead of schedule is often called a short-term prediction [5, 6]. As a hot theme in Intelligent Transportation [7–9], there were lots of relating research studies about short-term traffic flow prediction. Wang et al. [10] proposed a hybrid short-term traffic speed prediction framework based on empirical mode by decomposition (EMD) and autoregressive integrated moving average (ARIMA) and achieved short-term traffic flow prediction of expressway in different scenarios, but there are

great differences in the prediction effect for different types of vehicles. Vasantha Kumar and Vanajakshi [11] developed a SARIMA short-term traffic flow prediction model under constrained data. The model needed high stable data and was weak at generalization. A two-step prediction method based on stochastic differential equation (SDE) was implemented in reference [12], which improves the prediction accuracy of a periodic data, but neglects the prediction effect of periodic traffic flow. Salamanis et al. [13] studied a density-based clustering method which can accurately predict traffic flow under normal and abnormal conditions. The prediction effect is good, but the time complexity is high and the feasibility is slightly lower. Neuhold et al. [14] established a model to predict traffic flow and an algorithm to optimize lane allocation in front of the toll plaza in Austria. The prediction model and optimization algorithm are not site specific and can be applied to different toll plaza or expressway bottlenecks (such as road engineering, transit, and

highway intersections). But for the data that are one-day or one-hour interval traffic flow, this model cannot fully meet the intelligent traffic management needs. A prediction model based on deep recurrent neural network (RNN) was designed in reference [15]. While the prediction effect is better, there are great differences in the prediction effect of a periodic data. Qu et al. [16] used historical traffic flow data and environmental factor data to predict all-day traffic flow based on deep neural networks, using multilayer supervised learning algorithm to train predictors, mining the potential relationship between traffic flow data and key contextual factors, an intermittent training method for reducing training time. But the prediction effect for smaller traffic flow data is poor. In [17], based on the BP neural network to predict the expressway traffic flow, the incentive function of the model is improved, and to some extent, the prediction effect is improved, but it is not suitable for all highways, and the limitation is great. In reference [18], the traffic flow information acquisition technology and combination model of video image analysis were applied to the traffic flow prediction to reduce the error and time for establishment. But the prediction effect is affected by the accuracy of data acquisition and fluctuates greatly. Luo et al. [7] implemented a CNN-SVR (convolutional neural networks-support vector regression) short-term traffic flow prediction model. The Adam optimization algorithm was used to ensure the completeness of the time-space flow characteristics, which reduces the interference of external factors and can effectively predict the traffic flow. However, because the data are relatively single, the generalization ability of the model is not strong. In reference [19], a stationary short-time traffic flow prediction method was proposed. The support vector machine predicts the traffic flow data after stationary, which solves the influence of the asymmetric distribution of the data on the prediction effect, but caused a bad prediction effect of the extreme point. Wang et al. [20] proposed an improved BP neural network model based on thought evolution algorithm. The accuracy of the prediction model was improved by phase space reconstruction of traffic flow time series using chaotic theory. However, because the model uses less data, lacks credibility, and did not consider the prediction effect of special time periods such as holidays, it is not universal. A traffic flow prediction model based on convolutional neural network is implemented in reference [21], and the paper considered the spatial-temporal correlation of regional traffic flow, which improves the prediction accuracy and stability of the model. Only taxi traffic flow data were studied, which do not fully reflect the road state. Previous neural network models used values from previous days or weeks as inputs to predict future traffic flow data [22, 23], and the real time is poor, which exists the problem of gradient vanishing. To address this, LSTM (Long Short-Term Memory) neural network was used to predict traffic flow [24–27], but the influence of commuting traffic flow on urban traffic state was not considered.

Tidal traffic flow phenomenon is one of the important factors causing congestion in toll stations. Accurate and real-time prediction of short-term traffic flow provides strong support for traffic management departments to guide traffic

flow. And it plays an important role in the information communication system [28]. This paper presents a multi-scale and high-precision LSTM-GASVR (Long Short-Term Memory Genetic Algorithm Support Vector Regression) short-term traffic flow prediction algorithm. Data preprocessing was utilized to filter, normalize, and reconstruct the data and improve the data dimension by workday flags, which effectively improves the convergence speed and prediction accuracy of the model; building prediction model based on the output LSTM, Long Short-Term Memory network, and GA-SVR model was proposed to optimize the prediction results to achieve real-time and high-precision prediction of short-term traffic flow. The proposed traffic flow prediction algorithm improves the prediction accuracy and stability and improves the generality and feasibility of the traffic flow prediction model.

## 2. Short Traffic Flow Data Preprocessing

In order to obtain the appropriate amount of data and the required data format, traffic flow data need to be pre-processed by data merging, expanding the amount of data, and data resampling to obtain time traffic volume. The preprocessing of short-term traffic flow data is divided into the following steps, as shown in Figure 1:

- (i) Data normalization makes the data model training have better convergence
- (ii) Considering the occasional and violent weekend and holiday tidal traffic flow, it is necessary to enhance the data dimension
- (iii) Data reconstruction aims to obtain a specific data format

Step 1: extract the data and merge the data for  $n$  consecutive months as needed to expand the dataset.

Step 2: resample the data as needed. Table 1 shows the charge data of Shaanxi Provincial Toll Station in August 2018; “STARTTIME” is the computer boot time; the “ENTRYLANE” is the entrance lane number; the “ENTRYTIME” indicates the vehicle entry time; and the “VEHICLETYPE” is the vehicle type; 0, 1, and 2, respectively, indicate the uncertain vehicle type, passenger car, and freight car; “VEHICLELICENSE” represents the license plate number. To extract the “ENTRYTIME” column of Table 1, we regard one line of data as a vehicle entering the station. These data are resampled according to 15 min, and the data shown in Table 2 are obtained. The “Value” represents the traffic volume within 15 min with the starting time of “Date.”

Step 3: data normalization. For a better convergence of the prediction results and the better results, the data are normalized by the maximum and minimum value standardization, assuming that the  $x$  is the traffic volume of a certain period of time, and it is normalized as follows:

$$x' = \frac{x - \min}{\max - \min}, \quad (1)$$

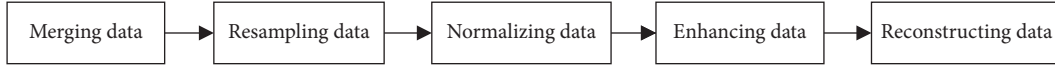

FIGURE 1: Data preprocessing.

TABLE 3: Format of traffic flow forecast training data for  $m$  period before the day.

| Sample no.                          | 0           | 1           | ... | $n$         |
|-------------------------------------|-------------|-------------|-----|-------------|
| Period 0 traffic volume (input)     | $v_0^0$     | $v_0^1$     | ... | $v_0^n$     |
| Period 1 traffic volume (input)     | $v_1^0$     | $v_1^1$     | ... | $v_1^n$     |
| ...                                 | ...         | ...         | ... | ...         |
| Period $m-1$ traffic volume (input) | $v_{m-1}^0$ | $v_{m-1}^1$ | ... | $v_{m-1}^n$ |
| Working day factors                 | $h_b^0$     | $h_b^1$     | ... | $h_b^n$     |
| Next period traffic volume (output) | $v_m^0$     | $v_m^1$     | ... | $v_m^n$     |

$x'$  is the values after  $x$  normalization fall, from 0 to 1, and the min and max in equation (1) are the minimum and maximum values in the dataset.

Step 4: dimension promotion. The traffic demand caused by commuter's commute is an important part of urban road traffic volume. Because of the urban planning problems, the traffic flow of commuters has an obvious influence on urban traffic state. The working day factors are divided into three categories according to "week," "weekend," and "holiday."

Step 5: data reconstruction. The data are reconstructed as needed, the data are divided into  $m+2$  row and  $n+1$  column, the first  $m+1$  row of each column is input, and the last row is compared with the predicted value as the real value. The final data structure is shown in Table 3.  $v_i^j$  represents traffic volume in sample  $i$  at period  $j$ .  $h_b^j$  represents the working day factor in sample  $j$ .  $h_b$  represents the working day factor,  $b$  is 1, 2, or 3,  $h_1 = 0.1$ ,  $h_2 = 0.5$ , and  $h_3 = 0.9$ .

### 3. Analysis of Time Series Predictive Assessment Indicators

The prediction results of time series need to evaluate each prediction model through indicators and adjust the parameters, so as to determine the high-precision short-term traffic flow prediction model. Equations (2)–(9) are evaluation indicators of time series prediction [2].  $f_i$  represents the predicted value of sample  $i$ ,  $y_i$  represents the actual value of sample  $i$ ,  $\bar{y}$  represents the average value of the real data, and  $n$  is the sample size.

① MAE (mean absolute error):

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |f_i - y_i|. \quad (2)$$

② MSE (mean square error is one of the most commonly used performance measures for regression tasks):

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (f_i - y_i)^2. \quad (3)$$

③ RMSE (root mean squared error):

$$\text{RMSE} = \sqrt{\text{MSE}} = \sqrt{\frac{1}{n} \sum_{i=1}^n (f_i - y_i)^2}. \quad (4)$$

④ MAPE (mean absolute percentage error) often used to measure prediction accuracy:

$$\text{MAPE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{y_i - f_i}{y_i} \right|. \quad (5)$$

⑤ Explanatory variance:

The explanatory variance represents the extent to which the regression model explains the variation of the variance of the dependent variable (i.e., fitting effect of the regression model to the true value), which is a common evaluation index for the regression model:

$$\text{Explained\_variance}(y, f) = 1 - \frac{\text{Var}\{y - f\}}{\text{Var}\{y\}}. \quad (6)$$

The explanatory variance is between  $[0, 1]$ , and the closer to 1 indicates the better the prediction effect.

⑥  $R^2$  ( $R$ -squared):

$R^2$  is the ratio of the sum of squared residuals to the sum of the total deviation squares, indicating the degree to which the regression equation can explain the variation of the dependent variable, and  $R^2$  is the fitting effect of the regression equation on the true value.

The sum of squared residuals:

$$SS_{\text{res}} = \sum_{i=1}^n (f_i - y_i)^2. \quad (7)$$

The sum of total deviation squares:

$$SS_{\text{tot}} = \sum_{i=1}^n (y_i - \bar{y})^2, \quad (8)$$

$$R^2 = 1 - \frac{SS_{\text{res}}}{SS_{\text{tot}}} = 1 - \frac{\sum_{i=1}^n (f_i - y_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}. \quad (9)$$

The value of  $R^2$  is between 0 and 1. The closer  $R^2$  is to 1, the more accurate the model and the better the regression prediction effect. It is generally considered that the model fit is higher when  $R^2$  exceeds 0.8.

Because ①②③ use the mean error, and the mean error is more sensitive to outliers, if there is a large difference between a certain regression value fitted by the regressor and the true value, it will lead to a large average error, which will have a great influence on the final evaluation value, that is, the mean value is not robust. According to Table 4, it is found that the value of ①②③ increases with the increase of  $y$ , so the reliability is low. By comparing and analyzing the curve fitting effect in Figures 2–13, in combination with the value of evaluation indicators in Tables 4–6, it is found that the evaluation value of ④⑤⑥ is more consistent with the curve fitting effect. By analyzing and comparing the above evaluation indicators, take ④⑤⑥ as the main index to evaluate traffic flow prediction and ①③ as the auxiliary index.

## 4. Short-Term Traffic Flow Prediction Algorithm Based on LSTM-GASVR

*4.1. Optimize the Model Based on GA-SVR.* Genetic algorithm (GA) is used to optimize the parameters  $(C, \varepsilon, r)$  in the SVR model, where the  $C$  is the penalty coefficient,  $r$  is the kernel function coefficient, and  $\varepsilon$  is the insensitive coefficient, which has the following main steps:

- (1) Constructing the chromosome assemblage  $(C, \varepsilon, r)$  and formulating the fitness calculation function of genetic algorithm
- (2) Determining the parameters of selection, crossover, mutation, and so on in the GA, and setting the iterative termination condition of the algorithm
- (3) Initializing the GA and generating the initialization population
- (4) Calculating individual fitness in chromosome populations
- (5) Generation of next-generation chromosomes through selection, crossover, variation, etc.

TABLE 4: Comparison of short-term traffic flow prediction effect at different time intervals.

| Time intervals | $R^2$ | Explanatory variance | MAPE  | MAE    | RMSE   |
|----------------|-------|----------------------|-------|--------|--------|
| 5              | 0.980 | 0.980                | 0.232 | 7.705  | 11.532 |
| 10             | 0.979 | 0.981                | 0.186 | 13.408 | 19.777 |
| 15             | 0.982 | 0.982                | 0.160 | 21.406 | 27.960 |
| 20             | 0.980 | 0.980                | 0.156 | 28.095 | 40.394 |
| 25             | 0.974 | 0.977                | 0.219 | 36.871 | 54.758 |
| 30             | 0.971 | 0.972                | 0.168 | 49.940 | 69.037 |

- (6) If the iterative termination condition of the algorithm is satisfied or not, jump to (4).
- (7) Termination of the iteration to determine the optimal parameters  $(C, \varepsilon, r)$ . Figure 14 shows a flowchart of GA solving SVR optimal parameters  $(C, \varepsilon, r)$ .

*4.2. Chromosome Coding.* Genetic method is based on chromosome coding, selection, crossover, and mutation, and other operations of the algorithm effectively depend on the chromosome coding method to some extent. Considering that the SVR model parameter selection itself is a constrained problem, we code the SVR model parameter by real number. That is the gene of each chromosome consists of three decimal float.

*4.3. Population Initialization.* Population number is an important parameter that affects the efficiency and convergence of the algorithm. In this paper, the population size  $\text{pop\_size}$  is set to 50, and the population initialization state is evenly distributed in the solution space. And  $C \in [275, 285]$ ,  $\varepsilon \in [0.4, 0.6]$ , and  $\sigma \in [0.001, 0.003]$ .

*4.4. Fitness Function Selection.* GA is used to find the best parameters of the SVR model, so the fitness function is chosen as average relative error percentage between the prediction results and the actual value, and the fitness function can be designed as follows:

$$\text{MAPE} = \frac{100}{n} \sum_{i=1}^n \frac{|y_i - f(x_i)|}{y_i}. \quad (10)$$

Among them, the MAPE is the average relative error percentage between the prediction results and the actual value of the algorithm.  $t_0$  is the initial time of training data,  $y_i$  represents the actual driving speed of the road at the time  $t_0 + i \times 15$  min, and the prediction result of the time  $t_0 + i \times 15$  min is  $f(x_i)$ .

*4.5. Selection Operations.* The selection operation used in this paper is the combination of roulette and elite strategy. The key of the roulette selection method is to produce offspring population by calculating the probability of each individual appearing in the offspring, that is, the greater the probability of individual selection when the adaptation value is higher. The probability of individual appearance is shown in Table 7. Roulette selection algorithm refers to the

FIGURE 2: 5 min LSTM training and prediction. (a) 5 min LSTM loss function and (b) 5 min LSTM prediction results.

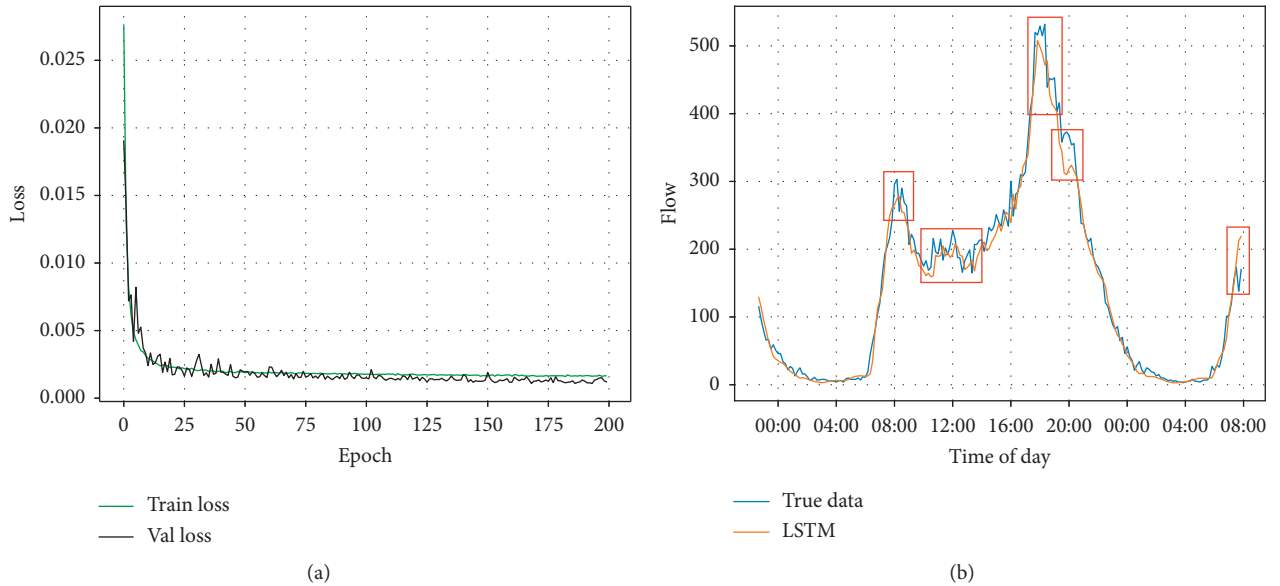

FIGURE 3: 10 min LSTM training and prediction. (a) 10 min LSTM loss function and (b) 10 min LSTM prediction results.

generation of random numbers in the interval  $[0, 1)$ , which falls within a certain probability interval shown in Table 7, which corresponds to individuals inherited to the next generation. For example, the random number generated is 0.3,  $0.3 \in [0.2, 0.45)$ , corresponding to individual 2, so individual 2 is inherited to the next generation. The disadvantage of this method is that it is easy to fall into local optimum when the range of adaptive value interval is small.

The elite strategy is to keep the better individuals in the last generation population and increases the number of the better individuals so as to guarantee the global optimum, but it is easy to fall into the local optimum when the proportion of the better individuals is large. Elite strategies retain better

individuals by copy better individuals into the next generation or cross and mutation better individuals in the population, and we select the latter method.

Therefore, the paper adopts the combination of roulette and elite strategy to keep the better population number in elite strategy proportionally dynamic, so as to get the solution of the population number, as shown in the following equation:

$$\text{GoodPop\_size} = \min\left(\text{Pop\_size}, \frac{k \times \text{current\_Gen}}{\text{Max\_Gen}}\right). \quad (11)$$

FIGURE 4: 15 min LSTM training and prediction. (a)15 min LSTM loss function and (b) 15 min LSTM prediction results.

FIGURE 5: 20 min LSTM training and prediction. (a) 20 min LSTM loss function and (b) 20 min LSTM prediction results.

FIGURE 6: 25 min LSTM training and prediction. (a) 25 min LSTM loss function and (b) 25 min LSTM prediction results.

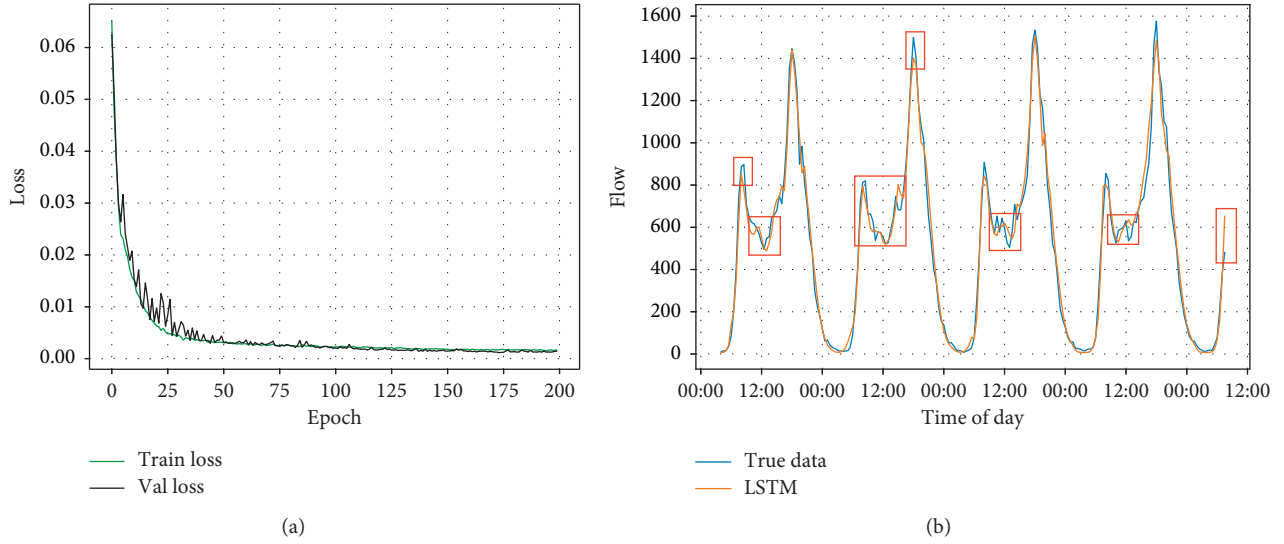

FIGURE 7: 30 min LSTM training and prediction. (a) 30 min LSTM loss function and (b) 30 min LSTM prediction results.

FIGURE 8: 4 steps LSTM training and prediction. (a) 4 steps LSTM loss function and (b) 4 steps LSTM prediction results.

The GoodPop\_size in equation (11) is to retain the number of better individuals, Pop\_size represent the number of populations,  $k$  is the sum of the parent and the offspring at each run time of the algorithm, current\_Gen is the number of runs of the current algorithm, and Max\_Gen is the maximum number of iterations set in advance for the algorithm. Equation (11) provides a corresponding guarantee for the efficiency and optimization performance.

**4.6. Genetic Operator Design.** Genetic operator mainly includes cross operator and mutation operator. Cross operation is one of the main operations of offspring innovation in GA. By simulating the cross inheritance of chromosome weight, the individual genes are exchanged according to certain probability. The mutation operation is to simulate the process of chromosome compilation and recombination

to change some genes in individuals according to certain probability. Cross operator and mutation operator are a way to produce innovation.

**4.6.1. Cross Operator.** During the evolution of natural organisms, the recombination of biological genetic genes is very important, and cross operators cannot be replaced in GA. The arithmetic cross operator is selected in the paper, as shown in equation (12).  $a$  in equation (12) represents the random number between 0 and 1 of the values of cross probability.  $P'_i$  and  $P'_{i+1}$  represent gene value  $P_i$  and  $P_{i+1}$  after cross operator, and  $i$  and  $i+1$  are gene positions:

$$P'_i = aP_i + (1-a)P_{i+1}, \quad P'_{i+1} = (1-a)P_{i+1} + aP_i. \quad (12)$$

FIGURE 9: 8 steps LSTM training and prediction. (a) 8 steps LSTM loss function and (b) 8 steps LSTM prediction results.

FIGURE 10: 12 steps LSTM training and prediction. (a) 12 steps LSTM loss function and (b) 12 steps LSTM prediction results.

**4.6.2. Mutation Operator.** Mutation operator is the operation of changing individual gene value  $x_j$  in chromosome population, as shown in equation (13). A random function  $\text{Random}(a_i, b_i)$  is used to generate a random number, and  $a_i$  and  $b_i$  are the upper and lower limits of the gene. And a gene position  $j$  in the chromosome is set to the value generated by the random function:

$$x_j = \begin{cases} \text{Random}(a_i, b_i), & i = j, \\ x_j, & i \neq j. \end{cases} \quad (13)$$

**4.7. Stop Sign.** The stop flag is the maximum number of iterations set for the experiment, and the value is set to 200 in the experiment.

During the GA training as shown in Figure 15, the blue boxes indicates where the optimal value goes up and the

optimal value increased to 0.86 after 30 iterations. The red curve in the figure represents the accuracy of the optimal parameter SVR of the prediction model. Because of the elite retention strategy, the green curve gradually approaches red, that is, the average accuracy tends to the optimal value. The SVR model parameters of the final GA tuning parameter  $(C, \epsilon, r)$  are  $(276.7, 0.05998, 0.001595)$ .

**4.8. LSTM Prediction of Short-Term Traffic Flow Based on GA-SVR Optimization.** Based on the research and analysis of various algorithms, it is found that the LSTM model prediction evaluation index  $R^2$  is higher, that is, the fitting degree between the predicted data and the real traffic flow data is higher, which is more consistent with the real data trend, and the prediction results are more reliable. GA-SVR prediction model evaluation index  $MAPE$  is smaller, the

FIGURE 11: 16 steps LSTM training and prediction. (a) 16 steps LSTM loss function and (b) 16 steps LSTM prediction results.

FIGURE 12: 20 steps LSTM training and prediction. (a) 20 steps LSTM loss function and (b) 20 steps LSTM prediction results.

model prediction value is closer to the real traffic flow data numerically, and the error is smaller. To balance the fitting degree and error of short-term traffic flow prediction model, this neural network model LSTM combined with SVR is optimized by GA, and the short-term traffic flow prediction model based on LSTM-GASVR is obtained.

The structure of LSTM-GASVR is shown in Figure 16. The neural network is partly composed of the input layer, two layers of LSTM, dropout layer, and full connection layer. The output of the neural network is processed by the SVR to obtain the output results. Next moment workday flags  $h^m$  input to the first layer contain 64 LSTM networks and get 64 features. The 64 features and  $v_0$ , which is the traffic volume of period 0 to form a new vector, then input to the second layer in the network and get 64 features. These characteristics and traffic flow data of the next time step constitute a new vector input to 64 LSTM networks and get 64 LSTM characteristics.

And so on, the first LSTM layer outputs  $(m + 1) * 64$  data as input of the second LSTM layer. The output from last time step of the second LSTM will input to the dropout layer; finally, the results will be output by the dense layer of the model. The average of the results and the traffic flow at the previous moment inputs to the SVR model and then outputs the final results. "A in Figure 16" is shown in Figure 17, it is LSTM unit structure.  $C_{t-1}$  is the cell state,  $h_{t-1}$  is the output of the last LSTM, and  $X_t$  is the input of LSTM.  $f_b$ ,  $i_b$ , and  $o_t$  are output of forget gate, input gate, and output gate.  $\sigma$  and  $\tanh$  is activation function.  $C_t$  is the new cell state, and  $h_t$  is the output of LSTM.  $t-1$  means the last moment, and  $t$  is the current moment.

The LSTM-GASVR prediction process is shown in Figure 18. The input traffic data are preprocessed using MinMaxScaler normalization. According to the current short-term traffic flow data affected by the previous  $m$  data

FIGURE 13: 24 steps LSTM training and prediction. (a) 24 steps LSTM loss function and (b) 24 steps LSTM prediction results.

and the workday flag, the array is reconstructed to  $[m + 1 : 1]$ . The data are divided into training set and test set, training set is used to train the model, and test set is used to test the prediction effect of the model. The data input to the neural network composed of LSTM, dropout, and dense, and then training of neural network. And the test data input neural network to make the preliminary prediction. The prediction results are renormalized, and the data are reset to the average of the LSTM model prediction results and the traffic flow at the previous time. The average input SVR model then optimizes the parameters of the model by the GA. After that, SVR model is trained according to the optimal parameters.

Finally, input the test data into the LSTM-GASVR model for prediction, and output the prediction results.

The prediction effect of the LSTM-GASVR model is shown in Figure 19. The time interval of the model is 15 minutes and the time step is 16. The green line in the figure represents the real traffic flow, and the red line represents the LSTM-GASVR model prediction value. It can be seen the prediction results of the LSTM-GASVR model are very close to the real value, which shows slightly higher error of prediction results at peak, but the error is small on the whole.  $R^2$  is 0.982, *explanatory variance* is 0.982, and MAPE is 0.118, and these are evaluation indicators of the model.

## 5. LSTM Prediction Model Parameter Determination

The batch size is 64, the epoch is 200, and the loss function is “rmsprop” as quantitative in the training of the LSTM model. The optimal performance of the model under different sampling time intervals and time steps is analyzed to determine the optimal sampling interval and time steps.

### 5.1. LSTM Prediction Model Sampling Interval Determination.

LSTM network model predicts the short-term traffic flow data with different time interval downsampling; then, we compare and analyze the training speed, loss function value, and the performance of the prediction results under different sampling intervals to determine the most suitable LSTM network model under the sampling interval.

The LSTM, trained with 5 min downsampling data, is shown in Figure 2(a). The loss function reaches a stable value of 0.002 at 25 epochs. As shown in Figure 2(b), the part marked by the red boxes is the larger part of the prediction difference. From Figure 2, the 5 min LSTM model is trained quickly, but the error of prediction results is large.

The LSTM of the trained 10 min downsampling data is shown in Figure 3(a). The loss function reaches a stable value

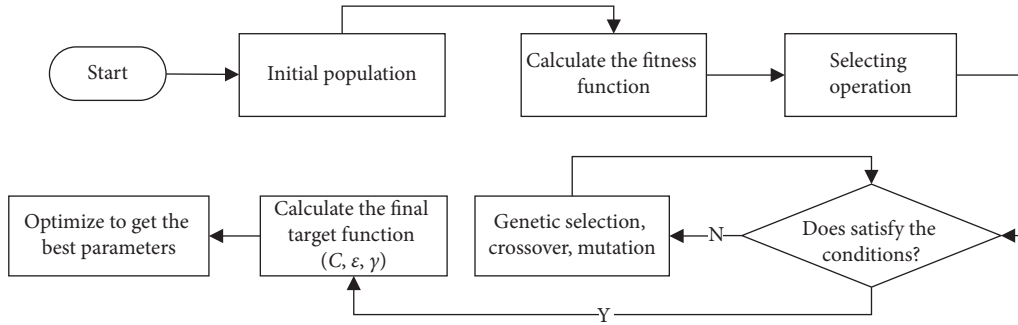

FIGURE 14: Flowchart of genetic algorithm.

TABLE 7: Probability interval.

| Individual                 | 1        | 2           | 3          | 4        |
|----------------------------|----------|-------------|------------|----------|
| Probability of individuals | 0.2      | 0.25        | 0.35       | 0.2      |
| Probability interval       | [0, 0.2) | [0.2, 0.45) | [0.45, 08) | [0.8, 1) |

FIGURE 15: GA training.

of 0.002 at 50 epochs. As shown in Figure 3(b), the prediction difference is mostly labeled in the red boxes. From Figure 3, we can see that the LSTM model training speed of 10 min data is slow, and there are some deviations from the prediction results.

The LSTM of the analyzed 15 min downsampling data training is shown in Figure 4(a), and the loss function reaches a stable value of 0.002 at 50 epochs. As shown in Figure 4(b), the part marked in the red boxes is a larger part of the prediction difference. It can be seen from the figure that the 15 min LSTM model has a fast training speed, and the prediction results are generally good, and the errors at the peak and fluctuation are larger.

The LSTM of 20 min downsampling data training is analyzed. As shown in Figure 5(a), the epoch is 75 where the loss function is stable at 0.003. As shown in Figure 5(b), the prediction difference is mostly marked in red boxes. From

Figure 5, the 20 min LSTM model training speed is better, the value of loss function is slightly higher, the prediction results are general, and the prediction error is large at peak and fluctuation.

The LSTM model obtained from the training of 25 min downsampling data is shown in Figure 6(a). The stable value of the loss function is 0.003 at 75 epochs. As shown in Figure 6(b), the part marked by the red boxes is the larger part of the prediction difference. From Figure 6 the 25 min LSTM model training speed is slightly slow, the value of the loss function is slightly higher, the prediction results are general, and the prediction error is large at the peak and the fluctuation.

The LSTM, trained under 30 min downsampling data, is shown in Figure 7(a). The loss function reaches a stable value of 0.003 at 75 epochs. As shown in Figure 7(b), the red boxes indicate that the prediction results showed slightly larger error. From the figure, the 30 min LSTM model training speed of the data is slightly slower, the loss function value is higher, the prediction results are general, and the prediction result error is larger at peak and fluctuation.

Since the difference judgment of the fitting curve is difficult, the prediction results of the LSTM network model with different sampling intervals are again compared and analyzed by various evaluation indexes. As shown in Table 4, the model evaluation trained by the data of 15 min is the best.

### 5.2. LSTM Prediction Model Time Step Determination.

The LSTM model predicts the short-term traffic flow data of 15 min downsampling with different time steps  $n$  (the current moment is affected by the previous  $n$  moment). The most suitable time step is selected by analyzing the stability of the training process, the value of the loss function, and the curve of the fitting degree of the predicted results to the real value.

The LSTM model is trained with 15-minute interval downsampling data at 4 time steps. Its loss function image is

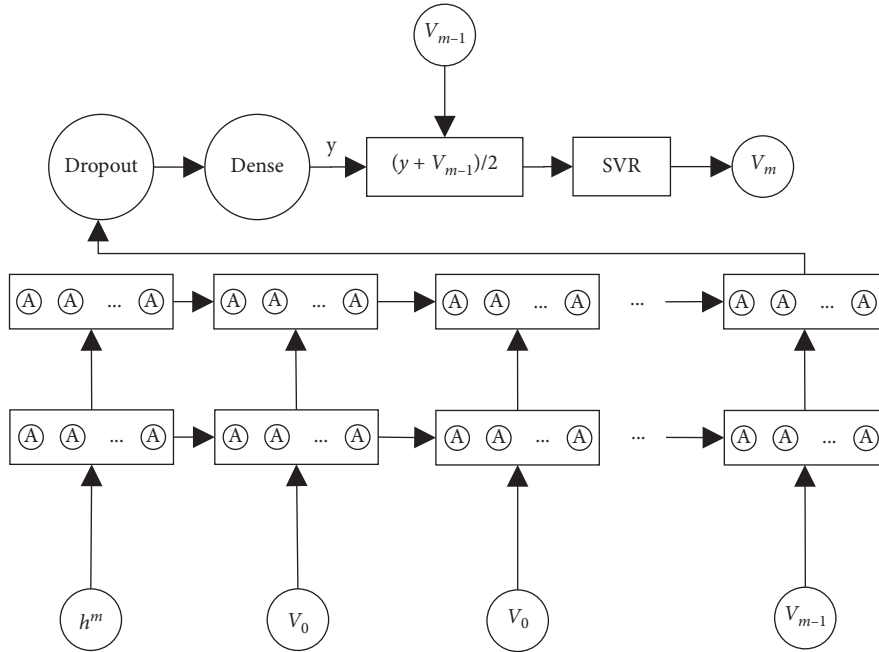

FIGURE 16: LSTM-GASVR structure.

FIGURE 17: The structure of LSTM.

shown in Figure 8(a), and the loss function is stable around 0.002 at 50 epochs. The prediction results are shown in Figure 8(b). The red boxes are marked with a large prediction difference. The training speed of the LSTM model with 4 time steps is slightly slower, the loss function value is higher, the prediction results are general, and the prediction result error at peak is very high.

Analyzing the 15 min of downsampling data trained at 8 time steps LSTM, as shown in Figure 9(a), the loss function is stabilized around 0.003 at 75 epochs. As shown in Figure 9(b), the part marked in the red boxes shows that the prediction difference is large. The training speed of the LSTM model with 8 time steps is slow, the loss function value is slightly larger, the overall prediction results are

general, and the prediction results at peak and fluctuation are obviously poor.

The LSTM model of downsampling data trained at 12 time steps and the loss function are shown in Figure 10(a), the loss function reaches a stable value of 0.002 at 50 epochs, the prediction results are shown in Figure 10(b), and the prediction difference is mostly marked in red boxes. It can be seen from the figure that the LSTM model with 12 time steps has a fast training speed, accurate prediction results, but a large error in the prediction results at the peak and with large fluctuations.

The LSTM model, trained with 15 min interval downsampling data at 16 time steps, is shown in Figure 11(a), and the loss function reaches a stable value of 0.003 at 50 epochs. As shown in Figure 11(b), the red boxes are marked with a

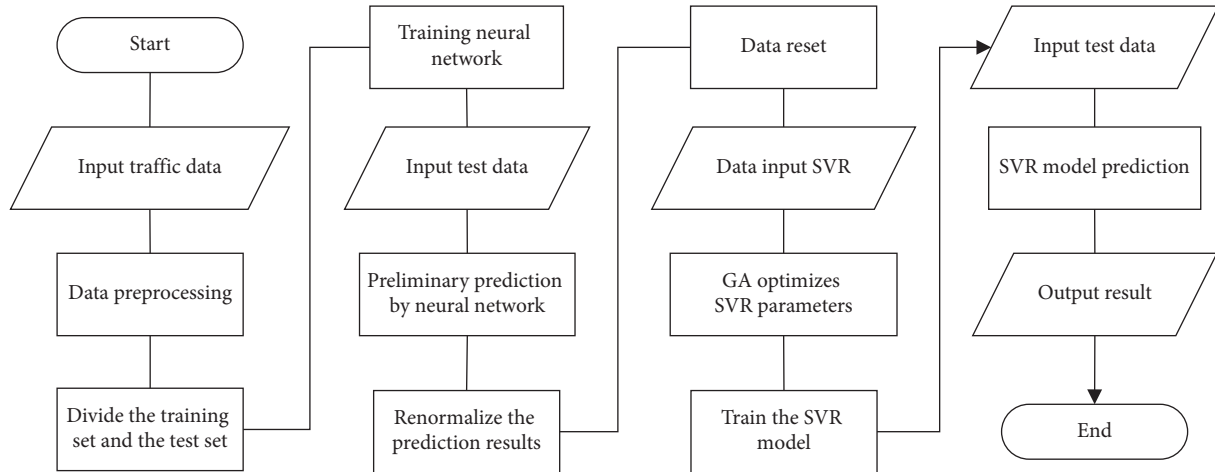

FIGURE 18: LSTM-GA SVR prediction process.

FIGURE 19: LSTM-GASVR prediction results.

large difference in prediction. The LSTM model with 16 time steps shows better training speed, and the loss function value is low. Overall, the prediction results are accurate, but slightly higher error of prediction results at peak.

The LSTM with downsampling interval of 15 min was trained at 20 time steps. As shown in Figure 12(a), the loss function at 50 epochs is stable at around 0.002. As shown in Figure 12(b), the prediction difference of red boxes part is large. The training speed of LSTM model with 20 time steps is general, the prediction results are general, and the error of peak, fluctuation, and valley bottom part is very high.

The LSTM model were trained of the data sampled at intervals of 15 min at 24 time steps, and the loss function is shown in Figure 13(a), reaching a stable value of 0.003 at 50 epochs. As shown in Figure 13(b), the part marked by the red boxes is the larger part of the prediction difference. From the figure, the training speed of LSTM model with 24 time steps is general, and the predicted results are general. The prediction error is large at the peak and the fluctuation, and the prediction results of the valley bottom are very high too.

The LSTM model predicts the short-term traffic flow data of 15 min downsampling with different time steps  $n$  (the current moment is affected by the previous  $n$  moment). Then, we compare the prediction results according to various evaluation indexes. As shown in Table 5, it is found that the prediction effect of 16 time steps is the best.

The optimal performance of the LSTM model under different sampling time intervals and time steps is analyzed, and the sampling interval is finally determined to be 15 min at 16 time steps. The LSTM model training speed is the fastest at this time, the loss function reaches the stable value at 25 epochs and the loss function value is small, and the prediction accuracy is the highest.

## 6. Comparative Analysis of Short-Time Traffic Flow Prediction Model

Through LSTM, GRU (gated recurrent unit), CNN (convolutional neural networks), SAE (stacked autoencoder), ARIMA (auto regressive integrated moving average), SVR,

FIGURE 20: LSTM training and prediction. (a) LSTM loss function and (b) LSTM prediction results.

LSTM-GASVR prediction of 15 minutes short time traffic volume, in this paper, the training speed and loss function of LSTM, GRU, CNN, and SAE in training are compared and analyzed, the prediction results of seven algorithms are compared to fit the curve of real value, and the prediction effect is analyzed.

Analyzing the LSTM model trained with the downsampling interval of 15 min data at the 16 time steps, as shown in Figure 20(a), the loss function reaches a stable value of 0.002 at 25 epochs. As shown in Figure 20(b), the part marked in the red boxes is the larger part of the prediction difference, the training speed of the LSTM model is faster, the prediction results are generally more accurate, and the error of the prediction results at the peak is slightly larger.

The data sampled by 15 min are trained to GRU model at the 16 time steps, and the loss function is stable around 0.002 at 75 epochs as shown in Figure 21(a). As shown in Figure 21(b), the partial prediction difference is marked by the red boxes. From the figure, we can see that the model training speed is general, the prediction accuracy is general, and the prediction result error at the peak is very large.

The 1D CNN model of 15 min downsampling data trained at 16 time steps is analyzed. As shown in Figure 22(a), the 50-epoch training sets get a stable training set loss function value of 0.007, and the validation set loss function stability value of 0.003. As shown in Figure 22(b), the red boxes are marked with a large difference in prediction, the model training speed is general, the loss function value is large, the prediction accuracy is not high, and the prediction error is large.

The SAE model trained with 15 min downsampling data at 16 time steps is analyzed. The loss function reaches a stable value of 0.001 at 100 epochs, as shown in Figure 23(a). As shown in Figure 23(b), the difference in prediction is mostly marked in red boxes, the SAE model training speed is

average, the loss function value is small, the prediction accuracy is not high, and the prediction effect is very poor at peak, fluctuation, and turning point.

The ARIMA model and the GASVR model were used to predict 15 min of short-term traffic flow, respectively. The prediction results of the ARIMA model are shown in Figure 24, the red boxes are marked with a large part of the prediction difference, it can be seen that the prediction accuracy of peak value is low, and it takes a long time in the prediction process of the ARIMA model, which does not meet the real-time requirement of short-term traffic flow prediction. As shown in Figure 25, for the prediction results of the GASVR model, the red boxes are marked with a large part of the prediction difference. It can be seen that the prediction accuracy is slightly lower at the peak value, and the GASVR model prediction curve is shifted backward compared with the real value.

