The multilayer feedforward neural network (MFNN) (refer to Figure 2) using the segmental feedback layer is given. The flow model is presented in the following figure. Here, it intimated the input process and the output process terms.

Multilayer feedforward neural network (MFNN) generates two classifications:

(i) Single multilayer feedforward neural network.

(ii) Multiple multilayer feedforward neural network.

The single-layer MFNN is helping the performance improvement to present the result alone. Another classification is multiple MFNN is used to find the difference between real integer resultant layers through the sigmoid activation process. The sigmoidal activation function in the MFNN presents an improved output with repespect to the individual input layers. In this investigation, MFNN is utilizing the testing and training sets of the image classification configuration. Meanwhile, 80% of the samples were utilized for training and 20% for testing. Input is one of the optimal features for the FNN from the objective of the research work. The trained single-layer feedforward neural network is tested on the feature extracted image. The performance metrics evaluate the results, and they are tabulated in the experimental part.

4. Experimental Analysis

In this, the Matrix laboratory software is utilized to execute the proposed technique in the simulation format. The proposed method is tested on the open-access brain tumor dataset (250 samples) collected from Kaggle data collection, which is used in the parallel k-means clustering for better analysis and comparison [25].

For training and testing, the dataset is split into 80% for training and 20% for testing. The following figures are the input and output of each stage of the proposed technique. The MFNN is reconfigured based on the features extracted by our proposed method. The reconfigured network was utilized for the training and testing of the data. The output of each process of the proposed method is shown in Figures 3–6.

The RGB format of the hyperspectral image is shown in Figure 3. The noisy image (refer to Figure 4) is preprocessed with a grayscale image shown in Figure 5. This noisy signal is processed with the GLCM method.

The filtered output image is shown in Figure 6. Based on these images, the mean absolute error value and peak signal-to-noise ratio are evaluated, and they are compared with the existing method, which is depicted in Table 2.

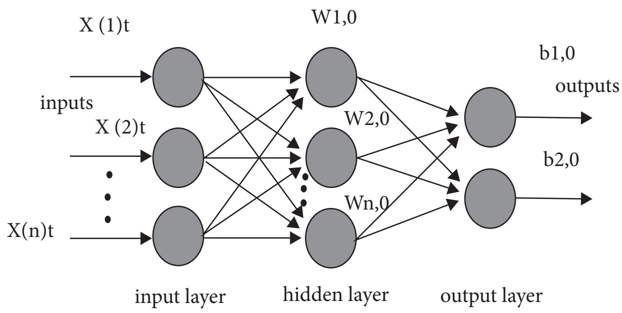

Figure 2: MFNN data flow model.

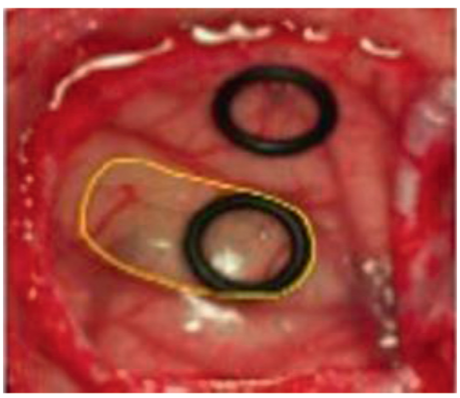

Figure 3: RGB format of HSI image.

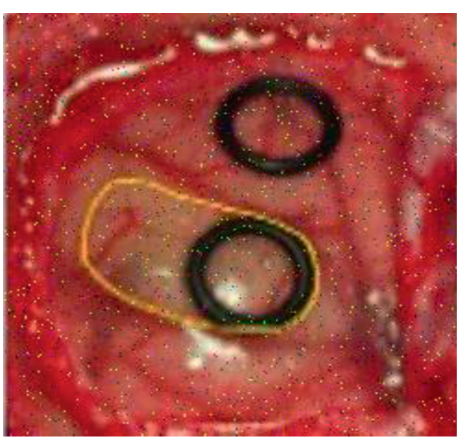

Figure 4: Noisy image.

The comparisons of the existing methods with the proposed method are made by calculating the following parameters:

MAE: MAE is the abbreviation of mean absolute error, which tells how much percentage of the detected labels has deviated from the original labels.

PSNR: PSNR is the abbreviation of the peak signal-to-noise ratio, which gives information about the image's quality after several processes to map the brain regions. The PSNR is increased in a hybrid firefly based on the k-means clustering technique by comparing the results. The results are compared with parallel k-means, optimized k-means, and SVM with k-means techniques. The mean absolute error is raised in the parallel k-means clustering technique and better in the proposed model (Table 2).

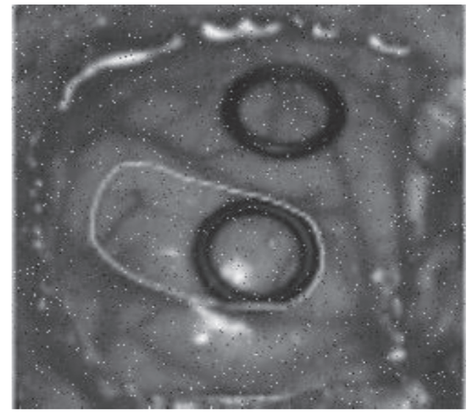

Figure 5: Preprocessed greyscale image.

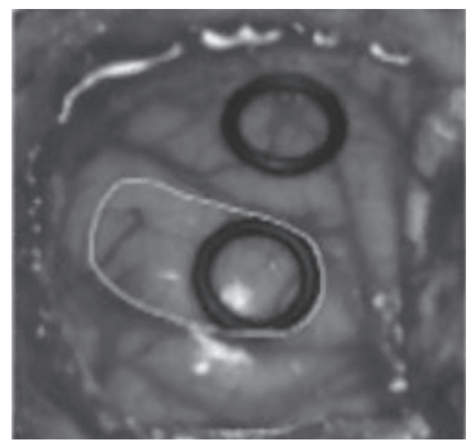

Figure 6: Postfiltered output.

The performance evaluation was carried out in order to assess the efficiency of the proposed model. Accuracy, sensitivity, and specificity are three performance measures used in the assessment. By merging specificity and sensitivity, a single metric, quality, may be obtained. Both metrics should have a value of one. These three comparable performance measuring evaluations are also used in this study, which are as follows:

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}}\%,$$
$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}}\%, \tag{6}$$
$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}}\%.$$

(i) TP: true positive was the total of truly identified brain tumor.

Table 2: Performance comparison results.

Parameters	Parallel k-means clustering	Optimized k-means clustering	SVM with k-means clustering	Hybrid firefly and k-based clustering
Mean absolute error value	75	70	68	65
Peak signal-to-noise ratio	72	75	80	85

Table 3: Comparison of performance analysis.

Classifiers	Accuracy	Sensitivity	Specificity
K-NN	94.93	94.26	94.55
DNN	95.30	94.85	97.70
PSO	95.11	94.71	97.01
Lagrangian SVM (LSVM)	93.34	91.22	96.69
DCNN [1]	94.50	95.10	95.86
Proposed method	96.47	96.32	98.24

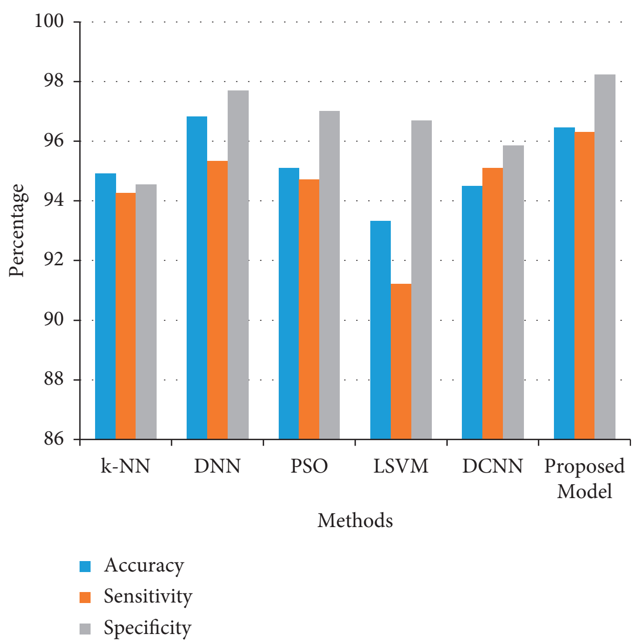

Figure 7: Graphical view of compared performance analysis.

(ii) FP: false positive was the total misclassified regions as a brain tumor.

(iii) FN: false negative was the total from inaccurately unidentified areas.

(iv) TN: true negative was the total of the truly identified nonbrain tumor.

In Table 3 and Figure 7, the comparisons of the performances analysis of the proposed model with other existing approaches were represented. Accuracy, sensitivity, and specificity are the parameters evaluated for this performance analysis. Based on the true positive and true negative values, the efficiency of the model was calculated. The proposed model is compared with k-NN, DNN, PSO, LSVM, and DCNN [1, 17–28]. The proposed model achieved 96.47% accuracy, which is 1.17% to 3.13% higher than other techniques, with a sensitivity of 96.32%, which is 2.06% to 5.1% better than other methods, and specificity of 98.24%, which is 0.5% to 3.6% improved compared to other techniques.

5. Conclusion

This research proposed an unsupervised approach for clinical treatment based on the patient's brain tumor estimation. The brain's mapping and localization are achieved using k-means clustering, firefly optimization, and MFNN. The proposed multilayer feedforward neural network (MFNN) addresses the brain-molecule optimization method's process and achieves minimum error and trial techniques. Hence, the proposed optimized mapping process produced improved outputs in every form, and it is suitable for mapping the molecules of the spectral medical image. The proposed model is compared with k-NN, DNN, PSO, LSVM, and DCNN. The proposed model achieved 96.47% accuracy, which is 1.17% to 3.13% higher than other techniques, with a sensitivity of 96.32%, which is 2.06% to 5.1% better than other methods, and specificity of 98.24%, which is 0.5% to 3.6% improved compared to other techniques. In future, to improve the performance, a hybrid deep learning method with a deep transfer learning model for the brain tumor classification process using related image datasets can be implemented. For the feature extraction process, a novel threshold-based method can be used [25–28].

Data Availability

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Objective. To detect problems of mental health disorders early and actively by constructing a comprehensive evaluation system of mental health. *Methods*. The evaluation system was constructed by the Minnesota personality questionnaire (MMPI), the personality questionnaire (EPQ), and the depression experience questionnaire (DEQ). Total 341 interns and residents in a general hospital were investigated with the questionnaire about psychological status, and the results were analyzed by SPSS22.0. *Results*. The KMO was 0.879, and the factor load of the seven factors was 0.49 to 0.856. The cumulative variance contribution reached 72.18%, and the overall consistency coefficient was 0.871. The relationship, emotional disorder, paranoia, reflection, and positive response were 0.893, 0.614, 0.867, 0.771 and 0.621, respectively. In this study, the mental health composite scores of all study subjects met a normal distribution, so level 3 scores of clinical interns and residents were established according to the deviation method. *Conclusion*. The constructed index system contains comprehensive indicators, good reliability efficiency, and a level 3 score, which helps individuals and hospitals to detect problems early, and provide guidance and advice for active intervention.

1. Introduction

Mental health problems are prevalent in every working population of the world. The Organization for Economic Cooperation and Development (OECD) study showed that about 5% and 15% of the working population in high-income countries have serious and moderate mental health problems, respectively [1]. This problem is particularly prominent for physicians, with an increasing proportion of mental illness (such as anxiety, depression, and substance abuse) [2]. For example, in the UK, 10 to 20% of doctors become depressed at some stage of their career and are at higher risk of suicide than the general population; another online survey of UK physicians found that 68% of 116 respondents were diagnosed with depression and others with bipolar disorder, anxiety, eating disorders, and substance addiction [3]. A 2014 study by researchers from the American Medical Association (AMA) and Mayo Clinic showed that 54 percent of U. S. doctors are experiencing burnout, which is higher than in other industries [4]. The suicide rate was also high, with a 40-year review study of clinicians' suicides demonstrating that male clinicians had 70% more odds of suicide than the general population and 250%–400% higher for female clinicians [5].

Clinician mental health problems are mainly affected by the following factors: special occupational nature [6], growing working pressure, and inflexible working hours [7]. Because they know more and it is easier to access drugs, doctors are also more prone to substance addiction and abuse than the general population [8]. In addition, doctors rarely seek professional help because of the humiliation of mental illness [9].

The poor mental health state of clinicians simultaneously affects their work. Research has shown that poor mental health status will reduce the accuracy of clinical diagnosis and increase medical costs while reducing the quality of medical services that patients receive [10]. Although the mental health problems of clinicians have received wide attention, there is no relatively comprehensive evaluation method to comprehensively assess their mental health.

Therefore, how to evaluate and improve the mental health of hospital clinicians has become an urgent problem for individuals, families, hospitals, and even society. As it is difficult to comprehensively evaluate the individual mental health level if the individual psychological indicators are qualified or not, this study aims to explore the comprehensive mental health evaluation method and mental health status of clinicians so as to provide a reference for early problem detection and intervention.

2. Materials and Methods

2.1. Subject Investigated. A total of 353 clinical medical interns in a third-class hospital in Shenyang with standardized training, 12 invalid questionnaires were removed, and 341 valid questionnaires were obtained, with an efficiency of 96.6%. Among them, 128 were boys (37.5%) and 213 were girls (62.5%). Among them, 18 clinical medicine interns (52.8%) and 161 residents (47.2%) conducted standardized training. The age range was 21–35 years, and the mean age was 23.2 years.

2.2. Selection of the Study Indicators. Using the literature analysis method, the preliminary screening indicators were discussed by the expert group of the psychiatric department of the Grade A hospital and combined with the mental health quality of Chinese adults, five psychological indicators of personality characteristics, emotion, coping mode, interpersonal relationship, and reflection function were finally established to evaluate the mental health status of doctors.

2.3. Source of Indicators. Data on the subjects' age, gender, and specialty were collected. The Minnesota Muhiphasic Personality Inventory (MMPI) was prepared by S. R. Hathaway and J. C. Mckinley. Song Weizhen et al. revised 566 questions, including 4 validity scales and 10 clinical scales, showing good reliability and validity of each subscale. In this study, psychopathies, paranoia, and schizophrenia 3 subscales were used as evaluation tools for personality characteristics [11].

The Eysenck Personality Questionnaire (EPQ) was prepared by J. Eysenck and revised by Liu [12]. The questionnaire has 88 questions, including 4 subscales, of which scale E measures internal and external dimension; the P scale measures neuroticism dimension; the Q scale measures psychoplasm dimension; and the L scale mainly measures the concealment of subjects. It has good reliability and validity in the Chinese population. The Q scale was used as an assessment tool for personality characteristics in this study.

2.3.1. The Depression Experience Questionnaire (DEQ). Written by Blatt et al. and revised by Liu et al. [13], the DEQ had 66 questions and a graded Likert7 score with an internal consistency coefficient of 0.65–0.79 for the five factors included in the scale and 0.81 for the full scale. The five factors of the questionnaire were significantly associated with the total score of the depression self-rating scale, and the highest correlation coefficient between self-criticism factor and SDS was 0.508, followed by the helpless factor of 0.382, the dependent factor and SDS was 0.252, the autonomy factor was 0.298, and the satisfaction factor showed a significant negative correlation with SDS of −0.148.

2.3.2. State-Trait Anxiety Inventory (STAI). Prepared by Wang [14], it is made up of subscales evaluating two different anxiety types, with a total of 40 entries. Items 1–20 are the state anxiety subscales (STAI-Form Y-I, S-AI), and items 21–40 are the trait anxiety subscales (STAI-Form Y-II, T-AI).

2.3.3. Coping Style Questionnaire (CSQ). Prepared by Xiao Plan et al., the scale consists of 62 entries with only two answers each, including six subscales with good reliability and validity, and has been widely used [15].

2.3.4. Emotional-Social Loneliness Questionnaire (ESLI). The Emotion-Social Solitude Questionnaire (ESLI) is a multidimensional questionnaire distinguishing between the four types of loneliness: emotional isolation, social isolation, emotional loneliness, and social loneliness. The ESLI contains 15 pairs of descriptions, each with four-grade scores, from 3 (usually) to 0 (rarely) [14].

2.3.5. Reflective Functional Questionnaire-8 (RFQ-8). Written by Fonagy, and revised by Xu et al. [16], it is a self-assessment tool used to assess adult reflective function. The questionnaire consisted of eight entries, a Likert7 grade score, with options from "great disagreement" to "great consent." The score of entry 1,2,3,4,5,6 as "0,0,0,0,0,1,2,3" to form the excessive mentalization (certainty about mental states, RFQ-C) subscale; entry 2,4,5,6,8 as "3,2,1,0,0,0,0" and the entry 7 score as "0,0,0,0,1,1,2,3" to form the mentalization defect (uncertainty about mental states, RFQ-U) subscale. This study finally established five first-level psychological indicators, including personality characteristics, emotion, coping mode, interpersonal relationship, and reflective function, and 23 secondary psychological indicators, such as psychological metamorphosis, paranoia, schizophrenia, mental quality, anxiety state, and anxiety characteristics, as the mental health evaluation indicators of doctors. Index numbers are shown in Table 1.

2.4. Investigation Method. The method of random group sampling was applied with clinical medical interns and standardized training residents in Shenyang. Under the unified guidance of standardized trained researchers, the students were given appropriate time to let the research subjects complete the questionnaire independently and recycle the questionnaire on the spot after filling it in.

Table 1: Mental health evaluation indicators of physicians.

Level 1 indicators	Secondary indicators	Number
Personality characteristics	Metaphrenia	X1
	Bigoted	X2
	Split personality	X3
	Psychoticism	X4
	Anxiety state	X5
	Anxiety traits	X6
	Self-criticism	X7
Emotional state	Helplessness	X8
	Rely on	X9
	Autonomy	X10
	Satisfied	X11
	Solve the problem	X12
Coping style	Self-accusation	X13
	Turn to sb. for help	X14
	Illusion	X15
	Withdraw and keep off	X16
	Rationalization	X17
	Emotional isolation	X18
	Social isolation	X19
	Emotional loneliness	X20
	Social loneliness	X21
Reflect function	RFQC	X22
	RFQU	X23

2.5. Statistical Analysis. The data were entered using SPSS 22.0 software. The data were analyzed by descriptive statistical analysis, internal consistency test, and factor analysis, and the comprehensive scores of the study subjects were subjected to the normality test and the independent sample *t*-test.

3. Results

3.1. Distribution of Basic Sample Information. A total of 341 samples were collected in this study, including 180 clinical medicine interns and 161 residents with standardized training. The information distribution of the study subjects is shown in Table 2.

3.2. Data Standardization

3.2.1. Structural Validity. Because the data is not uniform in the indicators and there are positive and reverse indicators, the original data were assimilated and normalized first. Part of the raw data are shown in Table 3.

The KMO value of this study was 0.879 ($p < 0.01$), indicating the suitability for factor analysis.

3.2.2. Factor Extraction. The variance was decomposed by principal component analysis, and the resulting variable eigenvalues, variance contribution rate, and cumulative variance contribution rate are shown in Table 4. The cumulative contribution was required to be greater than 70% so that seven principal components were retained in this study. Combining the inflection point of the eigenvalue curve and the gravel diagram (scree plot, SP) of the eigenvalue (Figure 1), the figure shows from another side that the first 7 main components should be taken. To better explain the extracted factors, we maximized the orthogonal rotation of the extracted seven factors, and the eigenvalues of each factor after rotation are shown in Table 5. However, the factor load matrix obtained after rotation is shown in Table 6, indicating that the structural validity of the evaluation system in this study is good.

3.2.3. Factor Interpretation and Naming. According to the rotating factor load matrix, Factor Y1 was significantly associated with the indices X18, X19, X20, and X21; that is, Y1 is correlated with emotional loneliness and social loneliness. Factor Y1 is called a human relationship factor. Factor Y2 was significantly associated with metrices X5, X6, X7, X8, X9, and X10; that is, Factor Y2 is associated with anxiety and depression, and Factor Y2 is called an emotional dysregulation factor. Factor Y3 was significantly associated with the indices X13, X15, X16, and X17; that is Factor Y3 is associated with immature coping methods, and Factor Y3 is called a neurosis factor. Factor Y4 was significantly associated with metrices X1, X2, X3, and X4; that is, Factor Y4 is associated with severe psychotic symptoms, and Factor Y4 is called a paranoid factor. Factor Y5 was mainly significantly associated with metrices X22 and X23; that is, Factor Y5 is associated with reflective function, and Factor Y5 is called a reflective functional factor. Factor Y6 was significantly associated with metrices X12 and X14; therefore, Factor Y6 is related to problem solving and asking for help, and Factor Y6 is called an active response factor. Factor Y7 is associated with the indicator X11; that is, the factor Y7 is associated with self-satisfaction, and Factor Y7 is called a confidence factor.

3.3. Confidence Analysis. The internal consistency of the comprehensive evaluation system was tested, and the overall Cronbach α coefficient of the comprehensive mental health evaluation system was 0.871. The internal Cronbach α coefficient of interpersonal relationships, mood disorders, neurosis, paranoia, reflective function, and positive response to these six factors were 0.893, 0.614, 0.867, 0.771, 0.626, and 0.621, respectively, indicating the good reliability of the evaluation system.

3.4. The Clinician Mental Health Level 3 Score Was Established. The comprehensive scores were calculated for all study subjects and tested for normality with a Z-value of 0.044 ($p > 0.05$). Therefore, 3 all subjects scored normally distributed, and the histogram of the frequency distribution for 341 subjects is shown in Figure 2. The differences in mental health composite scores between genders and seniority were compared using independent sample *t*-tests, and the results showed that the differences in gender and seniority were not statistically significant; that is, the abovementioned factors had little impact on the mental health composite scores in this study.

Table 2: Distribution of basic information.

		Clinical intern		Chief physician	
		Example number	Percentage	Example number	Percentage
Sample		180	52.8	161	47.2

Table 7: Level 3 scoring criteria for physician mental health.

Grade	Range	Same as	Preferably
Standard	≥M + S	M − S~M + S	≤M − S
Standard mark standardized score	≥23.462	−23.461~23.462	≤−23.461

Note. M is the mean number, and S is the standard deviation.

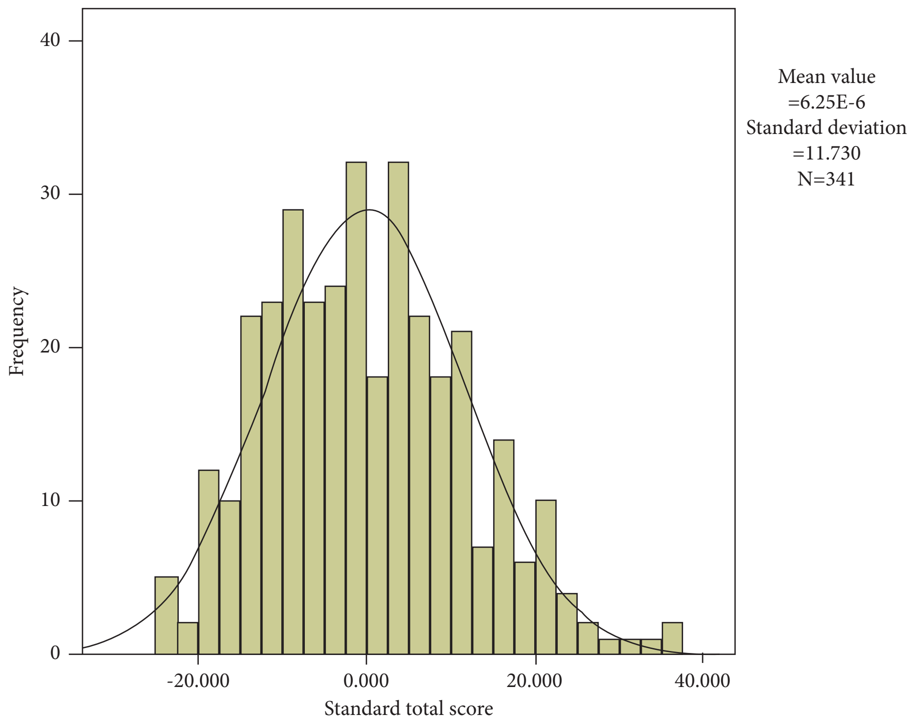

Figure 2: The histogram of frequency distribution of 341 study subjects in this study. Since the subjects fit a normal distribution, the level 3 score for establishing physician mental health with a standard deviation as a discrete distance according to the discrepancy method is shown in Table 7.

4. Discussion

Mental health problems are prevalent in every working population of the world [17]. It brings a great economic burden on individuals and families, but also brings huge economic losses to enterprises and society. This study completed the construction of a comprehensive evaluation system for physician mental health and was able to screen out doctors with mental health problems, contributing to early problem detection and active intervention.

In this study, we selected five psychological indicators, such as personality characteristics, emotion, coping mode, interpersonal relationship, and reflection function, and used widely used psychological measurement tools, such as the Minnesota Multiple Personality test (MMPI), the Eysenck Personality Questionnaire (EPQ), the Depression Experience Questionnaire (DEQ), and extracted psychological metamorphosis, paranoia, schizophrenia, schizophrenia, anxiety state, anxiety status, anxiety characteristics, and self-criticism as comprehensive evaluation theories [18]. A comprehensive evaluation system was built. Through the principal component analysis method, combined with the cumulative factor contribution rate, seven factors were extracted and rotated by the maximum orthogonal rotation method, which were named interpersonal factors, emotional dysregulation factors, neurosis factors, paranoid factors, reflective function factors, active response factors, and confidence factors, respectively. In study carried out by Liang [19], it is proposed that the mental health quality of Chinese adults is basically the same, indicating that the factors extracted from this study can comprehensively reflect the mental health status of individuals.

The KMO value in this study was 0.879. The factor load of the extracted factors ranged from 0.49 to 0.856. The cumulative variance contribution rate was 72.18%. It shows that the comprehensive evaluation system has a good structural validity; check the internal consistency of the comprehensive evaluation system. Among them, the overall Cronbach α coefficient of the comprehensive mental health evaluation system of clinicians was 0.871; the internal Cronbach of interpersonal relationships, emotional dysregulation, neurosis, paranoia, reflective function, and active response to these six factors, with coefficients of 0.893, 0.614, 0.867, 0.771, 0.626, and 0.621, respectively. It indicates that the evaluation system has a good reliability.

On the basis of the extracted 7 factors, the comprehensive scores of 341 subjects were calculated, and the data had a statistic Z-value of 0.044 ($p > 0.05$). The scores of 341 subjects were normally distributed, and they established a level 3 score of doctors with a standard deviation as a discretization to provide the basis for individual mental health evaluation. In addition, a comparison of mental health status between genders and posts showed that the differences in gender and posts were not statistically significant. Elwer et al. [20] studies showed that when individuals engage in nonsex-dominated occupations, their mental health is negatively affected and they are also more prone to absenteeism. But studies have also shown that men's mental health is largely unaffected when pursuing nongender-dominant occupations. However, in this study, significantly more women than men were present, so gender has no effect on mental health status, a conclusion that needs to be further confirmed in future studies.