In Figure 26, the prediction results of the LSTM-GASVR model show that the model effectively improves the migration phenomenon of the GASVR and improves the accuracy of the LSTM model. These are some differences were marked by the red boxes, the prediction accuracy of the LSTM-GASVR model is not enough at the peak of traffic flow. But it has a little influence on the results of the algorithm, and the LSTM-GASVR model predicted the most accurate results.

The timeliness of the LSTM-GASVR model is normal compared with other algorithms. The prediction time of the model is 0.003 s longer than GASVR, and the time is 2 s shorter than ARIMA. Compared with the LSTM model, the prediction time of the LSTM-GASVR is 0.001 s longer than that of the LSTM model. In addition, compared with CNN, SAE, and GRU models, the LSTM-GASVR model takes time to predict that traffic flow is same almost.

However, the LSTM-GASVR model's timeliness is normal compared with other algorithms and the accuracy is

FIGURE 21: GRU training and prediction. (a) GRU loss function and (b) GRU prediction results.

FIGURE 25: GASVR prediction results.

well. According to the above algorithm, the 15-minute downsampling data are predicted, and the prediction results are compared and analyzed according to various evaluation indexes. As shown in Table 6, it is found that the comprehensive prediction effect of the LSTM-GASVR model is the best.

Six prediction algorithms LSTM, GRU, CNN, SAE, GASVR, and LSTM-GASVR are analyzed and compared and the conclusions are summarized in Table 8.

## 7. Conclusion

Based on the charging data from May 2018 to May 2019 at a toll station around Shaanxi Province, the data normalization and reconstruction are adopted. And the working day flag bit is added to enhance the data dimension and to realize the data preprocessing of short-

TABLE 8: Analysis of short-time traffic flow prediction algorithm for different prediction algorithms.

| Algorithm  | Summary  |
|------------|--|
| LSTM       | The prediction effect is good and timeliness is general, but there are big differences for different models trained  |
| GRU        | Simpler than the LSTM structure, but the traffic flow prediction at the turning point is less effective. It is suitable for predicting stable traffic flow, and the prediction effect is not good when the volatility is large |
| CNN        | SAE model has large prediction error when traffic flow data is small   |
| SAE        | ARIMA model prediction error is general and timeliness is poor   |
| ARIMA      | The prediction effect is good and timeliness is better, but there is a certain shift phenomenon  |
| GASVR      | The timeliness of the model is normal, and a variety of time interval data prediction effect is better and more stable   |
| LSTM-GASVR |  |

term traffic flow. Comparing and analyzing the evaluation indexes of various time series, an effective combination evaluation index of short-term traffic flow prediction is established. Through analyzing the neural network prediction model and other machine learning prediction models and using GA to optimize the SVR model parameters, a short-term traffic flow prediction model based on LSTM-GASVR is proposed. By analyzing and comparing different time intervals in the multiple groups of experimental results, we selected 15 min as the time interval, and the time step is 16. This model is used to predict the short-term traffic flow data, and various prediction models are analyzed by combination index. The LSTM-GASVR model has normal timeliness and the best and stable prediction effect,  $R^2$  is 0.982, *explanatory variance* is 0.982, and *MAPE* is 0.118. The next step is to optimize the prediction accuracy at the peak traffic volume.

Screening and classification of characteristic genes is a complex classification problem, and the characteristic sequences of gene expression show high-dimensional characteristics. How to select an effective gene screening algorithm is the main problem to be solved by analyzing gene chips. The combination of KNN, SVM, and SVM-RFE is selected to screen complex classification problems, and a new method to solve complex classification problems is provided. In the process of gene chip pretreatment, LogFC and  $P$  value equivalents in the gene expression matrix are screened, and different gene features are screened, and then SVM-RFE algorithm is used to sort and screen genes. Firstly, the characteristics of gene chips are analyzed and the number between probes and genes is counted. Clustering analysis among each sample and PCA classification analysis of different samples are carried out. Secondly, the basic algorithms of SVM and KNN are tested, and the important indexes such as error rate and accuracy rate of the algorithms are tested to obtain the optimal parameters. Finally, the performance indexes of accuracy, precision, recall, and F1 of several complex classification algorithms are compared through the complex classification of SVM, KNN, KNN-PCA, SVM-PCA, SVM-RFE-SVM, and SVM-RFE-KNN at  $P = 0.01, 0.05, 0.001$ . SVM-RFE-SVM has the best classification effect and can be used as a gene chip classification algorithm to analyze the characteristics of genes.

## 1. Introduction

Since the birth of gene chip technology, a large number of feature selection methods for gene expression microarray data have emerged in academia. Most of these methods focus on the quality of the selected genes, while few people pay attention to the efficiency of the algorithm itself. Gene expression microarray data has a large number of characteristic genes. If it is not an efficient characteristic selection method, the whole process of key gene selection will become very long. Many existing classical feature selection methods have low efficiency, and some even reach unacceptable levels. Among them, representatives include CFS, mRMR, and SVM-RFE. Especially in SVM-RFE, the whole selection process is very time-consuming. Some researchers have also improved SVM-RFE, but the time-consuming problem has not been fundamentally improved. This chapter takes SVM-RFE as the research object, and SVM and RFE are improved, respectively. By

introducing a more efficient implementation of the classical linear support vector machine to reduce the time consumption of the basic feature selection process and proposing a recursive feature elimination strategy with variable step size to reduce the iteration times of the basic feature selection process, the combination of the two finally attempts to fundamentally solve the inefficiency problem of SVM-RFE.

A support vector machine based on recursive feature eligibility (SVM-RFE) [1] was proposed by Guyon et al. In 2002. This method makes full use of the characteristics of SVM; that is, it can rank and score all genes according to their importance while training the SVM classification method and combine the recursive feature elimination strategy to make feature selection. Duan et al. [2] improved SVM-RFE to deal with only two classification problems and proposed a one-to-one and one-to-many multiclassification SVM-RFE method, which enables SVM-RFE to deal with multiclassification problems.

Aiming at the low efficiency of SVM-RFE feature selection process, Ding and Wilkins [3] improved the iterative process of RFE, from deleting one feature at a time to deleting several, which improved the efficiency of the algorithm without losing the classification accuracy. Yoon and Kim [4] proposed a SVM-RFE method based on mutual information, which solves the problem that the SVM-RFE method does not consider feature correlation in the process of feature selection to a certain extent. Tang et al. [5] divided SVM-RFE into two stages. In the first stage, rough selection is carried out on the features to be selected, filtering out irrelevant features, redundant features, and noise features. In the second stage, finer feature selection is carried out on the basis of the first stage. The next two sections will introduce SVM-RFE in detail and analyze the reasons for its inefficiency in depth. Tang et al. [6] feature clustering SVM-RFE (FCSVM-RFE) feature clustering to enhance SVM-RFE gene selection. The proposed method first roughly selects genes and then ranks the selected genes. Clustering algorithm is used to cluster genes into genomes, in which each gene has a similar expression profile. SVM-RFE was used to rank these representative genes. FCSVM-RFE reduces computational complexity and redundancy. Although SVM-RFE can effectively delete irrelevant functions, it cannot handle most redundant functions [7]. In order to overcome this shortcoming, this paper develops a new feature selection method, the core of which is to delete redundant features according to the correlation between features before using SVM-RFE. The proposed method was tested on a pancreatic cancer microarray dataset. The method is much better than baseline SVM-RFE in classification accuracy. In order to improve the accuracy of classification, radial basis function (RBF) kernel is also introduced [8]. Chen and Zhu [9] proposed a feature selection method based on support vector machine recursive feature elimination (SVM-RFE) and binary particle swarm optimization (BPSO) algorithm. SVM-RFE removes some irrelevant features to reduce the data dimension and then continues to search for the best subset and uses some better SVM-RFE subsets as part of the initial PSO population and has a good starting point. SVM-RFE not only reduces the search space of particles but also provides prior experience, thus improving the search efficiency and accuracy of the algorithm. Anaissi et al. [10] used ESVM recursive feature elimination (ESVM-RFE) for gene selection. It follows the concepts of integration and bagging used in random forest but adopts backward elimination strategy, which is the basic principle of RFE algorithm. The principle behind this is that using randomly drawn boot program samples from the training set to build an integrated SVM model will generate different feature levels, which will then be summarized into one feature level. As a result, the decision to delete features is based on the ranking of multiple SVM models, rather than selecting a specific model. However, in the classification of unbalanced datasets, imbalance is a common problem in gene expression microarray data [11]. Generally speaking, people are only interested in a few categories because the few categories are usually patients, while normal people often account for the majority. For the classification method, too few samples in a certain category means that the category

contains less information, so the classification model finally learned by the classification algorithm can easily predict patients among normal people when making classification prediction [12]. Especially for small sample data such as gene expression microarray data, it becomes more important to solve the problem of category imbalance. The most basic methods to solve the problem of category imbalance are upsampling and downsampling. Zhou and Wang [13] proposed a feature selection method combining relief-F and SVM-RFE algorithm. The algorithm integrates the weight vector from relief-F into the SVM-RFE method. In this method, relief-F filters out many noisy functions in the first stage. Then, a new sorting criterion based on the SVM-RFE method is applied to the final feature subset. A SVM classifier is used to evaluate the final image classification accuracy. A new method for multiclass gene selection and classification based on multiple supports vector machines recursive feature elimination (SVM-RFE) is proposed [14]. For the multiclass DNA microarray problem, we solve it as a multibinary classification problem. The "one-to-all" method is used to decompose multiple types of tasks into multiple binary problems, and SVM-RFE selects genes for each binary problem. The SVM classifier is used to train selected gene data for binary problems. Firstly, the basic method of SVM is introduced, and the application of RFE algorithm is explained in detail. Secondly, the chip GSE76275 screens and classifies different  $P$  values under SVM-RFE algorithm. Finally, the classification effect of SVM-RFE algorithm after filtering with different  $P$  values is illustrated by comparative research under different SVM-RFE-KNN, SVM-RFE-SVM, and other four algorithms.

## 2. Relevant Theoretical Works

*2.1. Support Vector Machine.* A support vector machine (SVM) is recognized as one of the most classical machine learning algorithms. Its essence is the maximum interval classification method. At this time, a support vector machine can only deal with linearly separable data classification problems and is called hard interval support vector machine. Soft interval support vector machine was proposed in 1995. At this time, a support vector machine can deal with data classification problems that are approximately linearly separable. Subsequently, support vector machines have been further developed. Support vector machines, support vector regression machines, and multiclassification support vector machines based on kernel techniques have been proposed one after another. At this time, the support vector machine has formed a very complex and complete theoretical system, which can not only deal with linear separable problems but also classify nonlinear separable data, becoming very powerful. The SVM-RFE algorithm uses a support vector machine based on linear kernel. The support vector machine model is shown in Figure 1.

The algorithm idea of the support vector machine is actually very simple. For hard interval support vector machines, the whole process is divided into three steps: first, the dataset is linearly separable; second, finding two hyperplanes requires that no data points fall between the two planes.

FIGURE 1: Support vector machine model.

Third, maximize the distance between the two planes. The objective function at this time is

$$\max \frac{2\eta}{\|w\|} \quad (1)$$

$$\text{s.t. } y_i(w \cdot x_i + b) \geq \eta, \quad i = 1, \dots, n,$$

where  $(2\eta/\|w\|)$  is the distance between the two hyperplanes and is the target optimization value,  $x_i$  and  $y_i$  represent the  $i$ -th sample and the corresponding label, respectively, and  $y_i(w \cdot x_i + b)$  represents the distance from the point  $x_i$  to the nearest hyperplane.  $y_i(w \cdot x_i + b) \geq \eta$  means that point  $x_i$  cannot fall between two hyperplanes. In order to facilitate the solution, formula (1) is usually transformed into a quadratic programming problem:

$$\min \frac{1}{2} \|w\|^2 \quad (2)$$

$$\text{s.t. } y_i(w \cdot x_i + b) \geq 1, \quad i = 1, \dots, n.$$

In all classifications, the classification interval of the optimal plane is the largest; at this time,  $\|w\|^2$  is the smallest, H is called the optimal classification line, and the training samples on H1 and H2 are called support vectors. The Lagrange optimization method is used to obtain it. Assuming that  $b = (b_1, b_2, \dots, b_n)$  and equation (2) constitute Lagrange multiple terms, the maximum value is taken.

$$W(a) = \sum_{i=1}^n a_i - \frac{1}{2} \sum_{j=1}^n a_i a_j y_i y_j x_i x_j, \quad (3)$$

where  $a_i \geq 1$ ,  $\sum_{i=1}^n y_i a_i = 0$  is quadratic programming that can optimize equation (3). Assuming that there is a maximum vector  $a^0 = (a_1^0, a_2^0, \dots, a_n^0)$  of equation (3) and the optimal hyperplane is described by  $(w_0, b_0)$ , then  $w_0$  is shown in the following equation:

$$w_0 = \sum_{i=1}^n a_i^0 y_i x_i. \quad (4)$$

If the restriction condition is proposed in equation (4), the decision function of the optimal classification is shown in the following equation:

$$f(x) = \text{sgn} \left( \sum_{i=1}^n a_i^0 y_i x_i + b_0 \right) = 0. \quad (5)$$

Equation (5) introduces Lagrange's equation:

$$L(w, b, a) = \frac{1}{2} (w \cdot w) - \sum_{i=1}^n a_i y_i (w x_i + b) - 1, \quad (6)$$

where  $a$  is the Lagrange coefficient. By differentiating  $w$  and  $b$ , we obtain the quadratic programming problem:

$$\begin{cases} \min & \frac{1}{2} \sum_{j=1}^n a_i a_j y_i y_j [\phi(x_i) \cdot \phi(x_j)] - \sum_{i=1}^n a_i \\ \text{s.t.} & \sum_{i=1}^n y_i a_i = 0 \\ & a_i \geq 0, \quad (i = 1, 2, \dots, n). \end{cases} \quad (7)$$

**2.2. Recursive Feature Elimination (RFE).** The main idea of recursive feature elimination is to repeatedly build models (such as SVM or regression models). The importance of each feature is obtained through the attribute value returned by the learner or the importance score of the feature. Then, the least important feature variable is removed from the current feature set. Then, the model is constructed on the remaining characteristic variables. Repeat the abovementioned process until there is only one feature variable left. This process constructs a model of feature number minus one time. The order in which features are eliminated is the importance ranking of features. This is a greedy algorithm to find the optimal feature subset, which requires a lot of computation and requires high hardware requirements of computers. The stability of RFE depends to a large extent on which a model is selected at the bottom during iteration. For example, if the ordinary linear regression adopted by RFE is unstable without regularization, then RFE is unstable. If a ridge is used and the regression regularized by the ridge is stable, then RFE is stable. For example, a linear kernel support vector machine SVM-RFE, as an effective feature selection method, has been successfully applied to fault diagnosis. However, some problems may be nonlinear.

SVM-RFE is a supervised sequential backward selection algorithm. In the linear classifier, it takes the discriminant information of each feature to the objective function as the sorting coefficient. That is, the contribution of the weight vector to the classification surface  $y_i(w \cdot x_i + b)$  is used to construct the feature ranking table. If the weight corresponding to the feature is larger, the decision function will be affected more, and the feature with larger weight has more discrimination information. Each iterate removes a feature with the smallest weight and then retrains the classifier until the feature ranking table is completed. The sorting principle can also be analyzed from the objective function of the following formula:

Input: the training samples:  $X_0 = [x_1, x_2, \dots, x_i]^T$ ,  $x_i$  is the samples of d-dimensional space

Category label:  $y = [y_1, y_2, \dots, y_i]^T$

Initialization: feature sort  $r = []$ , current feature index sequence  $s = [1, 2, \dots, d]$

Feature sorting: iterates in a loop until  $s = []$ ;

Step 1: obtain a new data sample according to the current feature:  $X = X_0(:, s)$

Step 2: train SVM with a new sample set to obtain support vector related parameters:  $a = \text{SVMtrain}(X, y)$ ,  $X = X_0(:, s)$

Step 3: calculate the sorting factor

Step 4: find out the feature  $f = \arg \min(\text{Rank}(i))$  with the smallest sorting criterion and add it to the feature sorting table:

$r = [s(f), r]$

Step 5: remove the feature with the smallest sorting coefficient from the current remaining dataset:  $s = s(1: f - 1, f + 1: \text{length}(s))$

Output: sorted list of features.

ALGORITHM 1: SVM-RFE algorithm flow.

FIGURE 2: RLE box chart.

TABLE 1: Probes number and genes number under different  $P$  values.

|               | $P \leq 0.1$ | $P \leq 0.05$ | $P \leq 0.01$ | $P \leq 0.001$ |
|---------------|--------------|---------------|---------------|----------------|
| Probes number | 24017        | 6251          | 6022          | 5370           |
| Genes number  | 16383        | 5561          | 5361          | 4792           |

FIGURE 3:  $P < 0.0001$  chip cluster diagram.

$$J = \frac{1}{2} \|w\|^2. \quad (8)$$

Calculating that the  $i$ -th feature removal is the change of  $J$ ,

$$\Delta J(i) = \frac{\partial J}{\partial w_i} \Delta w_i + \frac{\partial^2 J}{\partial w_i^2} (\Delta w_i)^2, \quad (9)$$

where  $w_i$  also means that the  $i$ -th feature is deleted; so, as a sorting criterion, the later the feature means that the less information it contains, and the more it will be deleted first. The algorithm is a circular process.

The classic is a linear kernel function with sorting coefficients of

$$\begin{cases} \text{Rank}(i) = (w_i)^2, \\ w = \sum_{i=1}^l a_i y_i x_i. \end{cases} \quad (10)$$

In the case of nonlinearity, it is assumed that in the training sample matrix, when a certain feature is removed, the median of quadratic programming remains unchanged; that is, the obtained classifier does not change. On the premise of this assumption, the contribution value of each feature to the objective function, i.e., the ranking coefficient, is

$$\begin{cases} \text{Rank}(i) = \frac{1}{2} a^T Q a - \frac{1}{2} a^T Q(-i) a, \\ Q_{ij} = K(x_i, x_j) = \Phi(x_i)^T \Phi(x_j). \end{cases} \quad (11)$$

This assumption is also reasonable and feasible in practical application, where  $a = [a_1, a_2, \dots, a_l]$ ,  $Q(-i)$ , means the  $Q$  matrix value calculated when the  $i$ -th feature is assumed to be removed. In practical applications, nonlinear kernels and linear kernels often produce similar results. The SVM-RFE method executes this process iteratively and finally obtains a feature sorting table. Using the sorting list, several nested feature subsets are defined to train SVM, and the advantages and disadvantages of these subsets are evaluated according to the prediction accuracy of SVM, thus obtaining the optimal feature subset. It should be noted that the single feature in the front row does not necessarily make the SVM classifier to obtain the best classification performance, but the combination of multiple features makes the classifier to obtain the best classification performance. Therefore, SVM-RFE algorithm can select complementary feature combinations. The objects targeted by the two formulas are different, corresponding to linear and nonlinear kernels, respectively, but in fact the difference in the final selection of eigenvalues is not obvious.

SVM-RFE algorithm can define a set of nested feature subsets  $F_1 \subset F_2 \subset F_3 \dots F_n$  according to its feature sorting table. The prediction accuracy of SVM is used to evaluate the advantages and disadvantages of these subsets, so as to obtain the optimal feature subset.  $F_i (i = 1, 2, \dots, n)$  means that  $i$ -th features with the highest ranking are selected from the feature set as subsets to ensure that each subset contains features with relatively important information, and then the classifier is designed with the selected optimal subset. The algorithm is as follows in Algorithm 1.

FIGURE 4: PCA differential expression diagram.

### 3. Result Analysis

In this paper, the gene chip GSE76275 is used as the research basis and the relevant parameters of the chip are described. The GSE76275 dataset contains 265 samples, including 198 TNBC and 67 non\_TNBC, with a total of 54613 gene expression values. In the experiment, the relevant basic data are analyzed uniformly, and the expression level of most genes can be kept consistent. The relative logarithmic expression (RLE) box chart can reflect the abovementioned trend. It is defined as the logarithm of the expression value of a probe group in a certain sample divided by the median of

the expression value of the probe group in all samples. The distribution of RLE of all probe groups in a sample can be represented by a box chart commonly used in statistics, and the center of each sample should be very close to the position of ordinate 0. The RLE box chart of this experiment meets this requirement, as shown in Figure 2.

Normalization processing: the purpose of normalization is to enable each group of measurements or measurements under experimental conditions to compare with each other and eliminate nonexperimental differences between measurements, which may come from sample preparation, hybridization process, or

FIGURE 5: The genes number distribution of  $P < 0.001$  and the correlation LogFC and  $P$  value.

FIGURE 6: The genes number distribution of  $P < 0.05$  and the correlation LogFC and  $P$  value.

hybridization signal processing. The process to normalize the abovementioned data can be implemented by the `expssio` function in the `affy` software package. In fact, the integrated algorithm using preset parameters is more reasonable and efficient.

**3.1. Differentially Expressed Genes Selected.** The first step in the significance analysis of gene expression differences is to select and express genes with significant differences. Generally speaking, the basic assumption of this kind of analysis is that the standardized chip data conform to normal

FIGURE 7: The genes number distribution of  $P < 0.01$  and the correlation LogFC and  $P$  value.

FIGURE 8: The genes number distribution of  $P < 0.1$  and the correlation LogFC and  $P$  value.

distribution, so the statistical methods used are basically  $T$  test,  $F$  test, variance analysis, and the improved forms of these three statistical methods. In order to obtain standardized differential genes, the gene chip adopts the

Bayesian method. Empirical Bayesian method is currently the most commonly used analysis method, which has been completely implemented by limma package of Bioconductor, as shown in Table 1.

FIGURE 9: Comparison of correct rate of SVM optimization parameters.

FIGURE 10: Comparison of correct rate of KNN optimization parameters.

The gene clustering of different genes with  $P < 0.001$  was analyzed separately. Some samples are selected for clustering, and the same type of samples can be basically clustered together, as shown in Figure 3.

Select the differential gene expression data of sample  $P < 0.001$  and make a PCA diagram. From the diagram, it can be seen that the classification of the two groups of samples is obvious; thus, it can be seen that the two types of samples have obvious differences, as shown in Figure 4.

When  $P$  is at different values, SVM-RFE shows the difference of screening genes. When  $P$  values are 0.001, 0.05, 0.01 and 0.1, the number and distribution of genes are shown in Figures 5–8:

As can be seen from the above Figures 5–8, when the maximum value of  $P$  becomes larger and larger, the number of genes distributed becomes more and more. However, there is a certain correlation between LogFC and  $P$  value. Most of the points are published between  $[-2, 2]$ , which

TABLE 2: Optimal values under SVM parameters.

| Gamma     | Cost | Error     | Dispersion |
|-----------|------|-----------|------------|
| $10^{-6}$ | 10   | 0.1510823 | 0.06924002 |
| $10^{-5}$ | 10   | 0.1512987 | 0.07016349 |
| $10^{-4}$ | 10   | 0.2686147 | 0.07255622 |
| $10^{-3}$ | 10   | 0.2686147 | 0.07255622 |
| $10^{-2}$ | 10   | 0.2686147 | 0.07255622 |
| $10^{-1}$ | 10   | 0.2686147 | 0.07255622 |
| $10^{-6}$ | 100  | 0.1274892 | 0.07413187 |
| $10^{-5}$ | 100  | 0.1512987 | 0.07016349 |
| $10^{-4}$ | 100  | 0.2686147 | 0.07255622 |
| $10^{-3}$ | 100  | 0.2686147 | 0.07255622 |
| $10^{-2}$ | 100  | 0.2686147 | 0.07255622 |
| $10^{-1}$ | 100  | 0.2686147 | 0.07255622 |

accords with the characteristics of normal distribution. The larger the  $P$  value, the larger the number of genes screened out, which shows that selecting the appropriate value of  $P$  for screening can be effectively applied in SVM-RFE algorithm. In order to improve the effect and accuracy of algorithm classification, when  $|\text{LogFC}|$  approaches 0, the larger the range represented by  $P$  value, the more genes there are.

**3.2. Complex Algorithm Parameter Selection.** The parameter selection of the algorithm is an important part of the experiment, and better experimental results can be obtained by selecting better parameters. Therefore, some data in this experiment are selected for experimental parameter selection, and the final experimental comparison is carried out through the selected parameters.

In order to express the best parameter requirements, the cost of SVM is 10 and 100, the gamma is  $10^{-1}$ ,  $10^{-2}$ ,  $10^{-3}$ ,  $10^{-4}$ ,  $10^{-5}$ , and  $10^{-6}$ , and the kernel function is radial. After comparing and optimizing the algorithms, the corresponding error values are obtained under different parameters, and the effects are shown in Table 2.

The distribution comparison of the algorithms shows that when gamma =  $10^{-6}$  and cost = 100, the minimum error value is 0.1274892. There are only 49 samples to build the model, 41 of which are used as support vectors. The proportion of support vectors is too large (over 80%), which indicates that there are irrelevant and redundant features in the used features. It is suggested to use feature selection method RFE to eliminate redundancy and irrelevance and reduce dimension and then use SVM. It is also possible to consider reoptimizing the parameters, but since `tune.svm()` has been used to find parameters, the parameters found are not good. It is better to use fixed parameters and then use RFE for feature screening. Then, this model is used to classify the test set data and use the contingency table to count the accuracy rate, as shown in Figure 9.

When cost = 100 and gamma = 0.0001, cost = 100 and gamma = 0.1, and cost = 10 and gamma = 0.01, the average accuracy is only 75%. When cost = 10 and gamma = 0.001 and cost = 100 and gamma = 0.001, the accuracy of the algorithm is about 88%. With the increase of sample size, the accuracy also decreases. When the sample size is more than 200, the accuracy is less than 75%. When cost = 10 and

gamma = 0.0001, the accuracy of the algorithm is relatively high, about 92%, and relatively stable, as shown in Figure 10.

In the initial stage of the algorithm, the overall accuracy rate is relatively low, only 80%, and the lowest is only 75%. Due to the small sample size, the classification effect is not very ideal. When KNN takes 3, the correct rate is about 90%. When KNN takes 2, the accuracy rate is relatively low, only about 82%. The average accuracy rate of the whole sequencing set is about 84%, and when the sample size increases, the average accuracy rate is relatively stable.

**3.3. Comparison of Algorithms.** When  $P$  takes different values, the differential gene expression data are screened and the selected results are classified. In this paper, several algorithms are selected to screen and analyze genes. The algorithms SVM, KNN, SVM-PCA, KNN-PCA, SVM-KFE-SVM, and SVM-KFE-KNN are used to compare and analyze the performance of accuracy, precision, recall, and F1.

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}, \quad (12)$$

$$\text{precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}, \quad (13)$$

$$\text{recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}, \quad (14)$$

In order to evaluate the advantages and disadvantages of different algorithms, the concept of F1 value is proposed on the basis of precision and recall to evaluate precision and recall as a whole. F1 is defined as follows:

$$F_1 = \frac{\text{precision} * \text{recall} * 2}{\text{precision} + \text{recall}}, \quad (15)$$

Through the comparative study of the performance indexes of the abovementioned algorithms, the effects are shown in Figures 11–13.

As can be seen from Figures 11–13, the overall effect of the 6 algorithms is relatively consistent at different  $P$  values. When the  $P$  value selected is smaller, the performance of the six algorithms is improved. In particular, the performance of SVM-RFE-SVM algorithm is obviously improved; accuracy, precision, recall, and F1 are close to 0.99. Among them,

KNN and SVM algorithms have the worst performance because they have no advantages in gene screening effect. SVM-RFE-SVM and SVM-RFE-KNN algorithms have the best results after gene screening and have obvious advantages in gene screening.

#### 4. Conclusion

In this paper, SVM and KNN algorithms are tested, and important indexes such as error rate and accuracy rate of the algorithms are evaluated to obtain the optimal parameters. SVM-RFE-SVM was proved to be effective by screening and comparing SVM, KNN, KNN-PCA, SVM-PCA, SVM-RFE-SVM, and SVM-RFE-KNN binding genes. In the later research work, the effectiveness of the algorithm proposed in this paper is tested in different datasets, and normalization is carried out in unbalanced datasets for classification research. The effectiveness of the classification algorithm is analyzed by combining the number of exons and mutations of gene sequencing data in RNA-SEQ. Correlation analysis between different types of sequencing data is the ultimate goal of the research work.

This paper presents an automatic grading method DGRADER, which handles complex multifile programs. Both the dynamic and the static grading support multifile program analysis. So, it can be an advantage to handle complex programming problem which requires more than one program file. Dynamic analysis takes advantage of object file linker in compilation to link complex multifile program. The static grading module consists of the following steps. Firstly, the program is parsed into abstract syntax tree, which is mapped into abstract syntax tree data map. Then, the information of preprocessor is used for linking external sources called in main program by complex multifile program linker-fusion algorithm. Next, standardization process is performed for problematic code removal, unused function removal, and function sequence ordering based on function call. Finally, program matching successfully tackles structure variance problem by previous standardization process and by simple tree matching using tag classifier. The novelty of the approach is that it handles complex multifile program analysis with flexible grading with consideration of modularity and big scale of programming problem complexity. The results have shown improvement in grading precision which gives reliable grading score delivered with intuitive system.

## 1. Introduction

Automatic Grading System (AGS) is program which can determine student grade automatically based on score objective parameter. AGS is needed as popular courses especially in computer science often have hundreds or thousands of students but only a few staff [1]. Programming assignment in these courses is necessary to improve technical programming and problem solving skill of students. Manual assessment method of programming practices is a tedious and time-consuming task [2, 3]. This method is inadequate because first programming course are often typically complex for a lecturer to assess correctness accurately and comprehensively by manual assessment [4]. In here, AGS can become a key role to maintain accuracy and avoid biases as the grading process is based on objective scoring rules. Importantly, the system must provide immediate feedback to students so they can learn from their mistakes [5], allowing them to make self-learning without an instructor [6].

With the development of information technology, more and more schools and organizations try to realize the

inclusive and fair education through online learning, human-computer interaction [7, 8] learning, etc. Nowadays, various AGS systems already exist and are used by higher education institutions to enhance learning process [9, 10] or as programming communities to self-improve in programming and problem solving skills. The question “why do so many automatic assessment systems exist, and why are new ones created every year?” pops up into discussion in this research field [11]. One of the reasons for various AGS is that each system may deliver some features which are not provided by others to distinguish their advantage factor.

The research still continues until today to pursue reliable grading system and solve the issues existed in this field. In here, current major issues are listed, which work as a sample. This gives an idea to produce final reliable grading and potential future work.

According to Table 1, these are recent knowledge issues chosen as the main objective overview in this work to do novelty works.

Firstly, code variance which can be said as the biggest factor to affect the result of static program analysis. In static

TABLE 1: Current research issues in automatic grading system.

| Issue   | Approach   | Results   |
|---|--|---|
| Code variations are widely believed to impede program analysis because various source codes have to be recognized as the same [12]  | Program normalization by using system dependence graph (SDG) implemented in prototype called normalizer  | Successful for small-sized program, not big-sized or complex program                              |
| Most existing inlining algorithms not suitable for code analysis and interprocedural analysis can analyze the calling context but are very costly and cannot remove function call variations [13] | Inlining algorithm based on program dependence graph (PDGs) using simple function call tree (SCFT) applied to code normalization                           | Limited in dealing with programs with multiple files  |
| Deals with multiplicity of solutions that exists for the same programming problems providing automated evaluation: immediate feedback for students and grading assignment of program [14]         | Partitioned block by using control flow graph (CFG) and program behavior comparison with symbolic execution rather than textual context or concrete values | Solves a multitude of solution of problems but is complex in implementation for big scale program |

analysis, these issues must be considered to produce reliable and precise grading score. Code variance issues solved by introduced program normalization mechanism to change the program into an intended structure requiring a program representation. The program normalization approach uses system dependence graph as the program representation. It requires for changing the code or program component known as refactoring process. The results of the works that solve code variance issue have significant impact of grading quality result.

Secondly, state that current inlining algorithms are not suitable for code analysis. The work approach by using program representation in Program Dependence Graphs to expand and manipulate program component focused on function call is introduced. This issue is actually related to code variance and focused on the structure program, which is influenced by function call and function sequence order written in program code. Results of the approach give more suitable inlining algorithm for code analysis and improve mechanism by reducing step of conventional interprocedural analysis. However, the existing work cannot deal with functions in several files.

Thirdly, Arifi et al. have introduced how the program is partitioned by a block using Control Flow Graph and generated symbolic variance for program comparison to solve the problem of multiplicity of solutions [14]. This work solves a multitude of solution of problems, but is complex in implementation for big scale programs.

These research studies lay a good foundation for our work. However, further work is still needed to support complex multifile programs. As the current single file program analysis is a relatively straight forward and common, complex multifile program analysis is a plus to handle big complex program which is still not solved or suitable for the recent research [15]. In this paper, we present a novelty work to handle complex multifile program analysis.

## 2. Related Work

*2.1. Complex Multifile Program Analysis.* AGS should be capable to quickly grade multiple and complex computer literacy assignments while providing meaningful feedback in order to stimulate an efficient learning process [16].

Specially, for larger and complex programming assignment, it is still not possible for most existing systems to assess good programming solution. In this case, semiautomated system is still used, which requires the human evaluator to use partial part of results from system to decide final grading [17]. It makes the task more complicated for humans to assess modular code. This issue will be faced by the current grading system as a programming problem is more scaled and complex for advance programming courses or real practice programming project. It makes the automatic grading system not follow their primary principle as an automatic system and become ineffective.

Complex multifile program analysis can be an advantage to handle complex programming and scaled project, which requires more than one file program. As stated before, it also makes modularity and flexibility such as creating user-based custom libraries to support core program file without rewriting into main program. In this feature, the implementation of complex multifile program analysis uses their primary concept.

*2.2. Dynamic and Static Grading Methods.* Dynamic analysis uses black-box concept which depends on output results. The analysis requires program to be compiled and run with test cases. The final grade uses comparison results of the produced output with the expected output. However, it has fatal drawback, in which student program may not produce an output because problematic code such as syntactical errors makes the program fail in the compilation process [18]. This means the program will fail before processing test cases. Hence, dynamic analysis itself is not enough for completely giving all objective scores when it fails and static analysis is needed.

Static analysis uses white-box concept without compiling and running the program. It uses rapid advancement technology from compiler and language-based tool. The approach also uses code analysis knowledge to analyze program and gives grading based on scoring objective rules and parameters.

However, both methods are having their advantage and disadvantage since static analysis require more complex process of code analysis. It requires predefined rules and

objectives. On the contrary, dynamic analysis is a more direct approach but does not cover all aspect, especially, when it fails to perform grading. Choosing which methodology is more feasible makes dynamic versus static analysis become a topic for consideration for the grading system. According to dynamic and static analysis principle in the previous section, both methods have their advantage and disadvantage factors. Table 2 summarizes of their comparison.

In here, the knowledge summarizes that static analysis cannot be used for checking the correctness of student programs using test cases as an input which produces an output. On the contrary, traditional dynamic analysis systems will completely fail to perform grading and miss important aspects when assessing student programs such as checking the code quality [19]. This may be the reason to why some existing automatic grading systems combine the best of both approaches by improving dynamic testing mechanism with static technique. By carrying out mutual combination of both analysis and providing immediate feedback in grading result, it gives an additional positive value to the user and advantage of the grading system.

Back to 1992, when Cellidh [20] was introduced, it was actually a pioneer grading system which combined both approaches by introducing semantic error detection. It used for detecting infinite loop issue which is critical for dynamic grading. The system also uses static verification including structure, indentation, detect comment, readability measurement, and complexity metrics in dynamic analysis.

In 1997, system called ASSYST [21] combined both analyses in practice to automate some aspects of grading for introductory Ada classes, as well as a second-year C programming course. It gives grading score to students based on the correctness (actual output compared to the expected output), efficiency (run time) on dynamic analysis side, check program source code style, and its complexity on static analysis side. In 2000, more systems adopt this combined method for providing flexible analysis and pursuing potential grading system which provide meaningful intermediate feedback.

In 2006, Marmoset [22] was built in the University of Maryland. The main purpose of the system is to collect information about development of student programming skill while doing a programming assignment for triggering self-improvement. The unique feature is allowing a full snapshot about student progress in the system, so it can be analyzed in detail by using different types of test cases (student, public, release, and secrete) and a personal support from the lecturer through comments on the code in the page.

In 2008, Web-CAT [23] provided extensibility and flexibility as its plugins-based architecture taking advantage of recent development technologies was built using Java servlet. It provides security features by authentication, erroneous or dangerous code detection, and portability. It also supports manual grading by allowing the lecturer to check program submitted by the student. It allows lecturers to give the comment, suggestion, and grading modification. The programming language supported are C or C++, Java, Pascal, Prolog, and others flexibility support for integration.

The grade is based on correctness through test cases, completeness of program, and validity.

In 2011, eGrader [24] provided detailed feedback reports and allowed students to see model solution provided by the lecturer or course owner. It also gives specific comments on syntax and semantic errors if occurred. The static analysis process implemented in the system consists of two parts, which are the structural similarity and quality analysis. Structural similarity analysis is based on the graph representation of the program. Quality analysis was achieved by measurements using software metrics.

In the same year, a system called AutoLEP [25], as an automatic grading system tool, was developed. It improves the traditional static grading mechanisms by combining dynamic code testing. The approach is enriching static analysis in source code analysis with a comparison of the similarity degree of compared program. The dynamic analysis was used to evaluate correctness of the submitted program using test cases and comparing the expected output. The static analysis does not compile or execute the programs. It uses model program to evaluate student program construction and how close the student source code is from the correct solution which is model programs provided in programming assignment by the lecturer. The final grading result was achieved by calculation of summarization from each grading analysis. The works were reported to distinguish syntactic and semantic analysis from the previous work. The architecture includes (1) the client and a computer used by a student, and it performs the static analysis and can provide quick feedback; (2) a testing server which has to perform the dynamic analysis; and (3) a main server which has to control the information of the other components to establish a grade.

In 2012, a new automatic grading system called Quimera [26] was built as a web-based application. It was able to evaluate the program source code written in C language and provide a full management system for programming contests. It also allows to create and manage programming exercises both in competitive learning and programming contest environments. Besides the traditional dynamic approach, this system provides a static analysis of the program by measuring the source code quality. Thus, the final grade is based not only on the source code capability of producing the expected output but also on its quality and accuracy.

Finally, these are examples of automatic grading tools existed with flexible code analysis which primarily combine both method to achieve advantages of grading in their grading system. The listed tools will be used in comparison analysis.

### 3. Overview

As mentioned before, our approach is implemented in our automatic grading system tools called DGRADER as a web-based online automatic programming judgement platform. Web platform chosen as a researcher focused on web-based assessment system shows positive influence on learning effectiveness [27]. It is also very effective in distributing material and collecting the student assignment online [28].

TABLE 2: Dynamic versus static analysis in the automatic grading system.

| Method  | Concept   | Advantage  | Disadvantage  |
|---------|---|--|---|
| Dynamic | Black-box (output) with test cases                            | (i) More direct for grading<br>(ii) Correctness checking<br>(iii) Popular usage  | (i) Requires compilation process and fails when compilation is unsuccessful<br>(ii) Security issues<br>(iii) Does not cover all aspect of grading |
| Static  | White-box (code analysis) and comparison of the correct model | (i) Does not require compilation process<br>(ii) Capable to analyze code quality | (i) Computational complexity<br>(ii) Requires set of rule definitions for giving reliability grading<br>(iii) Not providing correctness checking  |

Our tool is built by using Spring Model View Controller (MVC) as framework foundation with Spring Tool Suite (STS) Integrated Development Environment (IDE) written in Java programming language. It uses several technologies integrated to the system to support MOOCs. The full system will be running on the host server which can support Apache Tomcat Server. The database technology used in this application is MySQL database.

Architecture: Figure 1 shows three blocks of the system, i.e., user, application (front and back-end), and expanded core grading API block. Every core page contains a block of the modular page with defined web services and API. The system manages basic web features provided by Spring such as servlet, session handler, and its core features.

Core grading Application Programming Interface (API) of the system is shown on the right side. It has several API for specific purposes and functions. The API is triggered by using defined query parameter and handled by the API handler. Core grading APIs cover main functions of DGRADER for the grading task. The first layered API is the assignment handler. Its main purpose is to handle raw materials of assignments and extract the information before the grading task. Submission API is the connector triggered by submission activities. Its role is to forward information to grading analysis process in the grading analysis APIs. The information passed by the query parameter is used to target specific grading in the system. Each grading will be detailed in its section. Finally, the grading activities will produce an output feedback which will be displayed in the interface to users.

**3.1. Main Features.** The main features of DGRADER are as follows:

- (1) Providing e-learning environment management for programming courses.
- (2) Supporting flexible grading analysis: dynamic and static analysis. Flexible grading makes the instructor or programming assignment task creator become more flexible to choose assessment methods. The grading method can be based on the complexity of programming task or its purpose. It also makes the system capable to cover grading assessment task when one of the grading fails.
- (3) Supporting complex multfile program analysis in submission activity for solving one programming problem.

- (4) Providing instant feedback and result of grading analysis for programming assignment problem. The grading is provided in both categorical and numerical results.