This study has certain limitations: the survey was mainly of clinical interns and residents; limited by professional, age, education, and job category; failed to explore the influence of different education and postcategories for mental health status; and the measurement of mental health should be extended to more hospitals, professionals, and posts, to confirm the utility of clinicians' comprehensive mental health evaluation system.

5. Conclusion

This study constructed a comprehensive evaluation system of clinicians' mental health, different from the single evaluation index, using factor analysis to evaluate the mental health from interpersonal relationship, emotion, personality characteristics, reflection function, coping mode, and self-evaluation, which comprehensively reflected the mental health status of clinicians. The evaluation system has good credibility and accuracy and can classify clinicians' mental health status, providing reference for personal identification symptoms and hospital mental health screening [18, 21].

Retracted: Evidence-Based Care Can Improve Treatment Compliance and Quality of Life of Patients with Acute Pancreatitis

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 25 January 2023

Journal of Healthcare Engineering has retracted the article titled "Evidence-Based Care Can Improve Treatment Compliance and Quality of Life of Patients with Acute Pancreatitis" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Acute pancreatitis represents a disease characterized by acute necro-inflammatory changes in the pancreas, which is histologically characterized by destruction of alveolar cells. We aim to explore whether evidence-based care can improve treatment compliance and quality of life of patients with acute pancreatitis. The changes of hemoglobin (HGB), serum pre-albumin (PAB), and serum albumin (ALB) before and after care were observed, as well as the incidence of complications after care, total effective rate after care, disease severity (bedside index for severity in acute pancreatitis, BISAP) before and after care, and psychological scores of the two groups before and after care were observed. Patients' compliance after care, self-management scores after care, and quality of life after care were compared between the two groups. After care, HGB, PAB, and ALB increased significantly in both groups ($p < 0.05$) and were higher in OG than CG. Compared with CG, OG had significantly lower incidence of complications ($p = 0.009$), significantly higher total effective rate ($p = 0.011$), significantly lower disease severity ($p < 0.05$), significantly better psychological condition scores ($p < 0.05$), significantly higher compliance scores ($p < 0.05$), higher self-management scores ($p < 0.05$), and significantly higher quality of life ($p < 0.001$). Evidence-based care can improve treatment compliance of patients with acute pancreatitis and can effectively improve their quality of life.

1. Introduction

Acute pancreatitis is a common digestive system disease, which is caused by abnormal digestive enzymes in the patient's own organs, resulting in inflammation of the pancreatic secretions [1]. The age range of the disease is wide, but most of the people who develop it are adults [2]. According to data, the incidence of acute pancreatitis is 34 cases per 100,000 in the general population and is increasing worldwide, and its incidence increases with age [3]. The main symptoms of acute pancreatitis are sudden onset of upper abdominal pain accompanied by nausea and vomiting [4], while patients with severe acute pancreatitis may be accompanied by hypotension or shock, leading to organ dysfunction and high mortality [5]. Patients need to be hospitalized immediately for diagnosis and treatment of the disease. Usually, symptomatic treatment and nonsurgical treatment are the main treatment methods [6]. Although most patients with acute pancreatitis have mild conditions and better treatment methods, there are still some patients with severe acute pancreatitis and the complications after treatment are very difficult [7]. Surgical treatment is required for complications, and the prognosis is poor [8]. Clinical data show that severe pancreatitis has a rapid onset and the patient is in dangerous condition, which causes a serious burden on pancreas, reduces patients' quality of life, and even endangers life [9].

Chronic alcohol ingestion, cholelithiasis, and overeating are usually the main causes of acute pancreatitis [10]. Therefore, choosing an appropriate nursing method is particularly important to improve the rehabilitation of acute pancreatitis and to avoid the continuous deterioration of the disease [11]. Over the past decade, cares in China have continued to shine in the treatment of clinical diseases, improving poor patient outcomes and enhancing the relationship between doctors and nurses [12], which greatly improves treatment compliance of patients and enhances treatment effects [13]. A review of previous studies suggested that evidence-based care based on evidence-based medicine is effective in constraining patient self-management and reducing disease complications [14]. Acute pancreatitis represents a disease characterized by acute necroinflammatory changes in the pancreas, which is histologically characterized by destruction of alveolar cells [15]. It is found that acute pancreatitis secondary to alcohol is more common in men and gallstone pancreatitis is more common in women [16]. At present, mild acute pancreatitis is usually treated with drugs, and the prognosis is generally good [17]. Moderate and severe acute pancreatitis should be treated according to the cause of disease, and if necessary, surgery should be performed, and the prognosis is generally poor due to frequent complications [18].

Besides, there are few clinical studies on the intervention effect of evidence-based care on patients with acute pancreatitis. Therefore, this experiment analyzes the effect of evidence-based care on patients with acute pancreatitis and observes the improvement of patients' compliance and quality of life, aiming at providing effective care for future clinical diagnosis and treatment of acute pancreatitis, so as to increase its recovery rate.

2. Materials and Methods

With deeper cognition of diseases and master of previous experience, the nursing staff can realize the adverse reactions of patients in time, adjust treatment strategies, closely cooperate with doctors, and improve the treatment effects from the patient's point of view [19], which is also suspected to be the main reason for the obvious improvement of disease status in OG after implementing care. Author Aviles et al. [20] pointed out that evidence-based care is of great help to promote the recovery of diseases by analyzing the effects of evidence-based care on enhancing the recovery of patients undergoing duodenectomy, which is similar to our experimental results.

A total of 117 patients with severe acute pancreatitis treated in our hospital from May 2017 to June 2019 were collected for prospectively analyzed, 65 of whom receiving evidence-based care during treatment were enrolled in the observation group (OG), and the other 52 patients receiving routine care during treatment were enrolled in the control group (CG). Note: this study has been approved by the Ethics Committee of our hospital.

2.1. Inclusion and Exclusion Criteria. Inclusion criteria were as follows: patients were diagnosed as severe acute pancreatitis after laboratory and imaging examination according to Chinese Journal of Pancreatology, patients were over 25 years old, patients underwent operation in our hospital, with stable vital signs, complete clinical data, and were in rehabilitation stage, and patients and their families knew and agreed to this experiment.

Exclusion criteria were as follows: patients had abnormal liver or renal function, other congenital diseases, or major diseases, patients did not have the ability to read and write, patients had immune dysfunction, and patients had drug allergy.

2.2. Nursing Methods. The team of Williams [21] also proposed that evidence-based care can effectively improve the recovery of patients after cardiac surgery, which has application value and supports this study. CG: routine care was adopted. The patients were assigned to the ward when they were admitted to the hospital. Then, the nursing staff followed the doctor's advice to monitor the vital signs of patients, performed routine examinations, made preparations before operation, and explained simple disease knowledge to the patients and their families. Besides, the nursing staff reminded patients of matters needing attention, performed routine care operations after operation, dispensed drugs, paid attention to the progress of the disease, and guided and restrained the behaviors and habits of the patients such as diet after operation.

OG: evidence-based care was given on the basis of routine care in CG. The nursing staff paid close attention to the patient's heart rate, blood pressure, and other vital signs before surgery, actively cooperated with the attending physician, registered, and completed the preoperative examination. The nursing staff should search for evidence based on previous nursing experience of acute pancreatitis and relevant literature, deepen their understanding of diseases, set reasonable care measures according to patients' own conditions, carry out disease education, psychological decompression, restrain misconduct, and perform other interventions, and closely grasp patients' first-hand information during and after operation. According to the patient's own situation and the requirements of the corresponding attending physician, the patient was given medication and diet control. The recovery of patients was also closely monitored by the nursing staff.

2.3. Outcome Measures. In the implementation of evidence-based care, nursing staff should closely observe patients' emotional changes, tell successful cases to patients before operation, enhance patients' self-confidence, reasonably regulate patients' diet and living habits after operation, and increase the doctor-patient relationship, so as to improve patients' cooperation and promote the treatment process [22]; the above are important factors in the value of evidence-based care. The changes of hemoglobin (HGB), serum pre-albumin (PAB), and serum albumin (ALB) before and after care were observed, as well as the incidence of complications after care, total effective rate after care, disease severity (bedside index for severity in acute pancreatitis, BISAPe) [23] before and after care, and psychological scores of the two groups before and after care were observed.

Patients' compliance after care, self-management scores [24] after care, and quality of life after care were compared between the two groups.

2.4. Statistical Methods. All statistical analysis of the experimental results was performed by using SPSS24.0 statistical software (Shanghai Yuchuang Network Technology Co., Ltd.). All graph results were plotted by Graphpad8 (SOFTHEAD Inc., Shenzhen). Enumeration data were expressed in the form of (%), and chi-square test was utilized for intergroup comparison. Measurement data were expressed in the form of (mean ± standard deviation), and t-test was used for intergroup comparison. Univariate analysis of variance (ANOVA) and LSD back testing were used for comparison among multiple groups. Repeated measures ANOVA and Bonferroni back testing were used for comparison between multiple time points. $p < 0.05$ was considered statistically significant.

3. Results

3.1. Patient Data. There was no statistic difference in age, gender, BMI, living environment, eating habits, smoking history, drinking history, family medical history, ethnicity, C-reactive protein, white blood cells, and so on ($p > 0.05$) as shown in Table 1.

3.2. Changes of HGB, PAB, and ALB in Two Groups before and after Care. The changes of HGB, PAB, and ALB before and after care were detected. The results showed that there was no statistic difference between the two groups before care ($p > 0.05$), but after care, HGB, PAB, and ALB in both groups increased ($p < 0.05$) and were higher in OG than CG ($p < 0.05$) as shown in Figure 1.

3.3. Incidence of Complications in Two Groups after Care. The incidence of complications after care in the two groups was observed. The total incidence of adverse reactions in OG was 2 (3.08%), while that in CG was 9 (17.31%), which was significantly lower in OG than CG ($p = 0.009$) as shown in Table 2.

3.4. Effective Rate of the Two Groups after Care. The effective rates of the two groups were observed after care. The markedly effective rate of OG was 75.38%, effective rate was 23.08%, and ineffective rate was 1.54%, with a total effective rate of 98.46%. The markedly effective rate of CG was 42.31%, effective rate was 44.23%, and ineffective rate was 13.46%, with a total effective rate of 86.54%. The total effective rate of OG was significantly higher than that of CG ($p = 0.011$) with statistic difference as shown in Table 3.

3.5. The Severity of Diseases in the Two Groups before and after Care. BISAP was used to analyze the disease severity before and after care. The results showed that there was no remarkable difference between the two groups before care ($p > 0.05$), but the scores of both groups decreased after care and were notably lower in OG than CG ($p < 0.05$) as shown in Figure 2.

3.6. Psychological Scores of the Two Groups before and after Care. The psychological status of the two groups of patients before and after care was observed. The results showed that there was no remarkable difference in psychological scores between the two groups before care ($p > 0.05$), but the psychological status scores of the two groups decreased after care, which were lower in OG than in CG ($p < 0.05$) as shown in Figure 3.

3.7. Comparison of Patients' Compliance after Care between the Two Groups. Comparison of the patients' compliance after care between the two groups showed that the compliance score of OG was notably higher than that of CG ($p < 0.05$) as shown in Figure 4.

3.8. Comparison of Self-Management Scores between the Two Groups after Care. After care, the self-management scores of patients in the two groups were observed. The results showed that the scores of disease management, diet management, medication management, and rehabilitation exercise management in OG were higher than those in CG, with statistical difference ($p < 0.05$) as shown in Figure 5.

3.9. Changes of Quality of Life after Care in Two Groups. By observing the quality of life of the two groups of patients after care, it could be seen that the scores of physical function, role physical, emotional function, cognitive function, social function, and other dimensions of the quality of life of the observation group after care were significantly higher than those of the control group ($p < 0.05$) as shown in Table 4.

4. Discussion

According to statistics, the mortality rate of patients with acute pancreatitis is estimated to be 5% [6], which seriously threatens the patient's life safety. It is known that poor diet and lifestyle are important factors in the onset of acute pancreatitis, so it is extremely important to improve bad habits after treatment for patients' rehabilitation, and a large number of documents have proved that effective care can effectively improve patients' quality of life during disease recovery period [25]. Therefore, this study focuses on evidence-based care in acute pancreatitis to improve patients' treatment compliance and quality of life, and the results are as follows: firstly, the changes of HGB, PAB, and ALB before and after care were detected. The results showed that there was no statistical difference between the two groups before care, but after care, HGB, PAB, and ALB in both groups increased and were higher in OG than CG, suggesting that evidence-based care can obviously improve the serum indexes of patients and promote the curative effect. We speculate that its value lies in the fact that evidence-based

care follows the basis of evidence-based medicine, and patients can be treated according to different situations, including nutritional agent adjustment according to individual physical abnormalities and rational nutrition supply, so as to improve serum indexes and promote curative effects.

The incidence of complications after care in the two groups was observed. The total incidence of adverse reactions in OG was 2 (3.08%), while that in CG was 9 (17.31%), which was significantly lower in OG than CG ($p = 0.009$). The results indicated that evidence-based care can effectively improve prognosis of patients and reduce complications. Comparison of effective rate showed that the total effective rate of OG was 98.46%, which was notably higher than that of CG (86.54%), showing that evidence-based care has high clinical nursing value. We speculate that it is the efficient evidence finding of evidence-based care, summarizing previous care experiences, refining previous deficiencies, and formulating reasonable nursing interventions based on the individual's physical

(d) The score of rehabilitation exercise management in the two groups after care.

Table 4: Comparison of quality of life between the two groups.

	Observation group ($n = 65$)	Control group ($n = 52$)	t value	p value
Physical function	91.23 ± 3.26	83.22 ± 3.37	13.010	<0.001
Role physical	85.52 ± 3.56	72.30 ± 3.14	21.020	<0.001
Emotional function	86.53 ± 3.25	70.74 ± 3.42	25.510	<0.001
Cognitive function	91.43 ± 3.59	83.34 ± 3.21	12.690	<0.001
Social function	65.55 ± 3.18	52.64 ± 3.24	21.640	<0.001

condition, thus further reduced the risk of complications and achieved consolidation of treatment outcomes. Then, we applied BISAP to analyze the degree of disease recovery before and after care. The results showed that there was no remarkable difference in BISAP between the two groups before care, but after care, the scores of both groups were reduced and were significantly lower in OG than CG, suggesting that evidence-based care can significantly reduce the severity of disease and relieve the pain of patients. Evidence-based care refers to the intervention of patients by consulting relevant disease data and combining with the actual situation of patients. Observation of psychological status of the two groups of patients before and after care showed that there was no remarkable difference in psychological scores between the two groups before care, but the psychological status scores of the two groups decreased after care, which were lower in OG than in CG. This result exemplifies the importance of evidence-based care in relieving patients' stress, anxiety, and other negative emotions. Comparison of the patients' compliance after care between the two groups also showed that the compliance score of OG was notably higher than that of CG, better reflecting the people-centered, comprehensive, and holistic interventions of evidence-based care. Finally, we observed the scores of self-management and the quality of life of patients in the two groups after care. The results showed that the scores of disease management, diet management, medication management, and rehabilitation exercise management in OG were higher than those in CG, and the quality of life was obviously better in OG than CG which further confirmed our above conjecture and showed that evidence-based care greatly improved the treatment outcome of patients.

5. Conclusion

In conclusion, evidence-based care can improve treatment compliance of patients with acute pancreatitis and can effectively improve their quality of life.

However, there are still some shortcomings in this experiment. For example, there are many nursing methods in clinic; the best nursing mode is still controversial. And the research objects in this paper are severe pancreatitis patients; it is not excluded that the application of evidence-based care in other diseases may be different from the experimental results. In addition, the time of this study was short, and long-term follow-up was not conducted. Hence, we will expand the sample size of the study as soon as possible, extend the experimental period, and conduct more detailed and comprehensive experimental analysis to obtain more perfect experimental results.

Data Availability

Retracted: Evaluation of Tresiba Combined with Six Ingredient Rehmannia Pill in the Treatment of Type 2 Diabetes

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

In addition, our investigation has also shown that one or more of the following human-subject reporting requirements has not been met in this article: ethical approval by an Institutional Review Board (IRB) committee or equivalent, patient/participant consent to participate, and/or agreement to publish patient/participant details (where relevant).

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

Objective. Insulin replacement therapy is the main treatment method for type 1 diabetes, and adjuvant comprehensive treatment to reduce the complications of diabetes is still the focus of research. The purpose of this study is to explore the clinical efficacy of Tresiba combined with Ingredient Rehmannia Pill in the treatment of type 1 diabetes. *Methods*. A total of 216 patients with type 2 diabetes admitted to our hospital from January 2019 to July 2019 were enrolled in this study. Patients in the control and observation groups were treated with Tresiba and Tresiba combined with Ingredient Rehmannia Pill, respectively. The change of TCM symptom score, blood glucose level and fasting insulin level before and after treatment were evaluated, and the insulin resistance index was calculated to observe the adverse reactions of patients. *Results*. After treatment, the TCM syndrome scores of the two groups decreased significantly, and the TCM syndrome scores of the observation group were significantly lower than those of the control group. The fasting blood glucose, 2 h postprandial blood glucose and insulin resistance index of the observation group were lower than those of the control group. The levels of FBG, 2 hBG and HbA1C in the observation group were significantly lower than those in the control group. The total effective rate of the observation group was 91.7%, which was significantly higher than that of the control group (77.1%). The adverse reactions of patients in the observation group were slightly more than those in the control group. *Conclusion*. Our study demonstrated that Ingredient Rehmannia Pill combined with Tresiba is effective in the treatment of type 2 diabetes, providing alternative therapies for the treatment of diabetes.

1. Introduction

Diabetes is the most common metabolic disease, which is characterized by partial or complete destruction of pancreatic cells leading to insulin deficiency [1]. Diabetic patients have impaired pancreatic islet function at a young age and may require lifelong insulin therapy [2]. According to the report of the International Diabetes Federation, approximately 542,000 children worldwide suffer from diabetes [3]. In addition, about 86,000 children under the age of 15 suffer from diabetes each year, with an estimated annual incidence of 3% worldwide. Complications of diabetes, such as ketoacidosis, should cause widespread concern during the treatment process [4]. Ketoacidosis is still the most common complication after discharge from hospital in diabetic patients [5]. Although insulin replacement therapy is the main treatment method for diabetes, adjuvant comprehensive treatment to reduce the complications of diabetes is still the focus of future research.

Tresiba is a long-acting human insulin analogue suitable for blood glucose control in diabetic patients [6]. There is a risk of hypoglycemia when using insulin to treat diabetes. The ideal insulin should reduce the risk of hypoglycemia while controlling blood sugar [7]. At present, the long-acting insulin commonly used in clinical diabetes treatment mainly include insulin glargine and insulin dete. Tresiba is a new type of long-acting insulin analogue, which can act for more than 24 h [8]. Many clinical studies [9, 10] and observational studies [11, 12] have shown that degu insulin can effectively treat type 1 diabetes and improve the quality of life of patients [13]. However, these drugs are not effective in treating diabetic complications.

Six Ingredient Rehmannia Pill is a famous prescription of “nourishing Yin and strengthening kidney” in traditional Chinese medicine books. Previous studies have demonstrated that Six Ingredient Rehmannia Pill has the effects of lowering blood sugar, preventing diabetes and complications [14]. Six Ingredient Rehmannia Pill combined with valsartan capsule can significantly improve the treatment effect of diabetic nephropathy [15]. It also can assist xiaoke pill in the treatment of type 2 diabetes to improve the efficacy and reduce adverse effects [16]. However, the efficacy of Six Ingredient Rehmannia Pill in the treatment of type 2 diabetes needs to be further verified. This study aimed to clarify the clinical effects of Six Ingredient Rehmannia Pill in the treatment of type 2 diabetes and its complications.

2. Materials and Methods

2.1. General Information. A total of 216 patients with type 2 diabetes admitted to our hospital from January 2019 to July 2019 were enrolled and divided into control group and observation group. The control group included 108 patients: 52 males and 56 females. The average age was 29.2 ± 15.9 years old. The average course of disease was 7.52 ± 0.71 years. The average body mass index was $21.92 \pm 2.63\,kg/m^2$. The observation group consisted of 53 males and 55 females. Mean age was 24.2 ± 13.8 years old, the average course of disease was 8.42 ± 1.35 years. The average body mass index was $21.39 \pm 2.71\,kg/m^2$. There was no significant difference in gender, age, disease course and body mass index between the two groups ($P > 0.05$).

2.2. Inclusion and Exclusion Criteria

Inclusion criteria: (1) the patient had symptoms of polydipsia, polyphagia, polyuria and other symptoms, such as easy to hunger, dry stool knot, red tongue, fear of heat, and upset, and fasting blood glucose was above 7.0 mmol/L. The patient was definitely diagnosed as diabetes; (2) good drug tolerance; (3) did not use glucocorticoids and other hormone drugs in the past month; (4) the patient is not insulin resistant; (5) the patients were informed and agreed to the study.

Exclusion criteria: (1) patients who do not follow the doctor’s advice to take drugs and test blood glucose and lipid; (2) patients with life-threatening serious complications during treatment; (3) patients with severe infectious diseases, renal failure, and immune system diseases; (4) combination of emotional tension and severe anxiety cannot cooperate; (5) women during lactation or pregnancy.

2.3. Treatment. Patients in the control group received routine Tresiba treatment with 0.4 U/kg once a day. Patients in the observation group were treated with Six Ingredient Rehmannia Pill (Henan Wanxi pharmaceutical co., LTD., specification: 240 pills, approval number: national drug approval Z41022128) orally three times per day and eight pills per time besides routine Tresiba treatment. Both groups were treated for 12 weeks.

2.4. Observation Indicators. According to the “Guiding Principles for Clinical Research of New Traditional Chinese Medicine” [17], the changes in TCM symptom scores before and after treatment were evaluated. Nine main syndromes: dry throat, dry mouth, heavy dizziness, sore waist and knees, chest tightness, chest pain, white and greasy tongue coating or less bitterness, heavy numbness of limbs, fatigue, fatigue, and obesity. These five symptoms include fever, insomnia and irritability, menstrual cramps or menstrual disorders, constipation, scaly skin and dryness. According to the severity of symptoms, the score was divided into four levels: none, mild, moderate, and severe. The main scores were 0, 2, 4, and 6 points, and the secondary scores were 0, 1, 2, and 3 points. The total score was 69 points. The blood glucose levels and fasting insulin levels before and after treatment were detected in the two groups, and the insulin resistance index was calculated. Insulin resistance index = (fasting insulin × fasting blood glucose)/22.5. The patient adverse reactions during treatment were observed. The fasting blood glucose, fasting blood glucose (FBG), 2 h postprandial blood glucose (2 HBG), and glycosylated hemoglobin (HbA1C) were detected before and after treatment.

All records are collected by our hospital and completed by trained and qualified investigators. Data management will be carried out under the guidance of medical statistics experts. To ensure the accuracy of the data, 2 data administrators will input and proofread the data.

2.5. Criteria for Therapeutic Effects. Significant effect was defined as the disappearance or improvement of clinical symptoms or signs, fasting blood glucose <7.2 mmol/L, and 2 h postprandial blood glucose <8.3 mmol/L. Effective was defined as significant improvement in clinical symptoms and signs, fasting blood glucose <10.0 mmol/L, and 2 h postprandial blood glucose <8.3 mmol/L. Ineffectiveness was defined as no improvement or aggravation of clinical symptoms and signs.

2.6. Data Analysis. SPSS 20.0 was used for statistical analysis. Quantitative data were used for independent t-test and qualitative data were used for χ^2 test. $P < 0.05$ was considered statistically significant.

3. Results

3.1. Comparison of TCM Syndrome Scores between the Two Groups before and after Treatment. No significant differences in TCM syndrome scores between the two groups before treatment were observed ($P > 0.05$, Figure 1 and Table 1). However, the treatment decreased TCM syndrome scores of the two groups significantly, TCM score of the observation group was significantly lower than that of the control group ($P < 0.05$).

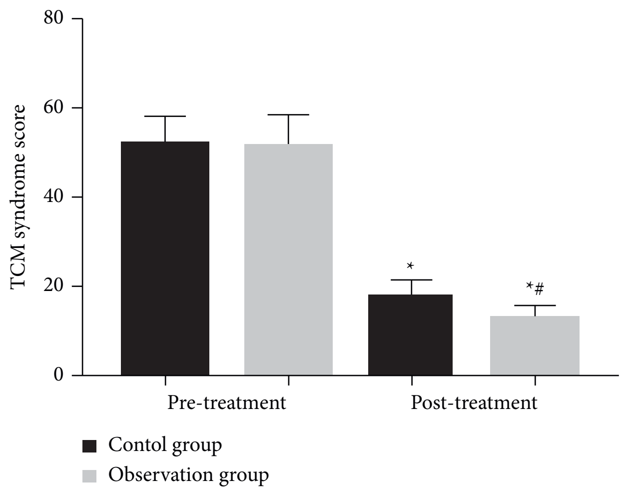

Figure 1: Comparison of TCM syndrome scores before and after treatment between the two groups. $^{*}P < 0.05$, compared with that before treatment; $^{\#}P < 0.05$, compared with the control group.

Table 1: Comparison of TCM syndromes before and after treatment between the two groups (mean ± standard deviation).

Group	Number	Before	After	T value	P value
Observation	108	51.63 ± 6.73	12.65 ± 2.77	36.489	0.000
Control	108	51.87 ± 6.29	18.97 ± 3.46	32.219	0.000
T value		0.178	7.936		
P value		0.428	0.000		

3.2. Comparison of Blood Glucose and Insulin Resistance Index before and after Treatment between the Two Groups (Mean ± Standard Deviation). Before treatment, there were no significant differences in fasting blood glucose, 2 h postprandial blood glucose, and insulin resistance index between the control group and the observation group ($P > 0.05$). After treatment, the fasting blood glucose, 2 h postprandial blood glucose and insulin resistance index of the observation group were significantly lower than those of the control group ($P > 0.05$, Table 2).

3.3. Comparison of FBG, 2 hBG and HbA1C between the Two Groups before and after Treatment (Mean ± Standard Deviation). As shown in Table 3, there was no significant difference in the levels of FBG, 2 hBG, and HbA1C before treatment between the two groups. After treatment, the levels of FBG, 2 hBG and HbA1C in the two groups decreased, and the levels of FBG, 2 hBG and HbA1C in the observation group were significantly lower than those in the control group ($P < 0.05$).

3.4. Comparison of Therapeutic Effect between the Two Groups. As shown in Table 4 and Figure 2, the total effective rate of patients in the observation group was 91.7%, which was significantly higher than that in the control group (77.1%) ($P < 0.05$).

3.5. Occurrence of Adverse Reactions During Treatment in the Two Groups. As shown in Figure 3, there were 3 cases of loose stools and 2 cases of anorexia the control group. The adverse reaction rate was 4.63% (5/108). In the observation group, there were 2 cases of nausea, 2 cases of headache, and 2 cases of bloating. The adverse reaction rate was 6.25% (6/108). The incidence of adverse reactions in the observation group was slightly higher than that in the control group (2 = 1.106, P = 0.293).

4. Discussion

As a systemic metabolic disease, diabetes mellitus is mainly manifested as elevated blood sugar [18], which is mostly caused by insufficient insulin secretion or dysfunction [19]. Diabetes is an autoimmune disease mediated by T lymphocytes. The destruction of β islet cells leads to inflammation, which leads to an absolute lack of insulin secretion, requiring lifelong treatment with exogenous insulin [20]. At present, insulin replacement therapy is the main treatment method for diabetes, but adjuvant comprehensive treatment to reduce the complications of diabetes is also the focus of research.

Previous studies have found that the intervention of Six Ingredient Rehmannia Pill can delay or prevent the occurrence of type 2 diabetes [21], and can improve the inflammatory response and increase the inflammation by regulating the expression of related genes, regulating cell apoptosis, and inhibiting the symptoms of liver and kidney yin deficiency caused by diabetes [22, 23]. In addition, compared with the use of metformin alone, Six Ingredient Rehmannia Pill combined with metformin have fewer adverse reactions, and the therapeutic effect is significantly improved [24, 25]. In this study, although the scores of TCM syndromes in the control group and the observation group were significantly reduced after treatment, the scores of the observation group were significantly lower than those of the control group, indicating that the therapeutic effect of Six Ingredient Rehmannia Pill combined with insulin degu was better than that of Degu insulin alone. Six Ingredient Rehmannia Pill combined with acarbose has accurate curative effect in the treatment of type 2 diabetes mellitus [26] and can be widely used in clinical practice, which further supports the conclusions of this study.

In addition, the comparison of fasting blood glucose, 2 h postprandial blood glucose and hba1c levels between the two groups and the clinical efficacy showed that Six Ingredient Rehmannia Pill had a significant treatment effect on type 2 diabetes. Although Six Ingredient Rehmannia Pill combined with Tresiba have more adverse reactions than Tresiba alone, the difference was not significant.

Our research has some limitations. The sample size of this research was limited. In the future, it is necessary to conduct a larger sample size research to further verify the conclusions of this research. At the same time, this study was not to verify the efficacy of Six Ingredient Rehmannia Pill on all complications of diabetes, which needs to be further verified by future studies.

Table 2: Comparison of blood glucose and insulin resistance index between the two groups before and after treatment.

Group	Fasting blood glucose (mmol/L)		2 h postprandial blood glucose (mmol/L)		Insulin resistance index	
	Before	After	Before	After	Before	After
Control	12.87 ± 1.24	6.35 ± 1.16	19.33 ± 3.27	7.87 ± 0.55	4.83 ± 0.84	2.83 ± 0.34
Observation	12.65 ± 1.37	5.12 ± 0.95	19.54 ± 3.35	6.35 ± 0.31	4.99 ± 0.78	2.27 ± 0.16

5. Conclusion

In summary, Six Ingredient Rehmannia Pill combined with Tresiba has a significant therapeutic effect on type 2 diabetes and has the potential for clinical application. This research provided a research foundation for the future research on the treatment of diabetes and its complications.

The anterior cruciate ligaments (ACL) are the fundamental structures in preserving the common biomechanics of the knees and most frequently damaged knee ligaments. An ACL injury is a tear or sprain of the ACL, one of the fundamental ligaments in the knee. ACL damage most generally happens during sports, for example, soccer, ball, football, and downhill skiing, which include sudden stops or changes in direction, jumping, and landings. Magnetic resonance imaging (MRI) has a major role in the field of diagnosis these days. Specifically, it is effective for diagnosing the cruciate ligaments and any related meniscal tears. The primary objective of this research is to detect the ACL tear from MRI knee images, which can be useful to determine the knee abnormality. In this research, a Deep Convolution Neural Network (DCNN) based Inception-v3 deep transfer learning (DTL) model was proposed for classifying the ACL tear MRI images. Preprocessing, feature extraction, and classification are the main processes performed in this research. The dataset utilized in this work was collected from the MRNet database. A total of 1,370 knee MRI images are used for evaluation. 70% of data (959 images) are used for training and testing, and 30% of data (411 images) are used in this model for performance analysis. The proposed DCNN with the Inception-v3 DTL model is evaluated and compared with existing deep learning models like VGG16, VGG19, Xception, and Inception ResNet-v28. The performance metrics like accuracy, precision, recall, specificity, and F-measure are evaluated to estimate the performance analysis of the model. The model has obtained 99.04% training accuracy and 95.42% testing accuracy in performance analysis.

1. Introduction

ACL tear is a typical physical problem among young athletes with an annual occurrence of 0.8 per 1000 in the general population but as high as 100 for professional football players for every 1000. With the noncontact loading of a valgus knee, ACL injuries most commonly occur when turning the other direction, causing a constrained internal rotation of the tibia [1].

ACL tear might be partial and completely teared. Partial tear ranges from the small tears, including only few fibres, to a high-grade, near, and complete tear including practically the entire ACL fibres. A partial tear can include both or just a single bundle to a varying degree. In some cases, the plastic deformity of the ACL without fiber discontinuity can cause ACL insufficiency [2]. ACL tear detection depends on assessing the obliquely oriented structures on several images segments with various tissues contrast utilizing the integration of MRI discoveries such as discontinuity of fiber, contour changes, and abnormality of signal inside the injured ligaments [3].

Over the past decade, the role of imaging in osteoarthritis (OA) research has grown significantly. Magnetic resonance imaging (MRI) was one of the key components of large-scale longitudinal tests, providing a rich array of musculoskeletal tissue functional and structural characteristics that were previously unavailable. It is necessary to improve data management, quality assurance, automated postprocessing images pipelines, and multidimensionality feature space dissection methods in order to make better use of this data resource, which comes at a higher cost and contains more perplexing quantitative information volume [4]. When examining the tear in the ACL, the coronal, sagittal, and axial planes are taken into consideration. When the ligaments were first detected on the sagittal planes, they were followed from distal to proximal in order to evaluate where the rip had occurred. As a result, the sagittal and coronal planes were thoroughly analyzed in order to confirm the presence of the teared region. As soon as the spirally teared pattern was recognized, the middle part of the spiral was designated as the teared region [5].

MRI is a sort of medical imaging that is believed to be a successful method due to the fact that it is noninvasive and that it has superior soft-tissue contrast compared to other types of imaging. When compared to ionizing radiation-based methods, it does not alter the structure, construction, or properties of particles in the way that they do. As a result, magnetic resonance imaging (MRI) can provide a wealth of information on tissue structures, such as their size, shape, and location. Massive amounts of attention are drawn to magnetic resonance imaging (MRI) for medical procedures and CADe (computer-aided detection) [6].

Furthermore, the two factors that had the biggest impact on the results of medical image processing and analysis were the picture acquisitions and the image interpretations. It is commonly known that improved image quality leads to better results when photographs are processed, and this is true in this case. In many circumstances, the image quality was dependent on the quality of the image acquisition; in this way, better image acquisitions resulted in higher image quality overall. Not only does magnetic resonance imaging (MRI) have the advantages of being noninvasive and providing superior soft-tissue contrast, but it also does not expose patients to high levels of ionizing radiation. As a result, magnetic resonance imaging (MRI) could provide useful information about tissue structures; it is essential in medical image processing. As a result, MRI scans are the primary focus of this investigation. It is necessary to develop an image interpretation system that integrates a variety of functions such as image detection, segmentation, registration, and classification in order to obtain exact picture interpretation results. The deep learning model was used in this study in order to obtain the desired system. Figure 1 shows the difference betwwenNormal and torn ACL in MRI.

Deep learning (DL) is the subcategory of machine learning approaches in artificial intelligences (AI). If the number of layers increases in the network, it is known as deep learning. It is additionally called deep neural network (DNN). It can learn from unstructured data, likewise by utilizing fine-tuning that is done by the backpropagation approach. Deep learning might be utilized to discover features automatically from the provided dataset for each particular application [7, 8]. Inspired by the effective and reliable execution of deep learning systems, DCNN was implemented for MRI medical images classification to classify ACL ligament tears.

In this research, an Inception-v3 DTL model based on DCNN was proposed for the classification of ACL tear using MRI images. The most important aspect of this study was the detection of an ACL tear from MRI knee image, which could be beneficial in determining the nature of a knee anomaly. Data preparation is the first stage of the process. During preprocessing, noise and other artifacts were eliminated from the images, and the images were adjusted to be suitable for the intended classification work. Following the preprocessing stage, the next step is to extract the features of the image. To carry out this research, the Inception-v3 DTL model was employed, which extracted features from an input preprocessed image and then delivered those features to a DTL model for training. The model that was created as a result of this training was eventually put to the test by deploying the DCNN classification model to distinguish between images of normal and abnormal (torn) ACL. Finally, the proposed model's performance was compared to those of other existing models for validation.

ACL tears and their associated complications are covered in this section, which serves as an introduction to the topic. In the next sections, related works will be covered in Section 2, the proposed methodology will be discussed in Section 3, the experimental analysis of results will be discussed in Section 4, and the conclusion and future directions will be discussed in Section 5.

2. Related Works

Valentina Pedoia et al. used 3D CNN to detect and stage the severity of patellofemoral and meniscus joint cartilage morphological degenerative alterations in patients with osteoarthritis and anterior cruciate ligament rupture. The deep-learning pipeline in this model is comprised of segmenting cartilaginous and meniscus tissue and classifying lesions within the region of the tissue that has been segmented. The U-Net model was employed for automatic segmentation, and a "shallow" 3D CNN was used for the staging and identification of the severity of meniscus lesions. The conventions that were used for architectural visualization were very similar to those that were used for U-Net. The feature maps that were obtained were flattened into one-

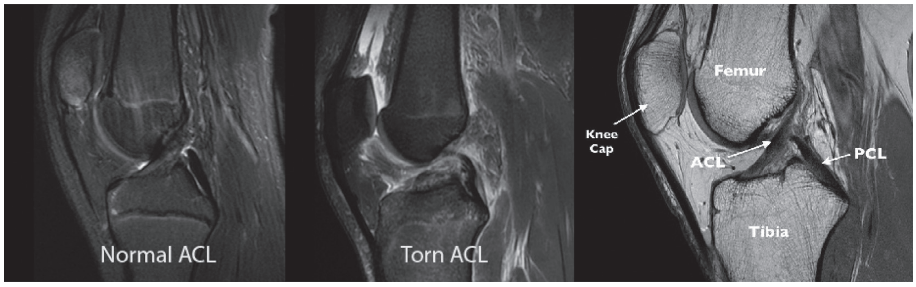

Figure 1: Difference between normal and torn ACL in MRI.

dimensional vectors and then used as inputs to a fully connected layer that created class probabilities based on the features that were obtained. A random forest was trained to make the final forecast after the probabilities were merged with demographic characteristics and coupled with the final prediction.

A DCNN classification approach based on three distinct CNN approaches for detecting ACL tears was proposed by Fang Liu et al., who used DenseNet, VGG16, and AlexNet to detect ACL tears. In this model, the classification models had to be trained separately, which resulted in a high training burden. In addition, the training y was inefficient, which can be improved with more practice. In general, the classification and detection of structural abnormalities present in the isolated ligament were performed correctly, and the results were satisfactory.

Rehan Ashraf et al. proposed a DCNN model for big data medical image classification using MRI images of various organs and tissues, which was tested in a real-world environment. The DCNN was used to carry out the feature extraction and classification steps in this particular model. An approach based on GoogleNet's pretrained GoogleNet layer classifier was used to extract the features, and a softmax layer classifier was used to extract deep features. A total of 144 layers, including convolution and fully connected layers, were used. When comparing the performance analyses from different classes, the model attained an overall accuracy of 98 percent in total.

Christoph Germann et al. employed the DCNN to diagnose ACL tears in MRI images as well. Using homogenous versus heterogeneous knee MRI cohorts with varied pulse sequenced methods and variable magnetic field strengths, a performance comparison was seen in this study [9], which compared the performances of the two groups.

Milica M.B. and Marko C.B. created a brain tumor classification algorithm based on CNN using MRI scans, which they believe will be successful. This model was proposed to classify three types of cancer in the brain tumor, and it was found to be effective. To obtain distinct viewpoints, the MRI scans were obtained in three separate planes: axial, coronal, and sagittal. Images with T1-W contrast enhancement were used to do the classification, which was done by comparing images from different databases. According to this model, CNN performed well with an accuracy of 97.28 percent when using 60 percent of training and 20 percent of validation and 20 percent of testing data. While taking additional approaches into consideration, it is possible to improve the generalization capability of the network [10].

CMAK Zeelan Basha employed machine learning methods to automate the classification of MRI images in this research. Using this model, a novel MRI image classification approach was developed for recognizing self-activation descriptions, which was then used to provide specialists and radiologists with a well-ordered selection devising result. In order to remove noisy data, a Gaussian filter was utilized, and the FCM technique was used for partitioning the data. The statistical features were retrieved with the use of mean, kurtosis, and median values, and the PNN, SVM, and K-NN algorithms were employed for classification. SVM with statistical characteristics outperformed the other two algorithms in terms of accuracy, with 93.1 percent accuracy [11].

In [12], a model for categorization and identification of anomalies in MRI brain images was suggested, which makes use of convolutional neural networks. A CNN containing feature maps that had been preprocessed in the curvelet domain was employed for MRI classification. Because of its multidirectional capability, the curvelet gave a good sparse representation, and the features recovered were more exact than those obtained using other standard methodologies. The accuracy of this curvelet domain combined with CNN was improved during the training and validation processes [12].

According to [13], a DCNN model has been developed for comparing the diagnostic interchangeability and image quality of nonaccelerated images to 15-layered DCNNs or 3-layered CNNs images with the optimal number of layers for a sixfold acceleration of the knee MRI dataset, with the optimal number of layers being three.

Mazhar Javed Awan et al. suggested an automatic detection algorithm for ACL tears based on deep learning techniques. In this study, two models of CNN technique were used, one of which was a regular CNN model and the other was a customized CNN model. ACL MRI pictures were classified using a conventional model with five layers and a customized model with eleven layers. Both models were tested for classification using ACL images. According to [14], the modified CNN model has produced superior results than the regular CNN model in terms of learning rate, accuracy, and other factors.

3. Proposed Methodology

A DCNN model with pretrained Inception-v3 is proposed in this research. This Inception-v3 model is based on DTL as it is proposed to identify the ACL ligament tears from the input dataset by classifying the MRI scan images. To extract features from the dataset, a pretrained Inception-v3 model is used, and the DCNN model is used for classification. $299 \times 299 \times 3$ is the input image resolution. DCNN usually performs well with a larger dataset over a smaller one. TL could be useful in the CNN applications where the dataset is not huge [13]. For applications with comparatively smaller datasets, the concept of TL utilizes the learned model from large datasets such as ImageNet. This removes the need for a large dataset and decreases the lengthy training time as needed when generated from scratch by the deep learning algorithm. TL is a deep learning method that uses the model trained for the single assignment as ainitial point to train the model for a similar assignment. It is typically much quicker and simpler to fine-tune a network with TL than training a network from scratch. By leveraging standard models that have already been trained on large datasets, it allows training models using similar small labeled data. Training time and computing resources can be significantly decreased. With TL, the model does not need to be trained for as many epochs (a complete training period on the entire dataset) like a new model.

There are many kinds of transfer learning; an effective way was to initialize from pre-rained models the parameters of deep architectures and thus fine-tune learning parameter for making it adaptable for the target domains. This technique was used if the dataset was smaller, and, related to feature spaces or tasks, the target domains shared similarities with the domain sources. In image, lower-level characteristics were generally among various classes of image like edges, curves, gradients, and so on; thus higher-level features were classes-specific. The pretrained deep architecture for the classifications of ACL MRI images was modified based on this assumption. TL is an efficient way of achieving meaningful results in classification issues with small data size. Also, the hypertuning of DTL models will further enhance the performance. A DTL model-based Inception-v3 is implemented in this work. The proposed model is used for feature extraction by utilizing its learned weights on the ImageNet dataset together with a convolution neural network. The proposed DCNN technique with Inception-v3 architecture for the classification of ACL images is shown in Figure 2.

Inception-v3 based DCNN model is considered for retraining; this model consists of AvgPool, convolution, maxpool, concat Layer, dropout, fully connected layer, and softmax function.

3.1. Average Pooling. It is a 2-dimensional (2D) function with a pool size of (8×8), which decreases the data variance and the computational complexity. This layer allows the outcome to flow to the next layer.

3.2. Convolution. A $299 \times 299 \times 3$ input size is used by convolution function, and this layer generates the feature maps through convolving the input data.

3.3. Maxpool. It is a two-dimensional maxpooling function and it reduces the variance at data and the computational complexity. The maxpooling is used to extract essential features such as edges, and average pooling is used to extract features smoothly.

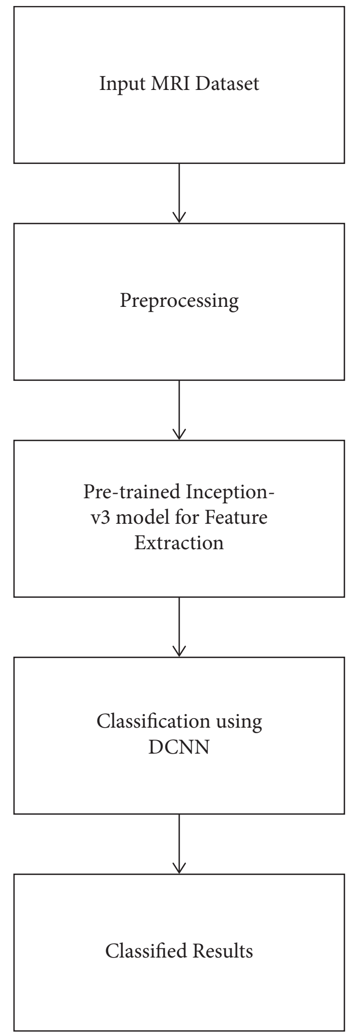

Figure 2: Proposed model.

3.4. Concatenation. This layer is used to concatenate its several input blobs into a single blob of output, and it takes a list of tensors as the input, where all have the same type of shape expect concatenation axis. It returns an output of a single tensor while concatenating all the inputs.

3.5. Dropout. It is considered as the regularization approach to minimize overfitting in the ANNs by overcoming complexed coadaptations from the training data. Here, the dropout scale is considered as 0.4, and it was the very effective method for executing averaging with the neural network model. Moreover, dropout refers to dropout of the units such as visible and hidden sides in a considered neural network.

3.6. Fully Connected. This is used to connect all neurons to one layer and another layer, which works based on a conventional multilayer-preceptor (MLP) neural network.

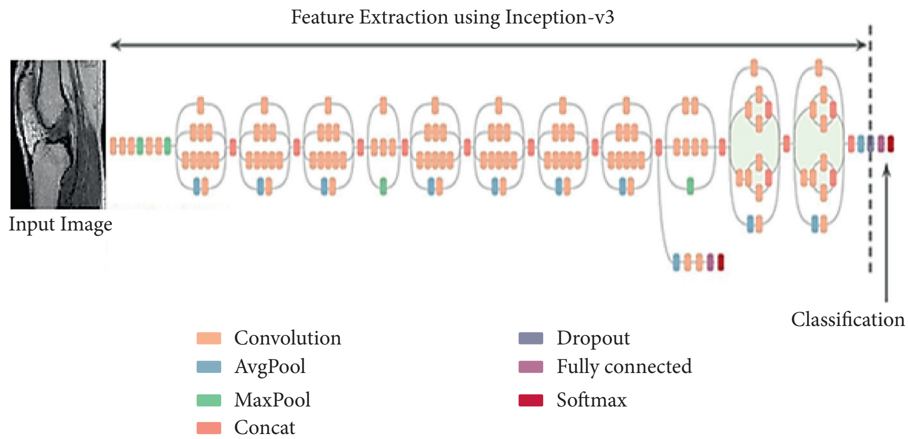

Figure 3: Architecture of the proposed model.

3.7. Softmax. The softmax function is used like the output function, which works similarly to maxlayer when it was variable for training via gradient descents. The exponential functions would cause an increment in the probability of preceding layers and compared to the other values; correspondingly, all output summations will always be equal to one [15].

In general, a two-dimensional plane can form many independent neurons, and the DCNN was made of several layers in which multiple 2D feature mapping planes structure. There are four core segments of the DCNN. The first segment was the local perceptions that the global image does not need to be interpreted by each neuron in neural networks, yet just local and global information waacquired by collecting local data. Next was the method of convolutions. The convolution functionality which was for extracting features of image is shown in Figure 3, and, by using convolution kernel, the total parameters could be reduced higher. Weight sharing is third. It means that parameters of the similar convolution kernels were utilized for the entire image and because of different positions in an image, the weights in the convolution kernels would not be modified. In addition, convolution operations' weight sharing will significantly reduce the parameters of the convolution kernel. Pooling is the final segment. The pooling layer was normally set in the CNN behind the convolution layer, which could be utilized for decreasing feature dimensions of the performance of previous layer's convolution layer, simultaneously to retain adequate key images information details.

To evaluate the dot products of the weights and the values in the input, a filter, which was an array of weights, was used in a convolutional layer, which slides over the input from a previous layer. These weights are discovered through the process of backpropagation of errors. After applying an activation function that incorporates element-wise nonlinearity, a feature map is produced, with each entry representing an individual neuron output from a tiny local region of the input. The feature map was then used to train a neural network.

As filters are considered, if the number of filters is higher, then it is possible to extract more feature mappings, and the better the model performances are. The comparative trails of 32-32-64, 32-32-32, 64-64-64, and 64-64-128 filters were therefore used for selecting the most appropriate filters on the conditions that both resources of computing and DCNNs network performances were considered on holding the different hierarchical structures and various influencing unchanged factors. 64-64-64 was therefore chosen as convolution layer filters, considering the performance considerations, and every receptive field size is 5×5 [16].

In the case of Inception-v3, the probability of every label $k \in \{1, \ldots, K\}$ for every training example is calculated by

$$Q(k \mid z) = \frac{\exp(y_k)}{\sum_i^K \exp(y_i)}, \tag{1}$$

where y represents the nonnormalized log probabilities. Distribution of ground truth over labels $p(k \mid z)$ was normalized; hence, that $\sum_k p(k \mid z) = 1$. For this system, the loss was provided by cross-entropy:

$$C = \sum_{k=1}^{K} \log(q(k))p(k). \tag{2}$$

For logits yk, the cross-entropy loss is differentiable and can therefore be used for deep model gradient training, where the gradients have the simple form of $\partial C/\partial y_k = q(k) - p(k)$, bound between -1 and 1. Normally, this means that the log-probability of the correct label is maximized when the cross-entropy is minimized. Thus, it can produce few overfitting issues. Inception-v3 considered the distributions over label with a smooth parameter ϵ independent of training examples *v(k)*, where, for training instance, the label distributions $p(k \mid z) = \partial_{k,z}$ were exchanged by

$$p'^{(k \mid z)} = (1 - \epsilon)\partial_{k,z} + \epsilon v(k), \tag{3}$$

which is a mixture of the original $p(k \mid z)$ distribution with 1- ϵ weights and the *v(k)* fixed distribution with ϵ weights.

For a uniform distribution *v(k) = 1/K*, the label-smoothing regularization was applied such that it becomes

$$p'^{(k|z)} = (1-\varepsilon)\delta_{k,z} + \frac{\varepsilon}{K}. \quad (4)$$

Alternately, this could be interpreted like cross-entropy as

$$H(p', q) = -\sum_{k=1}^{K} \log(q(k))p'^{(k)} = (1-\epsilon)H(p', q) + \epsilon H(v, q). \quad (5)$$

On the activation layer, there are several activation features, such as sigmoid, ReLU, and softmax. Its functionality was to combine nonlinear factors for improving the model's conditions; hence it needs to be nonlinear. The activation function of the sigmoid function can be expressed as

$$f(x) = \frac{1}{1+e^{-x}}. \quad (6)$$

The activation function of ReLU is expressed as follows:

$$f(x) = \begin{cases} 0, & x \le 0, \\ x, & x > 0. \end{cases} \quad (7)$$

The activation function of the softmax layer is expressed as follows:

$$f(x_j) = \frac{e^{x_j}}{\sum e^{x_i}}. \quad (8)$$

In these above equations, *f(x)* is the activation function, and x is the activation function input.

It is a nonlinear function like ReLU or sigmoid, which is applied to the elements of a convolution and was known as the activation function. When one or more pooling layers were deployed to the feature maps generated by the convolutional layers, the computational difficulty of a CNN was reduced. This was accomplished by decreasing the size of the maps created by the convolutional layers. The methods of maximum pooling and average pooling are the most widely utilized. The output layer has as many nodes as the number of classes in the dataset, which was one hundred. The output was classified using the softmax function, which was implemented in the proposed work. The number of epochs defines the number of times that the neural network will be trained and validated before it is performed. It may take thousands of epochs for an algorithm to converge on a set of weights that provides an acceptable level of accuracy. In neural network's training and validation, the batch size is defined as the number of samples in the dataset that will be loaded and propagated throughout the training and validation of the neural network.

The learning rate regulates the size of weight and bias changes in the training algorithm's learning as it progresses. It was the value that should be specified at the level low enough to allow the neural network to converge while also being high enough to avoid spending an excessive amount of time training it. Hidden layer count refers to the number of FC layers in the neuron which have a specified weight for every identified neuron, which was updated as the training durations are completed. Every neuron has an activation value, which was determined depending on the values of its inputs and the weights assigned to them. When this calculation was completed, it returns a value that was used as input for the final layer, which uses the softmax function to classify MRI images into two categories: normal and torn ACL.

4. Performance Analysis

The performance analysis of the proposed DCNN with the Inception-v3 model is assessed using the dataset in this section. The model was evaluated using parameters such as accuracy, precision, recall, specificity, and F-measure. Also, a comparative analysis was conducted for the validation of the model proposed. The output is compared to other current deep learning models used for classification, such as VGG16, VGG19, Xception, and Inception ResNet-v28. On the MATLAB 2019a Simulink toolbox, all the experiments are implemented and carried out. The dataset is split into 70 percent for training and 30 percent for testing the performance analysis.

4.1. Dataset Description. The dataset used in this work is collected from the MRNet database. It is an open-access database for the knee MRI dataset. It can be downloaded from https://stanfordmlgroup.github.io/competitions/mrnet/site.

The MRNet dataset includes 1,370 knee MRI images diagnosed at Stanford University Medical Center. There are 1,104 (80.6%) abnormal images, 319 (23.3%) ACL tears, and 508 (37.1%) meniscal tears in this dataset; labels were acquired from clinical reports through manual extraction.