Feedback results in static analysis include

- (i) Presenting the final linked-fused program source code and its standardization result
- (ii) Presenting AST traverse log with visitor activities
- (iii) Providing visualization for transformation graph comparison for final linked-fused and standardized program structure
- (iv) Presenting function information such as function list in program, function call sequence, and unused function list removed by standardization
- (v) Presenting the original AST data mapper of final program and standardized AST data mapper of standardized program
- (vi) Providing root tree visualization by AST root data mapper
- (vii) Providing experimental AST visualization of standardized program by standardized AST data mapper
- (viii) Presenting AST simple tree matching trace analysis in data mapper
- (5) Flexible source program uploading or submission by using file upload or directly using integrated CodeMirror text editor.
- (6) Supporting course system management similar to Massive Open Online Courses (MOOCs) and Learning Management System.

## 4. Multiple Program Files Analysis

Multiple program file analysis is a novel feature of our automatic grading system. The reason to present this feature is because existing systems usually support single file to keep simplicity of its grading analysis process. However, if a programming problem is more complex and users need more files, this will become a limitation factor. In other cases, users may want to use some libraries which do not require to be written again or the compiler in dynamic analysis does not support the library. In order to support multiple program file submission, this section presents implemented approaches including file model, multiple program file linker in each grading process, and linker-fusion algorithm.

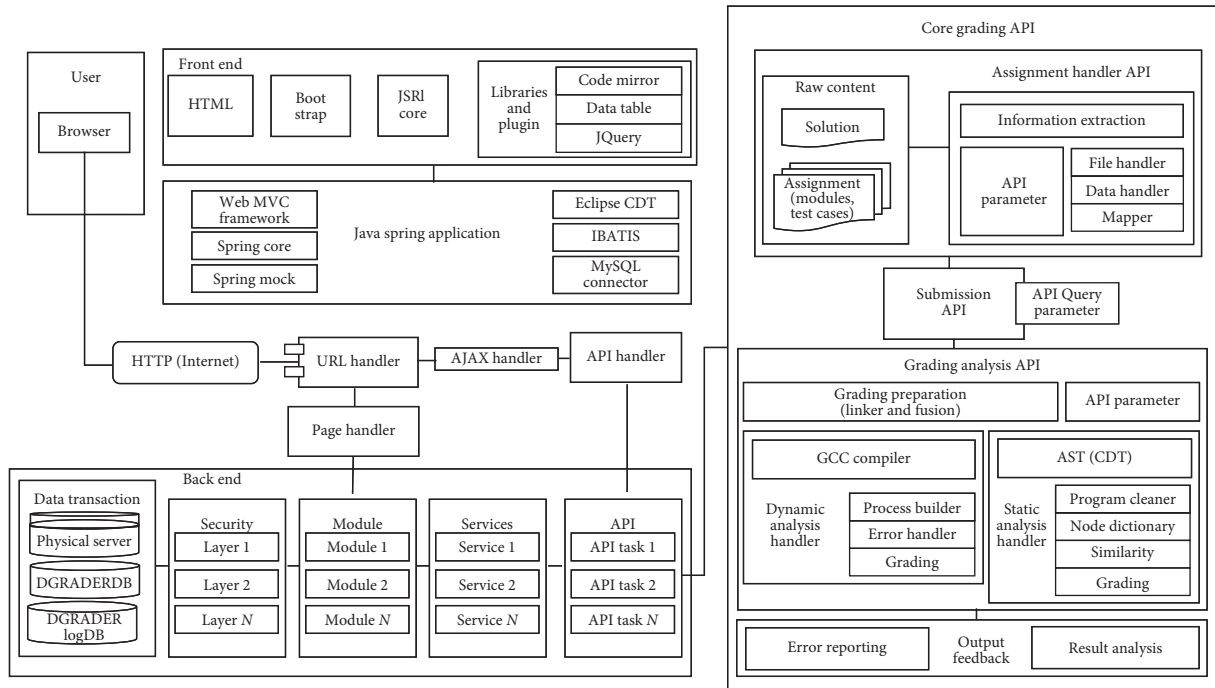

FIGURE 1: System architecture.

4.1. *File Model.* File model is implemented to handle multiple file program submission. It separates into the following two parts:

- (1) **Preprocessor:** the beginning part of source statement or preprocessing statement `#include<[library]>` which can be parsed by using `ASTPreprocessorStatement`. The user can use several external files to support main files for solving one programming problem. The filename of the sources should be the same in file upload process because it will be linked via parameter search. Custom libraries by the user can be written in this defined statement `#include "[external_sources_filename]"` as a rule. The double quote indicates its user custom libraries or external sources. The system will process linker-fusion process to combine linked multiple program file.
- (2) **Content:** this part contains the body of source program or other parts below preprocessor statements.

4.2. *Multifile Linker in Dynamic Grading.* Dynamic grading use compilation for handling complex multfiles to be linked, as shown in Figure 2. As an example for linking complex multifile program C or C++ programming language, it uses the linking process of GCC compilation process. It uses two input: main source and path of external source (multiple files paths). The differentiation from static is the type of the main source in here which will become .bin files from `ProcessBuilder`. The linking process in the system is possible with GCC command by using the parameter in backend program as an example:

```
> gcc-o [main].exe [multiple_files_path] -w (for C
complex multifile program) > g++ -o [main].exe [multi-
ple_files_path]-w (for C++ complex multifile program)
```

`Multiple_files_path` expression is files' path of external sources used in `main_source`. The command will process the main program in the compilation process to become an object and call every external source in the linking process. The linking process will continue to analyze and expand the preprocessor to make every external source become intended object of executable file with `-o` command. The `-w` command used to give warning error feedback such as preprocessor is not linked in case of file not found which makes compilation process fail.

4.3. *Multifile Linker in Static Grading.* The process still has two inputs: main source (raw source) and the external source path of multiple files which are already generated in the preparation process. The two inputs will be linked and fused in the next process, as shown in Figure 3 by linker and fusion. Static grading using source program linker-fusion algorithm is in Algorithm 1. Final output is a fused program with all the source code as a whole. The fused source code will not be processed through compilation but processed with code analysis using AST to parse element of program in external source used in the main program.

The algorithm is divided into four steps:

Step 1: get preprocessor statement set  $ps$  of the main source program by Eclipse CDT/JDT API features which can generate AST of main source using `getAllPreprocessorStatements()`.

Step 2: handling preprocessor statement set  $ps$ . Every  $ps$  found will be filtered by using `patternMatch()` to detect

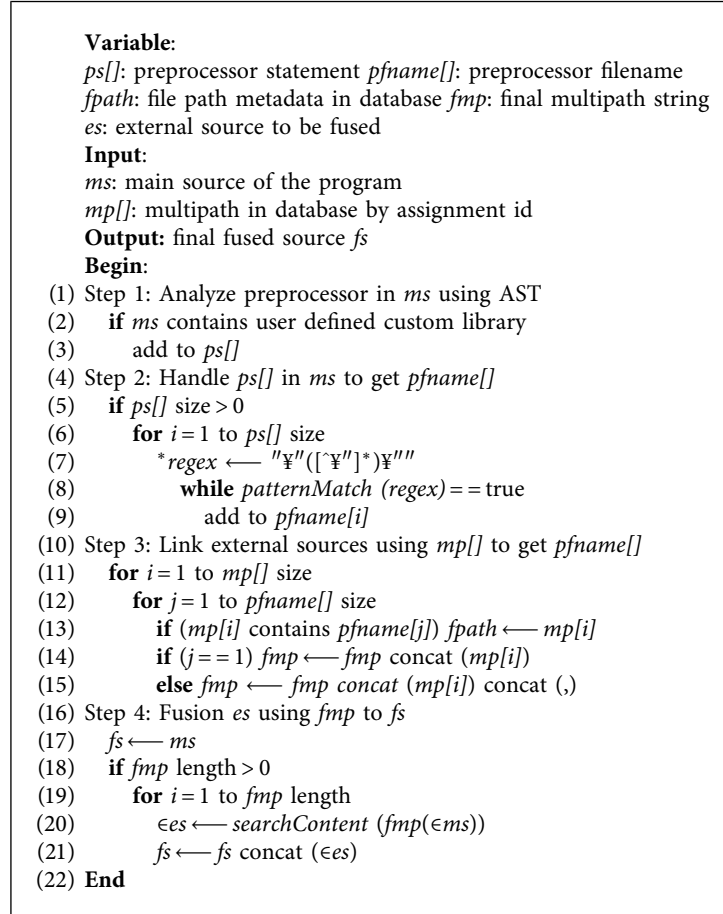

FIGURE 2: Complex multifile program linker in dynamic grading.

ALGORITHM 1: Multifile program linker and fusion algorithm.

FIGURE 3: Multifiles linker in static grading.

user custom libraries defined by the following format:  
`[TYPE_OF_LANGUAGE_IMPORT_WAY(import/include)]<space>["FILENAME"].` Regex is used to parse preprocessor filenames into  $pfname$  set.

Step 3: linking process by analyzing the file path database  $mp$ . Each  $pfname$  found  $mp$  will generate  $fmp$  as final linked string query for every external source used in main source of the program.

Step 4: final step of the process is to get fused source code  $fs$ . The  $searchContent()$  function will analyze the

code by using textual search (e.g., `.dll.h`) or AST (source code which can be parsed) to get the contents of the files, denoted by  $\in es$ , used by the main source of the program. These contents are fused into one source file.

**4.4. Dynamic Grading.** The dynamic grading method covers multiprogram file submission for solving one programming assignment. The main source file triggered in here stated as a student program with several preprocessor statements is used to direct the external sources files. The first phase is

**Variable:**

ASTdata[]: program AST data map

fASTdata[]: final refactored program AST data map

**Input:**

pAST: program AST

sb[]: syntax bank

**Output:** final standardized program AST fsAST**Begin:**

- (1) Step 1: Traverse and visit pAST with ASTVisitor class, do Step 2
- (2) Step 2: Handle AST node for AST data mapper to get ASTdata[]
- (3) Index = 0
- (4) for every AST node
- (5) initialization ASTdata[] key (see detail in Table 3)
- (6) node = AST node, current tag = AST tag
- (7) if current tag = function statement or expression
- (8) syntax = nodeParser(node)
- (9) if syntax not exists on sb[]//syntax classifier
- (10) inner user function node
- (11) else
- (12) inner standard function node
- (13) if current tag  $\neq$  previous tag
- (14) exit no = index (exit AST node branch tree)
- (15) node info = flag based on node and tag information, process no = index
- (16) index ++
- (17) add ASTdata[index]
- (18) Step 3: Handle AST data for refactoring to get final ASTdata[]
- (19) fASTdata[] = RefactoringCore(ASTdata[i])
- (20) Step 4: Rebuild final source from fASTdata[] to get fsAST
- (21) for  $i = 0$  to fASTdata[] size
- (22) fsAST = fsAST add node(fASTdata[i])
- (23) **End**

ALGORITHM 2: Program standardization using AST algorithm.

TABLE 3: AST data map.

| Key               | Description  |
|-------------------|--|
| Index             | Used for indexing of visiting and traversing process sequences while using <i>ASTVisitor</i>   |
| Node              | Visited syntax node  |
| Parent node       | Node parent to indicate its parent   |
| Child node        | Node child to indicate its child by node parser  |
| Flag              | Indicating node type<br>(i). Root (node does not have parent and has child or its entry, and it also can indicate starting of program function)<br>(ii). Parent (node has parent and child)<br>(iii). Child (node has parent only, or its leaf node) |
| Syntax classifier | Indicating syntax to distinguish whether its user defined syntax or standard programming language syntax; it can be distinguished by comparing standard programming language syntax data provided and learned in database                            |
| Process           | Indicating process entry (starting process) and exit number of node  |

program preparation, involving program builder process to prepare .bin file for C/C++ and class for java or other languages will be supported in future update. It also processes external source locator for linking process based on the preprocessor statement. Linking and compilation task example for C and C++ program use GNU GCC compiler which produce executable file.exe of linked and final program. Next process is using the executable file to run in DGRADER host machine with input from test case data. The running process of each test case produces an output.txt file. It will be compared with the test

case expected output in database grading criterion. The grading process will be taken after achieving the comparison value of real output and expected output. Finally, final dynamic grading score will be produced.

**4.5. Static Grading.** The inputs of the static grading process include a student program with external sources (if any) and model programs. A student program and its external source will be finalized with program linker-fusion which was already explained before. In this case, both fused student

TABLE 4: Experiment setup for testing dynamic grading.

| Assignment name | Main goal                       | No. of test cases                   | Concurrent process |
|-----------------|---------------------------------|-------------------------------------|--------------------|
| Task 1          | Calculate numbers based on data | Calculate $n$ of $i_n$ data         | 10                 |
| Task 2          | Reverse Fibonacci number        | Print $n$ reversed Fibonacci number | 15                 |

program and model programs will be parsed and produce their program AST. Next process will conduct refactoring of both programs. In our preferred way, model programs are already have been standardized before by the course assignment creator in assignment registration menu to save total time of analysis process. Only student program will be refactored as standardization rule in program matching. This standardization as “one-rule” for avoiding some variances issues will impact the accuracy result in the matching process. After this process, both sides can be compared using program matching using modified AST simple tree matching-pattern algorithm. The task of standardization and program matching will breakdown in Section 4.5.1.

**4.5.1. Program Standardization.** The program standardization algorithm is shown in Algorithm 2. It is an essence work to solve program matching issues such as code variance in programs.

It starts with program AST and continues with traversing and visiting tree process using ASTVisitor. In here, the approach introduces AST data mapper rather than using raw program tree or AST directly to manipulate program which is required in the refactoring process to ease the process of data representation and rebuilding program tree. The AST data mapper stores AST information from ASTVisitor by using map with indexing key (*ASTdata* key written in Table 3). After mapping process, it continues to refactoring process by calling RefactoringCore() to modify or transform the program by using this data map. This procedure will create final *fASTdata*. It will be used for rebuilding final standardized program source code and program tree representation in feedback.

Program refactoring consists of the following steps.

Step 1: removal of problematic code such as syntax error, expression error, and any other with tag problem in *ASTdata* by problem binder which processed while

TABLE 5: Dynamic grading result.

|        | Grading feedback | Result                      |
|--------|------------------|-----------------------------|
|        |                  | Average execution time (ms) |
| Task 1 | Yes              | 20                          |
| Task 2 | Yes              | 136                         |

TABLE 6: Static programming assignment example.

|        | Assignment name          | Main goal  |
|--------|--------------------------|--|
| Task 1 | Calculate numbers (data) | Calculate $n$ of $i_n$ data  |
| Task 2 | Reverse fibonacci number | Print $n$ reversed fibonacci number  |
| Task 3 | Coin changing            | Consider the problem of making change for $n$ cents using the fewest number of coins   |
| Task 4 | <i>Bitonic</i> tour      | Input: $n$ Points: $v_1, \dots, v_n$ on a plane with different $x$ coordinates; $d_{ij}$ : distance between any pair of points ( $v_i, v_j$ ), $i \neq j$ ; output: a <i>bitonic</i> tour with smallest distance |

traversing the program using AST and mapped into *ASTdata* mapper. The problem binder takes advantage of parser to detect syntactical problem. As an example for traversing the C and C++ program using Eclipse CDT *ASTVisitor CPPASTProblem*.

Step 2: identifying and removal of unused function in *ASTdata*. This task deletes its related elements by using start–end index of the node which is already mapped in *ASTdata*.

Step 3: reordering function calling sequences. In this case, main function will become first function call in sequence as the rule of program. The process continues to detect other call function by creating *ASTroot* data mapper. It only targets root type of the node with the root tag filter or classifier. The node is considered as a root node according to flag root detail in Table 3. The result of transformation can be seen from transformation from original AST into root AST.

Step 4: the final step is producing a final standardized program from *ASTroot*.

**4.5.2. Program Matching.** The program matching process requires two program trees as an input which are the student program and model program  $i$ . Both programs are already standardized automatically by the system in the previous process to achieve same structure as one-rule policy in process of program matching.

In program matching, AST simple tree matching is chosen to compare program AST which takes advantage of dynamic programming to calculate maximum node-pair between compared tree program with semantic similarity [29]. However, this algorithm has an issue with overhead memory as it does the code changes when code variance occurred in matching process to make the variance for both compared programs unified. It is also stated in the result test that some code changing activity fail in the process. This will impact the matching similarity accuracy score. Finally, we have improved the approach with AST simple tree matching algorithm, as shown in Algorithm 3.

The algorithm is modified to use advantage of AST tag classifier concept which can be implemented by the method in program AST traversing with any parser. This will solve the overhead and the variance issues.

The improved program matching algorithm has two steps:

Step 1: both programs will be mapped into *ASTMap* which contains key information. It uses root node  $r$  which is already ordered by following the rule in the standardization process. Tag and node are used as matching parameters. *TagMap* is used to take advantage of the AST tag classifier in tag matching comparison. *GlobalNodeMap* and *LocalNodeMap* are used for node element which will be considered equal if encountered in the same tag in the same root node position.

Step 2: after both program trees are mapped into *ASTMap*, the process will invoke *SimilarityMatching()*. Every index data in map will be compared and paired. Accumulate the global *TagMap* and compare *GlobalNodeMap* with *LocalNodeMap* per indexed data in *ASTMap*. Next process is to encounter the exact tag to be compared with it pairs and add into *TagMap* in tag matching task. *LocalNodeMap* used for detection of the identical node in node matching. As stated before, as long as the node follows the same tag and position it will be considered as equal otherwise it will add pattern to find the matching target invoking recursive *SimilarityMatching()* call. For every matching node with same position in local A and B will increase node similarity and pattern count. Total accumulate  $ns$  will be compared to maximum node coverage of both programs. Finally, the final score can be calculated based on how many maximum nodes are covered by  $ns$  in the grading process.

## 5. Experimental Analysis

**5.1. Dynamic Grading.** In dynamic grading, testing conduct with 2 tasks in Table 4. The concurrent process is used to measure system capability to handle concurrent grading process when students finalize their submission at the same time.

TABLE 7: General testing solution program condition.

|            | LOC | Function | Max node | Unused node | Standardization |   |
|------------|-----|----------|----------|-------------|-----------------|---|
|            |     |          |          |             | Transform node  | Program efficiency improvement rate (%) |
| Solution 1 | 12  | 1        | 40       | 6           | 38              | 1.9                                     |
| Solution 2 | 48  | 7        | 94       | 43          | 49              | 52.128                                  |
| Solution 3 | 55  | 9        | 182      | 24          | 158             | 13.19                                   |
| Solution 4 | 120 | 14       | 424      | 35          | 389             | 8.25                                    |

TABLE 8: General testing condition.

|                      | Task 1 | Task 2 | Task 3 | Task 4 |
|----------------------|--------|--------|--------|--------|
| No. of model program | 2      | 2      | 5      | 8      |
| Concurrent process   | 4      | 3      | 7      | 4      |

TABLE 9: General static grading result.

|        | Result           |                    |                 |
|--------|------------------|--------------------|-----------------|
|        | Grading feedback | Analysis time (ms) | Expected result |
| Task 1 | Yes              | 88                 | Yes             |
| Task 2 | Yes              | 90                 | Yes             |
| Task 3 | Yes              | 1022               | Yes             |
| Task 4 | Yes              | 678                | Yes             |

All submission results shown in Table 5 produce grading feedback both successful or error result explanation with the score. The feedback shows success or failure with real and expected output of each test case. In here, testing activity also considers average execution time which measures the time needed by the system to finish the job. Finally, it is successful to achieve dynamic grading mechanism. The concurrent process also can be handled by automatic queuing process and multithreading.

**5.2. Static Grading.** In static grading, programming assignment tasks are shown in Table 6. Task 1 and task 2 are reused in this testing as DGRADER offer flexibility grading assessment method change by updating the assignment configuration. The lecturer just needs to add model programs in the assignment material. Back to testing focus, each sample solution has its behaviour and condition according to Table 7 such as Line of Code (LOC), number of functions, max number of nodes (generated by traversing program AST), and number of unused nodes (code node which are not used in the program).

Standardization data present transforms result from maximum number of nodes to number of transform nodes as automatic transform by program standardization in the system. The number of transform nodes implies the efficiency of the standardized program. The program efficiency improvement rate can be calculated by comparing original maximum number of nodes and number of transform nodes. For example, solution 2 data showed significant 52.128% program efficiency improvement.

Based on Table 8 as the testing condition, the result is shown in Table 9. All solution submitted successfully gives grading feedbacks and results. Expected result means that every variance tolerant achieve full 100% mark as it uses tag

from the AST classifier. It makes every variation occurred in the program solved or tolerated as long as it has true condition from tag and node matching in program matching. The expectation of testing by manual assessment produced. Finally, static grading approach implemented in DGRADER can be found reliable as it is giving good precision of grading score and is also proofed by manual assessment.

**5.3. Reliability and Grading Precision Testing.** This testing is focused in reliability of the final grading score in the static grading assessment. In here, assignment “reverse Fibonacci number” in the previous assignment sample is chosen. The approach uses 1 solution submission and sees its comparison with 4 models (chosen) provided in the assignment. Solution and model programs are shown in Figure 4. The solution program is chosen solution 2 in the previous test, and its condition can be seen in Table 7, and model condition is listed in Table 10.

In here, testing activity hypothesis for model 1 and model 2 will give perfect grading score in the final result. Both the models are nearly same to program solution and also its algorithm which used recursive function to do the job for printing reversed Fibonacci number. The purpose is to check the reliability and precision of logically similar programs by manual assessment. Model 3 is actually .cpp program which uses array approach, and model 4 uses more variables to save values for producing reversed Fibonacci number without recursive function call. They adopt different algorithms to the student solution.

It is clearly evident from Table 11 that similar nodes of solution to models 1 and 2 have 100% final coverage. As stated before, model 1 and model 2 are not exactly the same to the solution. The perfect coverage achieved by variance tolerance successfully tolerates the code variance issues in program matching process. Variance type divided into 3 categories is used based on 9 listed code variance issues in Table 1. In here, the division is based on their related impact into the issue listed variable (name), function (invocation or call, expression, naming), and control structure (compound statement, redundancy, structure order, code format, and algorithm).

Starting analysis with model 1 which is nearly the same, but program solution has code structure data `{int x*, int y*}`. In matching, the pattern increased as it tries to find the node first related to the code with ending in not finding any possible node related to that code. In here, matching still processed and ignored as tolerant in the control structure as the code categorized to impact in the compound statement

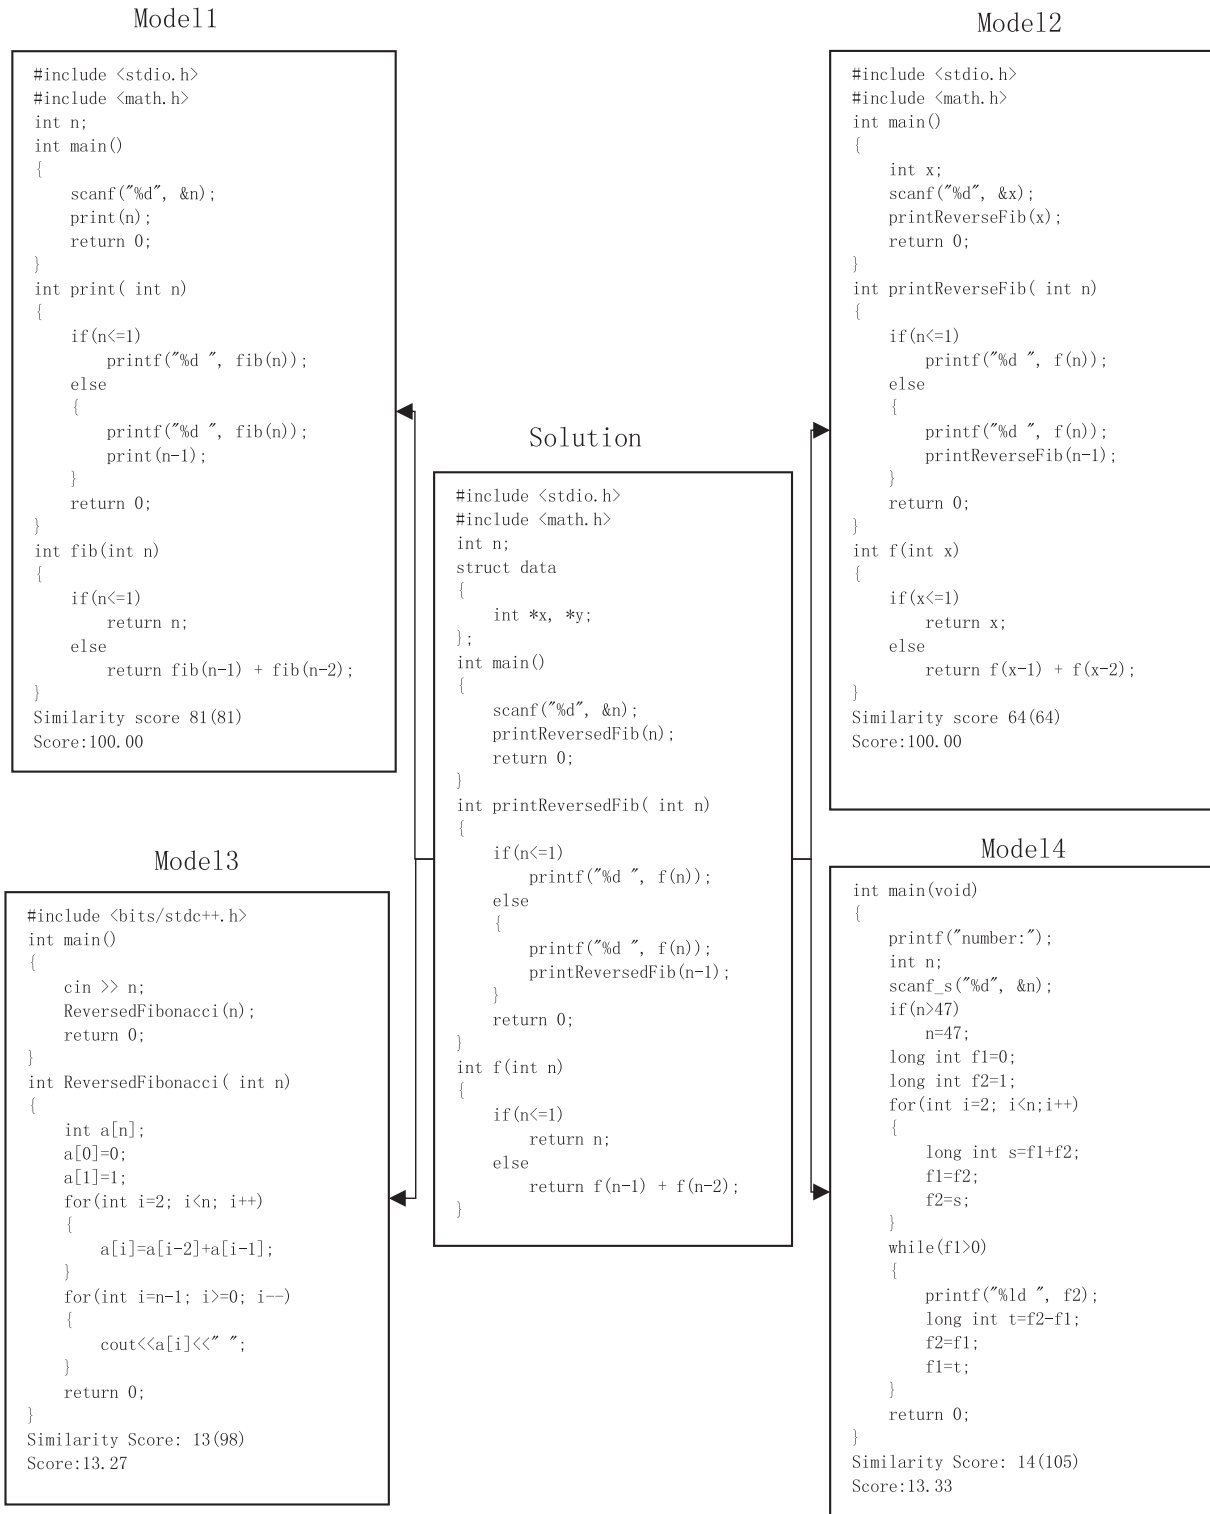

FIGURE 4: Feedback result of program matching trace analysis.

and structure order. It also occurs function naming variance print() and fib() in model compared with printReversedFib() and f() in solution which are successfully tolerated as it is expected to be considered the same. Left remaining codes are exactly the same with solution, which means similarity node coverage of program solution and model 1 is perfect. It

covers 81 nodes of model 1 program with 100% (tolerate all variances) in final coverage.

In model 2, there exists variable variances of node  $x$  which is node  $n$  in program solution. In matching process, it is found that  $x$  corresponds to node  $n$  for the following code. The matching process considered in this node is the same as

TABLE 10: Model program condition.

|         | LOC | Function | Max node | Variance |          |                   |
|---------|-----|----------|----------|----------|----------|-------------------|
|         |     |          |          | Variable | Function | Control structure |
| Model 1 | 48  | 3        | 81       | 2        | 2        | 1                 |
| Model 2 | 48  | 3        | 64       | 1        | 2        | 1                 |
| Model 3 | 25  | 2        | 98       | 1        | 1        | 2                 |
| Model 4 | 22  | 1        | 105      | 4        | 0        | 2                 |

TABLE 11: Static grading precision result.

expected, as algorithm uses the AST tag classifier in nodes. Besides, structure variance occurs as declaration of  $x$  inside `main()` compared to program solution which is global variable. The matching process is also successful to tolerate this variance and gives similarity 64 node coverages perfectly as expected.

However, models 3 and 4 as expected have low final coverage because both are completely different. The major factor is because both models have distinguished control structure such as algorithm, code format, and related factor which is categorized in this category. Model 3 as stated before is `.cpp` but the system still is capable to compare `.c` program solution with this model which is a plus point. Models 3 and 4 use different approach from solution that uses recursive method. It impacts the matching process

which gives less node coverage and tolerant percentage. The issues can be solved by providing more template program to the system for assignment problem. Finally, final grading score still gives correct score as expected.

*5.4. Case Study Similar Program Comparison Analysis.* The columns in Table 12 refer main features of this objective comparison parameter. From the above parameter, we compare DGRADER as our web-based automatic grading system with the other similar programs which provide flexible grading analysis.

The first key element for comparison analysis is programming language support. Marmoset and Web-CAT are strong in this aspect as they support multilanguages.

TABLE 13: Existing similar program comparison (scoring features).

| Approaches | Categorical grading | Numerical grading | Scoring features        |          |  |     | Ranking      | Plagiarism detection |
|------------|---------------------|-------------------|-------------------------|----------|--|-----|--------------|----------------------|
|            |                     |                   | Error                   | Feedback | Result analysis  |     |              |                      |
| Cellidh    | No                  | No                | Yes                     |          | Yes  | Yes | Yes          |                      |

| Marmoset   | No                  | No                | No                      |          | Yes  | No  | No           |                      |
| Web-CAT    | No                  | No                | Detailed (highlighting) |          | Code style (highlighting)  | No  | No           |                      |
| eGrader    | No                  | Yes               | Yes                     |          | Program structure  | No  | No           |                      |
| AutoLEP    | No                  | Yes               | Detailed (report)       |          | Semantic analysis  | No  | No           |                      |
| Quimera    | No                  | Yes               | Yes                     |          | Yes  | No  | No           |                      |
| DGRADER    | Yes                 | Yes               | Detailed (report)       |          | Standardization, AST map, transform graph, function call, AST visualization, and matching trace analysis (semantic analysis) | Yes | Configurable |                      |

The second one is complex multifile program analysis feature. Only DGRADER provides complex multifile program analysis for the user to solve one programming problem within more than one modules, libraries, or files. It improves flexibility to solve complex problems with an efficient approach without rewriting program if some libraries exist.

In platform perspective, web platform has become popular consideration rather than becoming a local tool such as AutoLEP and eGrader. Nowadays, everything can be accessed online easily by using browser or mobile device which increases the portability which adds value for flexibility scale.

Next on aspect of work mode, common tools only work as standalone or specific usage. Web-CAT provides plugin for their integration with other platform which require installation. Only DGRADER can work as standalone or integrated with other system by providing its API services which potential for widespread usage. It also delivers with MOOCs with user course management and programming contest platform as feature to support competitive learning. Cellidh, ASSYST, and Quimera also support this competitive learning. It is purposed to increase interest of the user as the content in the system can become user content based.

In grading metrics, compared tools provide flexible grading analysis, which are dynamic and static. However, each approach is different as listed. In dynamic approach, it can be generalized that all approaches are tested with code correctness by using test case input and the output is compared with the expected output. In static, there are various approaches using code analysis. DGRADER uses AST similarity matching with model programs. The approach with model is popularly used by the existing tools. This model is more practical and easier to be measured but requires more models to increase the accuracy and grading precision.

The columns in Table 13 refer the scoring features of this objective comparison parameter. DGRADER comes with various result analyses as their instant feedback and scoring. Instant feedback includes error explanation if any error occurred specially in dynamic grading. In static grading assessment, present feedback such as linked-fused program

source, standardized program source, and mapped into AST data map can be read by the user in result analysis. It also presents transformed graph structure to see change by automatic standardization process, function call sequence, AST visualization of program, and matching trace analysis.

Final scoring provided both in number range 0–100 and categorical score with stars to make the system more interactive. User ranking also provided to stimulate usage and improve user programming and problem solving skill through the reward system with point and level. Plagiarism detection feature is also considered in this scoring feature as it will impact the final grading score. In these compared tools, only Cellidh, ASSYST, and our tool DGRADER provide this feature. The programming assignment creator also can enable plagiarism detection features.

Finally, all comparison analysis can measure to see improvement of each compared tools. Back to DGRADER, our tool currently limited programming language as listed. However, API services will be potential for future development of cross platform integration which means more support of programming language and other features. DGRADER also provides meaningful and informative feedback with novelty complex multifile program analysis feature.

## 6. Conclusions

In this paper, we have presented a novel technique to handle complex multifiles program with flexible static and dynamic grading. It is implemented practically as an automatic grading system platform called DGRADER. In order to deal with multifiles program, the dynamic analysis process takes an advantage of the compiler in linking process to compile complex multifile program. The static analysis process uses the presented complex multifiles program linker-fusion algorithm which parsed preprocessor from program AST to find other external sources. It is successful to link and fuse elements in external sources which are used in the main program. In static analysis, code variance issues in program matching are tackled by the improved algorithm of AST simple tree matching. The AST tag classifier creates tolerant factor of variances from the compared node of solution and

model programs. Program standardization also contributes to transform the program by following the rules in program matching. The results have shown good accuracy in final grading precision as expected in the case of sufficient model programs.

Coronary artery bypass grafts (CABGs), including saphenous vein grafts (SVGs) or left internal mammary artery (LIMA) grafts, are recently applied to treat coronary artery aneurysm (CAA). Surgical outcomes are considered to be related to surgical strategies (types of the bypass graft and whether CAA ligated or not) and the size of the CAA (usually characterized by diameter). However, the understanding of the relationship between the surgical outcomes and the abovementioned factors is limited. Previous studies related to CABG treatments have shown hemodynamic studies could help evaluate surgical outcomes through graft mass flow rate, wall shear stress (WSS), and oscillatory shear index (OSI). It is believed that the hemodynamic study of applying CABGs to CAA, which is not studied yet, could help us understand the different CABG surgeries. The aim of the study was to evaluate the hemodynamic differences among different surgical methods. To do this, eight three-dimensional models were constructed, representing application of SVGs and LIMA grafts to CAAs (whether ligated or not) with diameters two, three, and five times the normal diameter, to perform computational fluid dynamics (CFD) simulation. The lumped-parameter model (LPM) was coupled to the boundary of the 3D models which increase the complexity of the simulation, but it can ensure the stability of the simulation boundary conditions. The results show that SVG (no matter whether ligated or not) hemodynamic characteristics are positive, with an average high graft mass flow rate of 70 ml/min, an average WSS of 0.479 Pa, and a low OSI of 0.001. LIMA with CAA ligation has the same characteristics with higher WSS (average 1.701 Pa). The hemodynamic characteristics of LIMA without CAA ligation are negative, including high reverse mass flow rate and high OSI (0.367). The results indicate that the surgical outcomes of LIMA with CAA ligation are likely to be the best among these models. The surgical outcomes of LIMA without CAA ligation seem to be undesirable due to the high reverse mass flow and high OSI. The CAA diameter may not have a significant effect on surgical outcomes.

## 1. Introduction

Coronary artery aneurysms (CAAs) are cardiovascular disease, which is defined as dilatation of the coronary artery exceeding more than 50% of the reference vessel diameter, and the incidence rate is approximately 0.3–5.3% [1, 2]. It

was learned that up to one-third of CAAs are associated with obstructive coronary artery disease and have been associated with myocardial infarction, arrhythmias, or sudden cardiac death [3]. Recently, coronary artery bypass graft (CABG) surgery is usually selected to treat myocardial ischemia and complications caused by CAAs [4–6]. However, because of

the rarity of CAA and the variety of surgeries, our understanding of applying CABGs to CAA is limited, most of which comes from case reports [7–11]. With the increase in patients and more and more applications of surgery, it is necessary to conduct a research on applying CABGs to CAA to help us understand the surgery.

There are usually two different surgical options and an important parameter to be considered when implementing CABG applying to CAA. The different surgical options include the types of CABGs and whether the CAA is ligated or not. Saphenous vein grafts (SVG) and left internal mammary artery (LIMA) grafts, harvested from the patients' own body, are the main choice for the bypass graft of CABG surgery [12]. SVG and LIMA have their own advantages and disadvantages, and there is no uniform standard. However, the SVG is the most widely used. Compared with LIMA, the SVG has the advantage of ease of use, sufficient length, and accessibility. Especially, for patients with a diffusely atherosclerotic ascending aorta, SVG composite Y-grafts may be necessary, particularly when there is some contraindication to the use of arterial grafts and severe (>70%) stenosis [13–15]. The CAA ligated or nonligated can cause different degrees of damage to blood vessels. Ligation is to cut off the original coronary arteries, which will cause huge structural damage to the cardiovascular system. Without ligation, it will only cause anastomotic damage and no other structural damage. The important parameter to be considered is the size of the CAA, which is usually characterized by diameter. Changes in the size of the CAA diameter could affect the complications, which means the surgical strategy may be affected.

To the best of our knowledge, because of scarcity of CAA and complexity of factors affecting the surgical outcomes of surgery, there are no research studies conducted on applying CABGs to CAA to investigate the differences in surgical outcomes caused by different types of bypass grafts, CAA ligated or not. The effect of CAA diameter on different surgical methods is also unknown. The study of hemodynamics provides an effective method for us to solve the abovementioned problems. Previous studies have pointed out that hemodynamic study of applying CABGs to treat other diseases such as coronary stenosis by using computational fluid dynamics (CFD), which has attracted wide attention in recent years and has many applications in the vascular field [16–18], has made progress. Also, those research studies confirm that surgical outcomes correlate with some important hemodynamic characteristics including mass flow rate, wall shear stress (WSS), and oscillatory shear index (OSI) [19–24]. Therefore, it is reasonable to believe that hemodynamic study of applying CABGs to CAA can be used to evaluate the surgical outcomes.

The aim of this study was to evaluate the hemodynamic differences between two different surgical methods (types of CABGs, whether CAA ligated or not) and the effect of CAA diameter on the hemodynamics of different surgical methods through the CFD method. It could allow us to evaluate different surgical procedures of CAA and make preliminary predictions and deduction for different surgical plans based on these hemodynamic characteristics from a

hemodynamic perspective. This research may be the first hemodynamic study that evaluates the hemodynamic characteristics of different types of bypass grafts on CAA of different diameters and makes a rank of treatment procedure based on the hemodynamic characteristics. This study may provide information to clinicians for better predicting of surgery and making more reliable treatment decisions.

## 2. Materials and Methods

**2.1. Model Development.** A patient-specific 3D geometric anatomical model was reconstructed based on medical images that were obtained by computed tomography angiography (CTA, Siemens). The CTA images of the patient, whose information was anonymized in this research, were provided by Anzhen Hospital with  $512 \times 512$  pixels of each image, 450 slice images, and 1 mm gap between adjacent slice. This study has been approved by the Medical Ethics Committee of Beijing Anzhen Hospital and Tohoku University. The construction processing of the 3D model was done by using Mimics (Materialise NV, BE) through both manual and threshold segmentation. Three different diameters of CAA, including the diameters of two, three, and five times compared with the adjacent coronary artery, were applied to the left anterior descending artery by using Geomagic Freeform (3D system, US) software. Virtual bypass surgery was implemented on these models including SVG and LIMA bypass grafts. Two more virtual bypass surgery models (SVG and LIMA) in which CAA was ligated were also established. Figure 1 shows the details of all different 3D models which were named model 1–8, respectively.

**2.2. Computational Model and Properties of Fluid.** The finite element analysis method will be adopted in which all models need to be preprocessed, including preprocessing of the inlets and outlets and the smooth processing of the area of interest. Preprocessing models need to be divided into meshes, which were hexahedral meshes that were controlled by means of size control with the software ANSYS Meshing (ANSYS, US), to generate the fluid computational models. The mesh of the area of interest is refined in order to get more accurate results in these areas. The mesh independency was analyzed to guarantee the reliability of the simulation results, which needed the number of elements and nodes to be large enough [25]. Table 1 shows the results of the mesh independency test. The differences in WSS between the chosen mesh were less than 0.5%. The calculation result can be considered stable. Table 2 shows the details of the number of elements and nodes of all 8 models in this paper. Blood flow simulations were performed with the ANSYS-CFX (ANSYS, US) Navier–Stokes solver. In the simulation, we assumed that the wall was rigid and stationary. This study assumed that blood was an incompressible Newtonian fluid with a viscosity of  $0.0035 \text{ Pa}\cdot\text{s}$  and a density of  $1050 \text{ kg/m}^3$ . Simulations were run for 3 cardiac cycles. We selected  $0.0025 \text{ s}$  time step to satisfy the calculation of stability conditions. The maximum convergence RMS residual of simulation was set to 0.0001.