Acute and chronic pain, follow-up or preoperative assessment, and injury/trauma are the most common indications for knee MRI examinations included in this dataset. GE scanners (GE Discovery, GE Healthcare, Waukesha, and WI) were used for examination with a regular knee MRI coil and a routine noncontrast knee MRI protocol that included the following sequences: coronal T1 weighted, sagittal proton density (PD) weighted, axial PD weighted with fat saturation, coronal T2 with fat saturation, and sagittal T2 with fat saturation. A total of 775 (56.6%) used a 3.0 T magnetic field; the remaining used a 1.5-T magnetic field for examination. This model uses 70% of data (959 images) for training and testing and 30% of data (411 images) for performance analysis [17, 18].

4.2. Performance Metrics. The proposed DCNN with the Inception-v3 DTL model is proposed in this research and compared with deep learning models like VGG16, VGG19, Xception, and Inception ResNet-v28. The performance metrics like accuracy, precision, recall, specificity, and F-measure are evaluated to estimate the performance analysis of the model. For every validation, both training and testing results are evaluated and compared. The primary

Table 1: Performance analysis of training evaluation.

Models	Accuracy	Precision	Recall	Specificity	F-measure
VGG16	95.13	95.05	94.64	96.25	94.72
VGG19	95.66	94.22	94.80	96.90	95.39
Inception ResNet-v28	90.74	89.90	89.26	91.72	90.56
Xception	92.48	91.94	91.67	93.36	92.07
Proposed	99.04	98.96	98.45	99.18	98.81

Table 2: Performance analysis of testing evaluation.

Models	Accuracy	Precision	Recall	Specificity	F-measure
VGG16	85.45	85.74	84.23	85.67	85.19
VGG19	87.90	87.50	86.06	88.72	86.09
Inception ResNet-v28	89.91	89.32	88.35	90.43	89.24
Xception	92.25	91.48	91.29	93.11	91.92
Proposed	95.42	95.02	95.13	96.34	94.83

objective of this research is to detect the ACL tear from MRI knee images, which can be useful to determine the abnormality of the patient. The result of this model can be based on the outcome detected as normal or abnormal. The true positive, true negative, false positive, and false negative are correctly analyzed to estimate this model's outcome [19–21].

True Positive (TP): It represents the total correct predictions in abnormal cases.

False Positive (FP): It represents the total incorrect predictions in abnormal cases.

True Negative (TN): It represents the total correct predictions in normal cases.

False Negative (FN): It represents the total incorrect predictions in normal cases.

Accuracy is the model's estimation of the performance subset. It is the primary output metric used to calculate the efficiency of the classification process. It is usually used to estimate when both the positive and negative classes are equally important. It is calculated using the following equation:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}. \tag{9}$$

Precision is a positive predictive value. The preciseness of the classification model is calculated using it. It is the measure of the cumulative predictive positive value of the correctly predicted positive observation. The lower precision value reflects that a large number of false positives affected the classification model. The measure of precision can be computed using the following equation:

$$\text{Precision} = \frac{TP}{TP + FP}. \tag{10}$$

The sensitivity is also referred to as recall. It is the proportion of correctly predicted positive observation of the overall positive predictive value. The lower recall value reflects that a large number of false-negative values affected the classification model. The recall estimation can be calculated using the following equation:

$$\text{Recall} = \frac{TP}{TP + FN}. \tag{11}$$

As per this model, specificity is the prediction that healthy subjects do not have an abnormality. It is the percentage of subjects with no injury/trauma that is tested as abnormal. The specificity estimation can be calculated using the following equation:

$$\text{Specificity} = \frac{TN}{TN + FP}. \tag{12}$$

The F-measure estimates the accuracy of the test and is defined as the weighted harmonic mean of the precision of the test and the recall. The accuracy does not take into account how the data is distributed. The F-measure is then used to manage the distribution problem with accuracy. The F-measure estimation can be calculated using the following equation:

$$F - \text{measure} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}. \tag{13}$$

As shown in Tables 1 and 2, the proposed DCNN-Inception-v3 model achieved better performance in training and testing for classifying the ACL tear MRI images. The model obtained 99.04% training accuracy and 95.42% testing accuracy, which is 3.1% to 9.9% increased performance compared to the other existing compared models. VGG16, VGG19, Inception ResNet-v28, and Xception achieved 95.13%, 95.66%, 90.74%, and 92.48% in training and 85.45%, 87.90%, 89.91%, and 92.25% in testing performance, respectively. Inception-ResNet-v28 and Xception model achieved better performance in testing compared to the training performance. The performance was the same as accuracy for other parametric evaluations like recall, precision, specificity, and F-measure.

Compared with both testing and training results, the VGG16 approach achieved the least performance in every parameter, and the Xception model has achieved close results to the proposed model. The graphical chart of the comparison is plotted in Figures 4 and 5.

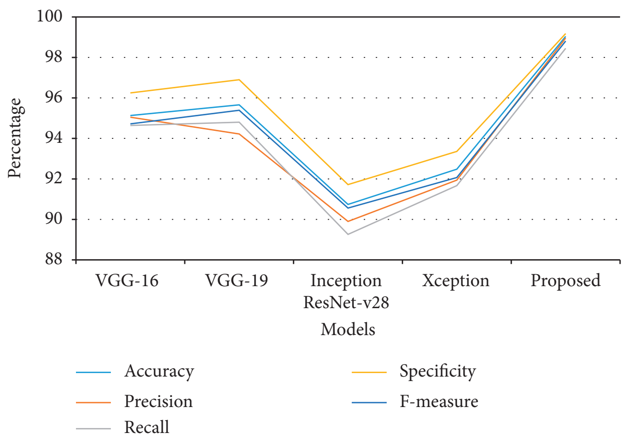

Figure 4: Graphical plot of performance analysis of training.

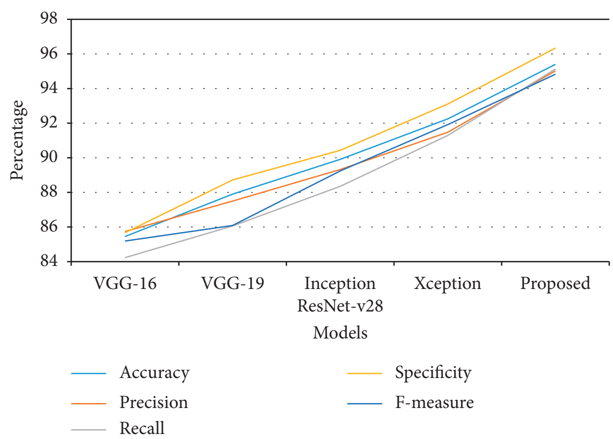

Figure 5: Graphical plot of performance analysis of testing.

5. Conclusion

In this research, a DCNN based Inception-v3 DTL model was proposed for classifying the ACL tear MRI images. The proposed model was executed in four stages. Data preprocessing is the initial stage. After preprocessing, the next stage is to extract the features of image and then to deliver the features extracted into the model to train. The trained model was finally tested. The dataset used in this work was collected from the MRNet database. It is an open-access database for the knee MRI dataset. A total of 1,370 knee MRI images were used for evaluation. 70% of data (959 images) were used for training and testing and 30% of data (411 images) were used in this model for performance evaluation. The proposed DCNN with the Inception-v3 DTL model was assessed and correlated with existing deep learning models like VGG16, VGG19, Xception, and Inception ResNet-v28. The performance metrics like accuracy, precision, recall, specificity, and F-measure were evaluated to estimate the performance analysis of the model. For every validation, both training and testing results were evaluated and compared. The model has obtained 99.04% training accuracy and 95.42% testing accuracy, which was 3.1% to 9.9% higher than the other existing compared models in performance. However, this model was proposed to classify the ACL tear injuries from knee MRI images and has obtained better results in validation. In the future, the proposed model can be used to find any abnormalities present in various body organs by using different datasets like a brain tumor, heart disease, lung cancer, and so forth. The performance can be further increased by implementing a new deep transfer learning model with better classification performance.

Data Availability

The datasets used and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Academic Editor: Enas Abdulhay

Background. With the development of the Internet, people are facing greater pressure. People in modern society are facing the threat of mental illness. For people with poor mental health, it is necessary to take an appropriate psychological intervention. Nanxian dihuagu is not only a form of folk dance but also a collection of local people's artistic wisdom. Now, Nanxian dihuagu artists use network media to record it. *Objective*. Introduce the cultural connotation and value function of dihuagu dance in Mingnan county. *Methods*. In this paper, literature and field survey methods, according to the logical analysis method of dance point of view, a detailed analysis of multiculture, from the perspective of comprehensive academic research methods, explore the value and cultural significance of dance. *Results*. The Internet has promoted the exchange of local art and culture, and the effective communication has been formed under the promotion of network media. But the Internet age has also led to some problems, and psychological intervention can effectively improve the psychological problems caused by the network. *Conclusions*. In this paper, the research process is not limited to the dance itself, at the same time, starting from the local folk customs, focusing on the analysis of the significance and value function of dance culture, which provides a reference for the development and optimization of folk customs. And through the analysis of Nanxian dihuagu, we can know more about the national culture and promote the development of Chinese national culture.

1. Introduction

Nanxian dihuagu is a dance performance art with local ethnic characteristics, which is usually held in the traditional Lantern Festival, Spring Festival, wedding, and funeral. It is formed on the basis of the original folk dance and folk musical instruments while absorbing a variety of cultural arts. This kind of art is not only happy and beautiful in music melody but also natural in dance action and full of rich breath of life and unique artistic style, which is deeply loved by people.

1.1. The Origin and Development of Dihuagu in Nanxian County. Nanxian dihuagu is a folk art invented by people who work every day. It is close to people's living conditions. This form of folk song and dance art inherits the living state and shows people's real living state by relying on the body language recorded from generation to generation. The inheritance and development of dihuagu in Nanxian County have experienced more than 200 years, and its development process can be roughly divided into five stages: the enlightenment period of the Jiaqing era of the Qing Dynasty, the prosperity period from the Xianfeng era to the Tongzhi era of the Qing Dynasty, the peak period from the early Republic of China to the postliberation period, the decline period from the Cultural Revolution to the end of the 20th century, and the revival period in the new century.

1.2. Definition of Psychological Intervention. Psychological intervention is based on psychological consultation and cognitive psychology, using social psychology to design the intervention process of mental health problems in detail so as to influence their action level (i.e., using specific methods) and adjust their mental state in order to lead their mental state to the expected target state.

Due to the increasing pressure of people's lives and the influence of various environmental factors, people under the background of the modern network are often affected by some bad emotions, thus damaging their mental health [1]. Timely psychological intervention can help to prevent personal injury caused by excessive action, form correct self-awareness and self-evaluation, promote communication with the outside world, and improve the quality of life of intervention objects. Taking into account the characteristics of the Internet age, in previous studies, due to the lack of expansion of art therapy methods such as Internet new media and apps, people receiving treatment are vulnerable to psychological intervention, and flower drum practitioners can express their ideas more simply.

1.3. The Influence of Psychological Intervention on the Dissemination of Rural Art and Culture. Rural art is a form of artistic expression, and people can obtain the required network information in a short time and pass on the network information that psychological interveners want to convey to the intervened objects in a convenient way [2]. Now, there are some preliminary exploratory studies on the application of psychotherapy suggestions on dihuagu. However, the research is usually a one-way psychological intervention method, most of which is to discuss the two-way interaction between the psychological intervener and the object, without a detailed discussion of the application of dihuagu in the psychological intervention [3]. From the perspective of reception aesthetics, artistic creation is a process in which the audience and the author create a horizon according to their own psychological understanding, which requires the interaction between them. They can create the color, action, emotion, and other aspects of spiritual communication in the process of interaction and guide the next iteration of creation. In this process, their mental state is constantly improved.

The purpose of this study is to make a detailed theoretical analysis of the psychological cognitive characteristics of various groups and design the most suitable interactive psychological intervention method for various groups [4]. Moreover, through the experiment of color, material, form of expression, work content, and psychological intervention effect of qualitative and quantitative analysis, it has certain guiding significance for psychological intervention. On the other hand, the use of interactive gradient has a very practical significance for psychological intervention. It can be directly used in the process of psychological diagnosis, psychological consultation, and psychotherapy to effectively and appropriately support the intervention objects to improve their mental health indicators.

1.4. Cultural Communication of Dihuagu in Nanxian County under the Background of Network. As a representative of the traditional dance of the Han nationality in Hunan Province, the dihuagu of Nanxian County has been inherited with vivid performance forms and rich and varied songs, which is a vivid portrayal of the culture of Nanxian County. In Nanxian County, the protection of flower drum can activate the national art, promote the development of national culture, and build a harmonious socialist society [5]. First, the flower drum ecosystem must be protected. In Nanxian County, the living environment of Huagu was combined with the natural environment to establish a complete ecological protection area, which saved Huagu culture and became a park to protect Huagu culture.

Fundamentally speaking, as intangible cultural heritage, Nanhua drum dance reflects the collective life, thoughts, feelings, and cultural spirit of the people in Nanxian County. It is the crystallization of the wisdom and great spirit of the people. The content of its dance performance is a mirror of the human spiritual lifestyle. It inherits a prosperous and unique cultural spiritual home [6]. In different historical periods, it has the most typical regional characteristics and is the continuation of history. It reflects the world outlook and living conditions of the people in Nanxian County, reflects the collective spirit and action mode of the people in this fertile land, and improves people's understanding of vision and lifestyle, so it has high historical value.

Nanxian dihuagu dance is the great spiritual and cultural wealth of Nanxian people, the living fossil of local folk culture, the crystallization of working people's wisdom, and the primitive cultural gene of Southwest China [7]. The protection and development of traditional ecological culture can improve the cultural awareness of the whole society and contribute to the recovery and development of culture, as well as the planning and construction of cultural ecology. This dance reflects the way of thinking, aesthetic, and social development of the Nanxian people and also reflects the unique historical and cultural charm of this area, showing its unique cultural value.

Nanxian dihuagu dance is a kind of Han nationality dance with distinctive performance and rich songs. It has unique local characteristics, unique dance art style, rich life taste, and deep mass foundation [8]. At the Gutian Meeting in 1929, Comrade Mao Zedong advised the Red Army soldiers to sing "flower drum" and other recreational activities. Exploring, rescuing, and protecting Huagu have played a certain role in promoting national art, inheriting national culture, and building socialist spiritual civilization. The essence of Nanxian dihuagu culture is reflected in Nanxian's history, thoughts, habits, etiquette, education, production, and life. We should organize cultural education, cultivate folk artists of Nanxian dihuagu dance, and do our best to explore, rescue, and protect the ecological culture of dance.

2. Methods

2.1. Participants. In order to better study the use of new online media in Nanxian County, the author has carried out preparations many times, taking the method of going to the scene in person, going to Nanxian County, conducting surveys on local residents, interviewing key figures, and distributing questionnaires to a large number of residents. Surveys and other methods to obtain a large number of documents required information.

2.2. Process. According to statistics, a total of 280 paper questionnaires were distributed, and 270 were recovered. According to statistics, Nanxian villagers posted 506 WeChat messages, including 92 students, 280 migrant workers, 54 migrant workers, 42 fishery professionals, 18 pure farmers, and 20 businessmen. According to the characteristics of the questionnaire, the coverage of this questionnaire is wide enough.

2.3. Research Design. The survey is analyzed and implemented from four aspects. First of all, it is necessary to understand the understanding of new online media in Nanxian County and the daily use of new online media. Second, it is necessary to understand the characteristics and hotspots of new media users in the Nanxian network [9]. Third, it is necessary to understand the new media users' understanding of the dissemination of national traditional culture. Fourth, it is necessary to understand the impact of online new media users on national culture.

2.4. Data Analysis. SPSS16.0 and Amos 7.0 software were used for data analysis. First, record the statistical questionnaire data, extract the data, and conduct statistical analysis. Then, according to the results of questionnaire statistics and statistical analysis, exploratory factor analysis and confirmatory factor analysis were used to verify the suitability and reliability of each measurement scale.

3. Results

3.1. Analysis of the Respondents' Understanding of Dihuagu in Nanxian County. According to Table 1, 96.6% of respondents knew or did understand the traditional culture, while only 3.40% did not know the traditional culture at all. Generally speaking, the respondents have a high understanding of traditional culture, but some people do not fully understand the traditional culture. The results show that the investigation content is comprehensive and reliable, which may reflect the original intention of the investigation.

3.2. Descriptive Statistical Analysis on the Dissemination of Rural Art and Culture. When establishing the influencing factor model, the author assumes that the level of the communication process and audience level have a certain impact on the social level and verifies the correlation through the correlation analysis between the influencing factors [10]. Based on SPSS, the author analyzes the relationship among personal level, social level, and communication process level. From the data in Table 2, it can be seen that personal concern is obviously related to other factors except communication ability, and government policy at the social level is significantly related to media technology at the communication process level [11]. The cultural environment at the social level is significantly related to the media technology and communication ability at the communication process level, and the media technology and communication ability at the communication process level at the social level are also significantly related. The results show that there is an obvious correlation among personal level, communication process level, and social level.

3.3. Time Distribution of Internet Use among Survey Population. From the questionnaire, it can be seen that a total of 515 people were surveyed. 196 people surf the Internet every day, accounting for 38.74%. 138 people (27.2%) used the Internet frequently. 156 people did not surf the Internet, accounting for 30.83%. 16% of the elderly could not access the Internet. Most of them can use the network independently. Therefore, the new Internet media has played a positive role in the popularization of Nanxian culture. Among them, 180 people use the Internet for 1–3 hours a day, accounting for 35.57%, 120 people for 3–5 hours, accounting for 23.7%, and 112 people for less than 1 hour, accounting for 22.3%. From the data, young people use the Internet for a long time (Table 3).

3.4. Survey and Analysis on the Installation of Network Tools among the Survey Population. With the use of mobile phones at the same time, WeChat, QQ, Weibo, and many other types of software were downloaded. WeChat, in particular, can greatly promote people's lives and bring convenience to the communication between the two. In addition, it is also an indispensable communication software in production and life [12]. Among 446 people, 88.14% used instant software, and 238 and 226 people used social networks and video websites, accounting for 47.04% and 44.66% of the total, respectively. Like TikTok, it is fun and popular, and many young people love it. Because of the fast pace of work, many people in Nanxian love it and help Nanxian culture expand rapidly (As shown in Table 4).

3.5. Analysis of the Cognition of the Survey Population to the Spread of Dihuagu Culture in Nanxian County. Of the 506 surveyed, 298 people barely know their own culture, accounting for 58.89%. 162 people know their own culture, especially Jienan county culture, accounting for 32.02%, and only 9.09% of the people do not understand the culture of Nanxian County. More than 90 percent of people know their own culture. Of the 506 respondents, 354 responded to spreading the culture of Nanxian County to other countries through various forms of network, accounting for 69.96% [13]. 152 people said their culture was not broadcast abroad, accounting for 30.04 percent. Therefore, most people like to inherit their own culture, which plays a positive role in the popularization of Nanxian culture. Of the 534, 304 used WeChat and TikTok, accounting for 85.88%, while 50 used BBS to contribute only 14.25%. But WeChat is worth mentioning. Because WeChat can send photos and videos through moments, a large number of users from different cultures have poured in, and WeChat has gradually promoted cultural exchanges. The details are shown in Table 5.

3.6. Analysis of the Types of Cultural Transmission of the Investigation Population to the Drum Culture. About using the new media channel of the network to spread Nanxian

Table 1: Statistical results of respondents' understanding of dihuagu in Nanxian County.

The level of understanding of Nanxian dihuagu	Frequency	Percentage	Effective percentage	Cumulative percentage
Know very well	30	11.2	11.2	11.2
Have a certain understanding	228	85.4	85.4	96.6
Do not understand at all	9	3.4	3.4	100.0
Total	267	100.0	100.0

Barely know	298	58.89
Special understanding	162	32.02
Do not understand	46	9.09

culture, 354 people know these methods, 294 people know the method of using photos, accounting for 83.05%, and 270 people choose text communication, accounting for 76.27%. A total of 230 people chose video communication, accounting for 63.97%, and 122 people chose audio communication, accounting for 34.46%. Because of the intuitive nature of the photos, the spread is relatively simple and high speed, so the acceptance of netizens and fans is relatively high [14]. The best way to transmit is to use language and photos. The effect is better. There are short videos with images and sounds in the videos. You can also use music, especially wedding pictures. The effect is very beautiful. In the circle of friends, the relevant videos and pictures were made public, which provided great convenience for the popularization of Nanxian culture (as shown in Table 6).

Table 6: Communication types of dihuagu culture among the investigated people.

Category item	Number of people	Proportion (%)
Pictures and photos	294	83.05
Text spread	270	76.27
Video dissemination	230	63.97
Audio transmission	122	34.46

3.7. Analysis of Rural Network Use Problems and Psychological Intervention Needs. According to the survey data, people with network psychological problems mainly use the network to play games and chat to make friends, and the proportion of playing games is the highest, accounting for 80%, and making friends accounts for 14.3%. This shows that people with psychological problems due to the Internet like the entertainment function of the Internet [15]. On the contrary, nonnetwork causes psychological problems. In order to achieve the purpose of learning, people tend to use the network to understand and obtain information. On the other hand, the proportion of people who have psychological problems due to the network and those who do not have psychological problems is very high, which is worthy of attention [16]. As shown in Table 7, playing games ranks first among the people who have psychological problems, which indicates that online games are an important factor causing middle school students' psychological problems on the Internet.

4. Discussion

4.1. Strengthen the Innovation of Communication Means of Dihuagu Culture in Nanxian County

4.1.1. New Style of Dance Vocabulary of Dihuagu in Nanxian County. Nanxian dihuagu, as a folk dance, can be properly and skillfully disassembled and reconstructed, which can not only enrich the vocabulary of dance but also be theoretically constructed for "poetry and painting." In the process of adaptation and innovation, we can start from the following points.

First, perform the best combination of actions. On the basis of traditional sports, change the original range of movement, intensity, rhythm development, and innovation [17]. On the basis of not changing the basic rhythm, it produced a new dance vocabulary and expanded along the trend to make it more emotional. For example, you can see the combination of simple step and long step squat.

Secondly, break the fixed mode of thinking, and make the dance more professional and artistic. According to the characteristics of the performers, Nanxian dihuagu designs dance movements, which can give full play to their

Table 7: Questionnaire of psychological problems in the process of rural network use.

	There is no need for psychological intervention	Need psychological intervention	x	P
Play online games	85 (16.2%)	28 (80%)		
Audiovisual entertainment	162 (30.8%)	2 (5.7%)		
Chat and make friends	114 (21.7%)	5 (14.3%)	85.286	0
Network information search	98 (18.6%)	0		
Learning and knowledge	67 (12.7%)	0		

respective advantages. The props and movements used by various roles of men and women can learn from each other, strengthen the fluency of movements, and enrich the vocabulary of dance [18]. For example, in traditional dance performance, dance can fully demonstrate the lifestyle of modern people. The foot movement is more flexible, adding a specific jump action. When dancing, the movements are relaxed, broad, open, and smooth. In addition, acrobatic movements such as "exploring the sea" and "front bridge" were added to improve dance appreciation and professional awareness [19]. Clowns can change the original dance movements. We can give full play to the talents of the actors and choose some specific skills and movements, such as flying feet, rotating feet, sweeping feet, and turning upside down so as to make the warm atmosphere of the scene further rise and fully show the positive and optimistic spirit of Nanxian people.

Finally, it can add luster to other arts. The creative ideas, processing means, and action design of dance are very innovative, which is the feeling of the current era, the pulse of the times and the action after the processing of modern dance vocabulary [20]. Today's square dance has caused a national fitness heatwave. It can selectively absorb the popular modern dance, hip-hop dance, and square dance, as well as the dance elements of teenagers, middle-aged, and elderly people. With the feelings of modern people, we can make the rhythm of original dance, combine simple movements and famous popular songs, and combine them closely with the modern life of young people [21]. Mix modern elements to show the charm of new art. In order to let people all over the country and even the world know this art form, we must depend on the original taste of Nanxian Dihua drum dance and get people's attention through a number of innovations.

4.1.2. Clever Use of Dihuagu Props and Lighting in Nanxian County. The use of beautiful dance composition, creating beautiful movements, and strengthening the innovation of small tools are helpful to strengthen the stage art performance of Nanhua drum dance. Compared with the "Er Ren Zhuan" in the northeast, the dance skills of Dihua drum dance in Nanxian are insufficient; that is to say, there are few "unique skills" [22]. Nanxian flower encouragers hope to show excellent skills and stage performance and cannot be satisfied with playing flower fans and other original performance skills. In addition to handkerchiefs, flowers, wine cups, chopsticks, umbrellas, and other small props, we must also maximize the use of a variety of small props. For example, in the handkerchief, the traditional flower fan dance has only one simple "rotation" [23]. You can learn skills from the northeast "Errenzhuan," such as adding a handkerchief around the shoulder and other physical activities to perform. Because the Nanxian Wai drum can be used as exaggerated dance props, it can expand the space of stage performance, and the dance pictures will become more overlapping.

Stage design enriches the role of dance, produces artistic concepts, stimulates imagination, and improves the overall charm of dance. For example, the accompaniment of Lang's seeing his sister in Gaopo is composed in accordance with the local folk song Lang's seeing his sister in Gaopo. It is just that the sisters who wash clothes by the river become "sisters who put clothes by the river" [24]. When performing on the stage, using new multimedia technologies such as stage lighting and scenery, the background of the stage becomes the scene of lyrics, which fascinates the audience and directly feels the beautiful feelings.

4.1.3. Innovation of Performance Program of Dihuagu in Nanxian County. At the first Nanxian dihuagu Art Festival, Yiyang Ziyang District Cultural Center's "drag bench" and so on can break Nanxian's traditional dance performance projects. In this program, the movement of dance elements and the traditional Nanxian dihuagu movement are retained, focusing on the details of the interaction between the dancers and the clowns [25]. As a flower drum performance, although the changes of dance modeling are relatively scattered, the movements are consistent with the rhythm of fixed music, and the whole is beautiful, neat, and hierarchical. The clown rolls forward from the bench, mastering somersault and other skills, combining with the characteristics of sports, adding a specific story performance plot, setting special performance skills, making the scene warm and the audience in a high mood, meeting the expression of modern people's emotion, temperament, spirit, and sense of rhythm to the greatest extent, and meeting the aesthetic psychology and needs of modern people [26].

Nanxian dihuagu dance can be transformed into a family comedy stage, creating new scripts and beautiful songs. The traditional dihuagu dance can be integrated into family comedy, and the accompaniment music can be integrated into chorus or Male Solo and female lead singing. Various dance segments, such as group dance and double dance, are added to enhance the artistic charm and stage performance of Nanxian dihuagu dance by using multimedia technologies such as stage space layout, original configuration, stage lighting, and scenery [27].

All the traditional dance projects of the Nanhua drum in Nanxian County need to be sorted out and maintained. For those that are still preserved, they should be selectively absorbed by all means of criticism and modernization and optimized in combination with modern aesthetics. It can adjust and transform the original music songs and movements and create new dance works [28]. Only in this way can we maintain the original vitality of the dance and inherit the traditional art of the country.

We should comprehensively study the contents and forms of flower drum and folk art in different times, regions, and styles, learn the advantages of others, make up for our own weaknesses, absorb the essence, eliminate the bad content, and optimize and improve them in the largest scope [29]. Although the content has changed, the essence remains unchanged. The function of dihuagu dance in Xinnan county still maintains the excellent characteristics of traditional culture, reflects the cultural connotation of the nation, and can adapt to the modern aesthetic and promote the development of modern culture.

4.2. Strengthen the Construction of Network Media Tools and Talent Quality in Rural Art Communication. With the development and application of network, human society takes knowledge and network information as the main resources to participate in the construction of a network information society. In the network information society, the relevant talents of Nanhua drum can not only learn multimedia technology and computer network technology and other professional skills but also face a large number of pieces of network information, know how to effectively obtain and identify network information, process network information, express network information creatively, and send network information [30]. Facing the severe challenges brought by the network information age, it is a new historical mission for modern educators to teach students to acquire, evaluate, and apply network information.

4.2.1. Cultivate Network Information Retrieval Skills of Talents Related to Dihuagu in Nanxian County. Before the emergence of the network, the network information retrieval skills mainly refer to the library information retrieval skills for the relevant talents of Nanxian dihuagu University, but now the network environment contains more important network information retrieval skills. This paper mainly introduces the network information retrieval skills under the network environment.

Network information is very rich in content and form, including politics, economy, sports, entertainment, medical care, education, science, and technology, mainly including color photos, text, audio, and video. Faced with the vast amount of network information, if we do not have the ability to search for network information resources, we will not only be unable to obtain effective network information, but also consume a lot of precious time [31]. Many talents associated with dihuagu in Nanxian originally intended to use the network to obtain learning resources, but in the face of many network connections, they did not know how to choose and finally turned their attention to other pieces of external network information; the loss exceeded the gain. Therefore, for educators, it is particularly important to cultivate talents related to Nanhua drum network information retrieval skills. In the network environment, the forms of network information retrieval include search engine and electronic database. Educators should not only teach students how to use search engines and electronic databases to obtain network information methods and skills but also let students quickly and effectively obtain the necessary network information.

4.2.2. Cultivate Network Information Evaluation Skills of Talents Related to Dihuagu in Nanxian County. Although the network information on the network is rich but complex, there are also a large number of pieces of unfiltered fake network information and pornographic network information [32]. Educators teach students to evaluate the reliability, appropriateness, and correctness of network information from the collected network information so as to prevent students from indulging in the virtual world. Students need to use critical thinking to evaluate these pieces of network information so as to avoid losing the sense of active participation or forming the character of indifference, isolation and lack of responsibility.

4.2.3. Cultivate Network Information Application Skills of Talents Related to Dihuagu in Nanxian County. The cognitive impairment caused by the Internet has sounded the alarm for educators. Therefore, education should not only let students understand the ability to obtain and evaluate network information but also creatively apply network information. Facing the network information, students cannot use it for their own purposes. Educators must guide students to reorganize the network information and combine the new network information with the original knowledge background. Students can use the network information reasonably and effectively, instead of being subordinate to the network information, and can become masters, so as to creatively construct the network information system owned by students.

In the process of cultivating students' network information literacy ability, educators should not put it in the priority of classroom education but should combine it with daily education. Let students develop excellent network information literacy ability unconsciously. In addition, considering the poor level of network dependence, in order to use and rationalize the network as a tool, the relevant talents of Nanhuagu need to introduce network information literacy education in the freshman year.

4.3. Reduce the Problems in the Process of Network Culture Communication through Psychological Intervention. The implementation of psychological intervention is to analyze the causes of psychological problems and formulate the exercise plan related to the success or failure of intervention. The causes of psychological problems caused by the Internet are quite different, and the people who have psychological problems seek different satisfaction on the Internet. Some people want to seek new stimulation on the Internet, some want to make more friends through the Internet, some want to reflect their own values, and some want to ease the pressure of reality through the Internet. Sports are also very rich and can provide athletes satisfaction, which is not the same. In order to interfere with the psychological problems caused by the Internet, we use the conditional emotional response to intervene, specifically analyze the specific causes caused by psychological problems, suggest the intensity of exercise, and formulate a specific intervention plan. It is suggested that the conditional emotional response intervention method should be used in the temporary improvement of psychological problems caused by the network in Nanxian County, and the necessary and appropriate differential treatment should be carried out.

4.3.1. The Psychological Problems Caused by the Internet Can Be Divided into Mild, Moderate, and Severe Psychological Problems. According to the research results, the intervention effect of a conditional effective response is better than that of moderate network psychological problems for mild network psychological problems. It is suggested that intervention should be carried out at the beginning of the problem. Even if there are no psychological problems, colorful sports activities and games will also be used to enrich students' spare time life. On the other hand, it also reduces the students' time using the Internet and the bad behaviors caused by the psychological problems caused by the Internet.

4.3.2. Suggestions on Adjusting the Psychological Problems of Network Culture Communicators through Psychological Intervention. Considering that the change of action needs a long-term accumulation process, we need to use the conditional emotional response intervention method to improve the psychological problems of talents in the Nanhua drum for a short time. The content of training needs to be adjusted according to the degree, reason, and interest caused by the network.

Nanxian dihuagu related talents have psychological problems due to network reasons; most of them have serious negative self-knowledge, often think that they cannot do it and give up, considering that they have been used to self-verification, or blame the failure caused by some factors on their own failure, and verify that they cannot do it. In order to temporarily improve the psychological problems caused by the Internet, it is suggested to use the conditional emotional response intervention method, and they can doubt their ability. However, please do not let them have absolutely impossible reasons, and only give them a chance to self-verify.

In the experimental study, if we consider that the subjects may change their physical and mental states due to training or other factors, we need to use the conditional emotional response intervention method to temporarily correct the psychological problems caused by network talents. Grasp the feedback information of the test object at any time, understand the physical and mental state of the test object, and formulate, adjust, and implement a timely, scientific, reasonable, and flexible intervention plan according to the feedback network information of the test object.

Considering the important intervention effect of this experimental study, it is suggested that it is necessary to use the conditional emotional response intervention method to temporarily correct the psychological problems caused by the talent network of dihuagu in Nanxian County. According to the actual situation of different individuals, different periods, and different stages, we should appropriately choose the content and time arrangement of this experimental study.

4.4. The Influence of Network New Media on the Dissemination of Rural Art and Culture in Nanxian County

4.4.1. The Network New Media Has Expanded the Dissemination Scope of Nanxian Culture. Nanxian people want to promote fish skin painting and other products, basically through radio and television teaching, not only spending time and labor but also spending a lot of money. As we all know, the advertising price on TV is very high, the economic burden of the people in Nanxian County has increased greatly, the product price has risen, and the sales volume has decreased greatly. Through the new media on the Internet, all problems can be solved simply. In the traditional way of communication, there are also people communicating with each other, but this way of communication has fewer people to understand, less influence, high cost, heavy economic burden, and high product cost. After adding new online media, you only need to take photos and videos through your mobile phone, add appropriate instructions, set up a web page, publish Weibo and WeChat, or use a social network platform, which can be seen by a large number of people. Moreover, the people of Nanxian County can record the life of the people of Nanxian County for the first time, anytime and anywhere, and they can also sell their own products. We all know the importance of smartphones in real life, which can be applied to all aspects of life. Now, people's communication completely depends on mobile phones, which is very convenient. Through QQ and WeChat, it is more convenient for people to communicate with each other and spread network information faster. At the same time, the network can connect the whole world, and the space distance between the whole Earth is reduced. With the help of network technology, network new media is moving towards a higher, faster, and stronger direction. The two combinations combine perfectly. As the popularization speed and scope of network information have been greatly improved, Nanxian County has ushered in a good development opportunity. Therefore, the emergence of new network media provides great convenience for the dissemination of Nanxian culture.

4.4.2. The Network New Media Has Promoted the Dissemination Speed of Nanxian Culture. The new network media is very convenient, and now, everyone has a mobile phone, no matter when and where all parts of life can be recorded. The

Wurigong meeting of Nanxian County will be held in Zhangjiakou. It is a comprehensive meeting, including religious belief, sports performance, clothing display, food feast, national song, and dance. The people of Nanxian County are singing and dancing, very lively. People who are not in Zhangjiakou cannot see it on the spot, but in the new media on the Internet, Nanxian culture lovers can enjoy this grand banquet by forwarding the videos, sounds, and photos of mobile phone videos to the Internet. The audience looked at Nanxian County from different perspectives. The grand event was displayed in an all-round way, achieving a good viewing effect and meeting the strong curiosity of the masses and Nanxian cultural lovers. Spreading to the outside world through the new media on the Internet is not only an important channel but also a window for the outside world to understand Nanxian. Nowadays, many ethnic minorities use the new media on the Internet to introduce their national habits and works of art. It provides an excellent platform for the display of minority culture, the interweaving and collision of various cultures, and the integration and exchange of various cultures. It greatly promotes the exchange and cooperation of national culture and constantly innovates and develops national culture. All these are the benefits of new media on the Internet to cultural development.

4.4.3. The Network New Media Has Widened the Digital Channel of Cultural Communication in Nanxian County. The so-called digitization means that, with the development of science and technology, computers can convert multiple sound signals, image signals, and other signals into digital signals. Compared with the analog signal, the digital signal has made great progress. It can transform numerous complex network information into binary digital code or data format and process multiple sound and image signals on a computer. Due to the existence of a large number of computer storage devices, it is very important for the digitization of Nanxian culture. This means that the national culture can always record the life of the people in Nanxian County and keep many beautiful things, regardless of regional and time restrictions. At the same time, the Nanxian people's marriage habits and other digital forms can also be promoted. This kind of record not only records the grand wedding on the wedding day but also records the preparations before marriage, including how to worship ancestors and the details of married life. It can record all the things about marriage habits from a complete perspective, and it can be spread on the Internet through video. The masses and Nanxian culture lovers can turn on their computers at any time, and they can find pictures and videos of marriage in Nanxian County without time and place restrictions. Such a media digital platform has created many favorable conditions for the continuous inheritance and rapid popularization of Nanxian culture. On the other hand, this network is widely used to shorten the Earth space distance and can spread information to any place on the Earth.

5. Conclusion

The basic conclusion of this study is that the Internet era must inherit excellent local traditional culture. This paper adopts the method of literature analysis and visiting survey, starting from the characteristics of rural art, carries out a detailed analysis of multiculturalism, and discusses the value and cultural significance of dance from the perspective of comprehensive academic research methods. This is not only a requirement of the Internet age but also because the local tradition contains the cultural truth of human existence. The culture of the Internet age is not imagined but produced at historic moments according to local traditions. Culture is not a rootless tree. Local tradition is the root of culture in the Internet age, providing valuable cultural resources for cultural construction and development in the Internet age. In the Internet age, people's cultural behavior is bound to be restricted by traditional culture. In the Internet age, people realize the urgency and importance of inheriting the excellent traditional Chinese culture. It is imperative to build the cultural spirit of the Internet age, and traditional regional culture cannot be fully absorbed. Guided by the materialist dialectics of Marxism and the methodology of seeking truth from facts, we must earnestly study and analyze the excellent cultural essence of local traditions, inherit the reasonable and beneficial culture of local traditions, and improve people's overall cultural level.

Background. It has been known that there are microecology disorders during lung cancer development. Theoretically, intratumoral microbiota (ITM) can impact the lung cancer (LC) survival and treatment efficacy. This study conducted a follow-up investigation of non-small cell lung cancer (NSCLC) patients without lung infection to prove whether ITM indeed impacts the first-line treatment efficacy and survival. *Methods*. We enrolled all patients diagnosed with NSCLC in our department from 2017 to 2019, whose tumor samples were available (through surgery or biopsy) and sent for pathogen-targeted sequencing. All patients received the first-line treatment according to the individual situation. In the short term, the efficacy of the first-line treatment was recorded. During the follow-up, the survival status, progress events, and overall survival (OS) period were recorded if a patient was contacted. *Results*. Firstly, 53 patients were included, and our following analysis focused on the stage III and stage IV cases with ADC, SCC, or ASC tumors (47 cases). Several bacteria are associated with the LC status and progression, including N stages, metastasis sites, epidermal growth factor receptor (EGFR) mutation, first-line outcome, and later survival. The risk bacteria include *Serratia marcescens*, *Actinomyces neesii*, *Enterobacter cloacae*, and *Haemophilus parainfluenzae*; and the protective (against LC development and progression) ones include *Staphylococcus haemolyticus* and *Streptococcus crista*. In the logistic regression, the two-year survival can be predicted using the results of four bacteria (*Haemophilus parainfluenzae*, *Serratia marcescens*, *Acinetobacter jungii*, and *Streptococcus constellation*), with an accuracy rate of 90.7%. *Conclusion*. ITM have links to malignancy, EGFR mutation, first-line outcome, and survival of NSCLC. Our results implied the potential anti-NSCLC activity of antibiotics when used reasonably. It is still necessary to deepen the understanding of the characteristics of ITM and its interactions with NSCLC tumors and the immune cells, which is significant in individualized approaches to the LC treatment.

1. Introduction

Lung cancer (LC), especially non-small cell lung cancer (NSCLC), is one of the primary causes of global death. Traditionally, the carcinogenic factors of LC mainly include genetic factors and environmental factors. In recent years, it has been realized that microbial flora possibly impacts LC development [1]. The role of the microbiome has become increasingly clear, and variation of the microecology has been noticed in LC patients [2]; different clinicopathologies may be related to different conditions of the lung microbiota (LM) [3]. LM is also involved in LC onset and malignant progression. Understanding the diverse contributions of the bacterial microbiota to carcinogenesis is of great importance in LC diagnosis and treatment. Currently, studies do not distinguish LC cases with or without lung infection (LI). Bacterial and viral infections had influence on the patients' prognosis, affecting the immune system and impairing the outcome of anticancer treatments [4]. These cases have two major diseases, and the situation should be more complicated than LC alone. For patients free of LI, the features of tumor-associated microbiota are particularly informative in the investigation of tumorigenesis driven by LM. Additionally, published studies concerning the intratumoral microbiota (ITM) mainly focused on the basal clinical characteristics. Theoretically, IMT may impact the immune response and inhibit the treatment efficacy. So far, these factors and consequences are poorly understood in LC. It is reasonable to evaluate whether these interactions can impact the LC survival and treatment efficacy. However, very limited studies have analyzed the prognosis and investigated these potential influences induced by ITM.

Here, we conducted this 5-year follow-up study of NSCLC patients without respiratory infection and proved that ITM indeed impacts the first-line treatment efficacy and survival, which will show the potential anti-NSCLC activity of antibiotics. It is still necessary to deepen the understanding of the characteristics of ITM and its interactions with NSCLC tumors and the immune cells, which is significant in individualized approaches to the LC treatment.

2. Materials and Methods

2.1. Patients. We enrolled all patients diagnosed NSCLC in our department since 2017, whose tumor samples were available (through surgery or biopsy) and sent for pathogen-targeted sequencing. The inclusion criteria are as follows: (1) patients diagnosed with lung cancer, including adenocarcinoma (ADC), squamous cell carcinoma (SCC), and adenosquamous carcinoma (ASC) and (2) patients with the basic demographic information and tumor characteristics. The exclusion criteria are as follows: (1) patients diagnosed with a definite respiratory infection and other system disease. The smoking history and average number of cigarettes smoked every year were acquired. The EGFR and TP53 mutation features were extracted from the electronic medical record system. In addition, 5 μm paraffin-embedded tumor-tissue sections were prepared, and the PD-L1 expression in the immunohistochemistry analysis was acquired from the Department of Pathology. All patients received the first-line treatment according to an individual situation. In the short term, the efficacy of the first-line treatment was recorded. During the follow-up (at most 5 years), the survival status, progress events, progression-free survival (PFS), and overall survival (OS) period were recorded if a patient was contacted.

2.2. Targeted Sequencing of Intratumoral Microbiota (ITM). We used all the collected tumor samples to perform the pathogen-targeted sequencing. The sequencing process was performed in the Pathogeno One Pan-Infectious Pathogen high-throughput sequencing system by Shanghai Bingyuan Medical Technology Co. The report of each patient was acquired and documented in the dataset. For each known pathogenic microorganism, two fields were used for analysis: the reads of known bacteria and the presence of each microorganism.

2.3. Outcome Measures. 53 patients were included, and 47 cases were followed for analysis.

The risk bacteria include *Serratia marcescens*, *Actinomyces neesii*, *Enterobacter cloacae*, and *Haemophilus parainfluenzae*; the protective (against LC development and progression) ones include *Staphylococcus haemolyticus* and *Streptococcus crista*.

Table 1: Clinical characteristics of NSCLC patients.

Characteristics		Case number	%
Total cases		53	100
Gender	Male	38	71.7
	Female	15	28.3
Smoking history	Never smoking	21	39.6
	Smoking	31	58.5
	Smoking quitted	1	1.9
Major stage	I	1	1.9
	II	2	3.8
	III	25	47.2
	IV	25	47.2
Pathological type	ADC	26	49.1
	SCC	21	39.6
	ASC	3	5.7
	Others	3	5.7
PD-L1 positive		13	24.5
EGFR mutation		12	22.6
Metastasis	Mediastinal lymph nodes	11	20.8
	Lung	11	20.8
	Bone	10	18.9
	Liver	7	13.2
	Brain	6	11.3
	Pleura	3	5.7
	N	Mean	SD
Age (years)	53	66.08	8.786
Cigarettes per year	53	385.85	436.813

2.4. Statistical Analysis. The data are expressed as numbers with proportions (%), mean with SD, or median with 95% confidence interval (CI). The differences in values derived from categorical variables were compared using the chi-squared test. One-way ANOVA was used for three or four groups. Overall survival (OS) in relation to the bacterial result was evaluated by Kaplan–Meier survival curve and log-rank test. The Cox proportional hazard model was also used to discover the potential risk of the relationship between multiple factors and the overall postoperative survival. Statistically significant prognostic factors identified by univariate analysis were further included in the multivariate analysis. A P value <0.05 was considered statistically significant.

3. Results

3.1. Clinical Characteristics of Enrolled NSCLC Patients. Firstly, 53 patients were included, and the clinical features are presented in Table 1. There were 38 (71.7%) males and 15 (28.3%) females. About 40% of patients were smokers. There were 25 (47.2%) stage III and 25 (47.2%) stage IV cases. Only three patients were in stage I or II. The pathological types were as follows: the numbers for adenocarcinoma (ADC), squamous cell carcinoma (SCC), and adenosquamous carcinoma (ASC) were 26 (49.1%), 21 (39.6%), and 3 (5.7%), respectively. Besides, there were three cases of other types, including two poorly differentiated carcinomas and one large cell lung cancer. The main metastasis sites were mediastinal lymph nodes, lung, bone, liver, and brain.

3.2. Association between Intratumoral Microbiota (ITM) and Disease Characteristics. Given there were only three stage-I/II cases, and only three cases had the other pathological types (including poorly differentiated carcinoma and large cell lung cancer), our following analysis focused on the stage III and stage IV cases with ADC, SCC, or ASC tumors (47 cases). If some microbiota had no more than four positive cases, the results might be unreliable. Therefore, those microbiota results with rare cases were culled from the raw data. First, the association between the microbiota and the pathological type was probed. Among ADC, SCC, and ASC, the ASC tumors had a higher abundance of *Serratia marcescens* (2.67 ± 4.619 counts) versus ADC (0.27 ± 0.962 counts, $P < 0.05$) and SCC (0 counts, $P < 0.05$). However, the case number of ASC was three, and this conclusion is still to be verified. Next, there was no association between ITM and the major stage (T stage and M stage). But for N stages, among N0 to N3, we noticed different features in the presence of *Actinomyces neesii* and *Haemophilus* (Table 2). These two bacteria were negatively related to the metastasis in the lymph node ($P < 0.01$). Next, the main metastasis organs/tissues (including mediastinal lymph nodes, lung, bone, liver, brain, and pleura) showed noticeable association with the ITM. Tumors with *Serratia marcescens* were more likely to develop brain metastasis ($P < 0.01$, Table 3), and those with *Enterobacter cloacae* were more likely to develop metastases to the mediastinal lymph node ($P < 0.05$, Table 3). Moreover, for the first time, we noticed that ITM can link to the EGFR mutation (Table 4). For example, EGFR mutation was negatively related to *Haemophilus parainfluenzae* ($P < 0.05$) but positively with *Serratia marcescens* ($P < 0.01$). Furthermore, *Acinetobacter jungii* was positively correlated with PD-L1 expression (PD-L1 positive/negative = 4/8) in *Acinetobacter jungii*-positive cases, in comparison with 7/41 in *Acinetobacter jungii*-negative cases, (chi-square = 4.168, $P = 0.041$). Collectively, ITM is notably associated with disease characteristics of NSCLC.

3.3. Association between ITM and the First-Line Treatment Outcomes. Next, we evaluated whether ITM may impact the efficacy of first-line treatments (targeted therapy or chemotherapy). Also, only stage III and IV cases were analyzed. Overall, there is no association between ITM and the response to the first-line treatment. However, in the hierarchical analysis, we noticed that the presence of *Haemophilus parainfluenzae* was negatively correlated with response to the first-line treatment for stage IV patients (Table 5). The patients with intratumoral *Haemophilus parainfluenzae* had a poorer control rate (3/6 vs 18/19).

Table 2: Association between ITM and N stages.

Bacteria		N0	N1	N2	N3	Chi-square	*P* value
Actinomyces neesii	−	0	1	28	8	18.875	<0.001
	+	1	1	1	0		
Haemophilus	−	0	2	25	8	8.473	0.037
	+	1	0	4	0

Outcome	Median	95% CI		Log-rank chi-square	*P* value
−	7 months	4.891	9.109	3.940	0.047
+	4 months	1.600	6.400		

3.4. Association between ITM and Survival. Initially, we used the Kaplan–Meier method to evaluate the association between ITM and survival in stages III and IV. If any case, the number of the ITM/target event (progressed or death) double-positive set was not more than two, this index was omitted. Similar to the response to the first-line treatment outcomes, the presence of *Haemophilus parainfluenzae* was related to the poorer PFS of stage IV patients (Table 6 and Figure 1(a)). When stage III and IV cases were pooled together, we found that *Staphylococcus haemolyticus* infection was linked to the longer PFS (Table 7 and Figure 1(b)). Meanwhile, for pooled cases (stage III and IV), *Serratia marcescens* was related to better OS (Table 8 and Figure 1(c))

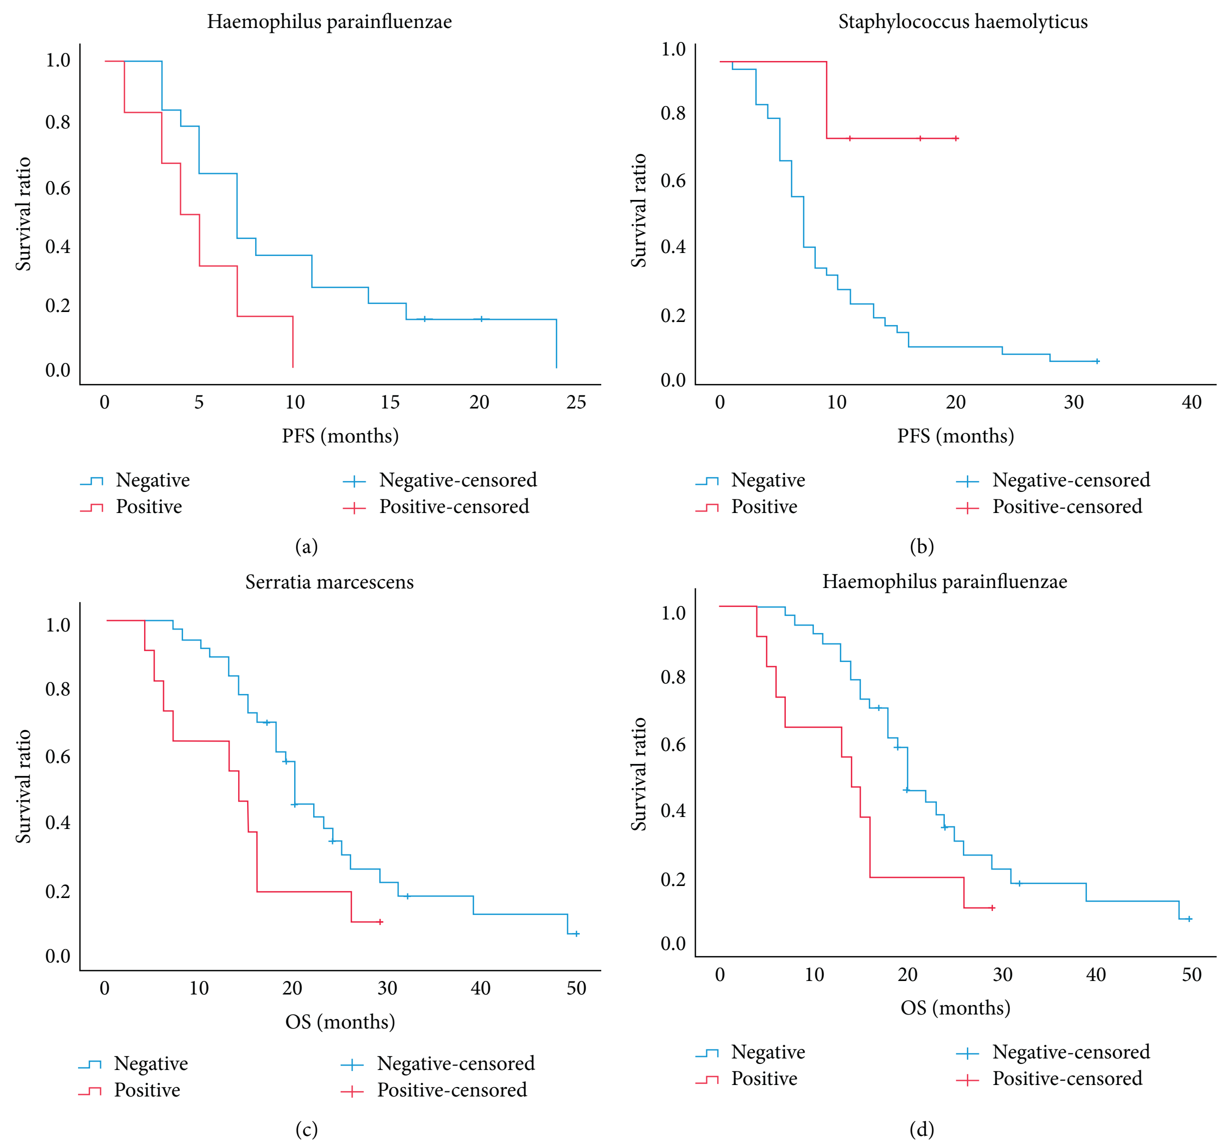

Figure 1: The association between intratumoral microbiota and survival in stage III and IV non-small cell lung cancer patients using the Kaplan–Meier method. (a) The presence of *Haemophilus parainfluenzae* was related to poorer PFS (only for stage IV patients). (b) *Staphylococcus haemolyticus* infection was linked to longer progression-free survival (PFS). (c) *Serratia marcescens* was related to better overall survival (OS). (d) *Haemophilus parainfluenzae* was related to poorer OS.