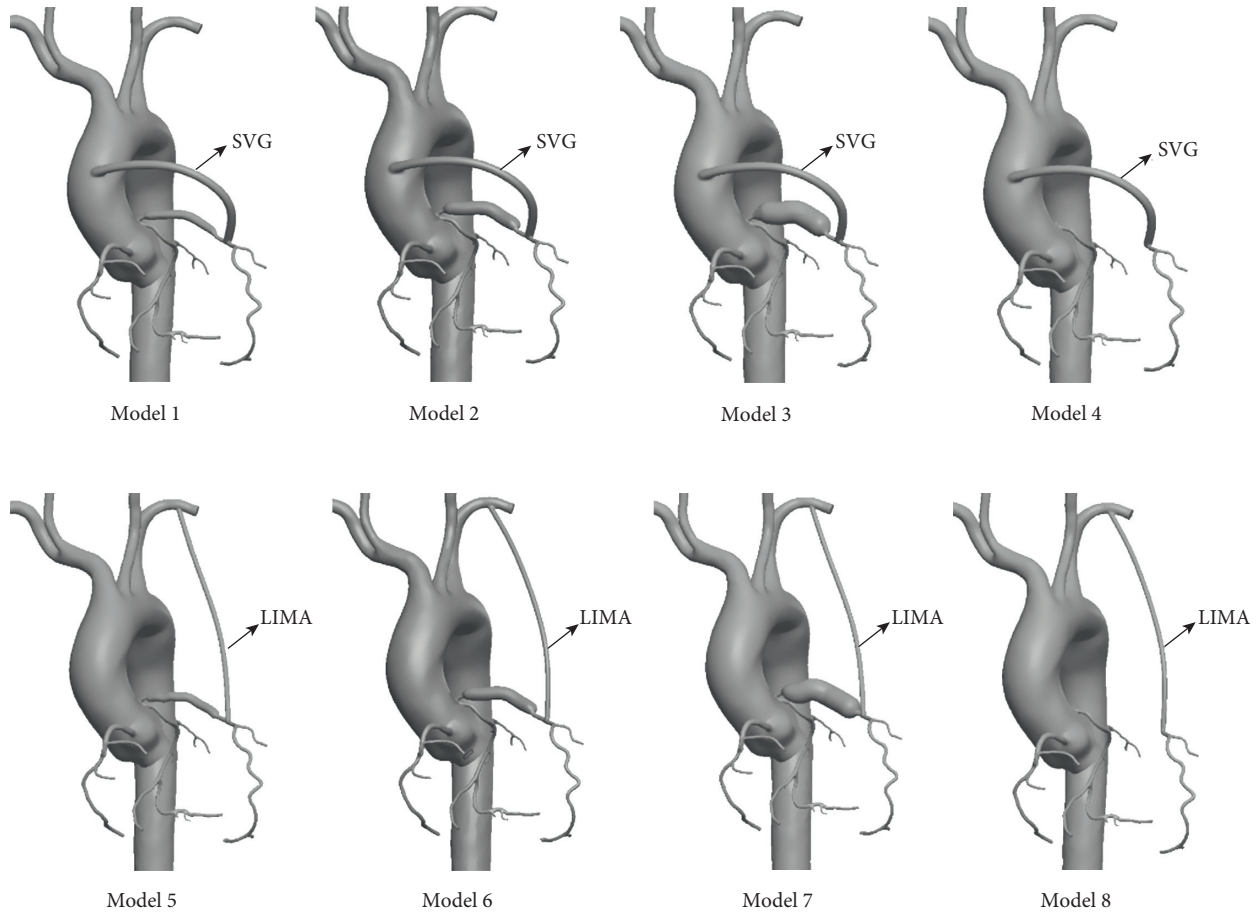

FIGURE 1: All eight 3D CABG surgery models which describe the location and the size of the CAA and the way of how to perform the bypass surgery. Models 1–4: bypass graft is SVG and the diameter of CAA is 2x, 3x, 5x, and 0 (CAA ligated), separately. Models 5–8: bypass graft is LIMA and the diameter of CAA is 2x, 3x, 5x, and 0 (CAA ligated), separately.

$\epsilon$  is the percentage change of the parameter value (WSS and pressure) due to the increase in the number of meshes.

**2.3. Boundary Conditions: Lumped-Parameter Model Boundary Conditions.** Boundary conditions of computational simulation play an important role that can affect the accuracy of the results and determine whether the calculation is successful. The ideal situation is to obtain the real human beings' physiological parameters as the boundary conditions of the simulation calculation. However, obtaining coronary artery physiological parameters is not easy due

to its small size, numerous branches, and distribution on the heart's surface. Therefore, in order to obtain life-like boundary conditions, we selected the lumped-parameter model (LPM), which is a circuit model that can simulate the blood flow and pressure through current and voltage, to provide boundary conditions for the CFD simulation [25–27]. One reason for choosing LPM is its simplicity. Complex coronary branches can be simulated by simple

TABLE 2: The values of nodes and elements of all models.

|          | Model 1   | Model 2   | Model 3   | Model 4   | Model 5   | Model 6   | Model 7   | Model 8   |
|----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
| Nodes    | 1,007,389 | 1,016,509 | 1,145,628 | 1,003,758 | 1,004,659 | 1,018,965 | 1,159,365 | 1,007,932 |
| Elements | 1,238,694 | 1,335,889 | 1,369,378 | 1,218,463 | 1,239,574 | 1,339,365 | 1,359,436 | 1,228,346 |

circuit modules while retaining the characteristics of coronary blood supply. On the other hand, less demand for computing resources, which means better adaptability and lower consumption, is meaningful.

LPM consists of three modules, which are arterial module, coronary module, and heart module. The arterial module consists of many branches which base a three-element model (Windkessel RCR model) [28] structure that consists of two resistors and one capacitor. The coronary module consists of the arterial module and coronary microcirculation module. The main feature of coronary microcirculation is the resistance to drastic changes caused by the contraction of the heart. The myocardial compliance ( $C_{i-micro}$ ) and microcirculation resistance ( $R_{v-micro}$ ) were used to simulate this feature, where the cathode of the capacitor is loaded with intramyocardial pressure to simulate the pressure generated by the contraction of the heart during the systolic phase. In the LPM heart model, all the simulation equations of the left ventricle is based on the previous research [25] including  $C(t)$ ,  $E(t)$ ,  $E_{max}$ ,  $E_{min}$ ,  $E_n(t_n)$ , and  $t_n$ , and we determined the specific value of each component including resistors and capacitors, which are adjusted to match the patient's blood pressure.

Based on the abovementioned 0D model and 3D models, the multiscale 0D/3D coupling model used in this research was constructed. Figure 2 shows coupling interface details of the 0D/3D coupling model. All 3D models were coupled with the same 0D model whose parameter values adopt the values of the normalized coronary model, which is confirmed by observing that the geometric structure of the distal coronary artery was not changed. Models sharing the same LPM can also exclude other factors to ensure that the change of the values of hemodynamic parameters is only related to the geometric structure.

**2.4. Hemodynamic Parameters.** Hemodynamics can reveal the characteristics of the blood flow. We will focus on several key hemodynamic parameters including mass flow rate, WSS, and OSI. The WSS represents the force per unit area of fluid applied along the wall surface in the direction of the local tangent plane [29]. Formula (1) is as follows:

$$WSS = \tau_\omega = \mu \left( \frac{\partial u}{\partial y} \right)_{y=0}, \quad (1)$$

where  $\mu$  is the dynamic viscosity,  $u$  is the velocity parallel to the wall, and  $y$  is the distance to the wall. OSI quantifies WSS direction changes. OSI is calculated using the following formula:

$$OSI = \frac{1}{2} \left( 1 - \frac{\left| \int_0^T \vec{\tau}_\omega dt \right|}{\int_0^T |\vec{\tau}_\omega| dt} \right). \quad (2)$$

### 3. Results

In this finite element simulation, we evaluated some key hemodynamic parameters which could help evaluate surgery, including mass flow rate, WSS, and OSI on the bypass graft.

**3.1. Mass Flow and Pressure Drop.** The values of mass flow through the bypass grafts and the pressure difference between the upstream and downstream of the bypass grafts over a cardiac cycle are shown in Figure 3. The results show that the mass flow rate of the SVG (no matter) is much higher than that of LIMA, in which the peak value is up to 120 ml/min and the mean value is 50 ml/min, except the LIMA model with ligation of CAA. The mass flow rate of the LIMA in model 8 with ligation of CAA is almost the same as that of the SVGs. The mean mass flow rate of the LIMA in models 5–7 without ligation of CAA is almost 0. The reverse flow which means the blood flows from the bottom to the top of the LIMA can be found in these models without ligation of CAA during the systolic phase of the heart. The negative pressure difference is found in the LIMA models without CAA ligation (models 5–7), while the pressure difference of other models is always positive. Pressure difference is the main driving force of liquid in fluid simulation, which may indicate the main cause of the reverse flow.

**3.2. Wall Shear Stress.** WSS is a force applied to a tangent plane which indicates the per unit area force exerted by the fluid [30]. The values of WSS on SVGs and LIMAs of all models over a cycle and WSS distribution on the SVGs and LIMAs of all models (peak point) are shown in Figures 4 and 5. The mean area WSS on the bypass grafts of models 1–8 over a cycle is 0.477, 0.483, 0.516, 0.443, 0.851, 0.877, 0.896, and 1.701 Pa, respectively. Under the same conditions, WSS on the LIMA is higher than that of the SVG. WSS on the LIMA with CAA ligation (model 8) is especially higher.

**3.3. Oscillatory Shear Index.** OSI is a parameter that can quantify the change in direction and magnitude of the WSS [31]. The distribution of OSI on all models is shown in Figure 6. The mean area values of OSI on SVGs and LIMAs of all models are 0.001, 0.001, 0.001, 0.001, 0.343, 0.281, 0.476, and 0.001, respectively. The values of OSI on SVGs (no matter whether CAA is ligated or not, models 1–4) and the values of OSI on LIMA with CAA ligation (model 8) are almost 0 which means the direction of blood flow has almost no change. In contrast, the values of OSI on LIMAs without CAA ligation (models 5–7) are decades of orders of magnitude higher than the same condition of SVGs (no matter whether CAA is ligated or not).

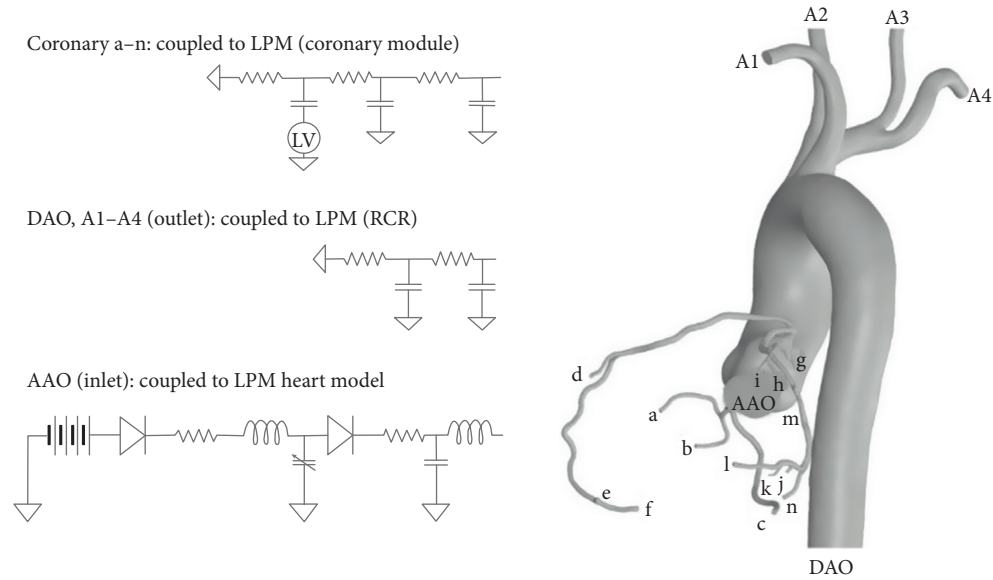

FIGURE 2: The construction of interfaces of the 0D/3D coupling model. In the coupled system, the coronary module of LPM is coupled with the coronary arteries of the 3D model, the LPM heart module is coupled with the aortic inlet of the 3D model, and the common artery LPM module (RCR) is coupled with other branch arteries of the 3D model.

## 4. Discussion

CABG (including SVG and LIMA) surgical operation nowadays is generally selected to treat CAA. Moreover, whether CAA is ligated or not is another choice. Surgical outcomes differ depending on the types of bypass grafts and diameter of CAA (ligated or not). Hemodynamic characteristics (mass flow rate, WSS, and OSI) of different types of CABG surgeries (SVG and LIMA) applied to CAA (different diameters, ligated or not), which were related to surgical outcomes based on the previous studies, are obtained through the CFD method.

We found that the hemodynamics of CAA ligation models is better than those of models without CAA ligation. When CAA was not ligated, the SVG has better hemodynamic characteristics than LIMA. When the same type of bypass graft is used, the change of CAA diameter has basically no effect on the hemodynamic characteristics of the bypass graft.

We deduced that surgical outcomes of LIMA with CAA ligation may be the best and surgical outcomes of the SVG may be superior to LIMA without CAA ligation. Surgical methods, including the type of bypass graft and CAA ligated or not, may be the main factors affecting the outcomes of the operation, and CAA diameter could be a minor factor.

**4.1. Characteristics of Mass Flow Rate of Bypass Grafts.** Mass flow rate, which is one of the few parameters that can be measured directly during the procedure, is one of the key hemodynamic parameters for clinical surgery. Most of the time, this indicator is the most direct indicator for judging the success of surgery [19, 32]. There are no significant differences in the mass flow rate of SVG between different diameters of CAA. The mass flow curves of SVG with and

without CAA ligation are similar in which the minimum and maximum values are 50 ml/min and 120 ml/min. The mass flow curves of LIMA models 5–7, without CAA ligation, are similar in which the minimum and maximum values are –50 ml/min and 60 ml/min. There is significant reverse flow during the systolic phase. Studies have shown that reverse flow is harmful to bypass grafts and is associated with the string phenomenon which indicates the failure of the bypass grafts [19, 20]. A reverse flow value of  $\geq 3.0\%$  can be considered as a cutoff value that predicts early graft failure [20]. The reverse flow value of 43.5% without CAA ligation is much higher than 3.0% in this research. Therefore, early graft failure may happen in LIMA without CAA ligation. However, by comparison, mass flow rate of LIMA with CAA ligation is much higher than that of LIMA without CAA ligation, in which the minimum and maximum values are 30 ml/min and 100 ml/min and no reverse flow exists. Mass flow rates of SVGs with and without CAA ligation and LIMA with CAA ligation are usually the expected results which are with higher mass flow and no reverse flow.

The inlet locations and the diameters of the grafts are the major geometrical differences between SVG and LIMA grafts in this research. On the one hand, the inlet of an SVG is closer to the aortic root than that of an LIMA graft. Therefore, the pressure delay of SVGs is less than that of LIMAs. On the other hand, the location close to the aortic root ensures that the pressure upstream of the bypass graft is close to the aortic pressure which can keep the pressure difference between the upstream and downstream of the bypass graft positive. The inlet of the LIMA is far from the root of the aorta which caused a negative pressure difference across the LIMA. The pressure difference has been shown in Figure 3 which can confirm our point of view. Except for LIMA without CAA ligation, the pressure difference of the bypass grafts in other models is always positive in the cardiac

FIGURE 3: The mass flow rate depending on times of the bypass grafts through the cross plane and the pressure difference between the bypass inlet and the bypass outlet. (a) Representation of the SVG virtual surgery model and three locations on the SVG. (b) Representation of the LIMA virtual surgery model and three locations on the LIMA. (c) The mass flow rate through the cross plane of the bypass grafts in all models, as shown in (a) and (b), and the pressure difference between the bypass inlet and bypass outlet in all models, as shown in (a) and (b).

cycle. In the models of LIMA without CAA ligation, the significant negative pressure difference was found which might be the major reason for the reverse flow during the

systole period in an LIMA graft. A larger diameter means less resistance. This may be the main reason why the mass flow of SVG is higher than that of LIMA with CAA ligation.

FIGURE 4: The WSS depending on times of the bypass grafts (SVG and LIMA) in a cardiac cycle.

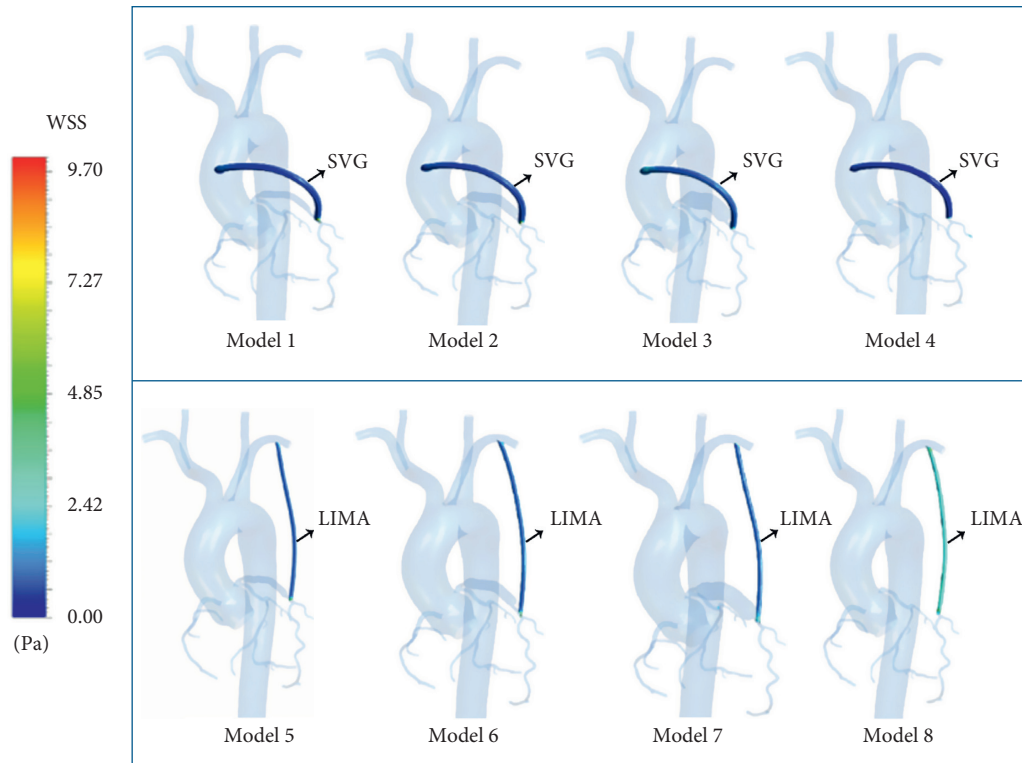

FIGURE 5: The WSS distribution on the bypass grafts (SVG and LIMA) at the peak point ( $t=0.24$  s) in a cardiac cycle.

**4.2. Characteristics of WSS of Bypass Grafts.** WSS is related to some important physiological processes of endothelial cells, such as the formation of important compounds [21, 22]. According to previous research including simulation and experimental research, WSS values have different effects on physiological processes of endothelial cells when they are in different ranges. According to the experimental reports, the results from experiments in parallel-plate flow chambers revealed that a low WSS value of 0.4 Pa induced extensive platelet aggregation [33]. This

abnormal behavior is considered to have the potential to cause vascular diseases. The simulation study also reached a similar conclusion, that is, when the WSS is less than 0.4 Pa, the blood vessels are prone to lesions [34, 35]. Simulation studies also found that the WSS interval which maintains normal physiological functions of blood vessels is generally considered to be 1–7 Pa. WSS values ranging from 0.4–1 Pa is usually considered a transition zone where the trend of blood vessel development cannot be easily predicted. Therefore, even if the WSS is greater than 0.4, we cannot

FIGURE 6: The OSI distribution on the bypass grafts (SVG and LIMA) in a cardiac cycle.

guarantee that the function of the blood vessels will not be affected at all. Our research results are as follows. WSS in SVGs (with and without CAA ligation, models 1–4) is similar, with an average value of 0.479 Pa. WSS in LIMAs (without CAA ligation, models 5–7) is similar, with an average value of 0.874 Pa. WSS in LIMA (with CAA ligation, model 8) is much higher, with a value of 1.701 Pa. In the simulation results, only the WSS value in LIMA with CAA ligation is in the range of 1–7 Pa and all others are in the range of 0.4–1 Pa. Therefore, LIMA with CAA ligation may be most in line with expectations. WSS values in other methods are not the best, but the results are still acceptable.

**4.3. Characteristics of OSI of Bypass Grafts.** OSI is used to reveal the degree of WSS vector direction change which can help us understand the oscillation information of blood flow [36]. Simulation studies have pointed out that low OSI may reduce the risk of graft failure [23, 24]. *In vitro* studies using bovine endothelial cells revealed that slowly oscillating (1 Hz) shear stress (equal to the upper limit of OSI of 0.5) induced the expression of monocyte chemoattractant protein-1 and increased binding of monocytes to the endothelium which indicate high OSI has the potential to increase the risk of vascular failures [37]. Smaller OSI means more stable blood flow and better guarantee of blood vessel stability. The simulation results of this study showed that OSI in all SVGs (with and without CAA ligation) is quite small and close to 0. OSI in LIMA (without CAA ligation, models 5–7) is quite high with an average value of 0.367. OSI in LIMA (with CAA ligation, model 8) is quite small which is close to 0. The results of different surgical methods are significantly different. OSI levels are two orders of magnitude lower in the

SVG with and without CAA ligation than LIMA without CAA ligation. LIMA with CAA ligation has similar condition as the SVG. Therefore, the simulation results of the SVG and LIMA with CAA ligation are in line with the target. LIMA without CAA ligation is at risk due to too high risk of failure.

**4.4. Summing-Up and Deduction.** As mentioned above, we extracted and analyzed three key hemodynamic parameters including mass flow rate, WSS, and OSI. The results show that high mass flow rate, relatively low WSS, and low OSI (almost 0) are the main features for the SVG with and without CAA ligation. Low mass flow rate, low WSS, and high OSI are the main features for the LIMA without CAA ligation. In contrast, high mass flow rate, high WSS, and low OSI (almost 0) are the main features for the LIMA with CAA ligation. The results show that changes in CAA diameter have no significant effect on hemodynamic features of the same category. According to previous research, achieving high mass flow, high WSS, and low OSI to reduce adverse hemodynamic factors is important, in order to reduce the risk of surgical failure and prolonging long-term effectiveness of the graft. Among the several surgical methods in this study, LIMA with CAA ligation has the optimal hemodynamic parameters compared with other models. SVG with and without CAA ligation have similar hemodynamic conditions which are all anticipated apart from the relatively low WSS. LIMA without CAA ligation has negative hemodynamic parameter results that are not expected. Based on our hemodynamic results, we deduced that surgical outcomes may have nothing to do with CAA diameter. LIMA with CAA ligation may have the best surgical

outcomes, and SVG (both with and without CAA ligation) surgical outcomes are better than that of LIMA without CAA ligation. LIMA without CAA ligation may not be desirable. When a coronary artery is ligated, it means that the blood supply to this branch is completely cut off. The blood supply at this time can only rely on the bypass grafts. Once the bypass grafts have problems, the blood vessels themselves cannot perform compensatory adjustments in time which originally can be performed without ligation. Therefore, even though CABGs with CAA ligation may have better surgical outcomes, we need to be very careful with this surgical approach due to other potential risks.

**4.5. Limitations of the Work.** An important limitation of this study is the number of patients. The model in this study was only based on one patient's data, so the results of the study may be special and accidental. The second limitation is the assumption of rigid arterial walls in the simulation, which does not account for the significant motion and curvature changes of the coronary arteries and bypass grafts during the cardiac cycle. In addition, rigid arterial walls mean that the effect of material deformation on blood flow is ignored. This problem can be solved by adopting a fluid-solid interaction (FSI) method in the future. An additional limitation is limited data on flow split percentages to the left and right coronary arteries and the relationship between the intramyocardial pressures to the left and right ventricular pressures, and these are possible minor sources of error during building the LPM.

## 5. Conclusion

In this paper, the hemodynamic differences between two different surgical methods (types of CABGs, whether CAA ligated or not) and the effect of CAA diameter on the hemodynamics of different surgical methods were compared by using CFD simulation. A hemodynamic-based evaluation of these procedures was performed. The results suggest that LIMA with CAA ligation has the best hemodynamic characteristics, including high mass flow rate, high WSS, and low OSI. Hemodynamic characteristics of the SVG (with and without CAA ligation) are better than those of the LIMAs without CAA ligation including high mass flow rate, WSS, and low OSI. Significant reverse flow that can increase the risk of graft failure was found in LIMAs without CAA ligation during systole. The change of CAA diameter has basically no effect on the hemodynamics of the same bypass graft. Based on the previous hemodynamic research, we deduced that the outcomes of ligation surgery may have more benefits than those of nonligation surgery. SVG may be a better choice than LIMA when CAA is not ligated. This preliminary result warrants extensive research involving a larger aneurysm database for further analysis.

## Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

## Conflicts of Interest

The authors declare no conflicts of interest.

## Acknowledgments

This research was supported by the National Natural Science Foundation of China (nos. 11832003 and 11772016), and JSPS KAKENHI (no. JP18K18355). This research was partially supported by the creation of a development platform for implantable/wearable medical devices by a novel physiological data integration system of the Program on Open Innovation Platform with Enterprises, Research Institute and Academia (OPERA) from the Japan Science and Technology Agency (JST).

With the decrease and depletion of shallow coal resources, the depth of mining is increasing. The mechanism of high crustal stress blasting is not clear, and the effect of crustal stress on blasting effect is obvious. The law of the differential detonation is similar without crustal stress. The crustal stress of rock masses increases linearly with the increase in excavation depth, and the influence of crustal stress on blasting effect is great. In order to study the rock-breaking process of complex differential blasting under deep high crustal stress, the instantaneous detonation of each model and the priority detonation of the central hole are numerically simulated. The evolution law of the blasting crack and the method of optimizing blasting effect by differential blasting and increasing the aperture of the priority detonation hole under high crustal stress are put forward. The authors proposed a study on the 2D optimization simulation of complex five-hole cutting blasting under different lateral pressure coefficients of 400 m and 800 m with software ANSYS/LS-DYNA and analyzed the evolution rules of blasting cracks and lateral pressure coefficients. The results show that setting delayed detonation and hole diameter and optimizing blasthole spacing can optimize the rock-breaking effect under high crustal stress and different lateral pressure coefficients.

## 1. Introduction

With the reduction and depletion of shallow coal resources, deep mining has become an inevitable trend. With the passage of time, the future will be mined towards deeper rock formations. In the current excavation process of the deep rock mass, the drilling and blasting method is still the main method of rock breaking. As the depth of the excavation increases, the influence of the initial crustal stress on the blasting effect becomes more and more important. According to the variation of vertical and horizontal stress with depth in various countries given by Brady and Brown, the vertical stress generally increases linearly with the increase of depth, and the variation law of horizontal stress is more complicated, which makes the blasting excavation of deep rock mass have great difficulties [1, 2]. At present, the research on deep rock mass mining is still in the initial stage,

the design of excavation parameters is still based on the design method of shallow rock mass blasting, and the influence of initial crustal stress is not considered enough, which makes the blasting effect poor, the excavation speed slow, the late support time long, and even have the rock burst and other major disasters. This makes it particularly important to study blasting rock breaking under initial crustal stress, and it is particularly urgent to study the design of blasting parameters and the rapid and safe excavation of rock mass stability under initial crustal stress.

In view of the rock-breaking mechanism of deep rock mass under initial crustal stress, scholars at home and abroad have carried out extensive research on physical experiment and numerical simulation. Based on the stress state equation of the rock mass in the cut area established by Schwarz alternating iteration method and elastic mechanics theory, two-dimensional numerical simulation of

straight cut blasting under different stress fields was carried out, and the maximum tensile stress was generated on the line connecting the hollow hole and the slot hole after the initial crustal stress field and the explosion stress field were combined by the rock mass [2]. The damaged model of rock blasting built on the basis of damaged mechanics analyzed the influence of different lateral pressure coefficients and buried depth on the crack growth rule [3]. The coupling model of Cowper–Symonds hardening model and tension and compression damaged model was embedded in LS-DYNA software for a two-dimensional numerical simulation. It was found that the central hole had an impact on rock damage [4]. Blasting parameter design method is suitable for deep high-stress rock roadway excavation by using numerical simulation and field test [5]. Wang et al. did numerical simulation by creep experimental data, obtained the creep equation of the surrounding rock in the deep soft rock roadway under high crustal stress, and established the quantitative creep relationship between time and stress [6]. He et al. summarized and analyzed the main differences of rock mass mechanical properties between deep mining and shallow mining through experiments [7]. The theoretical calculation model of the fragmentation size distribution containing the damage variable is proposed. Simulations and tests show that the action of the extrusion and collision between motive fragment blocks is a significant factor affecting the average fragmentation size regardless of the type of rock mass, especially for the rock mass with very bad quality [8]. The new model named MAGRM is a group recommendation model based on multiattention. It can well utilize multiattention-based deep neural network structures to achieve accurate group recommendation [9]. Based on LS-DYNA finite element program, NA finite element program, and optimization of cutting blasting in high-speed drivage process of an iron mine roadway, the authors carried out a study about numerical simulation and field test to the cutting blasting method with different blasting holes [10]. In order to eliminate the simplification of the interaction in data processing and improve the generated working efficiency, a method of redundant electrode determination based on the theory of variance is proposed [11]. Simulation of the complex rock-breaking mechanism under crustal stress included the prediction model of carbonation depth of slag high-performance concrete [12, 13]. Based on rock blasting theory, the authors used ANSYS/LS-DYNA to simulate the process of rock fragmentation of double-blasthole blasting with one empty hole at the center position [14]. The crack propagation in the rock under composite stress was studied by using digital image correlation technique [15]. The design and realization of the magnetic suspension controller are discussed, and a nonlinear mathematical model of the magnetic suspension system is built [16]. Based on the theory of the BP neural network and the engineering geological database as the research and development platform, this paper establishes the prediction of geotechnical parameters based on the analysis of the characteristics of geotechnical materials and the distribution of geotechnical sediments and geotechnical

parameters [17]. Local plane wave decomposition method considered from the perspective of inversion is employed to obtain higher-quality slant stack data, and the dynamic focused beam propagator is adopted to control the divergence of beams [18]. To reduce the impact of blasting vibration on the existing tunnel during the excavation of small-distance tunnel blasting, software was used to simulate the blasting vibration of the tunnel in different positions and forms [19].

Under the action of crustal stress, two-dimensional numerical simulation of complex five-hole blasting under different lateral pressure coefficients is carried out using ANSYS/LS-DYNA. Aiming at the differential detonation and increasing the diameter of the central blasthole under high crustal stress, the simulation study is provided for the blasting construction of deep rock mass.

## 2. Theoretical Analysis of Rock State with Different Confining Pressures and Lateral Pressure Coefficients

The drilling of the rock under the condition of initial crustal stress has changed the original stable state of the rock so that the rock around the blasthole produces an instant loosening zone. Since the blasthole is relatively small compared to the roadway, the concentrated stress value around the blasthole is smaller than the rock strength, the surrounding rock is in an elastoplastic state, and the surrounding rock is self-stabilizing. However, the stability of the loosening zone around the blasthole is less than that of the original rock. Similar to the loosening circle theory, in bidirectional confining pressure (side lateral pressure coefficient is equal to 1), vertical stress and horizontal stress are equal, the loosening zone is circular, the rock stability around the blasthole is evenly distributed, and the direction of rock crack propagation after explosion is randomly distributed, which is inhibited by the crustal stress. In the case of bidirectional unequal confining pressure (lateral pressure coefficient is not equal to 1), vertical stress and horizontal stress are not equal, the loosening zone is elliptic, and the long axis of the ellipse is perpendicular to the direction of the maximum crustal stress. Rock around the blasthole is affected by the initial stress field, and the explosion crack is restrained by the crustal stress and mainly expands to the side with large crustal stress. Figures 1–3, respectively, show the effect diagrams when the lateral pressure coefficient is 1, 0.2, and 4 under the initial vertical stress of 10 MPa. As can be seen from the figure, when the lateral pressure coefficient  $\lambda = 1$ , uniform stress concentrations are produced around the rock. When the lateral pressure coefficient  $\lambda = 0.2$  and 4, the tensile stress concentration is generated on the side with larger crustal stress. The maximum tensile stress is generated by the coupling of crustal stress and explosion stress under the action of constant pressure on both sides, this analysis analyzed the cause of the maximum tensile stress and the influence of different side pressures on the maximum tensile stress direction from the initial stress of the blasthole [2].

The initial stress state of the rock has an important effect on the blasting rock. Rock blasting under the initial stress

FIGURE 1: The effect diagram when the lateral pressure coefficient is 1.

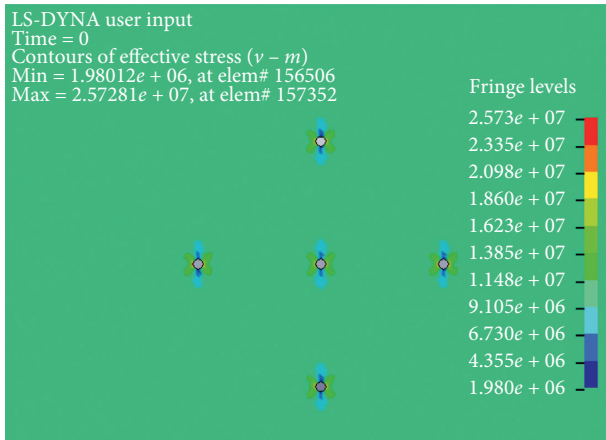

FIGURE 2: The effect diagram when the lateral pressure coefficient is 0.2.

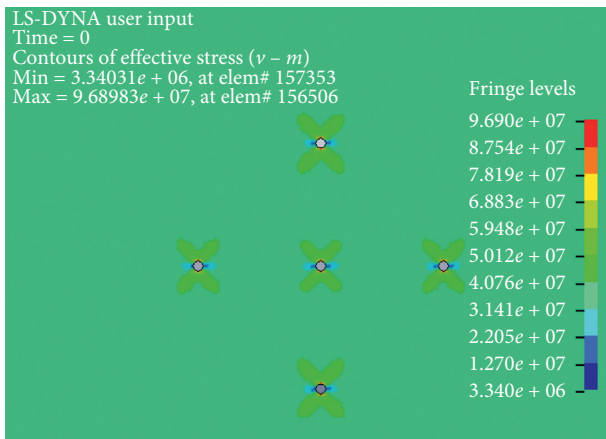

FIGURE 3: The effect diagram when the lateral pressure coefficient is 4.

condition is the effect of the coupling field formed by the coupling of the stress field redistributed in the rock around the blasthole and the explosive stress field after the explosion.

2.1. *Calculation of the Initial Crustal Stress Field of the Rock.* Radial effective stress  $\sigma_{r0}$ , tangential effective stress  $\sigma_{\theta0}$ , and shear stress of the rock  $\tau_{r\theta}$  around the blasthole under initial crustal stress can be calculated according to the elastic theory [20]:

$$\begin{cases} \sigma_{r0} = \frac{\sigma_H + \sigma_h}{2} \left(1 - \frac{R^2}{L^2}\right) + \frac{\sigma_H - \sigma_h}{2} \left(1 + \frac{3R^4}{L^4} - \frac{4R^4}{L^4}\right) \cos 2\theta, \\ \sigma_{\theta0} = \frac{\sigma_H + \sigma_h}{2} \left(1 + \frac{R^2}{L^2}\right) + \frac{\sigma_H - \sigma_h}{2} \left(1 + \frac{3R^4}{L^4}\right) \cos 2\theta, \\ \sigma_{r\theta} = \frac{\sigma_H - \sigma_h}{2} \left(1 - \frac{3R^4}{L^4} + \frac{2R^4}{L^4}\right) \sin 2\theta, \end{cases} \quad (1)$$

where  $\sigma_H$  and  $\sigma_h$  are the maximum and the minimum horizontal crustal stress;  $\theta$  is the angle between the radial direction of the point around the hole and the direction of the maximum horizontal crustal stress;  $R$  is the radius of the blasthole; and  $L$  is the distance from the calculation point to the center of the blasthole.

2.2. *Calculation of the Rock Stress under Explosive Load.* The stress state around the rock is further changed by the reflection and tension of the stress wave on the rock around the blasthole under the explosion stress [21]. The radial stress of an explosion at a certain point in the rock  $\sigma_{r1}$  and the tangential stress of an explosion at a certain point in the rock  $\sigma_{\theta1}$  can be calculated according to the attenuation formula of the stress wave [22]:

$$\begin{cases} \sigma_{r1} = p_0 \left(\frac{L}{R}\right)^{-\alpha}, \\ \sigma_{\theta1} = -\lambda_d \sigma_r, \end{cases} \quad (2)$$

where  $p_0$  is the initial pressure acting on the hole wall after the explosion of the explosive; the value of  $\alpha$ , stress wave attenuation coefficient, is  $2 - (\mu_d/1 - \mu_d)$ ;  $\mu_d$  is the dynamic Poisson ratio and the relationship between it and the static Poisson ratio is  $\mu_d = 0.8\mu$ ; and  $\lambda_d$  is the dynamic lateral stress coefficient, and its value is  $\lambda_d = (\mu_d/1 - \mu_d)$ .

Therefore, the tangential stress after superposition is  $\sigma_r = \sigma_{r0} + \sigma_{r1}$ . That is, when the tangential stress in the rock is greater than the ultimate tensile strength of the rock under the combined action of the initial stress and the explosion stress, the rock will produce cracks, and then failure occurs.

### 3. Establishment of a Numerical Model for Rock Blasting

3.1. *Rock Constitutive Model and Material Parameters.* In order to observe the change of the rock damaged vertically and horizontally under the initial crustal stress field, the theoretical model of complex five-hole cutting blasting is selected under the condition of RHT rock constitutive, the fixed constraint is applied to the bottom of the model, the surrounding compressive stress is applied in the other

three directions, and the initial crustal stress field is simulated by using the implicit-display order of DYNA [23]. Because the law mainly analyzes and summarizes the damage degree of the rock, it does not involve the formation process of the groove cavity, and it directly simulates the damage evolution process of rock profile with a thickness of 0.01 m. When the computer carries out the numerical simulation, the mesh quality affects the accuracy of the numerical simulation, and the size of the mesh division and the number of the quantity affect the accuracy of the simulation. The model size is  $5\text{ m} \times 4\text{ m} \times 0.01\text{ m}$ , wherein 5 blastholes with a radius of 20 mm are arranged, and the blasthole spacing is 0.5 m. Because the aperture size of the blasthole is small relative to the model size and the interface size does not change vertically with the model, the simulation can be reduced to a plane strain problem calculated by a single layer mesh, and the model is shown in Figure 4.

The explosive material model adopts \*MAT\_HIGH\_EXPLOSIVE\_BURN, using the JWL state equation, and the specific explosive parameters are shown in Table 1 [24]. Rock mechanics parameters are shown in Table 2 [25].

The JWL equation of the state defines that the pressure is

$$p = A \left( 1 - \frac{w}{R_1 V} \right) e^{-R_1 V} + B \left( 1 - \frac{w}{R_2 V} \right) e^{-R_2 V} + \frac{wE}{V}, \quad (3)$$

where  $p$  is the pressure of the detonation product;  $V$  is the relative volume of the detonation product;  $E$  is the initial internal energy density of the detonation product; and  $A$ ,  $B$ ,  $R_1$ ,  $R_2$ , and  $w$  are material parameters.

The material for the cell is \*MAT\_NULL. Defining the mass, the modulus of elasticity, Poisson's ratio, and so on, to define the material. The air material model uses MAT\_NULL air material model, its state equation is defined by the keyword EOS\_LINEAR\_POLYNOMIAL, and the state equation is as follows:

$$p = C_0 + C_1 \mu + C_2 \mu^2 + C_3 \mu^3 + (C_4 + C_5 \mu + C_6 \mu^2) E, \quad (4)$$

where  $C_i$  is the equation parameter and  $E$  is the unit initial internal energy of relative volume  $\mu = (1/V) - 1$ ,  $V$  is the relative volume. Parameters of air material and state equations are shown in Table 3.

### 3.2. Loading Scheme of Crustal Stress with Different Lateral Pressure Coefficients in Blasting Damage

- (1) When the lateral pressure coefficient is  $\lambda = 1$ , model A:  $\sigma_z$  takes 10 MPa and corresponds to 400 m buried depth; model B:  $\sigma_z$  takes 20 MPa and corresponds to 800 m buried depth
- (2) When the lateral pressure coefficient is  $\lambda = 0.2$ , model C:  $\sigma_z$  takes 10 MPa,  $\sigma_x$  to 2 MPa, and model D:  $\sigma_z$  takes 20 MPa,  $\sigma_x$  to 4 MPa
- (3) When the lateral pressure coefficient is  $\lambda = 4$ , model E:  $\sigma_z$  takes 10 MPa,  $\sigma_x$  to 40 MPa, and model F:  $\sigma_z$  takes 20 MPa,  $\sigma_x$  to 80 MPa

## 4. Numerical Simulation Results and Analysis

In order to study the rock-breaking process of differential blasting under deep high crustal stress, the instantaneous detonation of each model and the prior detonation of the central hole are numerically simulated. The differential blasting initiation model sets the central hole to detonate first, and the remaining holes are set 50  $\mu\text{s}$  time delay and compared under different lateral pressure coefficients; the cloud map is output and analyzed after the computing cluster.