Table 7: Association between *Staphylococcus haemolyticus* and the PFS.

Outcome	Median	95% CI		Log-rank chi-square	*P* value
–	7 months	6.102	7.898	5.887	0.015
+	Not reached				

Table 8: Association between *Serratia marcescens* and the OS.

Outcome	Median	95% CI		Log-rank chi-square	*P* value

+	49	N.A.	N.A.		

and the presence of *Haemophilus parainfluenzae* was related to the poorer OS (Table 9 and Figure 1(d)). Also, the Cox regression analysis (using the Enter model) showed that, besides *Staphylococcus haemolyticus*, *Streptococcus crista* is also associated with better PFS (Table 10). On the contrary, *Haemophilus parainfluenzae* and *Corynebacterium jergeri* were two risk factors for OS (Table 11). Finally, in the logistic regression model, the two-year survival was predicted (for stage III or IV patients with ADC, SCC, or ASC), using the following seven variables: age, major stage, pathological type, and the results of four bacteria (*Haemophilus parainfluenzae*, *Serratia marcescens*, *Acinetobacter jungii*, and *Streptococcus constellation*). The variables and their contribution are listed in Table 12. Using this regression, the

4. Discussion

It has been recognized that LC has non-negligible links to pathogenic microorganisms, such as *Haemophilus influenzae*, *Moraxella catarrhalis*, *Granulicatella*, *Abiotrophia*, *Streptococcus*, and *Mycobacterium tuberculosis* [5–8]. With the development of sequencing technology, their relationships have been increasingly clear. However, there are still problems to be solved. One of the most important questions is whether and how ITM affect the treatment and prognosis of lung cancer. We here innovatively observed the link between ITM and disease characteristics and combined the results of ITM to construct a prognostic model. Overall, several bacteria are associated with the LC status and progression, including N stages, metastasis sites, EGFR mutation, first-line outcome, and later survival. Seemingly, the risk bacteria include *Serratia marcescens*, *Actinomyces neesii*, *Enterobacter cloacae*, and *Haemophilus parainfluenzae*; and the protective (against LC development and progression) ones include *Staphylococcus haemolyticus* and *Streptococcus crista*. So far, all the abovementioned associations were highly novel findings, so supporting evidence are limited. *Haemophilus parainfluenzae* has been regarded as an indicator of LM changes triggered by preoperative prophylaxis in LC patients [9]. It was observed in 43.3% to 63.3% cases of LC patients [9], and it is reasonable to believe that this bacterium is a cancer-promoting strain. Interestingly, there are also some seemingly unsupportive evidence. For example, prodigiosin is a secondary metabolite, isolated from a culture of *Serratia marcescens*. It induces LC apoptosis in both caspase-dependent and caspase-independent pathways [10]. It is still early to tell whether *Serratia marcescens* has a driving or suppressive effect on LC. However, based on Table 3, if *Serratia marcescens* drives LC progression, a possible pathway is metastasis in the brain. Similarly, as shown in Table 2, the reason for the driving effect by *Actinomyces neesii* may be due to the promotion of lymph node metastasis. Also, *Haemophilus parainfluenzae*, as a risk factor to survival, may promote the EGFR-WT carcinomas but not EGFR mutant ones, and these cases cannot be treated by targeted TKIs, which is a possible reason for the poor survival.

The mechanisms underlying the impact of ITM on survival may include the following and various aspects. First, ITM (as well as bacteria outside the tumor) may drive carcinogenesis directly. It is estimated that 20% of cancers are caused by infectious agents [11]. The dysbiosis of some carcinogenic microbiomes causes direct DNA damage and inflammation [12]. Moreover, inflammation triggered by microbial dysregulation can largely impact invasion and angiogenesis, which significantly drives the malignant progression. Known targets of microbiome-induced inflammation include TLRs, NF-κB, and STAT3 [13–15]. These direct effects exerted by microbes are highly possibly carcinogenic. Also, there are some indirect mechanisms. For example, through modulation of immune response, the response to treatment and prognosis can be influenced. Besides, the inflammatory effect triggered by IMTs, their inhibitive effects on the immune system can also play an essential role [12]. At least partially, ITM can result in the exhaustion of immune cells, and they inhibit antitumor immunity together with the tumor cells. For example, they may exert suppress NK cells [16]. However, given the digestive tract has more abundant flora, most attention to the relationship between microbiome and cancer has been paid to colorectal cancer and gastric cancer. There are limited data about the impact of ITM on the prognosis of LC, but related research can be used as reference. Recently, a Chinese study found nine enriched bacteria in the lung of NSCLC patients [17]. Also, the analysis of T cells and B cells implied that these bacteria in the lung may change the immune cell infiltration in LC tissues. Recently, a retrospective study of 69 NSCLC reported that patients treated with anti-PD-1 antibodies receiving antibiotics had greatly decreased objective response rate, OS, and PFS compared to those who did not use antibiotics [18]. This result highlights that inappropriate usage of antibiotics may influence the flora of the tumor environment and impair the treatment effect. Indeed, the use of antibiotics has been reported to be associated with an elevated risk of LC onset [19, 20]. Moreover, when not limited to the local lung tissue, another interesting issue is whether the gut-lung axis may impact the outcome of chemotherapy and later survival through the impact of microbiota. This issue is being investigated by a multicenter, prospective, double-blind randomized trial [21], but the final result has not yet been announced.

Still, the present study has some limitations. The main shortcoming is the small sample size. The number of many classification results was around 5 in one cell, which is the major reason for the inconsistency between the univariate analysis and binary regression analysis. Also, due to the limited sample size, the performance of bacteria in the 2-year prediction model is not outstanding enough, and we cannot divide the dataset into the training set and test set; hence, the scalability of the model is still unclear.

5. Conclusion

This novel study proved that ITM was related to malignancy, EGFR mutation, first-line outcome, and survival of NSCLC. Also, our results implied the potential anti-NSCLC activity of antibiotics when used reasonably. It is still necessary to deepen the understanding of the characteristics of ITM and its interactions with NSCLC tumors and the immune cells, which is significant in individualized approaches to the LC treatment.

This article examines distinctive techniques for monitoring the condition of fishes in underwater and also provides tranquil procedures after catching the fishes. Once the fishes are hooked, two different techniques that are explicitly designed for smoking and drying are implemented for saving the time of fish suppliers. Existing methods do not focus on the optimization algorithms for solving this issue. When considering the optimization problem, the solution is adequate for any number of inputs at time *t*. For this combined new flanged technique, a precise system model has been designed and incorporated with a set of rules using contention protocols. In addition, the designed system is also instigated with a whale optimization algorithm that is having sufficient capability to test the different parameters of assimilated sensing devices using different sensors. Further to test the effectiveness of the proposed method, an online monitoring system has been presented that can monitor and in turn provides the consequences using a simulation model for better understanding. Moreover, after examining the simulation results under three different scenarios, it has been observed that the proposed method provides an enhancement in real-time monitoring systems for an average of 78%.

1. Literature: A Brief Review

For applying the proposed indication on monitoring fisheries with smoking and cutting methods, many existing methodologies have been analyzed, and they are discussed in this section. Since many accurate predictions are needed under water, a smart quality sensor has been designed with a new adaptive system model [1]. The major exertion has concentrated on analyzing the varying nature of fishes, and an ice storage system has been used for storage where only a limited number of measurements have been provided. Consequently, association between index quality and standard quality is provided by selecting a sequencing method that validates calibration and corroboration of sensors. Also, wireless sensors have been integrated, and their performance on water quality has been checked in the western region of Andhra Pradesh where direct field visits have been made for designing an autonomous mode of operation [2]. The researchers examined and created an autonomous vehicle that is capable of traveling inside water and reports corresponding information to the base station. This type of system has been inspected in India for the first time, and it is significantly supportive for all aqua farmers to lead a better quality of life. A review has been prepared by comparing different methods for monitoring the health parameters of each fish [3] that are present inside the water. This type of review provides complete information on the usage of low-power devices that requires only minimum water for improving the productivity in farms. Moreover, the impact of freshwater has also been discussed, but only a small area has been considered, and it is not enough to make a prudent decision since the area of monitoring is much important for aquaculture research.

Moreover, an analytical method for monitoring water quality has been examined [4] under four different categories that even include the existence and nonexistence of different contaminants. For monitoring both physical and biological contaminants, a high-end network setup is needed with low-cost sensors. The major reason for using high-quality setup is to avoid microbes that affect the aqua farms, but the cost of implementation is higher when a high-end network setup is established. Once the fishes are gathered, they should be desiccated for a period of time; therefore, a smoking machine is established [5], which observes only a small quantity of water. However, the setup consists of a closed-loop circulation with Arduino Uno sustenance where high-cost pipes and chambers are established. This method serves as a basic perception of desiccating the fishes within three hours, and it can even be changed from one place to another. Even during the smog period, the fishes can be dehydrated for six hours, but the amount of energy that is consumed for this process is much higher due to the existence of a huge chamber. Therefore, to overcome the drawback of the big-sized chamber that cannot be used in the indoor environment, a machine learning algorithm for smoking fishes has been created [6]. This procedure uses the concept of k-nearest neighbor for receiving the data from the chamber with help of low-cost sensors. But, in most methods, only a binary value is not sufficient to determine the simplicity of prediction. The researchers have also rationalized the old technique of image classification to the video detection method [7] where an automated detection scale has been presented with different time scales. One additional advantage of the aforementioned method is that it paves way for transferring the video to all cable telescopes. But a high number of video nodes is needed for underwater, and it will be difficult to integrate all information from several nodes.

In a fish processing survey, it is observed that most of the fishes are smoked and expurgated before reaching the final stage [8] that is not good for health. Therefore, it is necessary to monitor the amount of proteins that are present in each fish, and they should be extracted for use in other sources. Furthermore, the researchers have explored that the amount of freshness in fish fillets should also be monitored [9] that is significantly useful for improving the accuracy of the entire system. This procedure can be implemented with multiple ethereal that can store fishes for a period of 12 days, and the high amount of power will be consumed during this process when images are extracted. For both assessment and data processing techniques the components of machine vision applications are extracted [10] that include the size and volume of fishes to be smoked. This type of machine vision application serves as an important component for the automatic processing of aqua food processing techniques. Moreover, for measuring both quality and quantity of fishes, an electronic sensor device has been implemented that detects tongue and nose for electronic authentication process [11]. This type of high advancement needs metal-oxide-semiconductor field-effect transistor electrochemical sensors to be implemented at a high cost.

Additionally, control guidance by the food processing industry for storing vulnerabilities has been provided [12] that serve as a contrivance for all countries to follow highly defined standards in aqua farms. By following these standards, an investigation has been made in the Mediterranean Sea [13] where attrition is prevented and fishes are protected in prematured stage itself. Since most of the process is implemented with sensors, a new system model is necessary; therefore, a semiconductor sensor model has been created [14], and it is integrated with machine vision algorithms. Besides, this system an agent-based simulator has also been introduced in the current system process that provides an inherent mechanism for monitoring fishes [15]. This type of model is having many hidden layers, and all these layers are fulfilled only using the cost of communication channels.

To improve the health of fishes in underwater, whale optimization algorithm is used. In this study, the behavior of fishes and their presented environment, that is, underwater, are analyzed for the number of sensors deployed. Both environment and fish-related information are analyzed using the sensors. Based on the current state, the performance of optimization is achieved using the sensors.

The rest of this paper is organized as follows. Section 2 summarizes the precise design methodology in which the proposed system overview is detailed. Section 4 discusses the proposed optimization algorithm for using the fishers improvement analysis. Section 5 discusses the results and discussion for the proposed methodology in which the overall results of the designed methodology are highlighted in detail, and finally, the system is concluded with the conclusions and further enhancements.

2. Precise Design Methodology

For designing a precise methodology, it is much important to calibrate the sensors, and all the decompositions that are used for smoking fishes must run in a parallel manner. Since parallel operations are performed, a likelihood model has to be formed that performs different sensor operations when data is distributed individually. Therefore, the likelihood function can be established using the following equation:

$$f(i) = \sum_{i=1}^{n} \frac{(\mu_i - p_i)^2}{\sigma_i^2}, \quad (1)$$

where p_i denotes the prediction of sensors for distributed data. μ_i and σ_i represents the mean and variance of given likelihood functions.

Equation (1) denotes that variation in size of fishes with different sizes in the smoking process has been considered using mean and variance functions. Also, during the cutting process, it is difficult to cut the fishes of the same size; therefore, for proper examination of length and breadth, data are predicted using a contact distance sensor that is indicated as LVDT has been integrated inside the corresponding cutting machines. After unknown likelihood values are known in the next step, all measurement counts gained during the cutting process have to be calculated using the following equation:

$$\frac{\mathrm{d}c_i}{\mathrm{d}t_i} = \mu_i\left(1 - 10^{m_i(t)}\right), \quad (2)$$

where $m_i(t)$ denotes various concentrations in the population of fishes at time $t = 0$ inside the smoking chamber. Equation (2) indicates that all concentrated population values will be segregated with respect to time, and it will be multiplied with mean values that are obtained from equation (1). One major reason for considering all segregated values in terms of time is that each fish will be kept inside the chamber at different times, and for each time, a separate size cannot be given as input likelihood values. Therefore, for cutting the fishes in equal size, it is necessary to separate fishes of different sizes, and all can be kept inside the chamber by following different time periods. In addition, for taking all measurements, it is obligatory to observe that output voltage of sensors during the temperature setting process. Thus, the output voltage in terms of time can be represented as follows:

$$\max \mathrm{volt}_i = \sum_{i=1}^{n} \frac{298K \times e^{\mathrm{temp}_i\left(1/t_1 - 1/t_0\right)}}{e^{\mathrm{temp}_i\left(1/t_1 - 1/t_0\right)} \times g_i}, \quad (3)$$

where $298K$ represents the initial temperature when fishes are kept inside the chamber for the smoking process. temp_i denotes distinguishing temperatures between 1,000K and 3,000K. t_1 and t_0 signify different timing characteristics when fishes are smoked inside the chamber. g_i represents greater resistance that is provided when corresponding voltages are divided.

Equations (1)–(3) indicates that the prediction of sensors should be a variable process and it should be eminent using a statistical test that follows a chi-square distribution as indicated in the following equation:

$$S_i^2 = \sum_{i=1}^{n} \frac{(E_i - P_i)}{P_i^2}, \quad (4)$$

where S_i^2 denotes the corresponding sampling times. E_i and P_i represent the observed and predicted values from LVDT sensors, respectively.

In order to establish the relationship between input and output variables, it is necessary to integrate a polynomial regression that is nonlinear in nature as given in the following equation:

$$\theta_i = \sum_{i=1}^{n} \gamma_i \tau_i, \quad (5)$$

where γ_i denotes the scaled cutting factor of fishes. τ_i represents the enduring measurement values of LVDT sensors.

If equation (5) is established correctly, then it indicates that the efficiency of the entire process is going to be decided using inclinations of the water quality process where high velocity needs to be applied for smoking fishes by integrating wide channels. Also, it is necessary to find the activity of each fish that is present inside the pond using two different parameters since cutting and smoking methods are used.

$$a_i = \sum_{i=1}^{n} e^{\omega_i * \vartheta_i}, \quad (6)$$

where ω_i represents the average swimming time of different fishes inside the pond. ϑ_i denotes the swimming speed of each fish.

Equation (6) is specified to calculate the speed and time of spinning for each fish since it is necessary to differentiate different types of fishes that are present inside the pond. Once the activities of different fishes are known, then the total area of the tarn will be monitored, and the rapidity of the airstream will be converted using control rule as follows:

$$R(i)_{100\,\mathrm{m}} = \aleph_{25} + \frac{E_{i25\,\mathrm{m}}}{E_{i14.4\,\mathrm{m}}}, \quad (7)$$

where $\aleph_{25}$ represents the rapidity of the air stream at an altitude of 25 meters. $E_{i25\,\mathrm{m}}$ and $E_{i14.4\,\mathrm{m}}$ represent the rapidity of the air stream at an altitude of 25 meters and 14.4 meters, respectively.

Equation (7) indicates the control rule where sensors are placed at an altitude of two different meters such as 25 meters and 14.4 meters. After establishing the altitude of each pond, measurement and regulation of the feed process for each fish have to be calculated; this is designed using the following equation:

$$\mathrm{feed}_i = 1 - \left(i_{\max} - i_{\min}\right), \quad (8)$$

where $i_{\max}$ and $i_{\min}$ denotes the maximum and minimum intestine values of each fish, respectively.

Equation (8) denotes that difference between the maximum and minimum intestine values will provide the amount and regulation of feed using calcium-sensing receptors. The perception behind this calculation is to determine the amount of water that is absorbed by each fish in its intestine. In addition, the sensitivity of absorbed water will be measured at various luminescence levels that are exposed by calcium receptors.

3. Optimization Algorithm

In this section, an optimization process is introduced for integrating the system model for defined objective functions such as monitoring of pond, measurement, and regulation of feed with proper natural contaminant proportions. Therefore, in the first step, a set of rules have been defined using contention protocols since the load of measurement is higher. For making this contention protocol work, the main node will be divided into many subnodes that is termed as adaptive tree method. The protocol is designed to distribute the work allocated to each sensor node and to provide a collision-free technique, while packets are distributed to intended recipients. With the use of collision-free protocols, collisions do not occur, and the CSMA/CD and CSMA/CA use the possibility of the collisions for the transmission channel that is acquired using any station. Therefore, for every successful packet transmission, an optimal path will be selected, and it can be given statistically as follows:

$$\mathrm{Prob}_i = \sum_{i=1}^{n} \left[\frac{z_i - 1}{z_i} \right], \tag{9}$$

where z_i represents a number of stations struggling to get channel access from the central node.

Suppose if a station is connected to the corresponding channel in the specified first slot, then the probability rate can be given as follows:

$$z_i \mathrm{prob}_i \left(1 - \mathrm{prob}_i\right)^{z_i - 1}. \tag{10}$$

Since many subnodes are present in the media access control sublayer for monitoring the condition of fishes that are present in underwater, the expected number of uniformly distributed stations must be discovered. This is expressed using the following:

$$U_i = \log_2 z_i. \tag{11}$$

For monitoring the entire pond, which is present in underwater using wireless sensors, four different steps are followed in every transmission cycle. In the first phase of transmission, a request for sending data will be sent, and in the next phase, once the request is accepted, entire data will be discarded in current node, and it will be sent back to the requested nodes. In the third and fourth phase data, acknowledgment will be sent from each subnet node that is connected in a pipe-like structure. Moreover, contention-free protocols will use the concept of time-division multiple access where each and every node will be allotted a separate slot for data transmission. At the final stage, all packets will be combined for providing suboptimal congestions, and it can be expressed using the following condition:

$$T_{i,j} = \sum_{i=1}^{n} \mathrm{Prop}_i + \mathrm{Prop}_j + T_{i0} + T_{j0}, \tag{12}$$

where Prop_i and Prop_j denote the propagation delay in seconds. T_{i0} and T_{j0} represents the delay from first i^{th} and j^{th} nodes, respectively.

Whenever protocols are defined using wireless sensors, a large computational complexity will be present that can be solved by the application of the corresponding algorithm. Therefore, in the proposed method, a whale optimization algorithm [16, 17] will be incorporated for optimizing the schedules in control and data transmission phases. The major advantage of selecting a whale optimization algorithm is that it provides an accurate system for allocating different resources in underwater that are consumed by fishes. In addition, the implemented algorithm is having the ability to provide solutions using very few parameters, and even global solutions can be obtained within less period of time. Since the problem is linear, it is necessary to calculate capacity constraints as follows:

$$\sum_{i,j=1}^{n} TW_{ij} \geq AW_{ij}, \tag{13}$$

where TW_{ij} denotes total water supply resource from i^{th} to j^{th} node. AW_{ij} represents available water supply resource from i^{th} to j^{th} node.

Equation (13) denotes that the total water supply should be greater than or at least equal to the available water supply in different resources. To calculate the current precise solution, distance between whale and generated prey should be observed. This can be calculated using the following equation:

$$\Delta_i = \left| d_w(t) - d_p(t) \right|, \tag{14}$$

where $d_w(t)$ and $d_p(t)$ represent the distance of whale and prey with respect to time.

Subsequently, it is necessary to explore the solution in whale optimization algorithm using exploration phase where two different coefficient will be used for performing a global search that can be expressed using the following equation:

$$d(t+1) = \overline{d_t} - i.j. \tag{15}$$

Here i, j represent two different coefficient that are used in the exploration phase.

Consequently, the aforementioned protocol and algorithm have to be implemented with a system model with different objectives. Therefore, step-by-step implementation is elucidated in Figure 1.

4. Results and Discussion

In this section, validation of the system model after integrating whale optimization algorithm by defining a set of rules has been deliberated. Since the proposed method is deciphering multiple objectives, the following three major scenarios are considered:

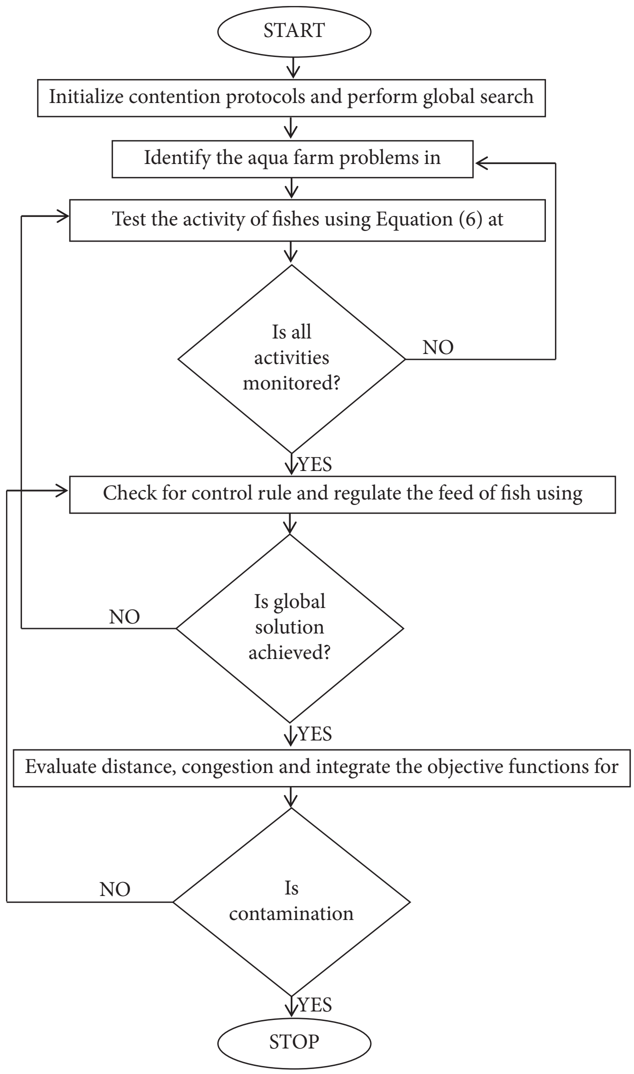

Figure 1: Implementation of WOA for monitoring activities of fishes.

(i) Scenario 1: surveillance of tarn
(ii) Scenario 2: regulation of feed
(iii) Scenario 3: proportion of natural contaminant

For these aforementioned scenarios, simulation analysis is performed by incorporating the corresponding hardware setup with Node-RED, and the reproduction is performed offline using MATLAB for better indulgence of day-to-day activities of fishes in underwater.

4.1. Scenario 1. In this scenario, the basic parameter that is necessary for monitoring the fish pond is investigated. Since more number of fishes is present in underwater, there is a necessity for monitoring the turbidity level of water inside the tarn. In the proposed exploration, fishes that are present inside the pond are monitored for a period of 20 days uninterruptedly, and all observed data have been stored in the online monitoring system. The data have been imported using MATLAB, and simulation results for scenario 1 have been reflected in Figure 2. If the turbidity level of water is reduced, then fishes can stay inside the water for a long period of time, and hence, level of health can also be increased.

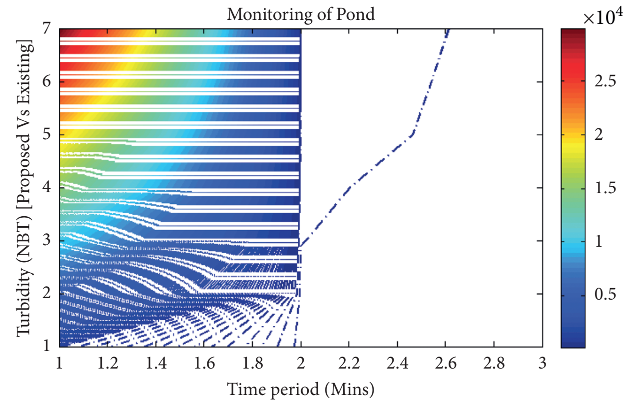

Figure 2: Turbidity level of the fish pond.

From Figure 2, it can be observed that for every time period, the maximum and accurate turbidity levels are monitored. Also, if an intelligent sensing device is present, it is possible to evaluate the precise value of turbidity level; therefore, in Figure 2, time period of sensors is reserved for one alignment, and turbidity values that are measured in NBT are reticent for another alignment. After examining the simulated results, it is ascertained that the proposed method using an intelligent sensing device performs well when compared to the existing method. For example, if the time period of sensors is 15,000 minutes, then the level of turbidity for an existing method is 168 NBT, but the proposed method provides the exact turbidity level that is observed as 108 NBT. This proves that within the selected time period and even if the time period is poignant, the proposed method can provide exact turbidity values without any error.

4.2. Scenario 2. After examining the turbidity level, the amount of feed that is supplied to fishes must be counteracted; this is examined in this scenario. If the amount of feed is much higher than the body length of fishes, then they cannot move to the exact position, and if it moves inside high depth, then it is difficult for fishermen to catch fishes.

Therefore, this method has been monitored using an intelligent sensing device, and simulation results for determining the amount of feed has been provided in Figure 3. Figure 3 is plotted by considering the body length of fishes that are measured in meters. By measuring the body length of fishes, the amount of feed that is supplied for each fish should be either increased or decreased. From Figure 3, it can be observed that only sensors can monitor the amount of feed in a precise way as compared to the existing method in absence of the intelligent sensing device. For example, if the body length of fish is 13.5 meters, then the amount of feed that needs to be supplied for a day is 10, but in existing methods, only 9 times the fishes are nourished. This will affect the health, and furthermore, it will decrease the lifetime of fishes. Since the proposed method can regulate

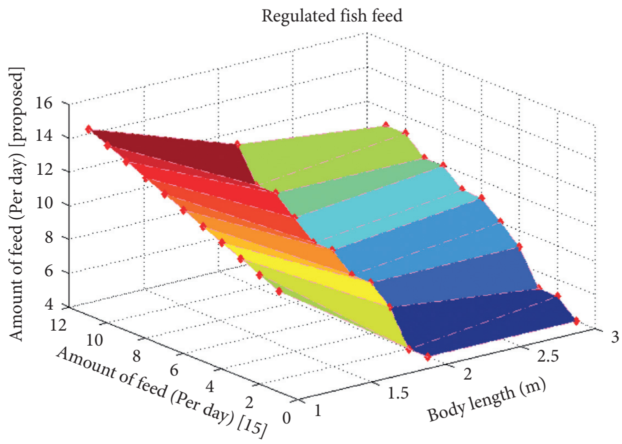

Figure 3: Level of regulating fish feed.

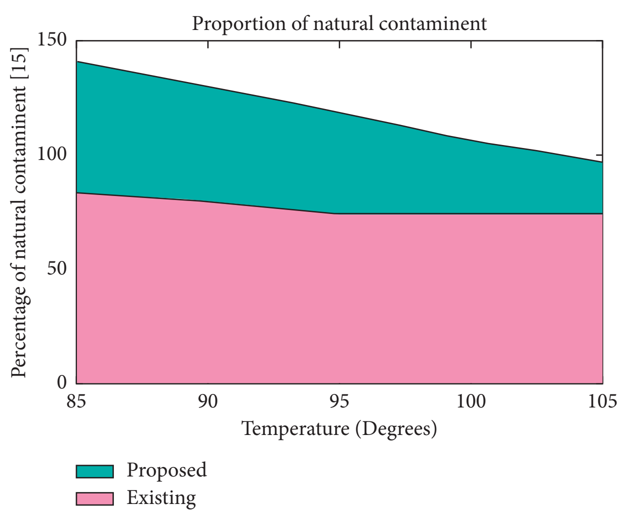

Figure 4: Percentage of contaminants in underwater.

the correct amount of feed, it can be preferred for real-time monitoring in underwater.

4.3. Scenario 3. This scenario examines the third major parameter that defines the maximum natural contaminant that is present in underwater. In real-time application of fisheries, natural contaminant should be much lesser for preventing the fishes before it enters the red zone region. Therefore, careful experimentation has been processed by establishing sensors, and the percentage of natural contaminant that is mixed with undesirable content has been observed. To realize the percentage of mixture simulation results using observed values are plotted in Figure 4.

Figure 4 is plotted by considering the temperature that is present in underwater where it is varied between 85° and 105°. The major reason for considering the temperature is that for each period of time, the level of contaminants will vary, and if the temperature is much higher, then the original contaminant level will be further reduced.

The growth of fishes will be much higher only when it is present in the bottom layer of water, and if natural contaminants are reduced, fishes will come up to the top level, and in early stages, they will be hooked. Therefore, to avoid this, the proposed method provides the exact amount of natural contaminants that are present in the pond. In this scenario, the proposed method performs much better than the existing method in terms of percentage identification of contaminants and prevents the fishes before it enters the upper layer.

5. Conclusions

A new flanged real-time monitoring and examination of fishes in underwater have been introduced with the simulation model in this article. Even though many methods are available for monitoring the state of fishes that are present in underwater, it is necessary that remote checks should be performed using intelligent monitoring devices. Therefore, the major advantage of the proposed method is that it reduces the time of fish vendors as they can able to smoke and dry the fishes within a short period of time. Since this new technique combines monitoring the health of fishes with cutting and smoking techniques a set of rules has been designed with contention protocols since large data is processed. This technique is also integrated with Node-RED for storing central data where users can able to access it using an authentication key. Subsequently, this online monitoring system can provide day-to-day results, and they are integrated with simulation fragments that are executed using MATLAB. It has been experiential that the integrated whale optimization algorithm that is integrated with system model can provide improved results around 78% that is much higher than existing methods. In future, the proposed method can be protracted by introducing robotic technology to further reduce the export time of vendors.

The study focused on the therapeutic effect of clinical treatment on urinary calculi with kidney failure and its relationship with the serum inflammatory factor levels. 90 children with melamine urinary calculi were selected as research subjects. Of them, 52 cases were in group 1 (nonrenal failure), and 38 cases were in group 2 (combined with renal failure). In addition, 35 hospitalized children with no history of melamine-contaminated milk feeding during the same period were used as healthy controls. They all underwent ultrasound imaging examination based on the speckle noise algorithm, and the prognosis was analyzed. It was found that the peak signal-to-noise ratio (PSNR), structural similarity (SSIM), and local edge preservation index (EPI) of the algorithm in this study were significantly greater than other algorithms ($P < 0.05$). The admission age of the children in group 1 was significantly younger than that of group 2, the bilateral stone rate was significantly higher than that in group 2, and the difference was statistically significant ($P < 0.05$). Of the 52 children in group 1, the stone disappeared in 25 cases after treatment, the stone was reduced in 20 cases, and the stone remained unchanged in 7 cases. The total effective rate of treatment was 88.46%. Of the 38 cases in group 2, the stone disappeared in 22 cases after treatment, the stone was reduced in 12 cases, and the stone remained unchanged in 4 cases. The total effective rate of treatment was 89.47%. No difference was noted in blood urea nitrogen (BUN), blood creatinine (Cr), TNF-α, and C-reactive protein (CRP) levels in group 1, group 2, and the healthy control group ($P > 0.05$). Hence, the denoising algorithm in this study has better denoising effects on ultrasound images than traditional algorithms, with higher definition and less noise and artifacts. The clinical treatment of children with urinary calculi and renal failure is highly effective, the renal function and serum inflammatory factor levels return to the normal range, and the inflammatory response is weakened.

1. Introduction

Kidney failure is a decline in kidney function that occurs when the kidneys are unable to maintain metabolism and water and electrolyte balance. Renal failure is divided into acute renal failure and chronic renal failure [1, 2]. Acute renal failure arises from the rapid decline of glomerular filtration rate, accumulation of nitrogenous waste in the body, water and sodium retention, and electrolyte imbalance, and patients will have symptoms such as reduced urine output or even anuria, general edema, and heart failure [3]. Acute renal failure is also known as acute kidney injury, and its causes include prerenal, renal parenchymal, and postrenal factors [4, 5]. Acute kidney injury caused by prerenal and postrenal factors is reversible but timely diagnosis and active treatment contribute to a good prognosis and in most cases can restore the kidney function to normal [6–8]. In clinical practice, chronic renal failure is common in nephrology, mainly arising from kidney damage and serious destruction of the nephron, which then lead to endocrine disorders, nitrogen metabolite storage disorders, and water electrolyte and acid-base balance disorders. In the case of chronic renal failure, the body's immunity and resistance will decrease significantly, and the internal environment disorders caused by renal excretion and metabolic dysfunction will further make the body's response to infection abnormal. Worse still, the clinical application of antibiotics is subject to various limitations [9]. Clinical treatment of acute renal failure and chronic renal failure generally uses hemodialysis. Hemodialysis is a renal replacement treatment for patients with acute and chronic kidney failure. It can drain blood from the body to the outside of the body and pass it through a dialyzer composed of countless hollow fibers. The electrolyte solution (dialysis solution) with a similar concentration of the blood exchanges substances with the blood to remove metabolic waste, maintain electrolyte and acid-base balance, and at the same time remove the excessive water [10]. In the study, hemodialysis was performed on children with urinary stones and renal failure.

With the continuous advancement of science and technology, medical ultrasound imaging technology has made great progress in both imaging quality and imaging speed [11]. Ultrasound has become one of the commonly used examination methods for kidney diseases due to its advantages of noninvasiveness, convenience, low cost, and reproducibility, and whether there are congenital malformations, cystic lesions, and stones can be determined by observing the shape of the kidney. In the meanwhile, it can also be used for the auxiliary examination of acute renal failure [12, 13]. However, due to the limitations of ultrasound imaging mechanisms, ultrasound images have inherent disadvantages. A large amount of speckle noise often appears in the original ultrasound image, reducing the readability, and it is impossible to observe the tiny structural edges and lesion areas, which increases the risk of misdiagnosis [14–16]. The removal of speckle noise in ultrasound images has always been a topic of great concern in the medical field. Traditional ultrasound image denoising techniques are mainly image filtering techniques in the spatial domain, such as classic median filtering, mean filtering, and Wiener filtering. However, these methods face an obvious contradiction between noise filtering and edge preservation, so they have certain limitations. Speckle noise algorithm solves the initial value of the partial differential diffusion equation of the original image and takes different diffusion coefficients and the numbers of iterations to generate the corresponding scale image and further produce the final filter image by image transformation. This kind of algorithm is not influenced by the filtering window and the shape. When applied to process ultrasonic images, it can effectively suppress noise while preserving image details and even enhance contrast and improve image quality, which can overcome the difficulties existing in traditional algorithms.

The study aimed to analyze the effect of clinical treatment of urolithiasis complicated with renal failure and the changes of serum inflammatory factors, expected to provide a reference for the clinical treatment of children with renal failure. Ninety children with melamine urinary calculi who were admitted to the hospital were selected as the research subjects. According to the presence or absence of renal failure, 52 cases were in group 1 (nonrenal failure), and 38 cases were in group 2 (combined with renal failure). They all underwent ultrasound imaging examination based on the speckle noise algorithm. The effect of clinical treatment was evaluated, factoring into the effective rate, prognosis, renal function, and changes in inflammatory factor levels. Additionally, the relationship between urinary calculi combined with kidney failure and serum inflammatory factor levels was analyzed.

2. Materials and Methods

2.1. Research Subjects. Ninety children with melamine urinary calculi who were admitted to the hospital from May 3, 2019, to January 15, 2021, were selected as the research subjects, including 53 males and 37 females. According to the presence or absence of renal failure, 52 cases were in group 1 (nonrenal failure), and 38 cases were in group 2 (combined with renal failure). In addition, 35 hospitalized children who had no history of drinking melamine-contaminated milk and were free of urinary tract diseases during the same period were selected as the healthy control group, including 23 males and 12 females. This study has been approved by the Medical Ethics Committee of the hospital, and the subjects and their family members fully understood the situation of the study and had signed an informed consent form.

Inclusion criteria were as follows: (I) children with complete clinical data; (II) children who had signed an informed consent form; (III) children under 3 years of age; (IV) imaging examination that confirmed the presence of urinary calculi; and (IV) hematuria examination showing normal red blood cell morphology. Exclusion criteria were as follows: (I) hematuria of glomerular origin; (II) children with urinary tract malformations; (III) children who withdrew from the experiment midway; and (IV) children with metabolic diseases.

2.2. Ultrasound Examination. Color Doppler ultrasound system was used to perform urinary tract ultrasound examination on the child with a probe frequency of 3.5 MHz. Before the examination, the child was allowed to drink a proper amount of water to fill the bladder. During the examination, the child was in a lateral position. The probe was placed in the double kidney area to scan the kidneys. Then, it walked along the renal hilum, renal pelvis, and ureter to check the junction of the renal pelvis and ureter and the upper part of the ureter. Next, in the supine position, the outer edge of the rectus abdominis was compressed. After the walking direction of the abdominal aorta was identified, the intestine was opened, and the probe walked along the ureter to scan the abdominal segment, pelvic segment, second stricture, and terminal segment of the ureter. Next, the bladder above the symphysis pubis was scanned, and the angle was adjusted to display the opening of the bilateral ureters in the bladder wall. Subsequently, the presence or absence of urinary calculi and the presence or absence of dilation of the collecting system of the kidneys and the ureter were observed. If there were urinary tract stones, the size, number, location, shape, and internal echo of the urinary tract were recorded, and it was checked whether there were urinary tract malformations.

2.3. Ultrasound Denoising Algorithm Based on Shearlet Transform and KDA Model. Shearlet transform (ST) [17] is a new type of multiscale geometric analysis tool. Compared with contourlet transform, it has lower time complexity and unlimited number of directions. However, ST does not have translation invariance, and the pseudo-Gibbs phenomenon will occur during image reconstruction. Therefore, in this study, the nonsubsampled shearlet transform (NSST) is introduced to optimize it.

First, the two-dimensional compound expansion affine system can be expressed as follows:

$$\lambda_{PQ}(\omega) = \left\{\omega_{i,j,n}(x)|\det P|^{1/2}\omega\left(Q^k P^i x - n\right):\ i,k \in W, n \in W^2\right\}, \quad (1)$$

where P and Q represent a 2×2 invertible matrix, $|\det P| = 1$, and both n and k are constants. If $\lambda_{PQ}(\omega)$, there is

$$\sum_{i,k,n}\left|\left(h,\omega_{i,k,n}\right)\right|^2 = \|h\|^2. \quad (2)$$

Then, the elements of the system are called composite wavelets. P^i is related to scale changes and Q^k is associated with geometric transformations with constant area. Let $P = P_0$ *or* P_1, $Q = Q_0$ *or* Q_1, $P_0 = \left\langle\begin{smallmatrix}5 & 0\\ 0 & 3\end{smallmatrix}\right\rangle$, $P_1 = \left\langle\begin{smallmatrix}3 & 0\\ 0 & 5\end{smallmatrix}\right\rangle$, $Q_0 = \left\langle\begin{smallmatrix}2 & 2\\ 0 & 2\end{smallmatrix}\right\rangle$, and $Q_1 = \left\langle\begin{smallmatrix}2 & 0\\ 2 & 2\end{smallmatrix}\right\rangle$; then, the set in (1) is a shear wave, $P = P_0$ or P_1 is an anisotropic stretching matrix, and $Q = Q_0$ or Q_1 is a shear matrix. Then, the shear wave transform function is as follows:

$$\begin{aligned}\omega^{(0)}_{i,k,n}(x) &= 2^{3i/2}\omega^{(0)}\left(Q_0^k P_0^i x - n\right),\\ \omega^{(1)}_{i,k,n}(x) &= 2^{3i/2}\omega^{(1)}\left(Q_0^k P_0^i x - n\right),\end{aligned} \quad (3)$$

where $i \geq 0$, $-2^i \leq k \leq 2^i$, $\omega^{(0)}(\beta) = \omega^{(0)}(\beta_1.\beta_2) = \omega_1(\beta_1)\omega_2(\beta_2/\beta_1)$, and $\omega^{(1)}(\beta) = \omega^{(1)}(\beta_1.\beta_2) = \omega_1(\chi_2)\omega_2(\beta_2/\beta_1)$. For any $(\beta_1.\beta_2) \in C_0$, $C_0 = \{(\beta_1.\beta_2) \in \mathfrak{R}^2 ||\beta_1| \geq 1/Q, |\beta_2/\beta_1| \leq 1\}$, $C_1 = \{(\beta_1.\beta_2) \in \mathfrak{R}^2 ||\beta_1| \geq 1/Q, |\beta_2/\beta_1| \leq 1\}$ constitutes the supporting domain of $\omega^{(0)}_{i,k,n}(x)$ and $\omega^{(1)}_{i,k,n}(x)$. Figure 1 shows the support frequency domain of the shear wave in the $\mathfrak{R}^2$ plane. The yellow line represents C_1, and the green line represents C_0.

Thus, for any image h $i \geq 0$, $-2^i \leq k \leq 2^i$, the ST can be expressed as follows:

$$\text{Shearlet}_\omega h_{(i,k,n)} = \left(h, \omega^{(c)}_{i,k,n}\right). \quad (4)$$

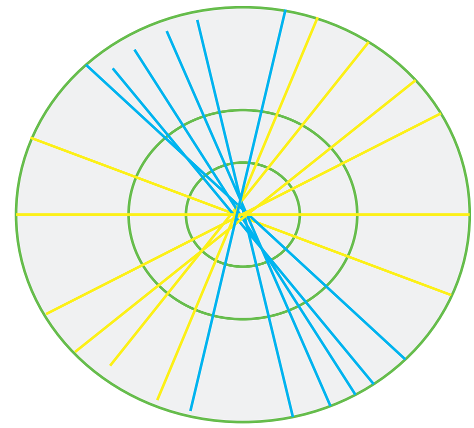

Figure 1: Shear wave support frequency domain in the $\mathfrak{R}^2$ plane.

The NSST transform discretization constructs the algorithm together with the Laplacian pyramid and the directional filter [18]. First, the image is decomposed by the Laplacian pyramid to obtain a high-frequency subband and a low-frequency subband. The subband represents the edge detail information in the image, and the low-frequency subband represents the overview of the original image. Then, the high-frequency subband is divided by directions with a directional filter to obtain the directional detail information in the image. Next, the low-frequency subband is further decomposed, and the above steps are repeated (Figure 2).

The threshold function is weighted by scale to prevent the decrease of noise pollution level with the reduction of resolution [19], and the scale function controls the size of the threshold under the resolution to effectively filter out the noise under each resolution. Therefore, the scaling function is defined as follows:

$$W(r) = \sqrt{\alpha\log\left(\frac{r+1}{r}\right)}, \quad (5)$$

where r represents the scale where the NSST transform coefficients are located, $r = 1$ represents high resolution, and α represents the attenuation degree parameter. Then, the hard threshold method is introduced for improvement, expressed as follows:

$$S_{i,j} = \theta W(r)\phi_i, \phi_j, \quad (6)$$

where θ is the constant that controls the global threshold, $W(r)$ represents the scale weighting function, ϕ represents the standard deviation of the noise image, and $\phi^2_{i,j}$ represents the noise variance in the NSST transform decomposition subband. The noise variance can be expressed as follows:

$$\phi^2_{i,j} = \frac{\sqrt{\sum_{x=1}^{Z_l}\sum_{y=1}^{Z_l} J^{\text{NSSST}}_{i,j}(x,y) J^{\text{NSSST\#}}_{i,j}(x,y)}}{Z_j}, \quad (7)$$

where $J^{\text{NSSST}}_{i,j}(x,y)$ represents the NSST transform coefficient of the j-th scale in the i-th direction, $J^{\text{NSSST\#}}_{i,j}(x,y)$ is the resurrection yoke of $J^{\text{NSSST}}_{i,j}(x,y)$, and Z_j represents the length of the subband.

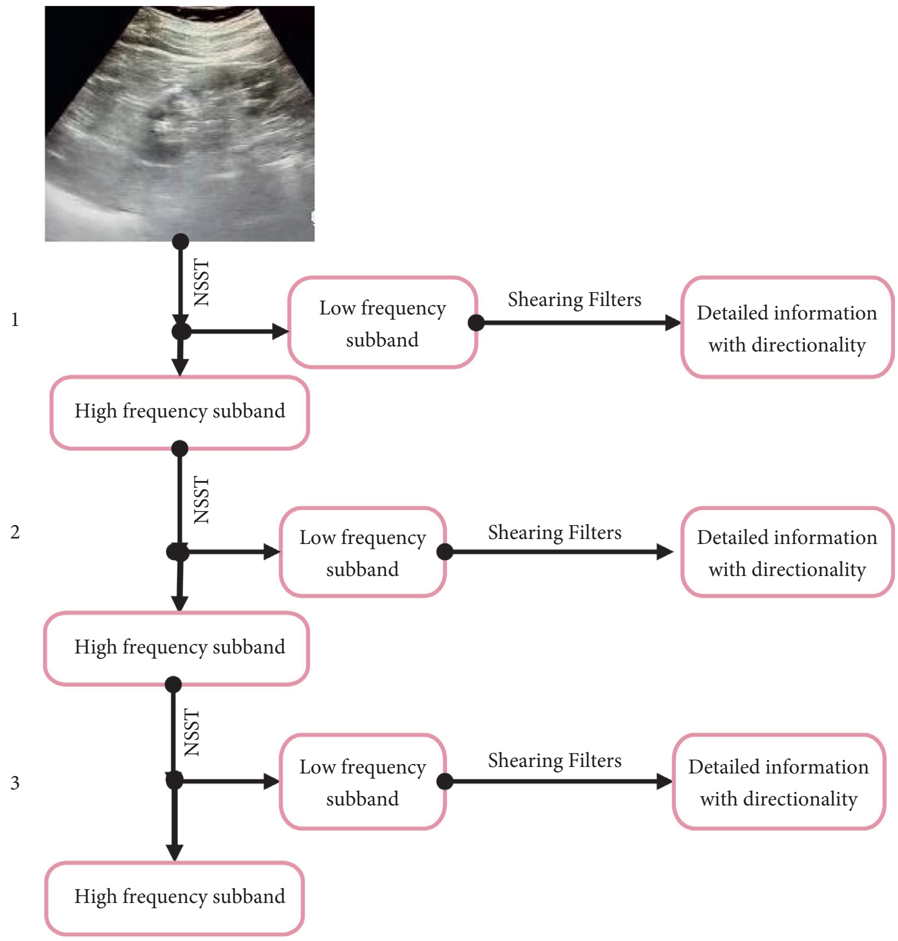

FIGURE 2: High- and low-frequency subband processing flow based on NSST transform.

Finally, the threshold of the high-resolution NSST coefficients is solved to obtain the denoising coefficients at various high resolutions. The NSST coefficients after threshold denoising can be expressed as follows:

$$\overrightarrow{J}^{\mathrm{NSSST}}_{i,j}(x,y) = \begin{cases} J^{\mathrm{NSSST}}_{i,j}(x,y), \left|J^{\mathrm{NSSST}}_{i,j}(x,y)\right| \geq S_{i,j} \\ 0 \end{cases}. \quad (8)$$

The above is the optimization process of the NSST. A larger threshold value is used at high resolution, and a smaller threshold value is used at lower resolution to effectively filter out the noise at each high resolution.

However, the low-resolution coefficients after the optimization still retain less low-frequency noise, so further processing is necessary. Therefore, the NSST coefficients are combined with the nuclear anisotropic diffusion model to perform anisotropic diffusion denoising on the NSST coefficients of the low-frequency subbands so that the low-frequency noise is filtered out and the low-frequency details are also well preserved. Next, the NSST coefficients substitute the two-dimensional image, and the new nuclear anisotropic diffusion model can be expressed as follows:

$$\begin{aligned} &J^{\mathrm{NSST}}(e=0) = J^{\mathrm{NSST}}{}_{0}, \\ &\frac{\partial J^{\mathrm{NSST}}(x,y)}{\partial e} = \mathrm{Div}\left[c\left(\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|\right)\nabla J^{\mathrm{NSST}}\right], \\ &\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|_{u} = \left[\frac{\sum_{v\in\lambda_u}\left\|J_u^{\mathrm{NSST}} - J_v^{\mathrm{NSST}}\right\|^2}{\left|\lambda_u\right|}\right]^{0.5}, \end{aligned} \quad (9)$$

where J^{NSST} represents the NSST coefficient matrix in the low-frequency subband after the ultrasound image is decomposed by NSST, Φ is the mapping function, $\|\nabla\Phi(J^{NSST})\|$ represents the nuclear gradient modulus in the eigenspace determined by the mapping function, λ_u represents the field of u, and $|\lambda_u|$ represents the size of the field. Then, kernel replacement is performed, and the square of the gray difference in a certain characteristic direction in the feature space can be expressed as follows:

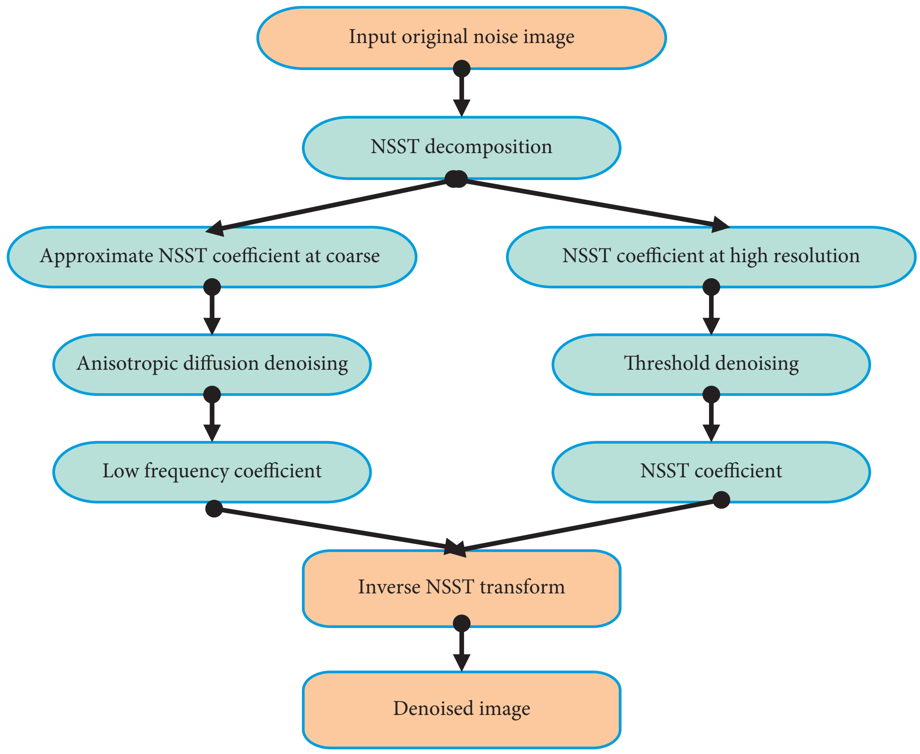

Figure 3: Image denoising process based on NSST coefficients and nuclear anisotropic diffusion model.

$$\begin{aligned}\left\|\Phi\left(J_u^{\mathrm{NSST}}\right)-\Phi\left(J_v\right)\right\|^2 &= F\left(J_u^{\mathrm{NSST}},J_u^{\mathrm{NSST}}\right)+F\left(J_v^{\mathrm{NSST}},J_v^{\mathrm{NSST}}\right)+F\left(J_u^{\mathrm{NSST}},J_v^{\mathrm{NSST}}\right),\\ \left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|_u &= \left[\frac{\sum_{v\in\lambda_u}F\left(J_u^{\mathrm{NSST}},J_u^{\mathrm{NSST}}\right)+F\left(J_v^{\mathrm{NSST}},J_v^{\mathrm{NSST}}\right)+F\left(J_u^{\mathrm{NSST}},J_u^{\mathrm{NSST}}\right)}{\left|\lambda_u\right|}\right]^{0.5}.\end{aligned} \tag{10}$$

To better control the degree of local diffusion, the grayscale and nuclear gradient models are jointly used to control the degree of diffusion of the image. Then, the optimized diffusion equation is as follows:

$$c\left(\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|\right)=\exp\left(-\left(\frac{\phi_F\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|}{4\tau}\right)^2\right), \tag{11}$$

where ϕ_F^2 represents the local grayscale variance of the image and τ represents the diffusion threshold, expressed as follows:

$$\tau=\mathrm{median}\left(\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|\right)-\mathrm{median}\left(\left\|\nabla\Phi\left(J^{\mathrm{NSST}}\right)\right\|\right), \tag{12}$$

where median represents the median function.