**4.1. Rock Damage Evolution Process with Lateral Pressure Coefficient Equal to 1.** Because the lateral pressure coefficient is equal to 1, the pressure around the hole is evenly distributed; in the early stage of the explosion, the explosion shock wave first acts on the rock mass around the hole so that the rock mass around the blasthole first produces damage. Before 50  $\mu\text{s}$ , the range of the rock damage around the blasthole under the same crustal stress model was similar, the explosion crushing area was basically molded, and the stress wave was not enough to produce direct damage to the rock mass while resisting the crustal stress and began to continue along the damaged area that had been formed. The damage range of the rock is comparable under 10 MPa and 20 MPa crustal stress, and there is no great difference. After 50  $\mu\text{s}$ , with the gradual attenuation of the stress wave, the inhibition of the crustal stress on the blasting effect began to show the following: due to the gradual attenuation of the stress wave, the influence of crustal stress on blasting effect is more and more in the later stage of

explosion, and it can be seen from the final damage cloud map that the damage range and damaged degree of model A are obviously higher than those of model B; the greater the initial crustal stress, the greater the attenuation speed of the

wave. Figures 5 and 6, respectively, show the damage evolution process of models A and B.

Because the lateral pressure coefficient is equal to 1, the evolution of differential blasting damage is also inhibited by

FIGURE 7: Damage evolution process diagram of model C.

FIGURE 8: Damage evolution process diagram of model D.

FIGURE 9: Differential initiation damage evolution process diagram of model D.

FIGURE 10: Instantaneous detonation damage evolution process cloud map of model E.

the crustal stress, but its evolution law is similar to that of noncrustal stress, so it is no longer described.

*4.2. Rock Damage Evolution Process with Lateral Pressure Coefficient Equal to 0.2.* By analyzing the damage evolution process with a lateral pressure coefficient of 0.2, it can be found that when the lateral pressure coefficient is 0.2, the

initial crustal stress around the hole is smaller when the bidirectional crustal stress is equal, so the inhibition of the initial crustal stress on the rock damage evolution is relatively small at this time. From the damage cloud diagram, it can be seen that because the crustal stress in the vertical direction is greater than the crustal stress in the horizontal direction, the rock damage mainly develops in the vertical direction, the damage range of the hole connection in the

FIGURE 11: Differential initiation damage evolution process diagram of model *E*.FIGURE 12: Instantaneous detonation damage evolution process cloud map of model *F*.FIGURE 13: Differential initiation damage evolution process diagram of model *F*.FIGURE 14: Instantaneous detonation damage evolution process cloud map of model *G*.

vertical direction is larger than the horizontal direction, and the guiding effect of the crustal stress on the crack propagation begins to show. Compared with models *C* and *D*, although the side pressure coefficient is the same, the gap between  $\sigma_z$  and  $\sigma_x$  of model *D* is larger, the guidance effect of model *D* on damage evolution is more obvious, and the damage evolution speed and damage range in the vertical direction are larger than those of model *C*; the gap between  $\sigma_z$  and  $\sigma_x$  in model *C* is smaller, the damage evolution

process in the horizontal and vertical direction is slightly different, but the damage range in the direction of the final hole connection is not much different. It can be seen that the guiding effect and inhibition of crustal stress on damage evolution are not linear. The damage evolution process for models *C* and *D* is shown in Figures 7 and 8.

Because the blasting effect of model *D* in the horizontal direction is not ideal, the central hole is set to detonate first, and the other holes are set to  $50 \mu\text{s}$  time-delay detonation.

FIGURE 18: Continued.

(b)

FIGURE 18: Comparison of the effective stress time-history curve of the selected element in model *D*. (a) Model *D* time-history curve of effective stress of multichoice element differential blasting. (b) Model *D* time-history curve of effective stress of multichoice element instantaneous blasting.

The damage evolution diagram of model *D* is shown in Figure 9. Compared with the instantaneous detonation, the damage range of the rock is obviously larger than that of instantaneous detonation, the guiding effect of high crustal stress on damage evolution is weakened, the range of horizontal damage is obviously increased, the damage zone on the outside of the vertical hole is shortened, and it is beneficial to the measures such as late support.

**4.3. Rock Damage Evolution Process with Lateral Pressure Coefficient Equal to 4.** With the increase of crustal stress, the inhibitory effect on rock damage evolution increases gradually, while the damaged area is further concentrated in the maximum crustal stress direction, the damage evolution speed in the direction of the maximum crustal stress is accelerated, the region of damage on the outside of the hole is increased, and rock blasting under the initial crustal stress is more difficult. The optimization effect of differential detonation on blasting effect is weakened, which mainly promotes rock damage of the intersection position of the stress wave, and the coupling field between stress wave and crustal stress beyond the limit tensile strength of the rock is further reduced and concentrated. The instantaneous and differential damage evolution diagram of models *E* and *F* with lateral pressure coefficient equal to 4 is, respectively, shown in Figures 10–13.

In model *F*, due to the large difference between  $\sigma_z$  and  $\sigma_x$ , the damage area in the vertical direction is not penetrated. At this time, in the case of differential blasting, it can be considered to increase the diameter of the central hole and shorten the hole spacing on the side with smaller crustal

stress. The model increases the diameter of the central hole to 30 mm, and the blasthole spacing decreases to 0.3 m for numerical simulation, defined as model *G*. The simulation results show that the vertical direction damage is already running through at 132  $\mu$ s, and the damage degree and damage area are still increasing, the final hole is completely running through, increasing the utilization rate of the hole, the difference of damage range in two directions decreases, and there will be no situation similar to that of model *F* blasting. The damage evolution process for model *G* is shown in Figure 14.

**4.4. Simulation Analysis of Five-Hole Cutting Blasting Results.** From the above model and simulation improvement, it can be seen that differential blasting plays a certain role in optimizing the blasting effect under the action of crustal stress, and with the increase of crustal stress, the optimization effect of differential blasting decreases gradually so that reducing the hole spacing in the smaller direction of crustal stress can achieve the optimization effect, and further optimization can increase the diameter of the central hole; in order to meet the blasting demand under the high crustal stress, the utilization rate of the blasthole is improved.

The attenuation law of the stress wave under crustal stress is observed at two observation points H150890 and H108091 in the same position when bidirectional compressive stress is 10 MPa and 20 MPa, respectively, and the selection position is shown in Figure 15.

From the equivalent stress-time curve of the two models, it can be seen that the time for the observation point to reach the first stress peak is similar, around 127  $\mu$ s, which is

because the observation point is close to the hole spacing, the force on the stress wave is not obvious, and the effective stress is around 115 MPa; when the observation point reaches its second peak, at this point, the stress wave begins to overlay, the crustal stress corresponds to the role of the wave which began to produce differences; for the observation points H150890 and H108091 in the confining pressure of 10 MPa, the peak time and size are (189  $\mu$ s, 168 MPa) and (166  $\mu$ s, 132 MPa), and when the confining pressure is 20 MPa, the peak time and size are (205  $\mu$ s, 120 MPa) and (185  $\mu$ s, 126 MPa); combined with the peak data of Figure 16 [26], it can be seen that, with the increase of crustal stress, the influence on the propagation of the stress wave increases, which is reflected in the increase of stress wave velocity and stress size attenuation velocity.

In order to study the impact of differential blasting on rock damage under different lateral pressures, the time-history curves of effective stress of differential blasting and instantaneous blasting in model *D* were selected for comparative analysis. The selected unit is shown in Figure 17.

In Figure 18, the effective stress of model *D* decays rapidly after reaching the peak and decays to the initial crustal stress value at around 112  $\mu$ s, while the differential blasting has experienced stress wave superposition for many times, and the effect time is longer and decays to the effective stress value at around 160  $\mu$ s. It can be seen that the action time of differential blasting is long, which can promote the rock damage. In addition, its peak stress is smaller than that of instantaneous blasting, and the resulting vibration is smaller, which is conducive to the stability of the surrounding rock mass under high crustal stress.

## 5. Conclusions

Using finite element analysis software ANSYS/LS-DYNA, the rock damage of complex five-hole cutting blasting under different lateral pressure coefficients is numerically simulated, and two-dimensional simulation can divide more meshes than three-dimensional simulation at the same time, which can improve the accuracy of simulation when simulating complex blasting. Rock blasting under high crustal stress can be regarded as the damage caused by the coupling position of the rock in the explosion field and the crustal stress field, which is greater than the ultimate tensile strength of the rock.

Under the bidirectional pressure, the crack propagation is inhibited with the increase of crustal stress field, and the evolution law of differential blasting damage is similar to that of noncrustal stress field, which is inhibited by the initial crustal stress field. In the two-way unequal pressure, the direction of damage evolution tends to be on the side of large crustal stress field, and the guiding effect and inhibition of crustal stress field on damage evolution are nonlinear; the priority detonation of the central hole can optimize the blasting effect on the smaller side of the crustal stress field and shorten the damage length of the larger side of the crustal stress field, which decreases with the increase of the crustal stress field; at this time, we can consider increasing the diameter of the priority detonation hole under the

condition of differential blasting. At the same time, shortening the hole spacing on the smaller side of the crustal stress field can further improve the blasting effect. The stress wave velocity and the effective stress attenuation velocity increase with the increase of the crustal stress field.

Risk management is a key factor for smart city running. There are many risk events in a strict process like transportation management of a smart city or a medical surgery in a smart hospital, and every step may lead to one kind of risk or more. In view of the fact that the occurrence of the flow risks follows the sequence formed by each process step, this paper presents a Bayesian network under strict chain (BN\_SC) to model this situation. In this model, the probabilistic reasoning formula is given according to the sequence of process steps, and the probabilities given by the model can do risk factor analysis to support the system to find an effective way to improve the process like machine manufacturing or a medical surgery. Finally, an example is analyzed based on the information given by doctors according to the situation of LC in their hospital located in Sichuan Province of China, which shows the effectiveness and rationality of the proposed BN\_SC model.

## 1. Introduction

Machine learning has applications in various fields for smart city running, such as machinery manufacturing, especially in probability evaluation [1–3]. Bayesian learning as a machine learning method can estimate the probabilities of risk occurrence like medical risk events in the medical process [4–7]. One or more of which will lead to the occurrence of other risk events, for example, in laparoscopic cholecystectomy, trocar puncture may cause intestinal injury, which often leads to infection.

In this kind of situation, the correlations of events can be quantified in a Bayesian network [8, 9]. However, the occurrence of risk events connected with the medical process, for example, LC must follow the surgical steps that construct a strict chain for the Bayesian net to follow. Existing quantitative research rarely studies on models for this special feature. According to this situation, we present a Bayesian network under strict chain (BN\_SC) model for the first time. In this model, the probabilistic reasoning formula according to the sequence of surgical steps processes the logical

inference for the probability of each risk subjected to the strict chain constructed by the surgical steps of LC. BN\_SC model can calculate the probabilities of risk flow more effectively than the traditional Bayesian network.

The remainder of the paper is organized as follows. Section 2 will review the research about the Bayesian network and we will illustrate the process of LC with a directed acyclic graph in Section 3. In Section 4, the BN\_SC model will be proposed, including the logical inference of the risks events and the formula to compute the probabilities of risks in LC. Finally, an example is analyzed based on the information given by doctors according to the situation of laparoscopic cholecystectomy in their hospital, which shows the effectiveness and rationality of the BN\_SC in Section 5.

## 2. Related Works

Previous studies have comprehensively expounded the concept and related properties of Bayesian networks. Tuyls and Maes pointed out that a Bayesian network is a directed acyclic graph, which consists of a set of random variables.

The meaning from node  $X$  to node  $Y$  is that node  $X$  has a direct influence on node  $Y$  [10]. The main feature of the Bayesian network is that it shows the interdependent relationship between variables. Koller and Friedman et al., Meinhshausen and Btihlmann, and Wainwright and Jordan pointed out that the graph connected by undirected edges between variables is an undirected graph known as Markov network [11–13]. These graphs produce undirected graph models, which are more suitable for analyzing the similarity and related behavior between variables. Ghahramani, Heckerman et al., and Neapolitan pointed out that a graph connected by a directed edge of variables is a “directed graph,” and a directed graph without a cycle is a “directed acyclic graph” (DAG) [14–16]. Directed acyclic graphs are usually based on the concept of family order. For example, in  $A \rightarrow B \rightarrow C$ ,  $A$  is the parent node of  $B$ ,  $C$  is the child node of  $B$ ,  $A$  and  $B$  are the ancestors of  $C$ , and  $B$  and  $C$  are the descendants of  $A$ . This ranking clearly expresses causality, and these figures produce a class of models called Bayesian networks. Andersson et al., Gillispie and Perlman, and Pearl have pointed out that some directed acyclic graphs have two-way edges, which are suitable for situations where some variables interact with each other [17–19]. They represent a class of Markov equivalent directed acyclic graphs.

Bayesian network is widely used in risk evaluation research. Ronald et al. show that chains of events can lead to increased or critical emissions of volatile organic compounds by assessing risks based on the Bayesian network [20]. Bhattacharjee applied a Bayesian model that can handle death data analysis without stratifying in the presence of competing risks [21]. Sanchez et al. develop a general framework and a method to estimate the impact of project management maturity on project performance by using Bayesian networks to formalize project management experts’ knowledge [22]. Masmoudi et al. used a discrete Bayesian network with a latent variable to model the payment default of loan subscribers [23]. Punyamurthula and Badurdeen represented operational risks of production line and their causal relationships based on Bayesian Belief Networks [24].

### 3. Process of LC

Laparoscopic surgery is a new method of minimally invasive surgery, which is the inevitable trend of the future development of surgical methods. Cholecystectomy is one of the most common abdominal operations, which is usually performed in laparoscopic surgery in developed countries. For example, 90% of cholecystectomy in the United States is performed by laparoscopy. Laparoscopic cholecystectomy is regarded as the “gold standard” for surgical treatment of cholelithiasis [25, 26].

Laparoscopic cholecystectomy is divided into five steps, which include trocar puncture (into the abdomen), separation of adhesion, anatomy bile triangle, dissection of gallbladder bed, and removal and suture of gallbladder. In the surgery, intestinal injury may be caused by trocar puncture, bile duct injury may be caused by separation of adhesion, anatomy of bile triangle, and dissection of

gallbladder, and vascular injury may be caused by removal and suture of gallbladder. Moreover, the three kinds of injuries may lead to infection and massive hemorrhage, which can eventually lead to death. In order to describe the risk probability in LC surgery more succinctly, Table 1 shows the mathematical symbols in this paper.

According to analysis, we can get the directed acyclic graph of LC operation as shown in Figure 1.

Figure 1 describes the specific process how the LC works. We can build a special model by following the logic derived from the strict chain. As shown in the figure, the risk of  $R_2$  happened in the process of Step 2. Moreover, the occurrence of  $R_1$  means the failure of Step 1, which means the surgery cannot be performed and  $R_2$  cannot occur. The five surgery steps formed a chain above the Bayesian network of risks in the surgery. The occurrence of each risk needs to follow the order of the steps in the chain strictly. This changes the rule of the traditional inference of Bayesian network. To solve the problem, we present a new model in Section 4.

### 4. Bayesian Network under Strict Chain (BN\_SC)

According to the analysis in Section 2, we build a Bayesian network to model the LC process. Different from the traditional Bayesian network, in many medical procedures, the risk Bayesian network is developed under the surgical process such as the Bayesian network of LC surgery in Section 2, and the surgical process is characterized by the fact that the next step can only be taken after the previous step surgical procedure is successful. So those medical steps construct a strict process chain naturally such as  $S_1$  to  $S_5$  of LC, and more importantly, the Bayesian network of surgery risks should follow the steps of the chain model. According to this characteristic, this paper proposes Bayesian network under strict chain model. Under BN\_SC model, if  $j = i + 1$ , then surgical step  $j$  can only begin after surgical Step  $i$  completes successfully. The formula for calculating the probability of the risk occurrence of the event  $j$  is as follows:

$$P(S_j) = \prod_{i=1}^{j-1} P(S_i)P(S_i). \quad (1)$$

Here,  $P(D_i)$  means the probability of the surgical Step  $i$  completed successfully. This paper assumed that only when the surgical Step  $i$  causes the risk  $i$  will lead to the unsuccessful surgery, and some other unexpected factors such as power outages are not under consideration. So,  $P(D_i)$  and  $P(R_j)$  form complementary relationship, that is,  $P(R_j) = 1 - P(D_i)$ . In laparoscopic surgery, the patient is bound to have the first surgical step after entering the procedure, so the first surgical step is bound to occur here, that is,  $P(S_1) = 1$ .

Therefore, the probability of intestinal injury risk  $P(R_1)$  caused by the first surgical procedure can be represented as follows:

$$P(R_1) = P(R_1 | S_1)P(S_1) = P(R_1 | S_1). \quad (2)$$

TABLE 1: List of symbol notations and description.

| Symbols         | Descriptions   |
|-----------------|--|
| $S_1$           | Trocar puncture (into the abdomen) happened              |
| $S_2$           | Separation of adhesion happened                          |
| $S_3$           | Anatomy of bile triangle happened                        |
| $S_4$           | Dissection of gallbladder bed happened                   |
| $S_5$           | Removal and suture of gallbladder happened               |
| $D_1$           | Trocar puncture (into the abdomen) has done successfully |
| $D_2$           | Separation of adhesion has done successfully             |
| $D_3$           | Anatomy of bile triangle has done successfully           |
| $D_4$           | Dissection of gallbladder bed has done successfully      |
| $D_5$           | Removal and suture of gallbladder has done successfully  |
| $R_1$           | Intestinal injury  |
| $R_2$           | Bile duct injury   |
| $R_3$           | Vascular injury  |
| $R_4$           | Infection  |
| $R_5$           | Massive hemorrhage                                       |
| $R_6$           | Death  |
| $W_1, W_2, W_3$ | Contribution ratio of $R_1, R_2, R_3$ to $R_4$           |
| $W_4, W_5, W_6$ | Contribution ratio of $R_1, R_2, R_3$ to $R_5$           |

FIGURE 1: Bayesian network under a strict chain.

The probability of bile duct injury risk  $P(R_2)$  caused by multiple surgical procedures  $S_2$ ,  $S_3$ , and  $S_4$  can be represented as follows:

$$\begin{aligned}
 P(R_2) &= P(R_2 | S_2)P(S_2) + P(R_2 | S_3)P(S_2 | S_3)P(S_3) + \\
 &\quad P(R_2 | S_4)P(S_4 | S_3)P(S_3 | S_2)P(S_2) \\
 &= (1 - P(D_2))P(D_1) + (1 - P(D_3))P(D_2)P(D_1) + \\
 &\quad (1 - P(D_4))P(D_3)P(D_2)P(D_1) \\
 &= P(D_1)(1 - P(D_2)P(D_3)P(D_4)).
 \end{aligned} \tag{3}$$

Moreover, the probability of incision tear risk  $P(R_3)$  can be represented as follows:

$$\begin{aligned}
 P(R_3) &= P(R_3 | S_5)P(S_5) \\
 &= P(R_3 | S_5)P(D_4)P(D_3)P(D_2)P(D_1).
 \end{aligned} \tag{4}$$

According to the DAG of LC, three risks can lead to the risk of infection  $R_4$  and the risk of massive hemorrhage  $R_5$ . However, this conditional probability cannot be calculated by statistics. It can only be quantitatively judged based on the experience accumulated by doctors in completed cases. In order to get this judgement value, two sets of comparison matrices are given by doctors who are allowed to score 1–9. The numbers 3, 5, 7, and 9 correspond to the verbal judgments “moderately more dominant,” “strongly more dominant,” “very strongly more dominant,” and “extremely more dominant” (with 2, 4, 6, and 8 for compromise between the previous values). We are permitted to interpolate values between the integers, if desired, or use numbers from an actual ratio scale of measurement. This scale is mathematically derived from stimulus-response theory and has been extended through the use of structuring and decomposition to assume arbitrarily large values as necessary. Firstly, for risk  $R_4$ , we use pairwise comparison to research which risk  $R_1, R_2, R_3$  is more likely to cause  $R_4$ . After entering scores given by doctors into matrix, the contribution ratio of three kinds of risk  $R_1, R_2, R_3$  to  $R_4$  is obtained by calculating the eigenvector, and the contribution ratio of  $R_1, R_2, R_3$  can be represented as  $w_1, w_2, w_3$ :

$$\begin{array}{c} R_4 \\ \hline R_1 \ R_2 \ R_3 \end{array} \begin{pmatrix} R_{ij} \end{pmatrix} \rightarrow \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix}. \tag{5}$$

By the same token, the contribution ratio of  $R_1, R_2, R_3$  to  $R_5$  can be represented as  $w_4, w_5, w_6$ :

$$\begin{array}{c} R_5 \\ \hline R_1 \ R_2 \ R_3 \end{array} \begin{pmatrix} R_{ij} \end{pmatrix} \rightarrow \begin{pmatrix} w_4 \\ w_5 \\ w_6 \end{pmatrix}. \tag{6}$$

In addition, by comparing the risk of massive bleeding and the risk of infection leading to death, the weight of risk  $R_4, R_5$  can be obtained, which can be represented by  $C_0, C_1$ :

$$\begin{array}{c} R_6 \\ \hline R_4 \ R_5 \end{array} \begin{pmatrix} R_{ij} \end{pmatrix} \rightarrow \begin{pmatrix} C_0 \\ C_1 \end{pmatrix}. \tag{7}$$

Then, the final weight  $C_2, C_3, C_4$  of  $R_1, R_2, R_3$  can be obtained by the following formula:

$$C_2 = C_0 w_1 + C_1 w_4, \tag{8}$$

$$C_3 = C_0 w_2 + C_1 w_5, \tag{9}$$

$$C_4 = C_0 w_3 + C_1 w_6. \tag{10}$$

Based on the above formula, we can use  $P(D_1), P(D_2), P(D_3), P(D_4), P(D_5)$  to express the probability of death. According to the following formula, we

analyze the relations between each surgery step and death risk:

$$\begin{aligned}
P(R_6) &= C_0P(R_4) + C_1P(R_5) = C_2P(R_1) \\
&\quad + C_3P(R_2) + C_4P(R_3) \\
&= C_2(1 - P(D_1)) + C_3P(D_1)(1 - P(D_2)P(D_3)P(D_4)) \\
&\quad + C_4(1 - P(D_5))P(D_4)P(D_3)P(D_2)P(D_1) \\
&= C_2 + (C_3 - C_2)P(D_1) + (C_4 - C_3)P(D_1)P \\
&\quad \cdot (D_2)P(D_3)P(D_4) \\
&\quad - C_4P(D_1)P(D_2)P(D_3)P(D_4)P(D_5).
\end{aligned} \tag{11}$$

## 5. Application: Validating Our BN\_SC Model

To further illustrate the calculation process of proposed method, we implement the BN\_SC model to a hospital in Sichuan Province of China. According to the existing laparoscopic cholecystectomy records of surgical cases, the hospital counted 1166 cases in the past year. The statistical results demonstrate the success ratios of trocar puncture, separation of adhesion, anatomy of bile triangle, dissection of gallbladder bed, and removal and suture of gallbladder were 0.990, 0.970, 0.873, 0.830, and 0.821. The probability of intestinal injury is 0.010 according to formula (2), and the probability of bile duct injury and vascular injury is 0.294 and 0.125 according to formula (3).

In addition, information about death, infection, and massive bleeding involves the privacy of patients, so doctors can only judge the relationship between them based on experience instead of providing specific values. According to the method given in Section 3, we asked the attending physician of laparoscopic cholecystectomy operation to give the subjective evaluation as follows:

Three surgical risk comparison matrices for infection are described as follows:

$$\begin{array}{c|ccc}
R_4 & R_1 & R_2 & R_3 \\
\hline
R_1 & 1 & 1/6 & 1/4 \\
R_2 & 6 & 1 & 3 \\
R_3 & 4 & 1/3 & 1
\end{array} \tag{12}$$

By finding the eigenvector of the matrix, the weight is obtained:

$$\begin{pmatrix} w_1 = 0.09 \\ w_2 = 0.64 \\ w_3 = 0.27 \end{pmatrix}. \tag{13}$$

Three surgical risk comparison matrices for massive hemorrhage are described as follows:

$$\begin{array}{c|ccc}
R_5 & R_1 & R_2 & R_3 \\
\hline
R_1 & 1 & 3 & 1/5 \\
R_2 & 1/3 & 1 & 1/7 \\
R_3 & 5 & 7 & 1
\end{array} \tag{14}$$

By finding the eigenvector of the matrix, the weight is obtained:

$$\begin{pmatrix} w_4 = 0.19 \\ w_5 = 0.08 \\ w_6 = 0.73 \end{pmatrix}. \tag{15}$$

The surgical risk comparison matrices for death are described as follows:

$$\begin{array}{c|cc}
R_6 & R_4 & R_5 \\
\hline
R_4 & 1 & 1/2 \\
R_5 & 2 & 1
\end{array} \tag{16}$$

By finding the eigenvector of the matrix, the weight is obtained:

$$\begin{aligned}
C_0 &= 0.333, \\
C_1 &= 0.666.
\end{aligned} \tag{17}$$

We can obtain  $C_2, C_3, C_4$  by formulas (8)–(10):

$$\begin{aligned}
C_2 &= 0.157, \\
C_3 &= 0.267, \\
C_4 &= 0.576.
\end{aligned} \tag{18}$$

According to the analysis, the death risk of laparoscopic cholecystectomy surgery in a hospital in Sichuan can be obtained as follows:

$$\begin{aligned}
P(R_6) &= C_0P(R_4) + C_1P(R_5) = C_2P(R_1) + C_3P(R_2) + C_4P(R_3) \\
&= C_2 + (C_3 - C_2)P(D_1) + (C_4 - C_3)P(D_1)P \\
&\quad \cdot (D_2)P(D_3)P(D_4) \\
&\quad - C_4P(D_1)P(D_2)P(D_3)P(D_4)P(D_5) \\
&= 0.157 \times 0.010 + 0.267 \times 0.294 + 0.576 \times 0.125 \\
&= 0.152.
\end{aligned} \tag{19}$$

The BN\_SC model is more effective than the traditional Bayesian model in reducing the computations of the particular conditional probabilities, because some of the conditional probabilities can be replaced by the probabilities of ex-step.

Sensitivity analysis for the quantitative relationships between the success rates of each laparoscopic cholecystectomy surgery step and the probability of death are as follows from Figure 2 to Figure 11:

$$\begin{aligned}
P(R_6) &= 0.157 - 0.005P(D_1), \\
P(R_6) &= 0.266 - 0.117P(D_2), \\
P(R_6) &= 0.266 - 0.130P(D_3), \\
P(R_6) &= 0.266 - 0.137P(D_4), \\
P(R_6) &= 0.215 - 0.077P(D_5).
\end{aligned} \tag{20}$$

Through the above experimental results, it can be observed that the most effective way to reduce the risk of death is to improve the success rate of dissection of gallbladder, and the second is to improve the success rate of anatomical

FIGURE 2: Sensitivity analysis of  $D_1 - D_2$ .

FIGURE 10: Sensitivity analysis of  $D_3 - D_5$ .FIGURE 11: Sensitivity analysis of  $D_4 - D_5$ .

bile triangle. In addition, the least efficient way to reduce the risk of death is to improve the success rate of trocar puncture surgery. These conclusions have certain guiding significance for the improvement of laparoscopic surgery of a hospital in Sichuan.

## 6. Conclusion

As a crucial factor of running smart city, risk flow management need to calculate accurately. Our BN\_SC model modeled a special situation for risks flow in Bayesian net, which logical inference has to follow a strict chain. This is to describe surge process especially LC in this paper. The BN\_SC computed the probabilities of risks in LC by Bayesian inference follow the particular process. Our model is a special Bayesian model for the specific system, limiting to the structure of the process, but can reduce computations in the suitable situations by the formula we presented.

The application of the BN\_SC has proved its rationality and practicality. The method also has a way to combine the judgments and data of several hospitals to representative group judgments to deal with the weights of risks. Our model can be applied in other probabilities inference problems that have a strict chain to follow; for example, stock prices follow a timeline or story events follow a plotline.

With the rapid development of mobile Internet, the social network has become an important platform for users to receive, release, and disseminate information. In order to get more valuable information and implement effective supervision on public opinions, it is necessary to study the public opinions, sentiment tendency, and the evolution of the hot events in social networks of a smart city. In view of social networks' characteristics such as short text, rich topics, diverse sentiments, and timeliness, this paper conducts text modeling with words co-occurrence based on the topic model. Besides, the sentiment computing and the time factor are incorporated to construct the dynamic topic-sentiment mixture model (TSTS). Then, four hot events were randomly selected from the microblog as datasets to evaluate the TSTS model in terms of topic feature extraction, sentiment analysis, and time change. The results show that the TSTS model is better than the traditional models in topic extraction and sentiment analysis. Meanwhile, by fitting the time curve of hot events, the change rules of comments in the social network is obtained.

## 1. Introduction

With the wide application of the Internet technology, the Internet has gradually transformed to the dynamic platform for information sharing and interactive communication. The 43<sup>rd</sup> statistical report indicated that China had 854 million Internet users, and 99.1 percent of them access the Internet via mobile phones [1]. Social networks of a smart city have become the mainstream platform for information exchange and opinion expression. The users are not only the receivers of information, but also the creators to publish text comments in social networks. The hot events of public opinion refer that personal opinions are released on upcoming or already happened events by online communication tools and network platforms [2]. The spread of public opinion will snowball and expand by social networks, and emergent events may develop in an uncontrollable direction. Chain events caused by inadequate supervision on social networks can bring about the bad influence, and the frequency and

harmfulness have shown an obvious rising trend in recent years [3].

Previous research has been studied from the qualitative aspects, such as the evolution mechanism of public opinion, information element classification, and influence judgment. However, the above research cannot meet the needs of online public opinion supervision, and the monitoring and management of hot events in social networks of a smart city need to implement quantitative judgment. For public opinion monitoring and management, Steyvers and Griffiths [4] proposed a topic model for public opinion detection in the social network. Yeh et al. [5] proposed a conceptually dynamic latent Dirichlet allocation (CD-LDA) model for topic content detection and tracking. The studies on probabilistic topic models for extracting hot topics from long texts have achieved good results [6], but these models are not suited to extract hot topics from short texts, such as Twitter and Facebook [7]. Kim et al. [8] introduced the sentiment scoring based on topics through the n-gram LDA

topic modeling technology and investigated the topic reports and sentiment dynamics in news about Ebola virus. Subeno et al. [9] proposed a collapsed Gibbs sampling method based on the latent Dirichlet allocation (LDA) model widely used on Spark. Park et al. [10] used partially collapsed Gibbs sampling for latent Dirichlet allocation and proposed a reasoning LDA method, which effectively obtained unbiased estimation under flexible modeling of heterogeneous text corpus by partially collapsed and Dirichlet mixed processing.

However, there are still some problems in the detection of public opinion for events in social networks of a smart city. Firstly, the detection and analysis of public opinions for hot events in social networks mostly remain in the qualitative analysis or empirical research, lacking quantitative research. Secondly, there is a lack of public opinion analysis method combining with the characteristics of the microblog in social networks. Thirdly, for the sentiment analysis of public opinion events, most research adopts the two-stage method. That is to detect the event firstly and then conduct sentiment analysis and judgment, which is likely to lead to the separation between the event and sentiment. Fourthly, the dissemination for public opinions of hot events is time sensitive, so it is necessary to involve the time factor in comment text analysis. Thus, this paper proposes a mixed model with dynamic topic-sentiment (TSTS) for short texts in the social network, which comprehensively incorporates the topics, sentiment, and time factor of events to detect the public opinion. By quantitative analysis of real experiment data, the model can not only show the quantitative evolution trend of public opinion, but also provide the propagation rule of sudden events.

The main contributions of this paper are reflected in two aspects. Firstly, the TSTS model is proposed by extending the topic model, which can not only extract both topic and sentiment polarity words, but also integrate the time factor to realize dynamic analysis of short texts. Secondly, this paper studies the detection and evolution analysis of Internet public opinion by the dynamic topic-sentiment model. The real datasets are used to conduct experimental analysis of the proposed model, which can reflect the evolution trend of public opinion diffusion.

## 2. Related Research

*2.1. Research on Relevant Topic Models.* The traditional opinion mining is to analyze the sentiment orientations based on the level of document and sentence. The traditional topic model was mainly used to compare the similarity among articles by comparing the number of repeated words in different articles. Blei et al. [11] proposed the latent Dirichlet allocation (LDA) topic model to mine the hidden semantics of the text. LDA is a three-layer Bayesian model involving the document, topic, and word. The document is composed of a mixed distribution of topics, and each topic follows a polynomial distribution. And, Dirichlet distribution is introduced as the prior information of the polynomial distribution. The schematic diagram of the LDA topic model is shown in Figure 1.

FIGURE 1: Schematic diagram of the LDA model.

*2.1.1. Research on Topic Model of Short Text.* For most topic models, the topic is the word that appears in the document and has some connection. In previous studies, the topic model of short texts was expanded by introducing relevant background or author information, which weakened the topic and produced meaningless word contributions. Similarly, if co-occurrence words are extended to the whole corpus in the experiment, the occurrence frequency of each word will be greatly increased, and the connection between words will be closer. Then, the modeling on documents will be easier. Based on the above hypotheses, Cheng et al. [12] proposed the biterm topic model (BTM), which is another way to explain the relationship between words, and text modeling of documents can be conducted based on the word co-occurrence model of the whole corpus. Rashid et al. [13] proposed the fuzzy topic modeling (FTM) for short texts from the fuzzy perspective to solve the sparsity problem. Based on BTM, Lu et al. [14] introduced the RIBS-Bigrams model by learning the usage relationship, which showed topics with two-letter groups. Zhu et al. [15] proposed a joint model based on the latent Dirichlet allocation (LDA) and BTM, which not only alleviates the sparsity of the BTM algorithm in processing short texts, but also preserves topic information of the document through the extended LDA.

*2.1.2. Research on Mixed Model Integrating Topic Sentiment.* To evaluate the sentiment tendency of documents, the joint sentiment topic (JST) model added the sentiment layer based on the LDA model, forming a four-layer Bayesian network [16]. In this structure, the sentiment polarity label is related to the document, and the word generation is also influenced by both topic and sentiment. In the traditional LDA model, the generation of the document and words is determined by the topic. But in the JST model, the word of the document is determined by the topic and the sentiment. Amplayo et al. [17] proposed the aspect and sentiment unification model (ASUM) with sentiment level. The difference between JST and ASUM is that words in a sentence come from different topics in the JST model, while all words of a sentence belong to one topic in the ASUM model.

*2.1.3. Research on Topic Model with Time Factor.* Yao et al. [18] revealed the semantic change process of words by correlating the time factor with Wikipedia text knowledge. In terms of event evolution, the associative topic model (ATM) is proposed [19], and the recognized cluster is represented as the word distribution of the cluster with the corresponding event. In addition, Topic Over Time (TOT) was proposed to integrate the time factor into the LDA model [20]. In the TOT model, word co-occurrence can affect the discovery of subject words, and time information can also affect the extraction of topic words. Unlike other models, each topic is subject to a continuous distribution of time and not rely on Markov models to discretize time in the TOT model. For each document generation, the mixed distribution of topics is determined by word co-occurrence and timestamp [21], which allows the TOT model to maintain independence in the time dimension and can predict the time for the document without any time information.

*2.2. Gibbs Sampling.* The derivation of the experimental model in the paper is a variant form of the Markov Chain, so the Markov Chain Monte Carlo (MCMC) method is used for sampling in the experiment. Gibbs sampling, as one of the MCMC methods, has been widely used in prior research. Gibbs sampling is used to obtain a set of observations that approximate a specified multidimensional probability distribution, such as the probability distribution of two random variables.

The Gibbs sampling method used for the latent Dirichlet allocation (LDA) model can significantly improve the speed of the real-text corpus [22]. Papanikolaou et al. [23] estimated latent Dirichlet allocation (LDA) parameters from Gibbs sampling by using all conditional distributions of potential variable assignments to effectively average multiple samples. Zhou et al. [24] proposed two kinds of Gibbs sampling inference methods, such as Sparse BTM and ESparse BTM, to achieve BTM by weighing space and time. Bhuyan [25] proposed the correlation random effect model based on potential variables and an algorithm to estimate correlation parameters based on Gibbs sampling.

### 3. Model Constructing

*3.1. Topic-Sentiment Mixture Model with Time Factor (TSTS).* Based on prior research, this paper mainly improves the topic model from three aspects. Firstly, the sparse matrix caused by short texts in the social network is solved. Secondly, the topic and sentiment distribution of the same word pair are controlled. Thirdly, the problem of text homogeneity is solved by incorporating the time factor into the topic model. Therefore, the TSTS model proposed in this paper is used to constrain the word pairs in the same document, which greatly reduces the complexity of time and space and makes up for the sparse matrix of short texts to some extent. Moreover, the sentiment layer is integrated into TSTS by extending the hypotheses of ASUM and restrains word pairs generated by constraining sentences to follow the same

topic-sentiment distribution. Finally, the TSTS model incorporating the time factor does not rely on the Markov model to discretize time, and each topic is subject to the continuous temporal distribution. For each document generation, the mixed distribution of topics is determined by the words co-occurrence and timestamps. TSTS model is shown in Figure 2.

The TSTS model simulates the generating process of online comments. Generally, the online comments from users can be regarded as a document, which is short, pithy, and highly emotional. The word co-occurrence from BTM is the most effective solution for the short-text topic model. In addition, the TSTS model with the time layer can continuously sample users' evaluation of hot events, as well as the dynamic changes of users' sentiment. Therefore, the hypotheses of the TSTS model are proposed as follows:

- (i) The probability distribution of the time factor is not directly equal to the joint distribution of the topic and sentiment
- (ii) The topic-sentiment distribution of each document is independent [26]
- (iii) Similar topics of different sentiment polarity are not automatically categorized [27]

Combined with the probability graph of Bayesian's network, the TSTS model proposed in the paper has four characteristics. First, a word pair is used to replace a single word to carry out the sampling model. Second, each timestamp is related by topic and sentiment. Third, the extraction of thematic characteristic and sentiment words is for the whole corpus. Fourth, in the derivation process of the TSTS model, it is not necessary to correspond between thematic feature and affective polarity words. That is because every topic and sentiment have the corresponding polynomial word pair distribution. In addition, the text modeling process of the TSTS model also follows the assumption that there is a connection between the sentimental polarity words of the topic features, which also changes with the time factor. So, the documents used to train the model must have a specific timestamp, such as the publishing time of the microblog.

*3.2. Generation of a Text in TSTS Model.* In the TSTS model, we assumed that a corpus is composed of several texts. For instance, a microblog is a text containing two dimensions of topic and sentiment. Considering the effectiveness of public opinions and related parameters of the microblog text, word distribution is determined by the topic, sentiment, and time. So, TSTS is an unsupervised topic-sentiment mixed model. The generation process of the document is as follows:

- (1) Extract a polynomial distribution  $\theta_d$  on a topic from the Dirichlet prior distribution  $\alpha$ , that is,  $\theta_d \sim \text{Dir}(\alpha)$
- (2) Extract a polynomial distribution  $\psi_{z,l}$  at some point from the Dirichlet prior distribution  $\mu$ , that is,  $\psi_{z,l} \sim \text{Dir}(\mu)$

FIGURE 2: TSTS model.

- (3) Extract a polynomial distribution  $\pi_z$  in a sentiment from the Dirichlet prior distribution  $\gamma$ , that is,  $\pi_z \sim \text{Dir}(\gamma)$
- (4) For each document  $d$  and for each pair of words in the article  $b = (w_{i1}, w_{i2}), b \in B$ ,
  - (a) Choose a topic  $z_i \sim \theta_d z_i \sim \theta_d$
  - (b) Choose an emotional label  $l_i \sim \pi_{z_i}$
  - (c) Choose a pair of words  $b_i \sim \varphi_{z_i, l_i}$
  - (d) Choose a timestamp  $t_i \sim \psi_{z_i, l_i}$

As shown in Figure 2, word pairs in a document may belong to different timestamps in the text generation process of the TSTS topic model. In theory, all the content of an article such as words and topics should belong to the same timestamp. Also, the introduction of the time factor into the topic model will affect the topic homogeneity of an article. However, the default time factor of the TSTS model in the topic model will not affect the homogeneity of the text. So, it is assumed that the time factor in the paper has no weight. Based on the TOT and the group topic (GT) model, the superparameter  $\mu$  is introduced into TSTS to balance the interaction of time and words in document generation. The parameters' explanation of the TSTS model is shown in Table 1.

**3.3. Model Deduction.** According to the Bayesian network structure diagram of the TSTS model, the polynomial distribution  $\theta$  of the topic, the distribution  $\pi$  of sentiment with the topic, the correlation distribution  $\phi$  of word pairs with <topic, sentiment>, and the correlation distribution  $\psi$  of time with <topic, sentiment> can be calculated according to the superparameters  $\alpha, \beta, \gamma$ , and  $\mu$ . Then, Gibbs sampling is done that can ensure the convergence of the TSTS model under enough iteration times. And, each word in the document is assigned the topic and sentiment that are most suitable for the facts.

According to the principle of Bayesian independence, the joint probability of word pair, topic, sentimental polarity, and timestamp is given as follows:

$$p(\mathbf{b}, \mathbf{t}, \mathbf{l}, \mathbf{z} | \alpha, \beta, \gamma, \mu) = p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \beta) \cdot p(\mathbf{t} | \mathbf{l}, \mathbf{z}, \mu) \cdot p(\mathbf{l} | \mathbf{z}, \gamma) \cdot p(\mathbf{z} | \alpha), \quad (1)$$

TABLE 1: Explanation of parameters.

|             |   |
|-------------|---|
| $D$         | Number of documents   |
| $V$         | Vocabulary size   |
| $T$         | Number of topics  |
| $S$         | Number of sentiment polarity  |
| $H$         | Number of timestamps  |
| $M$         | Number of word pairs  |
| $B$         | Set of word pairs   |
| $B$         | Word pairs, $b = (w_{i1}, w_{i2})$  |
| $W$         | Word  |
| $T$         | Time  |
| $Z$         | Topic   |
| $L$         | Sentiment polarity label  |
| $\Theta$    | $[\theta_d]$ : polynomial distribution of topics  |
| $\Phi$      | $[\varphi_{z,l}]$ : $T \times S \times V$ matrix, word pairs' distribution                                  |
| $\Pi$       | $[\pi_z]$ : $T \times S$ matrix, sentiment distribution   |
| $\Psi$      | $[\psi_{z,t}]$ : $T \times S \times H$ matrix, time distribution  |
| $\alpha$    | Dirichlet prior parameters of $\Theta$  |
| $\gamma$    | Dirichlet prior parameters of $\pi$   |
| $\beta$     | Asymmetric Dirichlet prior parameters of $\Phi$   |
| $\mu$       | Dirichlet prior parameters of $\psi$  |
| $n_d$       | The number of word pairs in document $d$  |
| $n_{d,j}$   | The number of word pairs for topic $j$ in document $d$  |
| $n_j$       | The number of word pairs assigned as topic $j$  |
| $n_{j,k}$   | The number of word pairs assigned as topic $j$ and sentiment polarity $k$                                   |
| $n_{i,j,k}$ | The number of word pair $b_i$ is assigned to the topic $j$ and sentiment polarity $k$                       |
| $n_{j,k,h}$ | The number of word pair $b_i$ is assigned to the topic $j$ and sentiment polarity $k$ when timestamp is $h$ |
| $n^{-p}$    | The number of word pairs in the current document except for the $p$ position                                |

where the parameters are independent such as word pairs  $\mathbf{b}$  and parameters  $\alpha, \gamma$ , and  $\mu$ , timestamps  $\mathbf{t}$  and parameters  $\alpha, \gamma$ , and  $\beta$ , sentiment polarity  $\mathbf{l}$  and parameters  $\alpha, \mu$ , and  $\beta$ , and topic words  $\mathbf{z}$  and parameters  $\beta, \gamma$ , and  $\mu$ . Therefore, the joint distribution in the equation can be obtained by calculating the four parts on the right side of the equation.

Given the sentiment polarity label of specific topic features, the distribution of  $\mathbf{b}$  can be regarded as a polynomial distribution. Based on the premise of topic words  $z_i$  and  $l_i$ ,  $b_i$  is generated by  $N$  times with the probability  $p(\mathbf{b} | \mathbf{l}, \mathbf{z})$  at each time. Given that word pairs are independent of each other, we can obtain

$$p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \beta) = \prod_{i=1}^N p(b_i | z_i, l_i) = \prod_{i=1}^N \beta \cdot b_i. \quad (2)$$

Superparameters are the representation parameters of the framework in the machine learning model [28], such as the number of classes in the clustering method or the number of topics in the topic model. In the Bayesian network, the distribution and density function of  $\theta$  are denoted as  $H(\theta)$  and  $h(\theta)$ , respectively. They are regarded as the prior distribution function and the prior density function, respectively, which are collectively referred to as the prior distribution. If the distribution of  $\theta$  is obtained after sampling, it is called the posterior distribution. Based on the conjugate property of Dirichlet~multinomial, when the

parameters in the population distribution conform to the distribution law of polynomial (Multinomial), the conjugate prior distribution conforms to the following distribution:

$$\text{Dir}(\boldsymbol{\theta} | \boldsymbol{\alpha}) + \text{Mult}(\boldsymbol{\delta}) = \text{Dir}(\boldsymbol{\theta} | \boldsymbol{\alpha} + \boldsymbol{\delta}). \quad (3)$$

For the general text model, the discretized Dirichlet distribution and multinomial distribution are as follows:

$$\text{Dir}(\mathbf{b} | \boldsymbol{\beta}) = \frac{\Gamma(\sum_{j=1}^T \boldsymbol{\beta})}{\prod_{j=1}^T \Gamma(\boldsymbol{\beta})} \prod_{j=1}^T n_j, \quad (4)$$

$$\text{Mult}(n | \mathbf{b}, N) = \binom{N}{n} \prod_{j=1}^T n_j, \quad (5)$$

where  $i, j, k$ , and  $h$  represent the iteration times of word pairs, topic, sentiment, and timestamp in the modeling process, respectively. Since the distribution of  $p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \boldsymbol{\beta})$  follows the Dirichlet distribution, this paper introduces  $\varphi$  for  $p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \boldsymbol{\beta})$ . It can be obtained by integrating  $\varphi$ :

$$\begin{aligned} p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \boldsymbol{\beta}) &= \int p(\mathbf{b} | \mathbf{l}, \mathbf{z}, \varphi) \cdot p(\varphi | \boldsymbol{\beta}) d\varphi \\ &= \left( \frac{\Gamma(V\boldsymbol{\beta})}{\Gamma(\boldsymbol{\beta})^V} \right)^{T \cdot S} \prod_j \prod_k \frac{\prod_i \Gamma(n_{i,j,k} + \boldsymbol{\beta})}{\Gamma(n_{j,k} + V\boldsymbol{\beta})}. \end{aligned} \quad (6)$$

To estimate the posterior parameters  $\varphi$  in the formula, we can combine with the Bayes formula and the conjugate property of Dirichlet~multinomial. The distribution of the posterior parameters can be obtained as follows:

$$p((\varphi | \mathbf{l}, \mathbf{z}, \boldsymbol{\beta})) \propto \text{Dir}(\varphi | n_{i,j,k} + \boldsymbol{\beta}). \quad (7)$$

Given that the expectation of the Dirichlet distribution is  $E(\text{Dir}(\boldsymbol{\varepsilon})) = \boldsymbol{\varepsilon}_i / \sum_j \boldsymbol{\varepsilon}_j$ , so the calculated parameters are estimated by the known posterior parameter distribution expectation. The estimated results are shown in equation (7). Similarly, for  $p(\mathbf{t} | \mathbf{l}, \mathbf{z}, \boldsymbol{\mu})$ ,  $\psi$  is introduced. By integrating  $\psi$ , it can be obtained as follows:

$$p(\mathbf{t} | \mathbf{l}, \mathbf{z}, \boldsymbol{\mu}) = \left( \frac{\Gamma(H\boldsymbol{\mu})}{\Gamma(\boldsymbol{\mu})^H} \right)^{T \cdot S} \prod_j \prod_k \frac{\prod_h \Gamma(n_{j,k,h} + \boldsymbol{\mu})}{\Gamma(n_{j,k} + H\boldsymbol{\mu})}. \quad (8)$$

For  $p(\mathbf{l} | \mathbf{z}, \boldsymbol{\gamma})$ ,  $\pi$  is introduced. By integrating  $\pi$ , it can be obtained as follows:

$$p(\mathbf{l} | \mathbf{z}, \boldsymbol{\gamma}) = \left( \frac{\Gamma(\sum_k \boldsymbol{\gamma}_k)}{\prod_k \Gamma(\boldsymbol{\gamma}_k)} \right)^T \prod_j \frac{\prod_k \Gamma(n_{j,k} + \boldsymbol{\gamma}_k)}{\Gamma(n_j + \sum_k \boldsymbol{\alpha}_k)}. \quad (9)$$

For  $p(\mathbf{z} | \boldsymbol{\alpha})$ ,  $\theta$  is introduced. By integrating  $\theta$ , it can be obtained as follows:

$$p(\mathbf{z} | \boldsymbol{\alpha}) = \left( \frac{\Gamma(\sum_j \boldsymbol{\alpha}_j)}{\prod_j \Gamma(\boldsymbol{\alpha}_j)} \right)^D \prod_d \frac{\prod_j \Gamma(n_{d,j} + \boldsymbol{\alpha}_j)}{\Gamma(n_d + \sum_j \boldsymbol{\alpha}_j)}. \quad (10)$$

The TSTS model can estimate the posterior distribution after estimated values  $z$  and  $s$  have been obtained by sampling calculations. Then, the calculated equations (2)–(6) are

brought into equation (1). Combining with the nature of Gamma function, the conditional distribution probability in Gibbs sampling can be obtained:

$$\begin{aligned} p(s_p = k, z_p = j | \mathbf{b}, \mathbf{t}, \Gamma^{-P}, \mathbf{z}^{-P}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma}, \boldsymbol{\mu}) \\ \propto \frac{n_{d,j}^{-P} + \boldsymbol{\alpha}_j}{n_d^{-P} + \sum_j \boldsymbol{\alpha}_j} \cdot \frac{n_{w_p,j,k}^{-P} + \boldsymbol{\beta}}{n_{j,k}^{-P} + V\boldsymbol{\beta}} \cdot \frac{n_{j,k}^{-P} + \boldsymbol{\gamma}_k}{n_j^{-P} + \sum_k \boldsymbol{\gamma}_k} \cdot \frac{n_{j,k,t_p}^{-P} + \boldsymbol{\mu}}{n_{j,k}^{-P} + H\boldsymbol{\mu}}. \end{aligned} \quad (11)$$

In order to simplify equation (6), the superparameter  $\mu = 1/n_d$  is introduced. When the superparameters  $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\mu}$ , and  $\boldsymbol{\gamma}$  are given, the set B of the word pair, the corresponding topic  $z$ , and sentiment label  $l$  can be used to infer the parameters  $\varphi, \theta, \pi$ , and  $\psi$  based on Bayes' rule and Dirichlet conjugate properties:

$$\begin{aligned} \varphi_{j,k,i} &= \frac{n_{i,j,k} + \boldsymbol{\beta}}{n_{j,k} + V\boldsymbol{\beta}}, \\ \theta_{d,j} &= \frac{n_{d,j} + \boldsymbol{\alpha}_j}{n_d + \sum_j \boldsymbol{\alpha}_j}, \\ \pi_{j,k} &= \frac{n_{j,k} + \boldsymbol{\gamma}_k}{n_j + \sum_k \boldsymbol{\gamma}_k}, \\ \psi_{j,k,h} &= \frac{n_{j,k,h} + \boldsymbol{\mu}}{n_{j,k} + H\boldsymbol{\mu}}. \end{aligned} \quad (12)$$

## 4. Experiment Analysis

**4.1. Data Collection.** In order to verify the TSTS model proposed in this paper, the four hot events are randomly selected from the trending searches of Sina Weibo in 2019. And, the comments of four events are regarded as the experimental datasets. The four datasets selected are "Military parade in National Day," "The assault on a doctor," "Hong Kong's event," and "Garbage sorting in Shanghai." The comments are extracted from the Sina social network platform. In the original datasets, there are some meaningless words in the microblog text, such as stop words, interjections in tone, punctuation marks, and numeric expressions. Before text modeling, the word segmentation package in Python is used to process the experimental initial dataset. In addition, considering that comments on social networks are relatively new, the fashionable expressions in the social network are collected and added to the customized dictionary. So, these emerging words can be identified as far as possible and replaced with normal expressions. In addition, there are some useless words in the text, such as URL links and numbers, which can be filtered by regular expressions. Finally, a total of 14288 experimental data in four events are obtained. The description of four datasets is shown in Table 2.

**4.2. Sentiment Dictionary.** The words or phrases in the sentiment dictionary have obvious sentiment tendency,

TABLE 2: Experiment datasets.

| The dataset (the number of comments) | Number of words in per microblog |              | Vocabulary size |              |
|--------------------------------------|----------------------------------|--------------|-----------------|--------------|
|                                      | Initial                          | Pretreatment | Initial         | Pretreatment |
| The dataset 1 (3562)                 | 134                              | 102          | 9789            | 6319         |
| The dataset 2 (3527)                 | 127                              | 94           | 9736            | 6242         |
| The dataset 3 (3617)                 | 131                              | 100          | 9780            | 6301         |
| The dataset 4 (3582)                 | 128                              | 96           | 9742            | 6254         |
| Average                              | 130                              | 98           | 9762            | 6279         |

which can be divided into positive and negative words. The sentiment dictionary in this paper has two major roles. On the one hand, we can identify sentiment polarity words and distinguish topic features and sentiment words. On the other hand, combining with sentiment prior information to make the model more accurate in judging the sentiment polarity of the text. Given that sentiment polarity words can reflect users' sentiment tendency, it is of great significance to analyze the sentiment orientation of the text.

At present, there are two major Chinese sentiment dictionaries: NTU and HowNet. The former dictionary contains 2812 positive words and 8276 negative words. The latter contains about 5,000 positive words and 5,000 negative words. Based on HowNet and the classification of sentiment polarity [29, 30], this paper constitutes the sentiment dictionary of the TSTS model evaluation experiment, as shown in Table 3.

**4.3. Parameter Setting.** In this paper, the Gibbs algorithm is used to sample the TSTS model and estimate four posterior parameters. According to the parameter setting in the traditional topic model, the superparameters are set as follows. First, the superparameter  $\alpha$  is set as  $50/K$ , and  $K$  is the number of topics extracted. Second,  $\beta$  is set as 0.01. Third,  $\gamma$  is set as  $(0.05 \times \text{AVE})/S$ . AVE stands for the average length of articles, that is, the average number of words in the microblog in this experiment, and  $S$  stands for the total number of polar tags. Finally,  $\mu$  is set as  $1/n_d$ .

**4.4. Evaluation Indicator.** For the extraction of topic features, perplexity is used as an evaluation indicator to measure the predictive power of unknown data in the process of model modeling. Also, the lower perplexity means better efficiency. The calculation formula of the perplexity is as follows:

$$\text{perplexity} = P(\bar{D}_t | \mathcal{M}) = \exp \left\{ -\frac{\sum_{d=1}^{D^t} \log P(\bar{b}_d^t | \mathcal{M})}{\sum_{d=1}^{D^t} \bar{N}_d^t} \right\}, \quad (13)$$

where  $\bar{D}_t = \left\{ \bar{b}_d^t \right\}_{d=1}^{D^t}$  represents an unknown dataset with the timestamp  $t$ .

$$P(\bar{b}_d^t | \mathcal{M}) = \prod_{n=1}^{\bar{N}_d^t} \prod_{l=1}^L \prod_{i=1}^T P(\bar{b}_{d,n} | l, z) P(z | l) P(l), \quad (14)$$

TABLE 3: Classification of sentiment words.

| Sentiment labels | Happy | Surprise | Sad  | Angry |
|------------------|-------|----------|------|-------|
| Vocabulary size  | 2467  | 276      | 3025 | 1897  |

where  $\bar{b}_d^t$  represents the vector set of word pairs in text  $d$ ,  $\bar{N}_d^t$  represents the number of word pairs in  $\bar{b}_d^t$ , and  $P(\bar{b}_d^t | \mathcal{M})$  represents the direct possibility of training corpus, and the formula is as follows:

$$P(\bar{b}_d^t | \mathcal{M}) = \prod_{i=1}^V \left( \sum_{l=1}^L \sum_{z=1}^T \varphi_{l,z,i} \cdot \theta_{d,l,z} \cdot \pi_{d,l} \right)^{\bar{N}_{di}^t}. \quad (15)$$

For sentiment segmentation, the sentiment judgment from the perspective of the document is used as the evaluation index, which is based on the sentiment polarity label in the sentiment dictionary. For the documents in this experiment, the positive and negative sentiment of a document can be judged. This paper adopts the consistency test method to mark the sentiment labels [31].

## 5. Results

**5.1. Extraction of Topics.** The primary task of the TSTS model is to extract topic features. As an extension of the topic-sentiment mixed model, the assessment is to judge whether the extracted topic features are reasonable and accurate. Before extracting topic features from text modeling, it is necessary to determine the number of topics to be extracted and the iteration times of Gibbs sampling. For the effective evaluation of topic discovery, the degree of perplexity is used as the measurement index in the paper. The lower the perplexity is, the better the fitting effect of the model is. Taking dataset 1 as an example, the simulation results are shown in Figure 3.

Based on the experimental results shown in Figure 3, the number of topics was set 20 in the subsequent experiments. In addition, we can calculate the perplexity of three models with the change of the iterations. By comparing the experimental results of TSTS and LDA, it can be found that the effect of TSTS is always better than LDA, and the degree of perplexity decreases with the increase of iteration. That indicates that the topic discovery ability of TSTS gradually improves, mainly because the TSTS model incorporates the word pairs to alleviate the sparse matrix of LDA for short texts. By comparing the experimental results of TSTS and BTM, it can be found that TSTS was better than BTM when the number of iterations increases. However, as the number

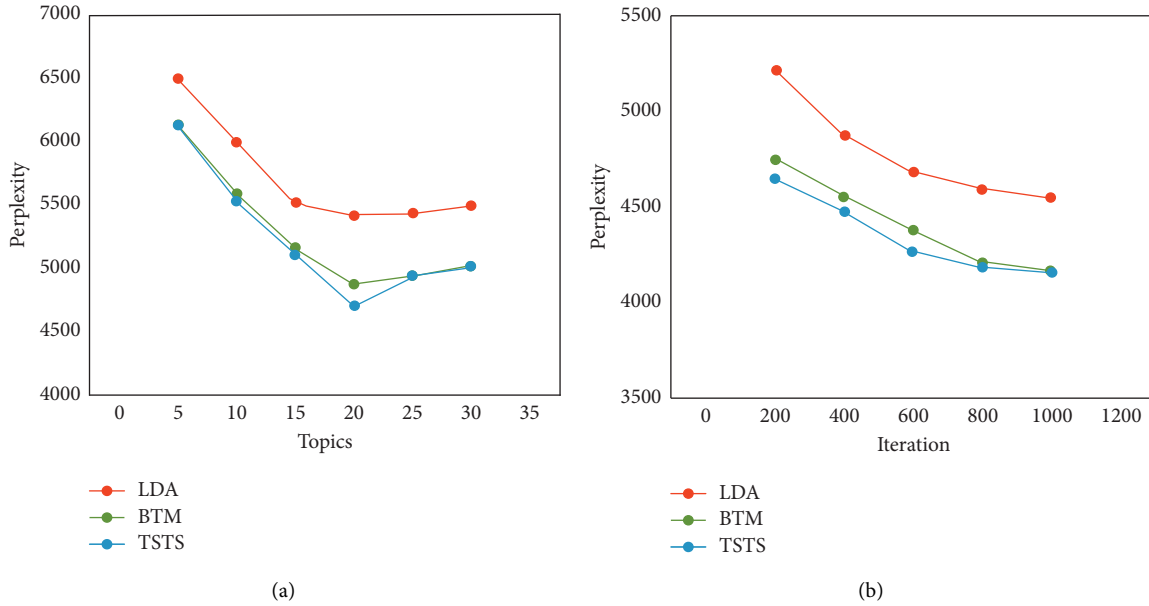

FIGURE 3: The relationship of the perplexity with the number of (a) topics and (b) iterations.

of iterations increased, the gap of both models became smaller. This is because the word pair of BTM is used for the whole corpus. When the number of iterations is small, the proportion of noise words is relatively large, resulting in poor quality of topic words. In addition, the sentiment layer is integrated into TSTS, and the error generated in the sentiment estimation will affect the next iteration. Although TSTS is worse than BTM when there are more iterations, the effect of TSTS can still be balanced with BTM. Therefore, during the extraction of topic features, the number of topics and iterations can be set as 20 and 600.

**5.2. Sentiment Polarity.** The information related to sentiment polarity is provided in accordance with the topic and sentiment polarity of words. The sentiment distribution of topics extracted from the TSTS model is shown in Figure 4. In addition, JST and ASUM are introduced as the comparison to measure the effect of sentiment recognition of the TSTS model. Each document has a binary sentiment label, such as positive or negative sentiment. Taking dataset 2 “The attack on the doctor” as an example, the result is shown in Figure 4. The number of topics is set to 5 at the beginning of the experiment. With the refinement of granularity, the performance of the TSTS model increases. Compared with JST and ASUM, the curve of the TSTS model changes greatly considering the topic and sentiment relationship among word pairs of the document. The change curve of the JST model shows a steady upward trend, and the identification efficiency of ASUM is low. That is because ASUM has strict assumptions, and the increase in the number of topics will cause the decentralization of topics and sentiments, which has a great negative impact on the overall performance of the model. The overall effect of the TSTS model was slightly better than JST and ASUM, but the effect decreased slightly after the number of topics increased to 20. This is because the

FIGURE 4: Accuracy of sentiment polarity judgment.

data collected in the dataset are limited, and the number of topics has been set to discretize the word distribution. Thus, the judgment of sentiment polarity is affected. The sentiment label classification of documents is compared under different topics, and the result of the TSTS model is better than JST and ASUM.

With the increase of topics, the recognition performance of the topic model has some fluctuations. But, the TSTS model was always better than JST and ASUM. When the number of obtained topics and iterations is set as 20 and 600, the TSTS is the best model in topic detection. When the number of topics in the four datasets was set as 20, the accuracy of sentiment polarity judgment is shown in Table 4.

From Table 4, the TSTS model is better than JST and ASUM in judging the sentiment polarity of documents. This

TABLE 4: Accuracy of sentiment polarity judgment.

|               | ASUM   | JST    | TSTS   |
|---------------|--------|--------|--------|
| The dataset 1 | 0.4763 | 0.5427 | 0.6348 |
| The dataset 2 | 0.4617 | 0.5398 | 0.6599 |
| The dataset 3 | 0.4832 | 0.5461 | 0.6475 |
| The dataset 4 | 0.4841 | 0.5294 | 0.6522 |

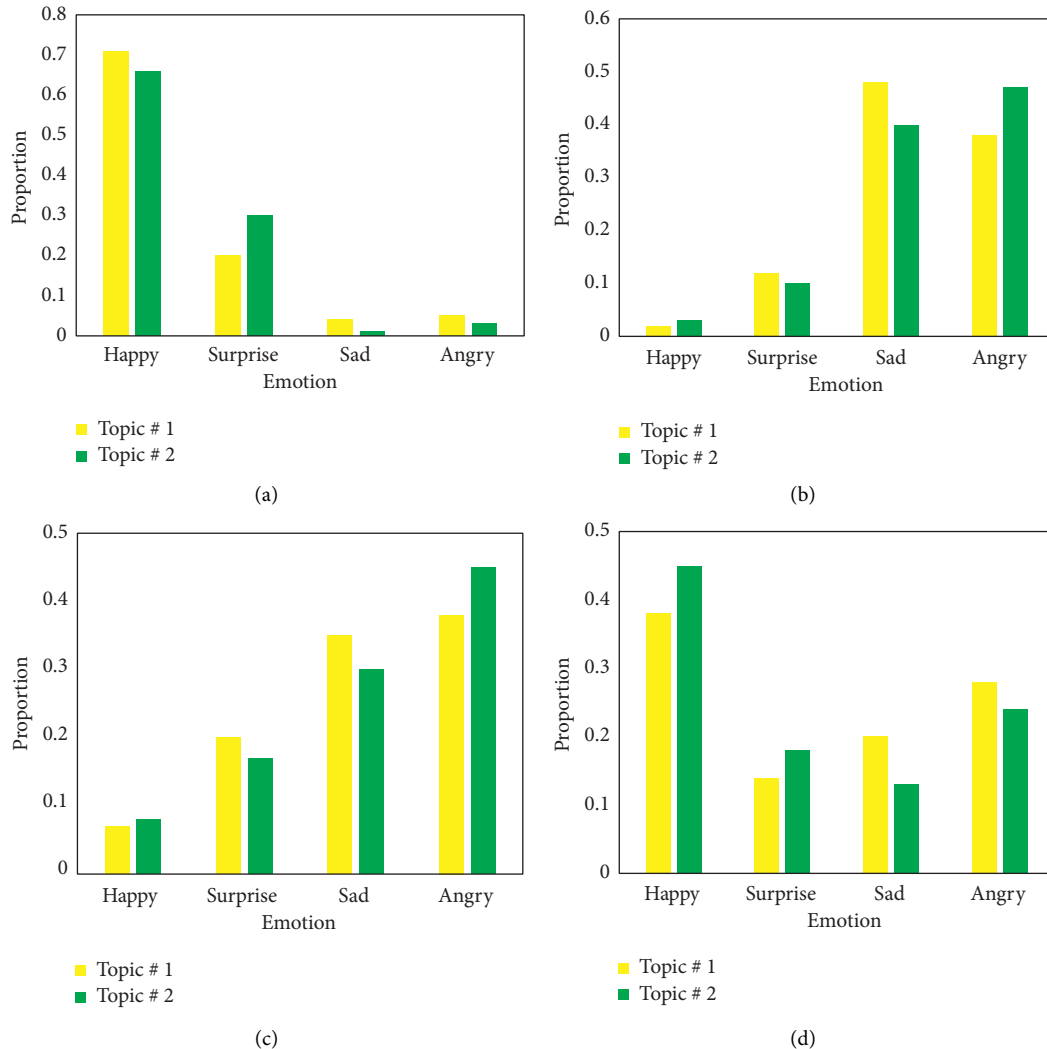

FIGURE 5: Sentiment distribution in four datasets. (a) Military parade in National Day. (b) The assault on a doctor. (c) Hong Kong’s event. (d) Garbage sorting in Shanghai.

is because sentiment polarity depends on the performance of topic discovery in the previous stage. In this experiment, the effect of JST and ASUM was exactly opposite. The difference was caused by the length of the original document, which also indirectly verified the effectiveness of the TSTS model.

From Figure 5, it can be seen that the proportion of positive sentiment is significantly higher than the other sentiments in the dataset “Military parade in National Day” and the dataset “Garbage sorting in Shanghai,” which is consistent with the sentiment tendency of users in the social network. For the second dataset “The assault on a doctor,” the two kinds of negative sentiment polarities of topic #1 and

topic #2 were compared. Topic #1 is more likely to be sad sentiment, while topic #2 is more likely to be angry sentiment. Topic #1 reflects the statement of the event, and topic #2 represents the follow-up discussion of the event.

5.3. *Topic and Sentiment Evolution.* The curves of topic features extracted from four datasets through the TSTS model are shown in Figure 6. Taking dataset 2 as an example, the topic curve conforms to the evolution law of social and abrupt events. The two curves represent the trend of feature words over time in topic #1 and topic #2. Topic #1 is the

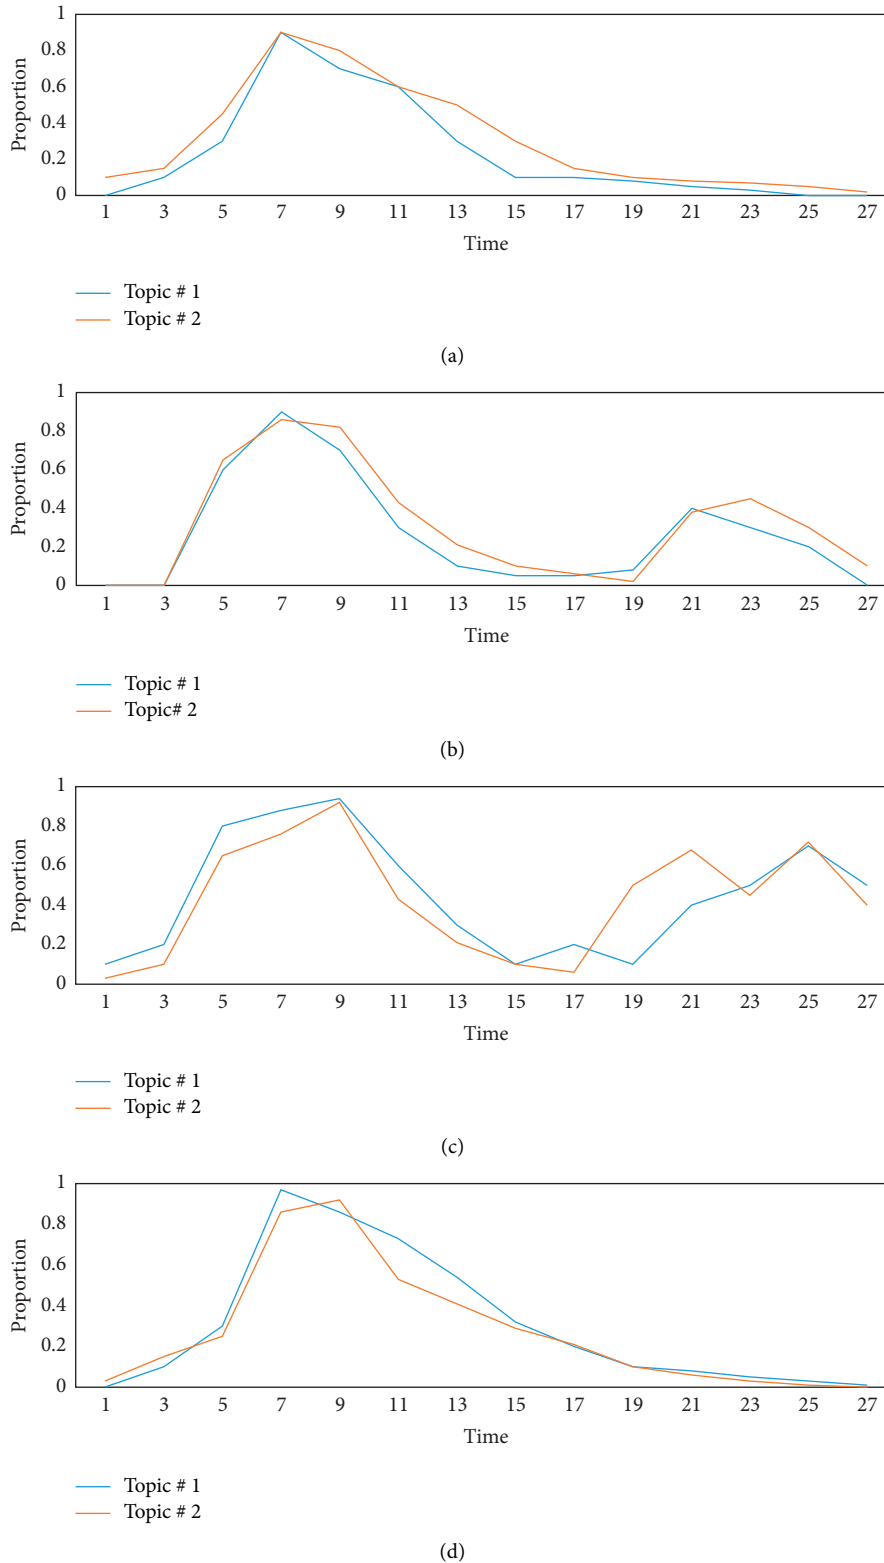

FIGURE 6: The changing of topics in four datasets. (a) Military parade in National Day. (b) The assault on a doctor. (c) Hong Kong's event. (d) Garbage sorting in Shanghai.

statement about the case itself. From the beginning of the event, the amount of discussion about the event on the social network rose sharply and then gradually declined. Topic #2

is a discussion on the development of the case, which has caused the second hot discussion again. The time is not consistent when two curves reach the high peak. The peak

FIGURE 7: Continued.

FIGURE 7: The changing of sentiment in four datasets. (a) Military parade in National Day topic #1. (b) Military parade in National Day topic #2. (c) The assault on a doctor topic #1. (d) The assault on a doctor topic #2. (e) Hong Kong’s event topic #1. (f) Hong Kong’s event topic #2. (g) Garbage sorting in Shanghai topic #1. (h) Garbage sorting in Shanghai topic #2.

value of topic #2 curve is lower than that of topic #1, which reflects the discussion of the same event will fade over time. Even if there is a new topic, discussion of a new topic is far lower than the beginning of the event. Meanwhile, similar results can be verified in other three datasets.

The proportion of the sentiment polarity in the four datasets is shown in Figure 7. Since the sentiment polarity proportion is measured, the four sentiment polarities are balanced distributed before the occurrence of the events. After the event occurred, the polarity of positive and negative sentiment began to change toward the two extremes. Among the four datasets, the positive sentiment was higher than the negative sentiment in the first dataset “National Day military parade event” and the fourth dataset “Shanghai garbage classification event,” which also conforms to the social sentiment of events. In addition, it can be found that the difference among the four sentiment labels is large in the initial stage, and the distribution of sentiment labels becomes stable in the later stage. It has proved that the second report of social events does not cause the heat for the first time. But, the sentiment tendency judgment in social networks will not decline sharply with the reduction of discussion, which can be proved in topic #2 of the second dataset “The assault on a doctor.” Given that the topic features come from the background of a corpus and contain a lot of noise words, the relative position of four curves is closer in terms of sentiment polarity evolution. However, there is still a gap between government feelings, which is different from the average distribution of sentiment polarity at the beginning of the event.

## 6. Discussion

From the perspective of theoretical significance, this paper extends the LDA model to some extent. First, in view of the sparse matrix caused by the short text, word pairs are introduced to replace a single word for text generation according to BTM. Based on the hypotheses of JST and

ASUM, the sentiment layer is introduced to form the Bayesian network structure, and the word pair is limited to the same sentiment polarity distribution. Second, in order to realize dynamic analysis and text homogeneity, the timestamp and the corresponding superparameter are introduced to alleviate the problem of the word order in the text generation. Third, this research combines behavioral experiments, big data mining, mathematical modeling, and imitating to promote the research expansion of new situations and new methods.

From the perspective of practical significance, this paper is of great value in tracking and monitoring topics of public opinion in social networks. The online public opinions of hot events can be monitored, which contributes to accurately judge social events and make emergency decisions for government or departments. In addition, this paper analyzed the evolution, response, and governance of public opinion, which is conducive to understand the formation mechanism and the collaborative evolution of public opinion. Meanwhile, the use of public opinion information can detect and screen information, prevent the spread of rumor, and scientifically formulate the mechanism of utilization to effectively reduce the loss risk.

## 7. Conclusions

In the context of the mobile social network, the number of short texts is growing explosively. In order to extract information from massive short texts quickly and monitor public opinions, the TSTS model is proposed in the study based on LDA, BTM, JST, ASUM, and TOT. From the experimental results, the TSTS model achieves good performance. In terms of topic feature extraction, the degree of perplexity of TSTS is always lower than LDA. Moreover, although the degree of perplexity is slightly higher than BTM with the increase of iteration times, it can maintain the balance with BTM. In the sentiment analysis, the effect of TSTS was significantly better than JST and ASUM. Finally,

the TSTS model incorporating the time factor can determine the change trend of the topic and sentiment.

There are still some shortcomings in this paper. Firstly, for the extraction of topic feature words, the global topic level can be added to the topic layer of the TSTS model to filter the common topic words. Secondly, in sentiment polarity judgment, the sentiment labels are manually marked based on prior knowledge. However, the sentiments are extremely rich and changeable. In the future research, the Bayesian network and entity theory can be used to judge sentiment bias.

Service robots have been introduced to hotel industry in the past decade and received various feedback on their performance. To provide better service, one needs to understand how the hotel customers look at the service robots. Understanding their interests, motivation, and behaviors in human-robot interaction is the key to develop high-quality services and improve robot's performance. This is the first work to study human-robot interaction in hotels in China. Frequent pattern mining and social network analysis techniques are used in this work to find out useful suggestions to both hotel management and robot manufactory. Turning on and off lights, TV, curtain, and window screens are popular services that most of the hotel customers preferred during their stays. Service robots are also found to entertain customers to carry out repeated commands for fun or to kill time. Customers also showed various motivations to stay in hotel rooms by calling different commands.

## 1. Introduction

Rapid development of IT and AI makes it possible to have intelligent robots in people's daily life. In terms of functionality, robots could be classified as industry robots and service robots [1]. By a close look at the service robots, a further categorization can be applied for professional use or for personal/private use [2]. Service robots for professional use are designed to accomplish a particular task or serve a target group of users. For example, professional service robots include cleaning robots, sewer robots, inspection robots, demolition robots, underwater robots, robots in medical institutions, robots with disabilities such as auxiliary robots and wheelchair robots, delivery robots, guidance robots, gas station robots, firefighting robots and air defense robots, construction robots, agricultural robots, etc. Service robots for personal and private use include domestic (home) robots, entertainment robots, educational robots, and so on. These service robots have been developed to assist human beings to finish daily tasks [3]. Both service robots are designed to assist and interact with human beings to complete tasks.

Current research focuses on the design, application, and evaluation of service robots. In terms of design, how do designers design robots, robot interactions, and experiences based on customer needs and preferences? They can weaken or strengthen customers' perception of value, leading to positive or negative word of mouth [4]. Ivanov and Webster [5] focus on the design of friendly hospitality robots. Korea Institute of Science and Technology (KIST) designed elderly robot [6]. Lakshmi et al. [7] designed a hospital nursing drug delivery robot. In terms of applications, unlike industrial robots, the accuracy or speed of service robots is not always the most important aspect. Their function or purpose is not only for entertainment but also to provide help, guidance, treatment, education, and communication [3]. In terms of evaluation, Ivanov et al. [8] used a questionnaire to explore how Iranians view the hotel robots, especially what Iranian consumers think robots can do for them and what they want robots to do. Ivanov et al. [8] investigated the attitude of young Russians towards introducing robots in hotels. Tussiyadiah and Park [9] focused on customer evaluation of hotel service robots. There is still a lack of understanding of the content and effects of robot services, which is why the paper is written. The existing studies have not explored

much in the service content of the hotel robots or effectiveness of the human-robot interaction.

Human-robot Interaction was distinguished by Thrun [10] into two categories: direct and indirect interactions. Direct interaction assumes a type of two-way communication, which shows equal status between humans and robots. Indirect interaction assumes a type of one-way communication, where the robot acts according to the users' command and reacts to its users. This work focuses on indirect interaction with remote-control robots. The remote-control robot is controlled by a human from a distance (near or far), and the human can control the robot through a joystick or instruction [11].

This work aims to study the actual services requested by human to be implemented by hotel robots by analyzing historical data collected from the real hotel rooms equipped with service robots from 2017 to 2018. This work tried to answer questions such as (1) what are the most popular services the users requested from the hotel robots, (2) what are the motivations for humans to interact with hotel robots, and (3) how often do users give commands to hotel robots. Furthermore, the responsiveness of the hotel robots to the commands received is another interesting topic in this work.

The rest of the paper is organized as follows: Section 2 reviews the current research work on service robots in hotel industry and customer feedback on their performance; Section 3 introduces the data resource and collection process followed by the details of selected data analysis methods; the interesting user command patterns as the experimental results are presented and discussed in Section 4; Section 5 concludes the entire work together with limitation and possible future work.

## 2. Literature Review

To conduct the study of human-robot interactions, the related literature has been carefully reviewed to have a comprehensive understanding of the current work of service robot applications in relevant industry, especially in hotel industry, and the technology level and the performance of the current hotel service robots in real world.

*2.1. Robot Applications in Service Industry.* Service robots are designed to support and service humans through physical and social interactions [12]. For frontline service robots, Martins [13] defined them as follows: a service robot is a system-based autonomous and adaptive interface to communicate and provide services to customers. Service robots play different roles, such as pets, companions, secretaries (or subordinates), and bystanders, just like the relationship with humans [14, 15]. Service robots can significantly reduce labor costs, and they are more like "tools" of technology and employees than their replacements [16]. Martins [13] considered the following three attributes related to service design: representation, personification, and task orientation. The service robot can have a physical representation (such as Pepper) or only a virtual representation (such as Alexa). Therefore, we believe that virtual AI software that can run

autonomously and learn over time can also be classified as a service robot. The service robot can be designed as a humanoid robot (such as anthropomorphic robot) that simulates the appearance of a human (such as Sophia) or it can be designed as a nonhumanoid robot (such as a cleaning robot). Finally, service robots can perform cognitive analysis tasks according to basic computer functions (such as image analysis software assistants for medical diagnosis) or emotional social tasks (such as receiving robots).

Robots are widely used in the service industry. In terms of home education, South Korea has developed the world's first available e-learning home robot and demonstrated the future of robots as a new educational medium. The survey found that home robots are superior in promotion and application and are more able to focus students' attention and interests and improve their academic performance [17]. Ju et al. [18] designed an educational robot platform for the needs of robot education for elementary and middle school students. In terms of senior care, van Osch et al. [11] developed a home care robot called Rose, which is controlled from a long distance (8 km) to perform small tasks for the elderly. The Korea Institute of Science and Technology (KIST) has launched a new project to develop an elderly service robot named T-Rot at the Intelligent Robot Center [6]. Lee and Naguib [19] introduced the design and implementation of the next-generation elderly care robot "Home Mate" based on innovative commitment to sociality and reliability and extensive user research, which can be used for infotainment, video chat, games, and drug reminders. In terms of guidance, Bohus and Horvitz [20] introduced directional robots that can use natural language to interact with one or more participants and provide directions to offices, conference rooms, and other public areas within the building, such as kitchens, cafeterias, and bathrooms. Kanda et al. [21] developed a robot for a shopping mall designed to interact naturally with customers and provide shopping information emotionally. Linder et al. [22] experimentally tested the performance of tracking robots in dense places such as airport terminals for shopping malls. In terms of medicine, Mirheydar and Parsons [23] reviewed the application of robotic surgery in urology and pointed out that the safety of patients with robotic prostatectomy increases. Lakshmi et al. [7] introduced the design and manufacture of a drug delivery robot for hospitals to provide alternate care services. Hu et al. [24] designed a planner based on Gaussian process classification, which aims to promote the further integration of multifinger manipulators and medical image detection.

*2.2. Service Robots in Hotel Industry.* Service automation, artificial intelligence, and robotics offer huge opportunities for the hospitality industry [25]. Hotel robot functions include interacting with travelers and entertaining them, as well as physical assistance, such as transport, checking baggage, and guidance. [26]. Starwood has introduced a robot butler in their Aloft hotel mainly to provide conveniences to guest rooms [27]. Henn-na Hotel is the first hotel to hire hotel robots during the entire operation from check-

in to automatic baggage delivery, using robots to check in occupants and escort guests to their rooms. The robotic receptionist speaks Japanese or English, depending on guest preferences. It can set reservations for people, take them to their rooms, and adjust the temperature of their accommodation. In the room, guests can use voice commands to change the lights and ask questions about time or weather [28]. In collaboration with IBM, Hilton Worldwide is the first to launch the world's first robotic concierge service (using SoftBank's NAO robots) to gain knowledge from artificial intelligence systems and inform guests of local attractions, restaurants, hotel facilities, etc. [29]. The Las Vegas Wayne Hotel has announced that it will introduce Amazon Echo voice roll-up speakers in all rooms with Alexa digital assistants [30]. By the end of 2018, Alibaba's first future unmanned hotel "Flyzoo Hotel" has been put into operation [31].

From the demand side, economically, hotel robots can help hotels cope with seasonal employment and labor costs. Dirican [32] believes that artificial intelligence, especially the introduction of robotic services to hotels, greatly improves the efficiency of hotel services and reduces hotel operating costs, although some hotels with robots still consider investment costs to be high. With increasing labor costs, decreasing labor availability, decreasing robot costs, and increasing robot capabilities, many low-wage service jobs in the hotel industry are expected to be replaced [33]. The time spent on robot labor is less expensive than paying humans [34]. On the noneconomic side, using robots to complete some daily tasks may be considered by hotel managers as a good choice because it will save them most of the concerns of legal authorities, unions, and immigration offices such as seasonal layoffs. [12, 35]. Stringam and Gerdes [36] used a combination of quantitative and qualitative methods, pointing out that the self-service of hotels has not yet led to a significant reduction in labor. Due to hotel technology's labor savings, most hotels choose to redeploy employees to other tasks. It is improving customer service, not reducing staffing. Managing robots will be different than managing tangible goods. How robots, staff, and customers interact is an important focus for future travel and hotel managers [37].

From the supply side, Murphy et al. [38] discussed the design of robots for hotel and tourism industries and training in robot management. The implementation of hotel robots is usually integrated with other technologies such as facial recognition, automatic payment, drone delivery, and autonomous vehicles [9]. According to [39, 40], a robot control system requires three development levels, including hardware, functions, and services. Hardware refers to the shape of the mechanical design, which includes the main part of the service robot, the perception system (sensor), and the motion system (actuator). Function refers to the software architecture of the control system, which can implement navigation, dialogue, visual and speech recognition, positioning and mapping mechanisms, and the representation of knowledge mental models. Service refers to the added value that the hotel aims to create and provide customers with services to maintain a competitive advantage. Chung et al. [41] believe that a key requirement of the robot is that the

robot should perceive people around the robot. Through two field studies of custom programs and iterative design, a programming system for social interaction applications of mobile service robots has been developed. The timing for widespread deployment of service robots anywhere in the hotel will depend on when technical limitations can be addressed [42]. Zhang et al. [43] proposed a smart hotel robot based on ROS, which simplifies the check-in process. López et al. [44] proposed an automated hotel assistant system based on a series of mobile platforms that interact with guests to help them complete different tasks, including bring small items to customers, show them the different attractions of the hotel, accompany guests into their rooms, and provide them with general information.

*2.3. Related Work on Robot Service Quality and Feedback.* Customers can feel valuable in the self-service process when interacting with service robots out of fun, enjoyment, and curiosity [45, 46]. Robot customization with user-friendly interface design is important to attract specific new customer markets [47, 48]. Although current robotics technology may not directly complement comprehensive human services, from a marketing perspective, service robots will indirectly attract existing and potential customers [49, 50]. Zhang and Qi [51] pointed out that people with high education and high income who are interested in AI technology are more looking forward to staying in AI robot hotels. Some authors have even suggested that marketers should start thinking about robots as attractions [52]. With the popularity of robots, curiosity will no longer be an important reason for guests to stay in hotels but instead will be service quality and customer satisfaction. Many scholars have researched and explored the service quality of robots [53–55]. Service robots can improve perceived service quality through new attractive interactive services, communication, and contact with customers [56]. Unlike industrial robots whose performance indicators depend entirely on efficiency, the success of service robots depends on user satisfaction [57]. Robots that fail to deliver services can severely impact customer satisfaction and hotel performance [58]. Nakanishi et al. [59] found that the warm heart interactive service of humanoid robots potentially improves customer satisfaction with the entire service.

Customer satisfaction with robot services is largely determined by the robot itself. Therefore, the optimal design of the robot is particularly important. One of the current research studies is to subjectively obtain feedback through customers' questionnaires, polls [60], secondary data analysis [61], hybrid approach [62], and so on. Jeonghye et al. [14] proposed an evolutionary model of service robots with LCD touch panels, such as home robots, by questionnaire survey of parents and children and proposed the importance of rebuilding the robot's facial expressions based on the evaluation model. Tussyadiah and Park [9] found that customers' perception of different types of hotel service robots is different through online surveys and the use of biosensors to measure automatic emotional responses, and the adoption of hotel service robots is significantly affected

by the following aspects: intelligent and perceived security. Another aim is to objectively optimize the algorithm, for example, Ju et al. [18] designed a Python plug-in management system based on the mechanical mechanism design of the robot platform to implement graphical programming to control the robot. Huang et al. [63] proposed a multi-attention-based group recommendation model (MAGRM), and experiments showed that its performance in solving group recommendation problems is significantly better than the latest technology.

The above methods are either subjective or disconnected from the customer, and it is important to find an objective and customer-relevant robotic optimization feedback channel, such as robot optimization through service commands issued directly by customers. Therefore, this paper analyzes the general situation of hotel robot service from the command, by studying what the consumer's commands to the robot mainly include, whether it has formed a certain pattern according to the time series, and whether there are different service differences from the response of the command. The aim is to analyze the service content and quality of hotel robots and to point out new directions and ideas for hotel robot design. It is expected to contribute to the further optimization of robot design, such as packaging preset behavior patterns, optimizing repetitive commands, and human development to improve the service quality of the robot.

### 3. Materials and Methods

To have a systematic analysis on human-robot interaction, a rich data source containing a large amount of interaction records is needed. Then, the collected big dataset is pre-processed to remove incorrect and irrelevant information to reduce possible bias in results. After a basic statistical analysis on the clean dataset, the paper uses a frequent pattern mining method to study the user command patterns and a social network-based clustering method, which aims to help understand users' motivations, interests, and particular behaviors.

*3.1. Data Collection and Preprocessing.* The data were collected from 88 hotels in 23 cities across the mainland China. The service robots are equipped in 789 hotel rooms in these hotels. A robot management system by robot manufactory recorded all the user commands received by the hotel robots in the rooms. In this work, the historical data of command records in 2017 are selected for analysis and evaluation purpose due to the stability of the robot operations and the completeness of data.

In the interaction between user and hotel robots, the commands were given by voice. The user spoke out their requests and then the robot received the entire voice sentences and converted them into simple text-based command labels by its voice recognition functions. The collected data were then preprocessed to remove the inconsistent command labels caused by the updation of the robot system. The unrecognized commands were also removed as they were mainly caused by accent issues. After preprocessing, 745,528

valid user commands from 49,955 hotel customers were kept and input into the next-step analysis processing.

*3.2. Association Analysis on User Commands.* To understand human-robot interaction, the commands given by the users are the only resource that can be carefully studied in this case. Frequent pattern mining is used to discover most popular user command patterns in order.

*3.2.1. Sequential Frequent Pattern Discovery from User Commands.* Frequent patterns are often used to present the most common or similar features among data examples in a dataset. Given a set of commands, frequent pattern mining aims to find the rules that enable us to predict the occurrence of a specific item based on the occurrence of other items in the commands. A frequent pattern can be determined by a set of standard constraints [64].

The simple form for frequency of a pattern can be easily gained by counting the total number of its occurrence in the entire dataset. This is commonly used for finding out the most popular patterns with only one individual command.

Support, as one of the widely used constraints, was proposed by Agrawal et al. [65] in their Association Rule Mining (ARM) algorithm to identify a frequent pattern with two or more user commands. Let  $C$  be the complete set of all user commands in the collected dataset  $D$ .  $c_1$  and  $c_2$  be two commands from  $C$ , that is,  $c_1 \in C$ ,  $c_2 \in C$ .  $c_1$  and  $c_2$  are two different commands. The support of these two commands can be obtained by

$$\text{Supp}(c_1, c_2) = \frac{\text{number of interactions containing } c_1 \text{ and } c_2 \text{ in } D}{\text{total number of interactions in } D}. \quad (1)$$

A pattern can be indicated as a frequent one if its support score is not less than a minimum support threshold  $\delta$ ,  $\text{Supp}(c_1 \text{ and } c_2) \geq \delta$ . The classic Apriori-heuristic-based ARM is not suitable for processing large-scale dataset as it is very time consuming and expensive in computation. The concept of interestingness is then considered into the process to avoid generating too many useless candidate command patterns [66]. Only the candidate patterns with a higher interestingness score than the minimum interestingness threshold can join the next round of candidate pattern generation. A candidate pattern with two commands is generated based on the single commands with acceptable support score in previous generation; the candidate patterns with three commands are generated from the candidate patterns with two commands, and so on. The interestingness is calculated by the leverage of two commands as an example below:

$$|\text{leverage}(c_1, c_2)| = |\text{supp}(c_1, c_2) - \text{supp}(c_1)\text{supp}(c_2)| \geq \theta. \quad (2)$$

In such a way, the computation time and waste can be controlled under an acceptable range. In this work, the

candidate command patterns are indicated as frequent patterns based on their frequency of occurrence. One of the reasons is due to the high repeats of the same command patterns in one interaction. The user could place the same set of commands one after another, for example, “turn on lamp, turn off lamp, turn on lamp, play music, turn off lamp, turn on lamp ...” Therefore, the strength measurement constraints in ARM do not fit and are ignored in this study.

Another special feature in this work is that the actual time when users placed the commands was recorded as well, which makes the collected data time-series data. Time-series data are often presented in data sequences. In this work, each sequence records an interaction between the user and the robot. Accordingly, the command patterns are not random combination of the commands, and the order of the commands is also important.

*3.2.2. Social Network Analysis for User Clustering.* In recent years, the world has become more and more complex, and the research community has done a lot of work on the measurement of complexity. Social network is an analysis and simulation method that attempts to use the relationship between points and lines to analyze complex systems through the algorithmic characteristics of graphs. Social network analysis is widely used to understand the nature and discover useful patterns representing the relationships among members in a group [67]. In this work, the relationships among the hotel customers (users) were studied based on the commands they placed. The dataset was reorganized into a collection of the sequences of commands recorded for each individual user. A  $n \times n$  matrix  $M$  was obtained where  $n$  is the total number of the user commands. The intersection  $m_{ij}$  records the number of occasions that command  $c_i$  and command  $c_j$  are in the same clique. A clique is a subset of commands that always occur together over all the command sequences [68]. The total number of links in the network is calculated by  $l = \sum \sum m_{ij}$ .

Hierarchical clustering (Johnson, 1967) was then used to group commands into clusters based on the nearest pair of commands. By clustering the commands together, the users’ interests are discovered, that is, what commands are always called together with high densities. The social network analysis was implemented using a software called UCINET [69].

## 4. Results and Discussion

This section presents the experiment results obtained by applying the selected method on the collected data. The results are explained with the method used, respectively, followed by discussion of overall findings.

*4.1. Dataset and Descriptive Statistical Analysis.* After data cleaning and preprocessing, a total number of 103 individual commands were extracted from the collected historical data. Table 1 lists the top 50 commands placed

TABLE 1: Top 50 frequent individual user commands received by hotel service robots.

| Top # | Command              | Frequency |        |
|-------|----------------------|-----------|--------|
| 1     | OpenLamp             | 125,855   | 16.97% |
| 2     | CloseLamp            | 118,271   | 15.95% |
| 3     | TVOFF                | 103,759   | 13.99% |
| 4     | OpenCurtain          | 91,146    | 12.29% |
| 5     | CloseCurtain         | 78,049    | 10.53% |
| 6     | CloseScreen          | 41,324    | 5.57%  |
| 7     | MusicPlay            | 33,254    | 4.48%  |
| 8     | AirON                | 30,307    | 4.09%  |
| 9     | OpenDoor             | 17,435    | 2.35%  |
| 10    | TVON                 | 15,416    | 2.08%  |
| 11    | AirOFF               | 9,099     | 1.23%  |
| 12    | OpenPowerLight       | 8,879     | 1.20%  |
| 13    | MeetingModeON        | 2,842     | 0.38%  |
| 14    | TVChannelChange      | 2,629     | 0.35%  |
| 15    | TVVolUp              | 2,325     | 0.31%  |
| 16    | ServiceON            | 2,267     | 0.31%  |
| 17    | OpenBedroomLight     | 2,236     | 0.30%  |
| 18    | CloseWCLight         | 2,207     | 0.30%  |
| 19    | MusicStop            | 2,045     | 0.28%  |
| 20    | OpenWCLight          | 2,002     | 0.27%  |
| 21    | SleepModeON          | 1,974     | 0.27%  |
| 22    | CloseReadLight       | 1,972     | 0.27%  |
| 23    | CloseDengDaiLight    | 1,860     | 0.25%  |
| 24    | OpenNightLight       | 1,719     | 0.23%  |
| 25    | OpenLangLight        | 1,503     | 0.20%  |
| 26    | OpenDengDaiLight     | 1,390     | 0.19%  |
| 27    | OpenTopLight         | 1,378     | 0.19%  |
| 28    | MusicNext            | 1,376     | 0.19%  |
| 29    | OpenReadLight        | 1,291     | 0.17%  |
| 30    | OpenBedLight         | 1,265     | 0.17%  |
| 31    | BlueTooth            | 1,242     | 0.17%  |
| 32    | ClosePowerLight      | 1,206     | 0.16%  |
| 33    | OpenLivingroomLight  | 1,031     | 0.14%  |
| 34    | AirCondSet25         | 956       | 0.13%  |
| 35    | OpenJingQianLight    | 953       | 0.13%  |
| 36    | AirCool              | 934       | 0.13%  |
| 37    | AirCondSet24         | 933       | 0.13%  |
| 38    | CloseLangLight       | 921       | 0.12%  |
| 39    | OpenStudyLight       | 888       | 0.12%  |
| 40    | CloseLivingroomLight | 856       | 0.12%  |
| 41    | AirCondSet26         | 852       | 0.11%  |
| 42    | CloseTopLight        | 852       | 0.11%  |
| 43    | TVVolDown            | 851       | 0.11%  |
| 44    | AirCondSet20         | 769       | 0.10%  |
| 45    | CloseBedLight        | 759       | 0.10%  |
| 46    | AirHeat              | 750       | 0.10%  |
| 47    | MusicPrev            | 713       | 0.10%  |
| 48    | OpenBackgroundLight  | 713       | 0.10%  |
| 49    | OpenScreen           | 696       | 0.09%  |
| 50    | AirCondSet30         | 688       | 0.09%  |

by the users in the interaction with hotel robots. The top 12 commands have much higher frequency to be called by the users than the rest, which have over 90% of the listed commands. Close to 70% of user commands fall into one of the OpenLamp, CloseLamp, TVOFF, OpenCurtain, and CloseCurtain commands. That is, about 90 commands have less than 0.4% of chances to be called once in a year.

*4.2. Time-Based User-Robot Interaction Analysis.* Analyzing the active degrees of user commands helps to understand the peak and off-peak periods of human-robot interaction. An hour-based activity frequency chart is presented in Figure 1. Some common senses can be detected including the interactions which always start alone with users waking up in the morning from 6 am and increase to reach the first high point around 10 am. A small drop is found around 12 pm when users leave the rooms for lunch, and the number of commands climbs back quickly from 1 pm and remains stable until dinner time. The peak time is around 10 pm when users stay in the room to enjoy entertainment. It is a surprise to see that users still communicate with service robots after midnight. Finally, the quiet time starts from 2 am to 5 am. Many people stay late in the hotel rooms and talk to service robots.

A month-based activity frequency chart is presented in Figure 2. During the whole year, the service robots are busy in July and August and most of them are in idle or standby status in January and February. This matches the factor that during summer time, more hotel reservations and travels are made in general. The monthly-based interaction data also indicate that most of the users who lived in the hotel rooms equipped with service robots tried to interact with them almost every time. The service robots are accepted by users who stayed in the hotels anytime.

*4.3. User-Robot Interaction Pattern Discovery.* Frequent command patterns are expected to provide some knowledge about users' interests, behaviors, and the responsiveness performance of service robots.

*4.3.1. Command Patterns for Popular Command Combinations.* In human-robot interaction analysis, a main object is to find out the user interests when they request robots for services. The frequent command patterns can indicate what groups of commands users preferred to work with service robots. The frequent individual user commands are listed in Table 1. Tables 2–4 list top 10 frequent patterns as the permutations of two, three, and four commands, respectively. The pattern generation stopped at four-command level since the frequency and support score of the candidate five-command patterns were too low to have significant influence. The frequency was measured by the total number of occurrences including the repeats in the same interaction. The number of interactions when a pattern appeared at least once was also recorded. The difference between these two numbers indicate that many patterns have high repeats in a single interaction. The reasons to have this situation are complex and will be explained in the following context. Note that the order of commands is a key concept to be considered in all cases.

In the frequent two-command and three-command patterns, most of the patterns contain operations of turn on and off lamp (all lights), curtain, and TV. In the frequent four-command patterns, close screen (for windows) as a new command can be seen in most of the patterns. However, the number of commands increased in the

patterns, and the total number of occurrences dropped significantly. A common behavior from all the pattern sets that can be seen is that users like to turn off light, curtain, window screen, and TV together. The difference is just the order of turning which one first. For those patterns regarding TV, users turned off the TV more frequent than to turn it on because the TV was automatically turned on after the user entered or returned to the rooms in many hotels in China region. In addition, from all the frequent patterns in these three tables, the lamps (lights) and the curtains were turned on or off together. If the curtain was closed, then the lamp would be off too, and vice versa. It is not a common case to close the curtain and turn on the lights, from which one can claim that such operation was normally done before the user went to bed. It also confirmed that the human-robot interactions were active in the late hours of the day (as shown in Figure 1). The patterns of opening curtain and turning on the lamps may suggest the natural lighting in the rooms is insufficient.

A particular behavior is found from the analysis, in which the users tried to “play” with service robots by placing paired commands. That is, when the first command was given, immediately another command followed. The paired commands are always to turn on or off one device, such as lamps, TV, curtain, and air conditioner. This indicates that the users were bored and called those commands without a clear purpose. They might just want to talk to service robots for fun or kill time. Table 5 lists the top 20 paired commands in this category. Rather than turning on and off a particular light, users preferred more to turn all the lights on and off. For TV and air conditioner, the same situations are detected. Users did not give details in order but went for simple and short commands.

*4.3.2. Robot Responsiveness Analysis.* Although the human-robot interaction is identified as the indirect one that only one-way communication is applied, the responsiveness of the service robots to the user's commands is an interesting topic to be explore more in this section.

The responsiveness analysis carried out in this work is to look at how many times a user needs to repeat continuously the same command until the robot takes action or the user gives up. From the frequent pattern analysis above, there are some differences between the total number of the occurrences of the patterns and the number of the interactions having the patterns. They are not the same numbers, and in many cases, there are big gaps between them. The reason for this is that some commands are repeated many times in one interaction. The commands with repeats were closely observed, and the findings are summarized in Figure 3. The number of repeats for one single command daily is around 2.9, which indicates that the service robot's responsiveness still has a big room for improvement. Top 20 repeated commands were extracted from the analysis. By comparing with the initial count on top 50 frequent individual commands in Table 1, 17 out of 20 most frequent commands are found to have high repeats. Most of the commands were repeated within 2 seconds.

FIGURE 1: Hour-based human-robot interaction.

FIGURE 2: Monthly human-robot interaction.

TABLE 2: Top 10 frequent two-command patterns.

| Two-command frequent patterns | Frequency         |                     |
|-------------------------------|-------------------|---------------------|
|                               | Total occurrences | No. of interactions |
| CloseCurtain, CloseLamp       | 33,255            | 15,250 (30.53%)     |
| CloseScreen, TVOFF            | 31,976            | 14,284 (28.59%)     |
| CloseLamp, CloseScreen        | 28,713            | 13,092 (26.21%)     |
| OpenLamp, CloseLamp           | 21,253            | 12,973 (25.97%)     |
| TVOFF, CloseCurtain           | 16,870            | 9,245 (18.51%)      |
| OpenCurtain, CloseCurtain     | 11,531            | 7,859 (15.73%)      |
| OpenLamp, TVOFF               | 11,410            | 7,417 (14.85%)      |
| OpenLamp, OpenCurtain         | 10,641            | 8,467 (16.95%)      |
| TVOFF, OpenCurtain            | 9,554             | 6,692 (13.40%)      |
| CloseCurtain, OpenCurtain     | 8,253             | 5,946 (11.90%)      |

Table 6 lists the top 20 commands that have the most repeats. Not all of them have repeats due to the poor responsiveness of the robots. The repeats may be caused due to the nature of the commands themselves. For example, MusicVolDown, TVChannelADD, TVVolUp, MusicVolUp,

TVVolDown, and TVMenuUp are six commands that the users will repeat several times to reach their satisfied status. It is understandable that a user will keep on calling the command MusicVolDown to turn the music volume down to an acceptable amount. However, other commands to be repeated are treated as the cases of poor responsiveness of service robots. ReadLightMax has the highest repeat rate over 85% followed by OpenPowerLight (81.32%). These commands with high repeats need special attention to the service robot manufactory for performance.

**4.4. User Command Clustering.** The user clustering based on the commands they called in the human-robot interaction is shown in Figure 4. In total, six user clusters were obtained from social network analysis by UCINET. They are colored in Figure 4 for visualizing the user groups and the commands used by each group. Overall, a set of common commands is detected, which confirms the most popular commands like switching lights, pulling curtains, watching TV, and playing music are the favorites for all six groups of

TABLE 3: Top 10 frequent three-command patterns.

| Three-command frequent patterns      | Frequency         |                     |
|--------------------------------------|-------------------|---------------------|
|                                      | Total occurrences | No. of interactions |
| CloseCurtain, CloseLamp, CloseScreen | 26,062            | 12,141 (24.30%)     |
| CloseLamp, CloseScreen, TVOFF        | 26,421            | 12,227 (24.48%)     |
| CloseScreen, TVOFF, CloseCurtain     | 7,846             | 4,528 (9.03%)       |
| OpenLamp, CloseLamp, OpenLamp        | 6,547             | 4,512 (9.06%)       |

users. Individual groups also have their preferred commands. Even with the same devices, they have different operations. Each group is discussed in more detail in the rest of the section.

Group 1 (in pink) has the biggest set of the commands. Except the commands related to switching TV, light, and curtain operations, this group works more active in playing

music and changing TV channels. The users in this group may prefer more to turn on TV to play music, but few of them used commands to adjust room temperature.

Group 2 (in dark blue) has the active users who used service robots to mainly adjust the room temperature by air conditioner. A set of temperature setting commands like “Aircondset25,” “Aircondset24,” “Aircondset26,”

FIGURE 3: Top 20 repeated user commands.

TABLE 6: Top 20 commands with most repeats.

| Top # | Command              | Repeat rate (%) |
|-------|----------------------|-----------------|
| 1     | Read LightMAX        | 85.28           |
| 2     | OpenPowerLight       | 81.32           |
| 3     | OpenDoor             | 77.32           |
| 4     | AirON                | 74.49           |
| 5     | TVChannelSub         | 74.42           |
| 6     | MusicVolDown         | 67.94           |
| 7     | OpenCurtain          | 67.62           |
| 8     | TVChannelADD         | 64.42           |
| 9     | TVVolUp              | 60.82           |
| 10    | OpenLamp             | 60.50           |
| 11    | MusicPlay            | 57.89           |
| 12    | BlueTooth            | 57.57           |
| 13    | TVChannelChange      | 54.62           |
| 14    | MusicVolUp           | 54.03           |
| 15    | CloseBedLight        | 53.75           |
| 16    | OpenLivingroomLight  | 53.35           |
| 17    | TVVolDown            | 50.65           |
| 18    | CloseLivingroomLight | 49.30           |
| 19    | TVMenuUp             | 48.61           |
| 20    | CloseDoor            | 48.12           |

“Aircondset20,” and so on is detected in this group particularly. The temperature range is from 17°C to 29°C across the year, which falls into the normal external temperature adjustment of the human body. This user group focused more on the operations with accurate requirements rather than some general commands preferred by Group 1.

Group 3 (in light blue) is a small one at the margin areas. The commands used more by this group are entertainment-related operations on TV and playing music. They used “Bluetooth” to connect with their own smart devices and played music on TV. They also used “Checkoutn”

command to inform the service robot before they left the room. They can be indicated as avant-garde customers for hotels.

Group 4 (in green) often used robots to call for room service. The users in this group put “Nodisturbon” and “Cleanon” to call for cleaning service. They also watched the charge channels on TV rather than browsing the noncharge channels. These customers preferred more to keep the hotel room as their private space and had strong control on the activities in their space.

Group 5 (in yellow) and Group 6 (in brown) are two groups with the users who spent more time on switching lamps in the room to adjust the lighting. These two groups do not share a lot of overlaps with the other groups; especially Group 6 has commands with only one connection. These two groups have high interests to particular lights at different positions in the room. They did not use general commands to turn all the light on or off, but carefully and clearly gave the name of the lights. This behavior shows that the users moved a lot inside the room. They are energy savers to use individual lights in small areas.

*4.5. Discussion.* From the analysis on the results above, a number of issues and valuable points obtained need special attention from hotel management and technical experts in service robot manufactory.

In terms of theoretical contributions, this article makes an in-depth analysis of the services provided by robots from the perspective of the service industry. Different from the traditional robot research, it closely integrates human feelings and robot design and provides more knowledge to this area. Furthermore, this paper proposed a command mode for hotel robots through a complex network analysis

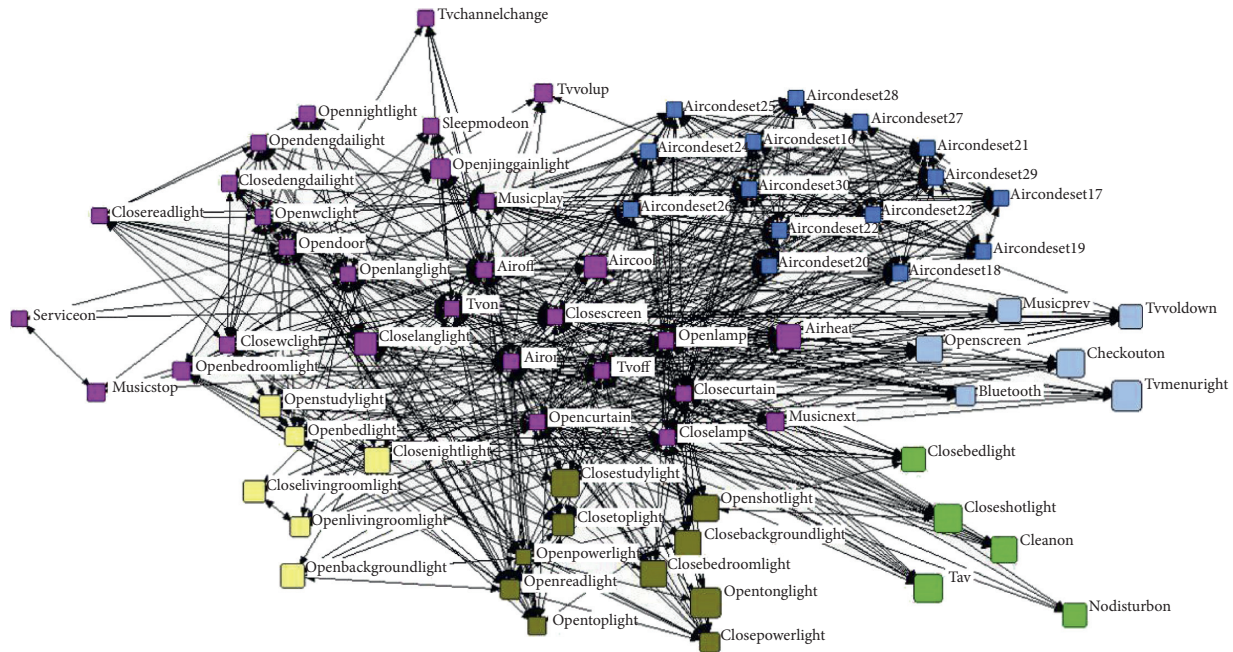

FIGURE 4: Six user clusters by social network analysis.

of a large number of robot commands. This is an innovative attempt in service robot research.

In terms of practical contributions, the robot needs to be improved in terms of human-computer interaction performance. From the same command in the same minute, the robot has certain problems in accepting customer orders, and there are many reasons for these problems. For example, the accent of the customer speaking Mandarin causes the robot not to be unrecognizable, or the voice of the customer is inaudible. Hotel robots lack semantic understanding of customer commands, which means that now hotel robots mostly use keywords matching and provide search results according to customers' command. Unrecognizable or too many external environmental interference factors cannot be removed by the robot. Regardless of the possible reasons, developers are still waiting to improve the performance of robots in human-computer interaction.

The customer conducts a curious operation. The typical performance is that the customer speaks many different types of operation commands in a short period of time, and thus the customer, being curious, is in a slow process of trying, trying, and accepting the service robot. Because of the curiosity about new things, the customer is willing to issue different commands to the robot. There are two kinds of mentality, one is the verification of the performance of the robot, and the other is the attempt of new things. Regardless of the mentality, it is conducive to the widespread use of future service robots. After repeated trials, the customer has a sensory feeling about the performance and service quality of the robot. In addition, because customers are more and more getting used to hotel robots and loss of interest, the paper provided a good reason for manufacturers to improve their service robots. This is crucial for the follow-up customer's willingness to continue using or staying in a hotel

with a robot. The following components can promote the customer's visit again; on the one hand, it is a good trial experience; on the other hand, it can bring convenience and comfort to customers. Of course, contrary to these two components, due to poor trial experience and complex or infinite operations, customers will be greatly reduced in the use and expectation of the robot.

Operation instructions are too limited. From the perspective of the type of operation instructions throughout the day, most of the operation instructions are control-type instructions. These instructions can only meet the customer's regular needs, and it is difficult to make a deep impression on the customer and urge the customer to have the urge to visit again. This is mainly due to the narrow range of hotel robot services. It is recommended that robot designers go to the hotel to experience the on-site experience of their products, think about the potential needs of customers from the perspective of customers, and develop some operational instructions that can impress customers. For example, automatic indoor temperature monitoring and adjustment, human body temperature automatic monitoring, potential hazard automatic alarm, customer demand input and implementation, and customer health care; only by developing these kinds of orders, we can grasp the customer's heart and promote and use service robots.

## 5. Conclusion

This paper proposed a first study on human-robot interaction between customers and service robots in hotels in China. Different from other service robot research studies that focused more on technical problems in robot design, development, and performance evaluation, this work made use of real data collected from live interactions between

customers and robots in the hotel rooms by applying frequent pattern mining and social network analysis techniques to find out hotel customers' interests, motivations, and behaviors when they interact with service robots.

Among a total of 103 user commands called by over 49,955 hotel customers during their stays in 88 hotels from 23 cities in China, the frequent command patterns indicate that most of the customers called service robots to do simple operations such as switching on or off the lights, TV, curtain, and window screen. Hotel customers have special preferences on services when they interacted with service robots. Some like to try a big range of service; some prefer to give accurate commands to adjust the room environment; some spend their time in hotel rooms for entertainment; some take time to enjoy themselves in hotel rooms as their private spaces; and others treat service robots as a company to kill time by repeating same set of commands continuously. Robots are also found to be slow to respond to some of the user commands, and potential improvement is expected to be made in near future.

Since this is the first work of this area, there were some limitations when the research was conducted. The raw data collected from the robot management system by manufacturer contain inconsistent command labels due to system updation. Only the data in 2017 are complete to be used in this work. The users' information is lacking in this work due to privacy concerns and since their personal information cannot be shared by hotels. In addition, whether social network analysis is applicable to robot commands needs to be carefully studied afterwards. However, these issues did not stop this work from discovering useful knowledge to understand hotel customers' interaction with service robots, and this is a remarkable step in human-robot interaction study in the future. The findings help hotel management to adjust the services that the customers are interested in and what the robots could provide.

### Data Availability

The data are owned by the robot company and could not be released.

### Conflicts of Interest

The authors declare that they have no known competing financial interest or personal relationships that could have appeared to influence the work reported in this paper.

### Authors' Contributions

Lina Zhong was responsible for conceptualization, methodology, writing, and funding acquisition. Liyu Yang contributed to literature review. Jia Rong reviewed and edited the manuscript and supervised the study. Xiaonan Li was responsible for software and formal analysis.

### Acknowledgments

This study was supported by the Beijing Social Science Foundation under grant nos. 19JDXCA005 and 18JDGLB013

and National Natural Science Foundation of China under grant no. 71673015.

Affected by the Internet, computer, information technology, etc., building a smart city has become a key task of socialist construction work. The smart city has always regarded green and low-carbon development as one of the goals, and the carbon emissions of the auto parts industry cannot be ignored, so we should carry out energy conservation and emission reduction. With the rapid development of the domestic auto parts industry, the number of car ownership has increased dramatically, producing more and more CO<sub>2</sub> and waste. Facing the pressure of resources, energy, and environment, the effective and circular operation of the auto parts supply chain under the low-carbon transformation is not only a great challenge, but also a development opportunity. Under the background of carbon emission, this paper establishes a decision-making optimization model of the low-carbon supply chain of auto parts based on carbon emission responsibility sharing and resource sharing. This paper analyzes the optimal decision-making behavior and interaction of suppliers, producers, physical retailers, online retailers, demand markets, and recyclers in the auto parts industry, constructs the economic and environmental objective functions of low-carbon supply chain management, applies variational inequality to analyze the optimal conditions of the whole low-carbon supply chain system, and finally carries out simulation calculation. The research shows that the upstream and downstream auto parts enterprises based on low-carbon competition and cooperation can effectively manage the carbon footprint of the whole supply chain through the sharing of responsibilities and resources among enterprises, so as to reduce the overall carbon emissions of the supply chain system.

## 1. Introduction

Smart city is a new concept and mode to promote intelligent urban planning, construction, management, and service by using the new generation of information technology such as the Internet of Things, cloud computing, big data, and spatial geographic information integration. The development of a smart city in China attaches great importance to the integration of the smart city and green low carbon [1]. With the global warming, glacier melting, and other environmental problems becoming more and more serious, the auto parts enterprises should not ignore the importance of environmental protection while pursuing economic interests. We should actively coordinate the relationship between human

beings and nature, so as to achieve sustainable development. The Kyoto protocol adopted in 1997 has set clear emission reduction targets for the countries that signed it. At the same time, it clearly takes the market mechanism as a new path to solve the problem of greenhouse gas emission reduction, which promotes the symbiotic model of carbon emission responsibility sharing and resource sharing. China's demand for establishing a carbon trading mechanism is very urgent; on the one hand, in order to achieve the dual goals of low cost and low emissions and to maintain the long-term economic vitality of enterprises, and on the other hand, to strive for the carbon pricing right and to master the initiative of resource allocation in the low-carbon economy [2]. Therefore, with the steady development of the domestic

carbon emission trading market and the rapid growth of trading volume, the research on the optimization of low-carbon supply chain decision-making based on carbon emission responsibility sharing and resource sharing is of great significance for promoting energy conservation and emission reduction and promoting the transformation of the economic development mode and upgrading of the industrial structure.

Based on the current situation of the construction of a traditional low-carbon city, Ma et al. analyzed the existing problems and the advantages of an intelligent city and then put forward the countermeasures to promote the construction of an intelligent city and the specific path to solve all kinds of problems in the construction of an intelligent low-carbon city [3]. Based on the low-carbon value chain, Yin and others made in-depth exploration on the main components of the low-carbon value chain in the automobile industry and built a three-dimensional low-carbon path system of the automobile supply chain [4]. Lee used the case study method to improve our understanding of the carbon footprint of the automobile supply chain under the management background, providing a new way for the integration of carbon emissions in the supply chain management [5]. Yang and Guitao took the minimization of carbon emissions and the maximization of enterprise profits as the dual objectives and comprehensively used the dual theory and variational inequality to obtain the equilibrium conditions. The research shows that the environmental protection performance and economic benefit of enterprises are improved when the proportion of environmental protection target weight increases [6]. Wei considered the situation of carbon trading, introduced the change of carbon emissions in different forms of research and development, and constructed a differential game model to get the optimal research and development strategy of supply chain emission reduction [7]. Wang and Han established the loss function of perishable products with the goal of reducing carbon emission and total cost and studied the supply chain optimization strategy of location path inventory combination [8]. Díaz-Trujillo et al. analyzed the carbon pricing tools of the energy sector in Mexico and found that the carbon tax and the carbon trading system are more conducive to improve economic and environmental benefits than the traditional carbon pricing policy by using the multiobjective optimization formula [9]. Efthymiou and Papatheodorou established a low-cost and low-carbon multiobjective decision-making model and verified that cost reduction and carbon emission reduction can meet the requirements at the same time [10]. Battini et al. established a two-objective model related to cost and carbon emission and analyzed the model according to the change of carbon price, which showed that the low carbon price could not stimulate the sustainable purchase behavior [11].

Zhang et al. took low carbon emissions as the goal, considered the constraints of customer demand time window and loading and unloading time, and used the hybrid particle swarm optimization algorithm to optimize the multiproduct and multiobjective supply chain [12]. Lanzirui et al. built a minimum cost model under the background of

low carbon and analyzed the influencing factors of production decisions of enterprises with high carbon emissions under the background of carbon emission quota [13]. Taleizadeh et al. used two scenarios to study the interaction between carbon emission reduction, return policies, and quality improvement efforts. The research showed that higher refund prices are beneficial to reduce carbon emissions and improve product quality and supply chain profits [14]. Noura et al. studied the impact of carbon emission sensitive demand on supply chain design decision [15]. Huang et al. proposed a new group recommendation model based on multiattention, which uses the deep neural network structure based on multiattention to achieve accurate group recommendation [16]. Purohit et al. studied the inventory lot size problem based on the constraints of carbon emission and cyclic service level. The research showed that cost, inventory, and carbon emission decrease with the increase in carbon price [17]. Saxena et al. constructed a supply chain design model that comprehensively considered carbon tax policy, economy, and carbon emission and used the improved cross entropy method to get the carbon price that can obtain the maximum environmental benefit [18].

Mauro et al. evaluated the pretreatment technology of a coal-fired power plant from two aspects of environment and technology economy and evaluated the impact of pretreatment technology on the carbon emission avoidance cost [19]. Di Filippo et al. compared and analyzed the effects of carbon pricing policy, command and control policy, and resource incentive three tools in order to solve the obstacles of market failure to take measures to reduce carbon emissions in the concrete supply chain. The research showed that the carbon pricing policy is relatively effective [20]. Aiming at the problem of grab point planning, Hu et al. proposed a grab planning method based on the Gaussian process classification of big data [21]. On calculating the carbon footprint of the grain, Roibás et al. proposed alternative transportation schemes that can reduce the carbon footprint of final products [22]. Wilson and Staffell found that the transformation of coal to natural gas can be realized through effective carbon pricing, so as to reduce carbon emissions [23]. Allevi et al. established a model including carbon emission policy, recovery, transportation, and technical factors to evaluate the effect of applying environmental policies on a multilayer closed-loop supply chain network and solved it by using the theory of variational inequality. The analysis shows that the combined application of the carbon emission tax of truck transportation and the EU emission trading system (EU-ETS) at manufacturer level is beneficial to environmental protection [24]. In order to improve the effectiveness of Internet of Things recommendation, Huang et al. proposed a multimodal representation learning-based Internet of Things recommendation model [25]. Shaw et al. used the Benders decomposition algorithm to solve the problem of the sustainable supply chain network design under the constraints of opportunities. By using an example, we found that the carbon credit price is positively correlated with the enterprise's changeable cost and negatively correlated with the variable emissions [26]. Yu et al. established a mixed integer nonlinear programming

(MINLP) model of shelf space allocation under the background of the carbon tax and discussed the influence of shelf space capacity on product allocation decision [27]. Singh et al. considered the carbon footprint in the traditional supplier selection process and proposed a framework to help reduce the carbon footprint of beef products using the combination of big data, operational research, and other technologies [28].

To sum up, the current research related to the carbon footprint and the low-carbon supply chain focuses on the optimization of the supply chain system of carbon emission, while the research on carbon emission responsibility sharing and resource sharing is less. Therefore, in the context of carbon emission, this paper establishes a low-carbon supply chain decision-making optimization model based on carbon emission responsibility sharing and resource sharing. This model takes economy and environment as the goal and uses variational inequality to analyze the optimal conditions of the whole low-carbon supply chain system by coordinating and transforming the two interactive goal equilibrium problems. On the basis of proving the existence of the solution of the variational inequality of the supply chain system, this paper analyzes the change rule of the profit and carbon emission under the carbon trading with various parameters (such as recycling coefficient and remanufacturing coefficient of waste products) by numerical simulation and verifies the rationality and effectiveness of the model. It can be seen from the results that through the competition and cooperation of upstream and downstream auto parts enterprises for low carbon, the carbon footprint of the whole supply chain can be effectively managed, so as to achieve the purpose of reducing the overall carbon emissions of the supply chain system.

The innovations of this paper are as follows: (1) from the perspective of research, in addition to considering carbon emission constraints, carbon emission responsibility sharing and resource sharing are also considered. (2) In the research method, the variational inequality is used to optimize the whole low-carbon supply chain system. (3) As for the research results, this paper draws the conclusion through simulation: through the competition and cooperation of upstream and downstream auto parts enterprises for low carbon, the carbon footprint of the whole supply chain can be effectively managed, so as to achieve the purpose of reducing the overall carbon emissions of the supply chain system.

## 2. Problem Description and Symbol Definition

The low-carbon supply chain network of auto parts is composed of suppliers, producers, physical retailers, online retailers, demand markets, and recyclers. The basic structure is shown in Figure 1. The solid line in Figure 1 represents the forward logistics, and the dotted line represents the reverse logistics. Auto parts raw material suppliers provide raw materials for manufacturers. The products of manufacturers are sold to the demand market through physical retailers and online retailers, and the products are recycled by recyclers

FIGURE 1: Network structure of the low-carbon supply chain.

after use. The definition of variables and function setting is shown in Tables 1 and 2, respectively.

## 3. The Establishment of Network Equilibrium Optimization Model for Supply Chain of Auto Parts

### 3.1. The Establishment of Network Equilibrium Model under the Economic Goal of Low-Carbon Supply Chain

**3.1.1. Network Equilibrium Model of Suppliers.** If  $Q_{sm}$  is the supply quantity from the supplier to the manufacturer,  $\rho_{sm}$  is the price of the material from the supplier to the manufacturer, and the profit of the supplier is the profit of the material supplied to the manufacturer minus the purchase cost of the supplier, then minus the transaction variable cost with the manufacturer, the objective function of the supplier  $s$  is

$$\max \sum_{m=1}^M \rho_{sm} Q_{sm} - \left( \sum_{m=1}^M f_s(Q_{sm}) + \sum_{m=1}^M c_{sm}(Q_{sm}) \right). \quad (1)$$

The optimal conditions of all suppliers are equivalent to the following variational inequalities, and the solution  $Q_{sm} \geq 0$  satisfies

$$\sum_{s=1}^S \sum_{m=1}^M \left[ \frac{\partial f_s(Q_{sm})}{\partial Q_{sm}} + \frac{\partial c_{sm}(Q_{sm})}{\partial Q_{sm}} - \rho_{sm} \right] \times (Q_{sm} - Q_{sm}^*) \geq 0, \quad \forall Q_{sm} \geq 0. \quad (2)$$

The variational inequality (2) shows that the transaction price of auto parts suppliers is equal to the sum of the marginal purchase cost and the marginal transaction cost for any supply greater than zero in the equilibrium state.

**3.1.2. Network Equilibrium Model of Manufacturers.** If  $Q_{mr}$  is the product quantity provided by the manufacturer to the

TABLE 1: Decision variables and parameters.

| Variable or parameter  | Definition of variable or parameter   |
|--|---|
| $s$  | Auto parts supplier, $s \in \{1, 2, \dots, S\}$   |
| $m$  | Auto parts manufacturer, $m \in \{1, 2, \dots, M\}$   |
| $r$  | Physical retailer and online retailer of auto parts, $r \in \{r_1, r_2\}$   |
|  | Physical retailer $r_1 \in \{1, 2, \dots, R\}$ ; online retailer $r_2 \in \{1, 2, \dots, R\}$   |
| $d$  | Auto parts market, $d \in \{1, 2, \dots, D\}$   |
| $n$  | Auto parts recycler, $n \in \{1, 2, \dots, N\}$   |
| $Q_{sm}, Q_{mr}, Q_{r,d}, Q_{dn}, Q_{mn}$  | The trading volume of auto parts supplier $s$ and manufacturer $m$ , auto parts manufacturer $m$ and physical retailer and online retailer $r$ , auto parts physical retailer and online retailer $r$ and demand market $d$ , auto parts demand market $d$ and recycler $n$ , auto parts recycler $n$ and manufacturer $m$  |
| $\rho_{sm}, \rho_{mr}, \rho_{r,d}, \rho_{dn}, \rho_{mn}, \rho_d$                         | Transaction price or sales price of auto parts supplier, manufacturer, physical retailer, online retailer, demand market, and recycler  |
| $f_s, f_{ms}, f_{mn}$  | Purchasing cost function of auto parts suppliers, production cost function of new materials used by manufacturers, and production cost function of old materials used   |
| $c_{sm}, c_{ms}, c_{mr}, c_{nr}, c_r, c_m, c_{r,d}, c_{dr}, c_{dn}, c_n, c_{nd}, c_{mn}$ | Transaction cost function of auto parts suppliers and manufacturers; transaction cost function of auto parts manufacturers and suppliers, physical retailers and online retailers, recyclers; storage cost function of auto parts physical retailers and online retailers, transaction cost function of physical retailers, online retailers and producers, transaction cost function of demand market; transaction cost function of auto parts demand market, physical retailers, online retailers and recyclers; auto parts recycling cost function of acquisition, transportation and storage, recycler and demand market, and transaction cost function of producer |
| $v_{im}, v_r, v_{in}$  | Production, sales, and recovery of auto parts and components unit energy use cost of each process input   |
| $u_{om}, u_{or}, u_{on}$   | Production, sales, and recovery of auto parts unit carbon emission cost of each process output end  |
| $CC_j^+, CC_j^-$   | The amount of carbon emissions purchased and sold by a node auto parts enterprise $j$ is calculated in tons of carbon dioxide equivalent ( $tCO_2e$ ), $j \in MURUN$  |
| $A^c, V^{cc}$  | Unit purchase and sale price of carbon trading  |
| $CF_{im}, CF_{ir}, CF_{in}$  | Weight coefficient of energy use at input nodes of production, sales, and recovery processes of auto parts  |
| $EF_{om}, EF_{or}, EF_{on}$  | Carbon emission coefficient of output nodes of production, sales, and recovery processes of auto parts  |
| $\phi_{sm}, \phi_{mn}$   | Availability factor of raw materials from auto parts suppliers or reprocessed products from recyclers   |
| $D_d(\rho_d)$  | Demand function of auto parts market $d$  |
| $\theta$   | Conversion and reuse coefficient of recycled auto parts   |
| $\chi$   | Disposal cost of unit scrapped auto parts   |
| $CO_j^{in}, CO_0^{out}$  | Characteristic coefficient of energy consumption and carbon emission converted into carbon dioxide equivalent   |
| $L^{COP}, L^{COS}, L^{CO_2e}$  | The maximum amount of carbon emission that can be purchased or sold and the amount of carbon emission distribution  |

TABLE 2: Function settings.

| Cost  | Cost function   |
|---|---|
| Purchase cost of auto parts supplier  | $f_1(Q_{sm}) = (\sum_{m=1}^2 Q_{1m})^2 + a(\sum_{m=1}^2 Q_{1m})(\sum_{m=1}^2 Q_{2m}) + b\sum_{m=1}^2 Q_{2m}$  |
| Transaction costs between auto parts suppliers and manufacturers                        | $f_2(Q_{sm}) = c(\sum_{m=1}^2 Q_{2m})^2 + (\sum_{m=1}^2 Q_{1m})(\sum_{m=1}^2 Q_{2m}) + \sum_{m=1}^2 Q_{1m}$<br>$c_{sm}(Q_{sm}) = aQ_{sm}^2 + eQ_{sm}$ , where $s = 1, 2; m = 1, 2$  |
| Production cost of new materials used by auto parts manufacturers                       | $f_{1s}(Q_{sm}, \varphi_{sm}) = (\varphi_{sm} \sum_{s=1}^2 Q_{s1})^2 + b(\varphi_{sm} \sum_{s=1}^2 Q_{s1})(\varphi_{sm} \sum_{s=1}^2 Q_{s2}) + f$   |
| Production cost of old materials used by auto parts manufacturers                       | $f_{2s}(Q_{sm}, \varphi_{sm}) = (\varphi_{sm} \sum_{s=1}^2 Q_{s2})^2 + (\varphi_{sm} \sum_{s=1}^2 Q_{s1})(\varphi_{sm} \sum_{s=1}^2 Q_{s2}) + g$<br>$f_{1n}(Q_{nm}, \varphi_{nm}) = a(\varphi_{nm} \sum_{n=1}^2 Q_{n1})^2 + b(\varphi_{nm} \sum_{n=1}^2 Q_{n1}) + b$<br>$f_{2n}(Q_{nm}, \varphi_{nm}) = (\varphi_{nm} \sum_{n=1}^2 Q_{n2})^2 + b(\varphi_{nm} \sum_{n=1}^2 Q_{n2}) + h$ |
| Transaction costs between auto parts manufacturers and suppliers                        | $c_{ms}(Q_{sm}) = aQ_{sm}^2 + kQ_{sm}$ , where $m = 1, 2; s = 1, 2$   |
| Transaction costs of auto parts manufacturers, physical retailers, and online retailers | $c_{nr}(Q_{nr}) = aQ_{nr}^2 + kQ_{nr}$ , where $m = 1, 2; r = 1, 2$   |
| Transaction costs of auto parts manufacturers and recyclers                             | $c_{nm}(Q_{nm}) = aQ_{nm}^2 + kQ_{nm}$ , where $m = 1, 2; n = 1, 2$   |
| Storage cost of auto parts physical retailer and online retailer                        | $c_1(Q_{m1}) = a(\sum_{m=1}^2 Q_{m1})^2 + k$ ,<br>$c_2(Q_{m2}) = a(\sum_{m=1}^2 Q_{m2})^2 + f$  |
| Transaction cost of auto parts physical retailer, online retailer, and manufacturer     | $c_{nr}(Q_{nr}) = aQ_{nr}^2 + lQ_{nr}$ , where $r = 1, 2; m = 1, 2$   |
| Transaction cost of auto parts physical retailer, online retailer, and demand market    | $c_{rd}(Q_{rd}) = aQ_{rd}^2 + kQ_{rd}$ , where $r = 1, 2; d = 1, 2$   |
| Auto parts demand function  | $D_1(\rho_d) = -b\rho_1 - o\rho_2 + p$<br>$D_2(\rho_d) = -o\rho_1 - b\rho_2 + p$  |
| Auto parts demand market and retailer's transaction cost                                | $c_{dr}(Q_{rd}) = Q_{rd} + f$ , where $d = 1, 2; r = 1, 2$  |
| Auto parts demand market and transaction cost of recycler                               | $c_{dn}(Q_{dn}) = Q_{dn} + h$ , where $d = 1, 2; n = 1, 2$  |
| Storage cost of auto parts recycler   | $c_1(Q_{d1}) = a(\sum_{d=1}^2 Q_{d1})^2 + h$ ,<br>$c_2(Q_{d2}) = a(\sum_{d=1}^2 Q_{d2})^2 + b$  |
| Transaction cost between auto parts recycler and demand market                          | $c_{nd}(Q_{nd}) = qQ_{dn}^2 + Q_{dn}$ , where $n = 1, 2; d = 1, 2$  |
| Transaction cost between auto parts recycler and manufacturer                           | $c_{nm}(Q_{nm}) = aQ_{nm}^2 + Q_{nm}$ , where $n = 1, 2; m = 1, 2$  |
| Conversion and reuse coefficient of recycled auto parts                                 | $\theta = cr_k - t$   |
| Availability factor of reprocessed products of auto parts recycler                      | $\varphi_{sm} = \alpha\mu - u$  |

physical retailer and the online retailer,  $\rho_{mr}$  is the product price of the manufacturer, the cost of the manufacturer includes the production cost, the cost paid to the supplier and the recycler, the transaction cost with the supplier, the physical retailer, the online retailer, and the recycler, and the

cost of energy and carbon emission consumed in the production shall also be considered, then assuming that the unit energy cost consumed in the production process is  $v_i$  and the unit carbon emission cost is  $u_o$ , the objective function of producer  $m$  is

$$\begin{aligned}
\max \quad & \sum_{r=1}^R \rho_{mr} Q_{mr} - \left( \sum_{s=1}^S f_{ms}(Q_{sm}, \varphi_{sm}) + \sum_{n=1}^N f_{mn}(Q_{nm}, \varphi_{nm}) \right. \\
& + \sum_{s=1}^S \rho_{sm} Q_{sm} + \sum_{n=1}^N \rho_{nm} Q_{nm} + \sum_{s=1}^S c_{ms}(Q_{sm}) + \sum_{r=1}^R c_{mr}(Q_{mr}) \\
& \left. + \sum_{n=1}^N c_{mn}(Q_{nm}) + \sum_{r=1}^R v_{im} CF_{im} Q_{mr} + \sum_{r=1}^R u_{om} EF_{om} Q_{mr} \right) \\
\text{s.t.} \quad & \sum_{r=1}^R Q_{mr} \leq \varphi_{sm} \sum_{s=1}^S Q_{sm} + \varphi_{nm} \sum_{n=1}^N Q_{nm}.
\end{aligned} \tag{3}$$

The optimal conditions of all producers are equivalent to the following corresponding variational inequalities:

$$\begin{aligned}
& \sum_{m=1}^M \sum_{r=1}^R \left( \frac{\partial c_{mr}(Q_{mr})}{\partial Q_{mr}} + v_{im} CF_{im} + u_{om} EF_{om} + \zeta_{1m} - \rho_{mr} \right) \times (Q_{mr} - Q_{mr}^*) + (Q_{sm} - Q_{sm}^*) \\
& \times \sum_{m=1}^M \sum_{s=1}^S \left( \frac{\partial f_{ms}(Q_{sm}, \varphi_{sm})}{\partial Q_{sm}} + \frac{\partial c_{ms}(Q_{sm})}{\partial Q_{sm}} + \rho_{sm} - \varphi_{sm} \zeta_{1m} \right) + \sum_{m=1}^M \sum_{n=1}^N \left( \frac{\partial f_{mn}(Q_{nm}, \varphi_{nm})}{\partial Q_{nm}} + \frac{\partial c_{mn}(Q_{nm})}{\partial Q_{nm}} + \rho_{nm} - \varphi_{nm} \zeta_{1m} \right) \\
& \times (Q_{nm} - Q_{nm}^*) + \sum_{m=1}^M \left( \varphi_{sm} \sum_{s=1}^S Q_{sm} + \varphi_{nm} \sum_{n=1}^N Q_{nm} - \sum_{r=1}^R Q_{mr} \right) \times (\zeta_{1m} - \zeta_{1m}^*) \geq 0, \\
& \forall Q_{mr} \geq 0, Q_{sm} \geq 0, Q_{nm} \geq 0, \zeta_{1m} \geq 0,
\end{aligned} \tag{4}$$

where  $\zeta_{1m}$  in is the Lagrange coefficient to ensure the constraint condition of the objective function is established, which represents the minimum supply cost of the producer, that is, the cost that the producer is willing to bear at most for the unit product. The economic interpretation of variational inequality (4) is as follows.

The first one indicates that in equilibrium, for any trading volume greater than zero, the sum of the marginal transaction cost of the manufacturer and the retailer, the marginal energy use cost of the production input, the marginal carbon emission cost of the production output, and its minimum supply cost is equal to the transaction price of the auto parts manufacturer.

The second item indicates that in the equilibrium state, for any trading volume greater than zero, the marginal production cost of new materials, the marginal transaction cost of suppliers and producers, and the sum of the transaction price of suppliers is equal to the product of the availability coefficient and the minimum supply cost of suppliers' raw materials, and the third item is similar.

The fourth item indicates that in the equilibrium state, for any trading volume greater than zero, the sum of the trading volume of the auto parts manufacturer and the retailer is equal to the product of the trading volume of the supplier and the manufacturer and their availability coefficient of raw materials plus the product of the trading

volume of the recycler and the manufacturer and their availability coefficient of reprocessed products.

**3.1.3. Network Equilibrium Model of Physical Retailer and Online Retailer.** Suppose  $Q_{rd}$  is the physical retailer's and the online retailer's sales volume,  $\rho_{rd}$  is the physical retailer's and the online retailer's sales price, the unit energy

consumption cost is  $v_i$ , and the unit carbon emission cost is  $u_o$ . When the physical retailer's and the online retailer's cost is storage cost, payment to the manufacturer cost, and the transaction cost with the manufacturer and the demand market, plus energy consumption and the carbon emission cost in sales operation, then the objective function of the physical retailer and the online retailer  $r$  is

$$\begin{aligned} \max \quad & \sum_{d=1}^D \rho_{rd} Q_{rd} - \left( \sum_{m=1}^M c_r(Q_{mr}) + \sum_{m=1}^M \rho_{mr} Q_{mr} + \sum_{m=1}^M c_{rm}(Q_{mr}) + \sum_{d=1}^D c_{rd}(Q_{rd}) + \sum_{d=1}^D v_{ir} CF_{ir} Q_{rd} + \sum_{d=1}^D u_{or} EF_{or} Q_{rd} \right) \\ \text{s.t.} \quad & \sum_{d=1}^D Q_{rd} \leq \sum_{m=1}^M Q_{mr}. \end{aligned} \quad (5)$$

The optimal conditions of all physical retailers and online retailers are equivalent to the following variational inequalities:

$$\begin{aligned} & \sum_{r=1}^R \sum_{d=1}^D \left( \frac{\partial c_{rd}(Q_{rd})}{\partial Q_{rd}} + v_{ir} CF_{ir} + u_{or} EF_{or} + \zeta_{2r} - \rho_{rd} \right) \times (Q_{rd} - Q_{rd}^*) + \sum_{r=1}^R \sum_{m=1}^M \left( \frac{\partial c_r(Q_{mr})}{\partial Q_{mr}} + \frac{\partial c_{rm}(Q_{mr})}{\partial Q_{mr}} + \rho_{mr} - \zeta_{2r} \right) \\ & \times (Q_{mr} - Q_{mr}^*) + \sum_{r=1}^R \left( \sum_{m=1}^M Q_{mr} - \sum_{d=1}^D Q_{rd} \right) \times (\zeta_{2r} - \zeta_{2r}^*) \geq 0, \end{aligned}$$

$$\forall Q_{rd} \geq 0, Q_{mr} \geq 0, \zeta_{2r} \geq 0,$$

(6)

where the “\*” sign indicates that the variable is in equilibrium, corresponding to the optimal solution of variational inequality (6). Among them, the Lagrange coefficient  $\zeta_{2r}$  ensures that the constraint condition of the objective function holds, which means the physical retailer's and the online retailer's minimum supply cost, that is, the highest cost that the physical retailer and the online retailer are willing to pay when selling each unit of product. The variational inequality (6) shows the following.

The first one indicates that in equilibrium, for any trading volume greater than zero, the sum of the marginal transaction cost, the input energy use cost, the output unit carbon emission cost, and the minimum supply cost of the retailer is equal to the transaction price of the auto parts retailer.

The second indicates that in equilibrium, for any supply greater than zero, the sum of the retailer's marginal storage cost, the retailer's marginal transaction cost, and the manufacturer's transaction price is equal to the minimum supply cost of the auto parts retailer.

The third indicates that in equilibrium, for any supply greater than zero, the sum of the transaction volume of auto parts manufacturers and physical retailers and online retailers is equal to that of retailers and the demand market.

**3.1.4. Network Equilibrium Model of Demand Market.** The variables that the demand market needs to decide include two parts. In positive logistics, the demand market meets the following conditions:

$$\rho_{rd} + c_{dr}(Q_{rd}) \begin{cases} = \rho_d, & Q_{rd} > 0, \\ \geq \rho_d, & Q_{rd} = 0. \end{cases} \quad (7)$$

The demand market has the following supply-demand balance relationship:

$$D_d(\rho_d) \begin{cases} = \sum_{r=1}^R Q_{rd}, & \rho_d > 0, \\ \geq \sum_{r=1}^R Q_{rd}, & \rho_d = 0. \end{cases} \quad (8)$$

The economic explanation is as follows: formula (7) indicates that if the sum of the physical retailer's and the online retailer's selling price and the transaction cost of the demand market is equal to the demand price, then there is a transaction between the physical retailer, the online retailer, and the demand market; otherwise, the transaction volume between the two is zero; formula (8) indicates that if the demand of the demand market is exactly equal to the quantity of products purchased from the physical retailer and the online retailer, then the equilibrium price is positive; if the two are not equal, then the equilibrium demand price is zero.

In reverse logistics, the demand market  $D$  determines whether to sell to the recycler according to the recycling price of waste products. This relationship can be expressed as follows:

$$c_{dn}(Q_{dn}) \begin{cases} = \rho_{dn}, & Q_{dn} > 0, \\ \geq \rho_{dn}, & Q_{dn} = 0, \end{cases} \quad (9)$$

$$\text{s.t.} \quad \sum_{n=1}^N Q_{dn} \leq \sum_{r=1}^R Q_{rd}. \quad (10)$$

Equation (10) indicates that the total amount recovered by the recycler from the demand market  $D$  does not exceed the total amount of products in the demand market. By synthesizing the behavior and constraints of the demand market in forward logistics and reverse logistics, the optimal conditions of all demand markets can be obtained, which are equivalent to the following variational inequalities, and the solution  $(Q_{dn}, Q_{rd}, \rho_d, \zeta_{3d}) \geq 0$  satisfies

$$\begin{aligned} & \sum_{d=1}^D \sum_{r=1}^R [\rho_{rd} + c_{dr}(Q_{rd} - \rho_d - \zeta_{3d})] \times (Q_{rd} - Q_{rd}^*) + \sum_{d=1}^D \sum_{n=1}^N (c_{dn}(Q_{dn}) - \rho_{dn} + \zeta_{3d}) \times (Q_{dn} - Q_{dn}^*) \\ & + \sum_{d=1}^D \left( \sum_{r=1}^R Q_{rd} - D_d(\rho_d) \right) \times (\rho_d - \rho_d^*) + \sum_{d=1}^D \left( \sum_{r=1}^R Q_{rd} - \sum_{n=1}^N Q_{dn} \right) \times (\zeta_{3d} - \zeta_{3d}^*) \geq 0. \end{aligned} \quad (11)$$

**3.1.5. Network Equilibrium Model of Recycler.** It is assumed that the quantity of waste products sold by the recycler to the manufacturer is  $Q_{nm}$  and the selling price is  $\rho_{nm}$ .  $Q_{dn}$  is the total quantity of recycled waste products. The profit of the recycler is the profit obtained from the sale of reusable products to the manufacturer minus the cost of acquisition, transportation, and storage of the recycler, the cost of

recycling paid to the demand market, and the transaction cost with the demand market and the manufacturer, plus a part of the recycled waste products that need to be scrapped. The total amount of scrapping is  $(1 - \theta) \sum_{d=1}^D Q_{dn}$ , the cost is  $\chi(1 - \theta) \sum_{d=1}^D Q_{dn}$ , and the energy consumption and carbon emission in the recycling process cost, the objective function of recovery quotient  $n$ , is

$$\begin{aligned} \max \quad & \sum_{m=1}^M \rho_{nm} Q_{nm} - \left( \sum_{d=1}^D c_n(Q_{dn}) + \sum_{d=1}^D \rho_{dn} Q_{dn} + \sum_{m=1}^M c_{nm}(Q_{nm}) + \sum_{d=1}^D c_{nd}(Q_{nd}) + \chi(1 - \theta) \sum_{d=1}^D Q_{dn} + \sum_{d=1}^D v_{in} CF_{in} Q_{dn} + \sum_{d=1}^D u_{on} EF_{on} Q_{dn} \right) \\ \text{s.t.} \quad & \sum_{m=1}^M Q_{nm} \leq \theta \sum_{d=1}^D Q_{dn}. \end{aligned} \quad (12)$$

The optimal conditions of all recovery quotients are equivalent to the following variational inequalities:

$$\begin{aligned} & \sum_{n=1}^N \sum_{m=1}^M \left( \frac{\partial c_{nm}(Q_{nm})}{\partial Q_{nm}} + \zeta_{4n} - \rho_{nm} \right) \times (Q_{nm} - Q_{nm}^*) + \sum_{n=1}^N \sum_{d=1}^D \left( \frac{\partial c_n(Q_{dn})}{\partial Q_{dn}} + \frac{\partial c_{nd}(Q_{dn})}{\partial Q_{dn}} + \rho_{dn} + v_{in} CF_{in} + u_{on} EF_{on} + \chi((1 - \theta) - \theta \zeta_{4n}) \right) \\ & \times (Q_{dn} - Q_{dn}^*) + \sum_{n=1}^N \left( \theta \sum_{d=1}^D Q_{dn} - \sum_{m=1}^M Q_{nm} \right) \times (\zeta_{4n} - \zeta_{4n}^*) \geq 0, \forall Q_{nm} \geq 0, Q_{dn} \geq 0, \zeta_{4n} \geq 0, \end{aligned} \quad (13)$$

where  $\zeta_{4n}$  is the Lagrangian coefficient to ensure the constraint condition of the objective function is established, which represents the minimum recovery cost of the recycler, that is, the cost that the recycler is willing to bear at most for the unit product recovery. The economic explanation of variational inequality (13) is as follows.

The first item indicates that in equilibrium, for any supply greater than zero, the marginal transaction price of the auto parts recycler is equal to the sum of the marginal transaction cost of the recycler and the manufacturer and the minimum recovery cost of the recycler.

The second item indicates that in the equilibrium state, for any supply greater than zero, the sum of the marginal storage cost of the recycler, the marginal transaction cost of the recycler and the demand market, the transaction price of the demand market, the energy use cost of the input end, the carbon emission cost of the output end, and the disposal cost of the unit scrap product is equal to the minimum recovery cost of the auto parts recycler.

The third item indicates that under the equilibrium state, for any supply greater than zero, the transaction volume of

the auto parts demand market and the recycler is equal to that of the recycler and the manufacturer.

**3.1.6. Network Equilibrium Model with Carbon Trading as Objective Function.** In the supply chain, when the carbon emission limit of  $A_{CC}$  node enterprise  $j$  is not enough, it can buy the carbon emission limit  $CC_j^-$  sold by other enterprises at a price through the carbon trading market; on the contrary, when the carbon emission limit of the enterprise with good energy conservation and emission reduction is redundant, it can sell the carbon emission limit of the enterprise  $CC_j^+$  needed at  $V^{CC}$  price. Carbon emissions are calculated in terms of carbon dioxide equivalent per ton ( $CO_2e$ ). Then, the objective function of the trading profit of a node enterprise  $j$  is

$$\text{Max } V^{CC}CC_j^+ - A^{CC}CC_j^-, \quad (14)$$

where  $j \in M \cup R \cup N$ .

The constraint is that the energy consumption and the carbon footprint of each node enterprise in the supply chain network are within the limit, that is,

$$\begin{aligned} CO_o^{\text{out}} \sum_{r=1}^R EF_{om} Q_{mr} + CO_i^{\text{in}} \sum_{r=1}^R CF_{im} Q_{mr} + CC_m^+ - CC_m^- &\leq L_m^{\text{CO}_2e}, \\ CO_o^{\text{out}} \sum_{d=1}^D EF_{or} Q_{rd} + CO_i^{\text{in}} \sum_{d=1}^D CF_{ir} Q_{rd} + CC_r^+ - CC_r^- &\leq L_r^{\text{CO}_2e}, \\ CO_o^{\text{out}} \sum_{d=1}^D EF_{on} Q_{dn} + CO_i^{\text{in}} \sum_{d=1}^D CF_{in} Q_{dn} + CC_n^+ - CC_n^- &\leq L_n^{\text{CO}_2e}, \\ CC_m^+ &\leq L_m^{\text{COS}}, \\ CC_m^- &\leq L_m^{\text{COP}}, \\ CC_r^+ &\leq L_r^{\text{COS}}, \\ CC_r^- &\leq L_r^{\text{COP}}, \\ CC_n^+ &\leq L_n^{\text{COS}}, \\ CC_n^- &\leq L_n^{\text{COP}}. \end{aligned} \quad (15)$$

The solution of the objective function with constraints on the carbon footprint of the whole low-carbon supply chain is equivalent to the solution of the corresponding

variational inequality below, which satisfies the following conditions:

$$\begin{aligned}
& (CC_m^+, CC_m^-, CC_r^+, CC_r^-, CC_n^+, CC_n^-, Q_{mr}, Q_{rd}, Q_{dn}, \zeta_{5m}, \xi_{5r}, \tau_{5n}, \alpha_{5m}, \alpha'_{5m}, \beta_{5r}, \beta'_{5r}, \gamma_{5n}, \gamma'_{5n}) \geq 0 \\
& \sum_{m=1}^M (\zeta_{5m} + \alpha_{5m} - V^{cc}) \times (CC_m^+ - CC_m^{+*}) + \sum_{m=1}^M (A^{cc} - \zeta_{5m} + \alpha'_{5m}) \times (CC_m^- - CC_m^{-*}) \\
& + \sum_{r=1}^R (\xi_{5r} + \beta_{5r} - V^{cc}) \times (CC_r^+ - CC_r^{+*}) + \sum_{r=1}^R (A^{cc} - \xi_{5r} + \beta'_{5r}) \times (CC_r^- - CC_r^{-*}) \\
& + \sum_{n=1}^N (\tau_{5n} + \gamma_{5n} - V^{cc}) \times (CC_n^+ - CC_n^{+*}) + \sum_{n=1}^N (A^{cc} - \tau_{5n} + \gamma'_{5n}) \times (CC_n^- - CC_n^{-*}) \\
& + \sum_{m=1}^M \sum_{r=1}^R (CO_o^{\text{out}} EF_{om} + CO_i^{\text{in}} CF_{im}) \zeta_{5m} \times (Q_{mr} - Q_{mr}^*) \\
& + \sum_{r=1}^R \sum_{d=1}^D (CO_o^{\text{out}} EF_{or} + CO_i^{\text{in}} CF_{ir}) \xi_{5r} \times (Q_{rd} - Q_{rd}^*) \\
& + \sum_{n=1}^N \sum_{d=1}^D (CO_o^{\text{out}} EF_{on} + CO_i^{\text{in}} CF_{in}) \tau_{5n} \times (Q_{dn} - Q_{dn}^*) \\
& + \sum_{m=1}^M \left[ L_m^{\text{CO}_2^e} - CO_o^{\text{out}} \sum_{r=1}^R EF_{om} Q_{mr} - CO_i^{\text{in}} \sum_{r=1}^R CF_{im} Q_{mr} - CC_m^+ + CC_m^- \right] \times (\zeta_{5m} - \zeta_{5m}^*) \\
& + \sum_{r=1}^R \left[ L_r^{\text{CO}_2^e} - CO_o^{\text{out}} \sum_{d=1}^D EF_{or} Q_{rd} - CO_i^{\text{in}} \sum_{d=1}^D CF_{ir} Q_{rd} - CC_r^+ + CC_r^- \right] \times (\xi_{5r} - \xi_{5r}^*) \\
& + \sum_{n=1}^N \left[ L_n^{\text{CO}_2^e} - CO_o^{\text{out}} \sum_{d=1}^D EF_{on} Q_{dn} - CO_i^{\text{in}} \sum_{d=1}^D CF_{in} Q_{dn} - CC_n^+ + CC_n^- \right] \times (\tau_{5n} - \tau_{5n}^*) \\
& + \sum_{m=1}^M (L_m^{\text{COS}} - CC_m^+) \times (\alpha_{5m} - \alpha_{5m}^*) + \sum_{m=1}^M (L_m^{\text{COP}} - CC_m^-) \times (\alpha'_{5m} - \alpha'_{5m}^*) \\
& + \sum_{r=1}^R (L_r^{\text{COS}} - CC_r^+) \times (\beta_{5r} - \beta_{5r}^*) + \sum_{r=1}^R (L_r^{\text{COP}} - CC_r^-) \times (\beta'_{5r} - \beta'_{5r}^*) \\
& + \sum_{n=1}^N (L_n^{\text{COS}} - CC_n^+) \times (\gamma_{5n} - \gamma_{5n}^*) + \sum_{n=1}^N (L_n^{\text{COP}} - CC_n^-) \times (\gamma'_{5n} - \gamma'_{5n}^*) \geq 0,
\end{aligned} \tag{16}$$

where  $\zeta_{5m}, \xi_{5r}, \tau_{5n}, \alpha_{5m}, \alpha'_{5m}, \beta_{5r}, \beta'_{5r}, \gamma_{5n}, \gamma'_{5n}$  is the Lagrange coefficient to ensure the constraint conditions of the objective function is established.

**3.2. The Establishment of Network Equilibrium Model under the Environment Goal of Low-Carbon Supply Chain.** Based on the carbon footprint management, the environmental objective function of the low-carbon supply chain is minimum carbon emission. Taking the carbon dioxide equivalent per ton tCO<sub>2</sub>e as the calculation unit, the environmental objective function of the whole low-carbon supply chain network is

$$\min CO_i^{\text{in}} C_i + CO_o^{\text{out}} E_o. \tag{17}$$

The total input energy consumption and output carbon emissions are as follows:

$$\begin{aligned}
C_i &= \sum_{m=1}^M \sum_{r=1}^R CF_{im} Q_{mr} + \sum_{r=1}^R \sum_{d=1}^D CF_{ir} Q_{rd} + \sum_{n=1}^N \sum_{d=1}^D CF_{in} Q_{dn}, \\
E_o &= \sum_{m=1}^M \sum_{r=1}^R EF_{om} Q_{mr} + \sum_{r=1}^R \sum_{d=1}^D EF_{or} Q_{rd} + \sum_{n=1}^N \sum_{d=1}^D EF_{on} Q_{dn}.
\end{aligned} \tag{18}$$

The optimal conditions of the above programming problems are equivalent to the following variational inequalities, and the solution  $(Q_{mr}, Q_{rd}, Q_{dn}) \geq 0$  satisfies the following requirements:

$$\begin{aligned}
& \sum_{m=1}^M \sum_{r=1}^R (CO_o^{\text{out}} EF_{om} + CO_i^{\text{in}} CF_{im}) \times (Q_{mr} - Q_{mr}^*) \\
& + \sum_{r=1}^R \sum_{d=1}^D (CO_o^{\text{out}} EF_{or} + CO_i^{\text{in}} CF_{ir}) \times (Q_{rd} - Q_{rd}^*) \\
& + \sum_{n=1}^N \sum_{d=1}^D (CO_o^{\text{out}} EF_{on} + CO_i^{\text{in}} CF_{in}) \times (Q_{dn} - Q_{dn}^*) \geq 0.
\end{aligned} \tag{19}$$

**3.3. The Network Equilibrium Model of the Whole Low-Carbon Supply Chain.** The quantity of purchase and recycled products in the demand market must be equal to the quantity received by the reprocessing recycler. The price and the carbon trading volume between the upstream and downstream networks of the supply chain must meet the sum of the equivalent variational inequalities of each equilibrium condition. When the low-carbon supply chain network finally reaches the equilibrium state, its decision variables must meet the optimal conditions of suppliers, producers, physical retailers, online retailers, demand markets, and recyclers, as well as the optimal conditions of carbon trading and carbon footprint environmental objective function.

## 4. Simulation and Result Analysis

In this section, the above models are simulated to discuss the change rule of trading profit and carbon emission with exogenous variables (recycling coefficient, remanufacturing coefficient of waste products, etc.). It is assumed that the supply chain network model of auto parts is a closed-loop supply chain composed of two suppliers, two producers, one physical retailer, online retailer, two demand markets, and two recyclers. For the purpose of simulation calculation, the parameters used in the model and the settings of the functions involved in the model are shown in Table 3. There are many parameters involved in the model. It mainly analyzes the recycling coefficient  $r_k$  and the remanufacturing coefficient  $\mu$  of the network members and observes the changes of the total profits of carbon trading and the total carbon emissions of the supply chain.

**4.1. The Influence of Recycling Coefficient on Carbon Emission and Total Profit of Supply Chain.** Under the different recycling coefficient  $r_k$ , the total carbon emission and the total profit of carbon trading and selling in the supply chain show an interval change trend, as shown in Figures 2 and 3, respectively. In order to facilitate the analysis of the impact of the change of the recycling coefficient on the carbon emissions and total profits of the supply chain, this paper considers the following.

It can be seen from Figure 2 that with the increase in the recycle coefficient  $r_k$ , the total amount of carbon emissions increases continuously and the range is large. This is because the larger the  $r_k$  is in the process of recycling waste products,

TABLE 3: Parameter setting.

| Parameter           | Value             |
|---------------------|-------------------|
| $v_{im}$            | 200/t             |
| $v_{ir}$            | 200/t             |
| $v_{in}$            | 200/t             |
| $A^{cc}$            | 2500/t            |
| $V^{cc}$            | 2500/t            |
| $a$                 | 0.5               |
| $g$                 | 4                 |
| $p$                 | 1000              |
| $u_{om}$            | 200/t             |
| $u_{or}$            | 200/t             |
| $u_{on}$            | 200/t             |
| $\varphi_{sm}$      | 0.9               |
| $\varphi_{nm}$      | 0.8               |
| $b$                 | 2                 |

| $\varepsilon$       | $10^{-3}$         |
| $\theta$            | 0.8               |
| $f$                 | 5                 |
| $o$                 | 1.5               |

the more the waste products will be recycled from the demand market, the more the waste products will be disposed, and the more the carbon emissions will be.

It can be seen from Figure 3 that with the increase in the recycling coefficient  $r_k$ , recycling conversion and reuse coefficient  $\theta$  shows an upward trend, while the trading profit of carbon trading shows a downward trend. It shows that the increase of recycled products recycling leads to the increase of recycled products conversion and reuse, which increases the carbon emissions of supply chain members, while the carbon emission quota allocated by most members of the supply chain is not enough to make up for the increased carbon emissions and reduced carbon trading, thus reducing the trading profits of carbon trading.

**4.2. Influence of Remanufacturing Coefficient of Waste Products on Carbon Emission and Total Profit of Supply Chain.** With different remanufacturing coefficient  $\mu$  of waste products, the total amount of carbon emissions in the

FIGURE 2: Change of total carbon emission with  $r_k$ .

FIGURE 3: Change of total profit of carbon trading with  $r_k$ .

supply chain and the total profit of carbon trading show an interval trend, as shown in Figures 4 and 5, respectively. In order to analyze the influence of the remanufacturing coefficient of waste products on carbon emission and total profit of the supply chain, this paper considers the following.

As can be seen from Figure 4, the carbon emissions in the supply chain increase with the increase in  $\mu$ , but the range is not very large. This is due to the increase of recycled materials and the corresponding increase of production, thus the carbon emissions increase. Recyclers have a great impact on carbon emissions. By properly increasing the remanufacturing coefficient of waste products, carbon emissions and trading profits can be optimized at the same time.

As can be seen from Figure 5, with the increase in the remanufacturing coefficient  $\mu$  of waste products, the availability coefficient of reprocessed products of recyclers is also slowly increasing and the trading profit of carbon trading decreases accordingly. This is because with the manufacturing of waste products, recyclers can process more products, and the carbon emission quota allocated by producers is not enough to make up for the increased carbon emissions, which reduces the carbon trading and thus reduces the profits of carbon trading. In order to improve the profit of carbon trading in the supply chain, manufacturers need to make a reasonable ordering plan in order to balance the carbon emissions and the profit of carbon trading.

### 5. Conclusion

The top-level design of a smart city should focus on green in strategy, aiming to build a green smart city. Smart cities plan and build around energy conservation, emission reduction, and environmental optimization and regard sustainable development as the starting point and destination. As an important strategic industry in the construction of smart cities, the auto parts industry should also take responsibility for low-carbon emission reduction. In this paper, by considering the optimal decision-making behavior of suppliers, producers, physical retailers, online retailers, demand markets, and recyclers, as well as the situation of carbon trading and carbon emissions, the equilibrium conditions of each node in the low-carbon supply chain of auto parts are analyzed by using variational inequality, and the network equilibrium optimization model of the low-carbon supply chain is established. Using the simulation analysis method, through analyzing the relationship between carbon emissions and trading profits with the recovery coefficient of

recycled products and the remanufacturing coefficient of waste products, we can get that carbon emissions directly affect the trading profits of carbon trading; recyclers have a great impact on carbon emissions. Properly increasing the recovery coefficient of recycled products and the remanufacturing coefficient of waste products can make carbon emissions and profits of carbon trading reach the optimal level at the same time. In order to improve the profits of carbon trading in the supply chain, manufacturers need to make reasonable ordering plans to balance carbon emissions and profits of carbon trading. It further shows that in order to achieve the network equilibrium of the low-carbon supply chain of auto parts, the coordination and cooperation of supply chain members is needed. Through recycling, process improvement, and other measures, the carbon emissions of the supply chain network can be reduced, and the excess carbon emissions can be sold in the carbon trading market. The profits can offset the cost investment in emission reduction and finally achieve the purpose of low-carbon supply chain management.