Combining the NSST coefficients with the nuclear anisotropic diffusion model can realize high-quality denoising of ultrasound images. Figure 3 shows the specific process.

2.4. Observation Indicators. Basic information of groups 1 and 2 was recorded, such as the admission age, bilateral stone rate, feeding time, amount of milk taken, and feeding methods (mixed feeding and artificial feeding). Then, groups 1 and 2 were compared for the effective rate (disappearance of stones, reduction of stones, and no change in stones) and prognosis (discharge rate with stones, stone disappearance rate after 1 year, discharge rate with water accumulation, and water disappearance rate after 1 year). Next, the renal function indexes (blood urea nitrogen (BUN) and blood creatinine (Cr)) and serum inflammatory factors (TNF-α and C-reactive protein (CRP)) of group 1, group 2, and the healthy control group were recorded after treatment.

2.5. Statistical Methods. The data was processed by SPSS19.0 version statistical software, the measurement data were expressed by the mean ± standard deviation ($\bar{x} \pm s$), and the count data were expressed by the percentage (%). One-way analysis of variance was used for pairwise comparison. The difference was statistically significant at $P < 0.05$.

3. Results

3.1. Denoising Results. The Lena images and Barbara images with different degrees of Gaussian white noise pollution (noise standard deviations were 5, 15, and 25, resp.) were used as samples, and the original images were all grayscale images with a size of 521×521. The anisotropic

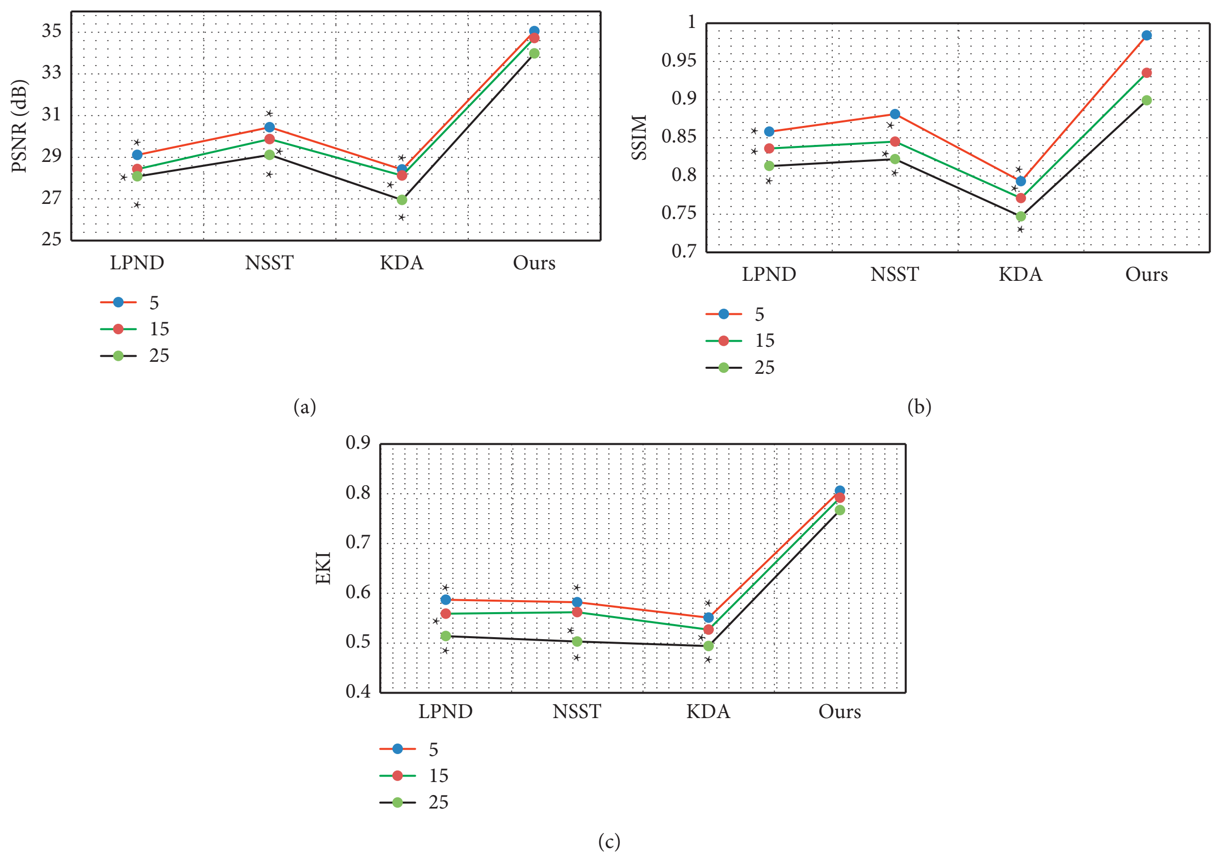

FIGURE 4: The denoising performance of the four algorithms for Lena images with different degrees of Gaussian white noise pollution: (a) PSNR; (b) SSIM; (c) EPI.*The difference compared with the algorithm in this study is statistically significant ($P < 0.05$).

diffusion denoising algorithm based on LPND, the denoising algorithm based on the traditional NSST transform, and the denoising algorithm based on KDA were introduced to compare with the algorithm of the study. The four algorithms were then compared for the PSNR, SSIM, and EPI [20].

As shown in Figure 4, for the Lena images with different degrees of Gaussian white noise pollution, the PNSR, SSIM, and EPI indicators of the four algorithms all decreased as the noise standard deviation increased. The indexes of PSNR, SSIM, and EPI of the algorithm in this study were always greater than those of LPND, NSST, and KDA, and the difference was statistically significant ($P < 0.05$).

As shown in Figure 5, for the Barbara images with different degrees of Gaussian white noise pollution, the PNSR, SSIM, and EPI of the four algorithms all decreased as the noise standard deviation increased. The PNSR, SSIM, and EPI of the algorithm in this study were always greater than those of the LPND, NSST, and KDA algorithms, and the difference was statistically significant ($P < 0.05$).

3.2. The Denoising Effect of the Algorithm for the Ultrasound Images of Children. Figure 6 shows the denoising performance of four algorithms for ultrasound images of renal failure. It was noted that the image noise and artifacts were significantly reduced versus the original image after being processed by the four algorithms, and the image quality was improved. Of the four algorithms, the algorithm in this study demonstrated the best denoising effects, with higher definition and less noise and artifacts.

Further quantitative comparison found (Figure 7) that the PNSR, SSIM, and EPI of the algorithm in this study were significantly greater than those of the LPND, NSST, and KDA algorithms, and the difference was statistically significant ($P < 0.05$).

3.3. Comparison of Clinical Data between Group 1 and Group 2. Figure 8 shows the clinical data of the children in groups 1 and 2. It was noted that the admission age of the children in group 1 was significantly younger than that of group 2, the bilateral stone rate was significantly higher than that in group 2, and the difference was statistically significant ($P < 0.05$). There were no statistically significant differences in the feeding time, the amount of milk taken, and the feeding methods of the children in groups 1 and 2 ($P > 0.05$).

Figure 9(a) is an ultrasound image of a child with melamine urinary calculi, and it shows dilated ureter and hyperechoic echo with acoustic shadow, central echo separation, and anechoic area around the kidney. Figure 9(b) is an image of a child with melamine urinary calculi and renal failure. It was noted that the kidney was slightly enlarged, the

cortex was thickened, the cortex and medulla were clearly demarcated, and the medulla contour was obviously enlarged.

3.4. Total Effective Rate of Treatment for Children in Groups 1 and 2. It was noted from Figure 10 that, of the 52 children in group 1, the stone disappeared in 25 cases after treatment, the stone was reduced in 20 cases, and the stone remained unchanged in 7 cases. The total effective rate of treatment was 88.46%. Of the 38 cases in group 2, the stone disappeared in 22 cases after treatment, the stone was reduced in 12 cases, and the stone remained unchanged in 4 cases. The total effective rate of treatment was 89.47%. There was no statistically significant difference in the total treatment effective rate between the two groups of children ($P > 0.05$).

3.5. Comparison of Prognosis of Children in Groups 1 and 2. Figure 11 shows the prognosis of children in groups 1 and 2. No difference was noted in the rate of discharge with stones, the rate of stone disappearance after 1 year, the rate of

children of groups 1 and 2 and the healthy control group after treatment. No difference was noted in the TNF-α and CRP levels of children between group 1, group 2, and the healthy control group after treatment ($P > 0.05$).

4. Discussion

Acute renal failure is a common kidney disease, and it is associated with many factors, such as changes in human hemodynamics and injury from toxic substances [21]. The clinical manifestations of urinary calculi in children are often atypical and easily confused with other abdominal diseases. If diagnosis and treatment are delayed, it may be complicated by acute kidney failure [22]. In this study, 90 children with melamine urinary calculi were selected as research subjects. Of them, 52 cases were in group 1 (nonrenal failure), and 38 cases were in group 2 (combined with renal failure). In addition, 35 hospitalized children with no history of melamine-contaminated milk feeding during the same period were used as a healthy control. They all underwent ultrasound imaging examination based on the speckle noise algorithm, and the prognosis was analyzed. Firstly, the Lena images and Barbara images with different degrees of Gaussian white noise pollution (noise standard deviations were 5, 15, and 25, resp.) were used as samples. It was found that the PNSR, SSIM, and EPI indicators of the four algorithms all decreased as the noise standard deviation increased. The indexes of PNSR, SSIM, and EPI of the algorithm in this study were always greater than those of LPND, NSST, and KDA, and the difference was statistically significant ($P < 0.05$). This was in line with the research results of Li et al. (2016) [23] that compared with the traditional ultrasonic denoising technology, this algorithm can overcome the contradiction between noise filtering and entry edge reservation, indicating that the algorithm in this study had a good denoising effect on images with different degrees of noise pollution. After the algorithms were applied to ultrasound images of renal failure, it was noted that the image noise and artifacts were significantly reduced versus the original image after being processed by the four algorithms, and the image quality was improved. Of the four algorithms, the algorithm in this study demonstrated the best denoising effects, with higher definition and less noise and artifacts [24].

The clinical data of the children in groups 1 and 2 were compared, and it was found that the admission age of the children in group 1 group was significantly younger than that in group 2, the bilateral stone rate was significantly higher than group 2, and the difference was statistically significant ($P < 0.05$), which indicated that renal failure might be related to the age [25]. Of the 52 children in group 1, the stone disappeared in 25 cases after treatment, the stone was reduced in 20 cases, and the stone remained unchanged in 7 cases. The total effective rate of treatment was 88.46%. Of the 38 cases in group 2, the stone disappeared in 22 cases after treatment, the stone was reduced in 12 cases, and the stone remained unchanged in 4 cases. The total effective rate of treatment was 89.47%. There was no statistically significant difference in the total treatment effective rate between the two groups of children. In this study, hemodialysis was used for children with renal failure, and there was no bleeding or infection during the treatment, and the treatment effect was good. As for the prognosis, no difference was noted in the rate of discharge with stones, the rate of stone disappearance after 1 year, the rate of discharge with water accumulation, and the water loss rate after 1 year ($P > 0.05$). It suggested that children with renal failure had a good prognosis after treatment, and most of the symptoms disappeared or were alleviated [26]. No difference was noted in the blood BUN and blood Cr of the children in group 1, group 2, and the healthy control group after treatment ($P > 0.05$). It suggested that the renal function of children with renal failure recovered after treatment to normal. In terms of the comparison of serum inflammatory factors, no difference was noted in the TNF-α and CRP levels of children between group 1, group 2, and the healthy control group after treatment ($P > 0.05$). It also showed that the serum inflammatory factor levels returned to normal after treatment, and the inflammatory response was weakened [27].

5. Conclusion

In this study, 90 children with melamine urinary calculi were selected as research subjects. Of them, 52 cases were in group 1 (nonrenal failure), and 38 cases were in group 2 (combined with renal failure). In addition, 35 hospitalized children with no history of melamine-contaminated milk feeding during the same period were used as a healthy control. They all underwent ultrasound imaging examination based on the speckle noise algorithm, and the prognosis was analyzed. The results showed that the denoising algorithm based on ST and KDA model in this study had good denoising effect on ultrasound images than traditional algorithms, with higher definition and less noise and artifacts. It has been proved that the clinical treatment of children with urinary calculi and renal failure is highly effective, the renal function and serum inflammatory factor levels return to the normal range, and the inflammatory response is weakened. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study. In conclusion, this study provides good theoretical support for the clinical diagnosis and treatment of urinary calculi complicated with renal failure.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

Objective. To explore the status quo of psychological resilience, mindfulness level, the sleep quality of pregnant women by Prenatal Diagnosis Screening, and the mediating effect of psychological resilience on sleep quality and mindfulness. *Methods*. A survey of 298 pregnant women was conducted using the psychological resilience scale, Pittsburgh sleep quality index, and the concise version of the five-factor mindfulness scale. *Results*. The total score of psychological resilience of pregnant women was (68.96 ± 17.27), mindfulness was (77.25 ± 12.65), the median of total sleep quality was 6, and the detection rate of sleep disorders was 31.9%. The sleep quality of pregnant women was negatively correlated with mindfulness level and psychological resilience ($p < 0.01$), and mindfulness level was positively associated with psychological resilience ($p < 0.01$). Bootstrap analysis showed that psychological resilience played an 14.1% mediating role between mindfulness and sleep quality. *Conclusion*. The psychological resilience of pregnant women is low, sleep quality is poor, and mindfulness is mild to moderate. Psychological resilience plays an important role in mediating between mindfulness level and sleep quality that suggests nursing staff should pay attention to and improve the psychological resilience of pregnant women screened by prenatal diagnosis to improve the mindfulness level and sleep quality of pregnant women screened by prenatal diagnosis.

1. Introduction

Studies at home and abroad show that about 78% to 87% of pregnant women have sleep problems during pregnancy [1, 2]. The sleep survey reported that nearly 80% of women complained about disturbed sleep during pregnancy [3]. This will increase the risk of comorbidities in pregnant women and increase the likelihood of preterm birth [4]. Clinically, pregnant women usually refuse to use psychotropic medications to treat sleep problems during pregnancy due to concerns about fetal growth and development. Mindfulness is to purposefully focus your attention entirely on the present, without attaching any judgment, perception, or awareness. Mindfulness interventions as effective drug alternative therapies have been shown to improve sleep quality [4]. Mindfulness meditation is becoming a method of mental health intervention, and theoretical concepts related to it have an effect on psychopathology [5]. Psychological resilience is a dynamic process that takes shape as a change allowing people to find balance and to evolve positively [6]. It is the product of the interaction between individuals and the environment. Improving psychological resilience help individuals reintegrate and grow in the face of difficulties [7, 8]. Psychological resilience can effectively enhance changes in the hormonal levels caused by sleep disorders. Therefore, this paper aims to understand the status of sleep quality, mindfulness level, and psychological resilience in prenatal diagnosis screening of pregnant women, and to explore the role of psychological resilience between mindfulness level and sleep quality, to provide a reference to improving the sleep quality of screening pregnant women with prenatal diagnosis.

2. Materials and Methods

2.1. Subjects. From July to September 2020, 298 pregnant women were selected from the outpatient department of obstetrics and gynecology in a tertiary hospital.

Inclusion criteria are as follows: (1) age >18 years old; (2) smooth language communication; (3) pregnant women who voluntarily participate in the study and actively cooperate; and (4) elected prenatal diagnostic screening.

Exclusion criteria are as follows: (1) pregnant women with previous mental illness; (2) low intelligence or combined with severe complications; (3) communication impairment and hearing impairment. There were no ethical conflicts in "Materials and methods."

2.2. Study Tool. General data shall be designed by the researcher, including basic data of age, education level, address, living status, working status and monthly family income, pregnancy week, adverse pregnancy history, mode of pregnancy, and other relevant data.

2.2.1. Five Facet Mindfulness Questionnaire-Short Form (FFMQ-SF). The scale consists of five dimensions: observation, description, perceived action, no judgment, and no behavior, with a total of 24 items. Using a grade Likert5 score method with a total score of 24 to 120, higher scores represent higher levels of individual mindfulness [9].

2.2.2. Connor Davidson Resilience Scale (CD-RISC). Connor and Davidson developed Connor Davidson Resilience Scale (CD-RISC) in 2003 [10]. Yu and Zhang [11], a Chinese scholar, introduced and Chineseizing it. The Cronbach's alpha of the Chinese version was 0.916, and the test-retest reliability was 0.821. The scale includes three dimensions: toughness, optimism, and self-improvement, with a total of 25 items. The Likert 5-level scoring method is used, with a total score of 100 scores. The higher the score, the higher the mental Resilience.

2.2.3. Pittsburgh Sleep Quality Index (PSQI). Applied Liu and Tang's Chinese version to evaluate the sleep quality in the past month. The scale includes 19 self-assessment items and 5 other-assessment items, and the scoring items are the top 18 items in the self-assessment items. Scoring items contain 7 factors, each factor 0~3 scores, total score range 0~21 scores, the higher the score, the worse the sleep quality [12]. PSQI total score greater than 7 scores for poor sleep quality [13].

2.3. Study Method. Researchers and trained nurses distributed the questionnaire. Unified guidance is adopted. On the premise of obtaining their consent, the corresponding help was given in the questionnaire filling process, and the empty items were filled again after the inquiry. All questionnaires are returned on the spot after completion and check the completeness and quality. A total of 300 questionnaires were distributed, and 298 were effectively recovered, with an effective rate of 99.3%.

2.4. Statistical Method. SPSS22.0 was used for statistical analysis. Counting data were tested by the number of people, in percentage description. Measurement data are described by mean and standard deviation. Pearson correlation analysis was used to analyze the correlation between mindfulness level, psychological resilience, and sleep quality of pregnant women in prenatal diagnosis screening. The hierarchical regression analysis was used to analyze the mediating effect of psychological resilience [14], and the structural equation model was established by AMOS23.0 software. The Bootstrap method is used to further verify the result.

3. Results

3.1. General Data of Prenatal Diagnosis Screening for Pregnant Women. A total of 298 pregnant women for prenatal diagnostic screening were included in this study. Age: less than 25 years old, 1 person, 0.3%; aged 25–30, 228 person, 75.7%; aged 30–35, 67 people, 22.3%; older than 35 years, 2 people, 0.7%. Education: students in junior high school and below, 2 people, 0.7%; high school, 28 people, 9.4%; specialized schools, 96 people, 31.9%; undergraduate, 161 people, 53.5%; masters or above, 11 people, 3.7%. Address: rural areas, 44 people, 14.6%; township, 120 people, 39.9%; urban areas, 134 people, 44.5%. Living status: with parents, spouses, 70 people, 23.3%, with spouses, 211 people, 70.1%; separated from spouses, basically live alone, 17 people, 5.6%. Family monthly income: less than 5000 yuan, 22 people, 7.3%; 5000–10000 yuan, 112 people, 37.2%; 10000 to 20000 yuan, 111 people, 36.9%; 20000 to 30000 yuan, 46 people, 15.3%; more than 30000 yuan, 7 people, 2.3%. Working situation: 216 employees, 71.8%; 82 nonemployees, 27.2%. Only child: 172, 57.1%; No, 126, 41.9%. Whether the pregnancy is planned: yes, 193,64.1%; No, 105,34.9%. The mode of delivery: 234 natural births, 77.7%; 64 births by cesarean section, 21.3%. Adverse pregnancy: yes, 2, 0.7%; no, 296, 98.3%. Pregnant week: less than 13 weeks, 78 people, 25.9%; 13–28 weeks, 188 people, 62.5%; more than 28 weeks, 32 people, 10.6%. Satisfaction degree of husband-wife relationship: 250 people were satisfied, accounting for 83.1%; 48 people, general, 15.9%.

3.2. Prenatal Diagnosis and Screening of Pregnant Women for Psychological Resilience (Table 1). The dimension score of the optimistic, self-improvement, as well as the tough and tensile group, was 10.59 ± 3.08, 22.46 ± 5.89, and 35.93 ± 8.94, respectively. The item average score of the optimistic, self-improvement, as well as the tough and tensile group, was 2.65 ± 0.77, 2.81 ± 0.74, and 2.76 ± 0.69, respectively.

3.3. Prenatal Diagnosis and Screening of Pregnant Women for Sleep Quality. The total Pittsburgh sleep quality score and the score of all dimensions of pregnant women with prenatal diagnosis is shown in Table 2, with 95 sleep disorders detected, 31.9%.

Table 1: Total score of psychological resilience and scores of all dimensions of pregnant women screened after prenatal diagnosis ($n = 298$).

Project	Number of entries	Score range (scores)	Dimension score ($\overline{x} \pm s$, component)	Item average score ($\overline{x} \pm s$, component)
Optimistic	4	1~15	10.59 ± 3.08	2.65 ± 0.77
Self-improvement	8	3~31	22.46 ± 5.89	2.81 ± 0.74
Tough and tensile	13	6~48	35.93 ± 8.94	2.76 ± 0.69
Total scores	25	12~92	68.96 ± 17.27	2.76 ± 0.69

Table 2: Total scores of sleep quality and all dimensions of pregnant women with prenatal diagnosis ($n = 298$).

Project	Median
Sleep quality	1.00
Sleep time	1.00
Hours of sleep	0.00
Sleep efficiency	0.00
Dyssomnia	1.00
Hypnosis drugs	0.00
Day dysfunction	1.00
Total scores	6.00

3.4. Prenatal Diagnosis and Screening for Maternal Mindfulness Levels (Table 3). The dimension score of the observational dimensions, describe dimensions, known dimension of action, do not judge dimensions as well as do not judge dimensions was 15.16 ± 2.94, 16.70 ± 3.45, 13.46 ± 5.00, 13.58 ± 3.59, and 18.36 ± 3.62, respectively. The item average score of the observational dimensions, describe dimensions, known dimension of action, do not judge dimensions as well as do not judge dimensions was 3.79 ± 0.73, 3.34 ± 0.69, 2.69 ± 0.10, 2.71 ± 0.72 as well as 3.67 ± 0.72, respectively.

3.5. Prenatal Diagnosis and Screening of Mindfulness Level, Sleep Quality, and Psychological Resilience. The results of person correlation analysis showed that PSQI was negatively correlated with the CD-RISC score range in prenatal diagnosis screening pregnant women ($r = -0.426$, $p < 0.01$). The PSQI was negatively associated with the FFMQ-SF score ($r = -0.429$, $p < 0.01$), and the FFMQ-SF was positively associated with the CD-RISC score ($r = 0.373$, $p < 0.01$).

3.6. Test of the Mediating Effect of Maternal Psychological Resilience between Sleep Quality and Mindfulness Levels. The results showed that the negative effect of mindfulness level on sleep quality decreased from −0.429 to −0.314, and the effect was still significant ($p < 0.01$), indicating that psychological resilience played a partial mediating role in the prediction of mindfulness level on sleep quality in pregnant women screened by prenatal diagnosis, as shown in Table 4. This conclusion needs to be further verified.

3.7. Validation of Mediating Effect Model of Psychological Resilience between Mindfulness Level and Sleep Quality in Prenatal Diagnosis Screening Pregnant Women. The structural equation model of psychological resilience, mindfulness level, and sleep quality of prenatal diagnosis screening pregnant women was established. The maximum likelihood method and AMOS23.0 software were used for mediating effect test. The path analysis is shown in Figure 1. The model absolutely fits the exponential $x^2/df = 3.067$, GFI (adaptation index) = 0.890, AGFI (adjusted fitness index) = 0.831, IFI (value is configuration) = 0.937, RMSEA (progressive square and square root) = 0.096, NFI (standard adaptation index) = 0.919, showing good data fit. As can be seen from Figure 1, the direct effect of mindfulness level on sleep quality is 0.28, and the indirect effect of psychological resilience on sleep quality is 0.141 (product of 0.47 and −0.30), accounting for 34.49% of the total effect, suggesting that psychological resilience plays a partial role between sleep quality and mindfulness level. Further interval estimation was performed using the variation correction bootstrap confidence region estimation method with a sample size selection of 5000 [15]. Under 95% CI results, the mediation of psychological resilience between sleep quality and mindfulness level was −0.146, the interval did not contain 0 (LLCI = −0.248, ULCI = −0.069), suggesting a mediation effect of psychological resilience between mindfulness level and sleep quality; the direct effect of mindfulness level on sleep quality was −0.251 and the interval did not contain 0 (LLCI = −0.435, ULCI = −0.047), indicating a significant direct effect.

4. Discussion

4.1. The Psychological Resilience Level of Pregnant Women with Prenatal Diagnosis Screening Is at a Relatively Low Level. This study showed that the psychological resilience of pregnant women in prenatal diagnosis screening was low, which was consistent with the results of Zhong et al. [16]. The score of optimism dimension was the lowest (10.59 ± 3.08), which was consistent with the study of Shang et al. [17]. The reason may be that prenatal diagnosis during pregnancy and screening of pregnant women need to face both physical and psychological pressure. As the growth of pregnancy week, pregnant women will have early pregnancy reaction, insomnia, anemia, urinary frequency, oedema, constipation, stature change, changes in hormone levels, and lack of awareness of pregnancy and childbirth. The fear of prenatal diagnosis results, resulting in negative emotions such as anxiety. Pregnant women's lack of confidence in a successful pregnancy weakened their psychological resilience. Clinical nursing staff should take positive and effective measures to establish mutual communication groups, on-demand education in pregnant schools, and one-to-one psychological counseling. While improving the nursing ability, help prenatal diagnosis screening pregnant women

Table 3: Total scores of mindfulness levels and all dimensions of pregnant women screened after prenatal diagnosis ($n = 187$).

Project	Number of entries	Score range (scores)	Dimension score ($\overline{x} \pm s$, component)	Item average score ($\overline{x} \pm s$, component)
Observational dimensions	4	6~20	15.16 ± 2.94	3.79 ± 0.73
Describe dimensions	5	7~24	16.70 ± 3.45	3.34 ± 0.69
Known dimension of action	5	5~23	13.46 ± 5.00	2.69 ± 0.10
Do not judge dimensions	5	7~23	13.58 ± 3.59	2.71 ± 0.72
Do not act dimension	5	7~25	18.36 ± 3.62	3.67 ± 0.72
Total	24	50~107	77.25 ± 12.65	3.09 ± 0.51

Table 4: Results of stratified regression analysis of mindfulness level, psychological resilience, and sleep quality for prenatal diagnosis ($n = 298$).

Project	Dependent variable	Argument	β price	t price	p price	R^2 price	F Price	p price
Step 1	Sleep quality (Y)	Mindfulness level (X)	−0.429	−8.181	0.000	0.182	66.933	0.000
Step 2	Psychological resilience (M)	Mindfulness level (X)	0.373	6.918	0.000	0.136	47.863	0.000

		Psychological resilience (M)	−0.309	−5.746	0.000			

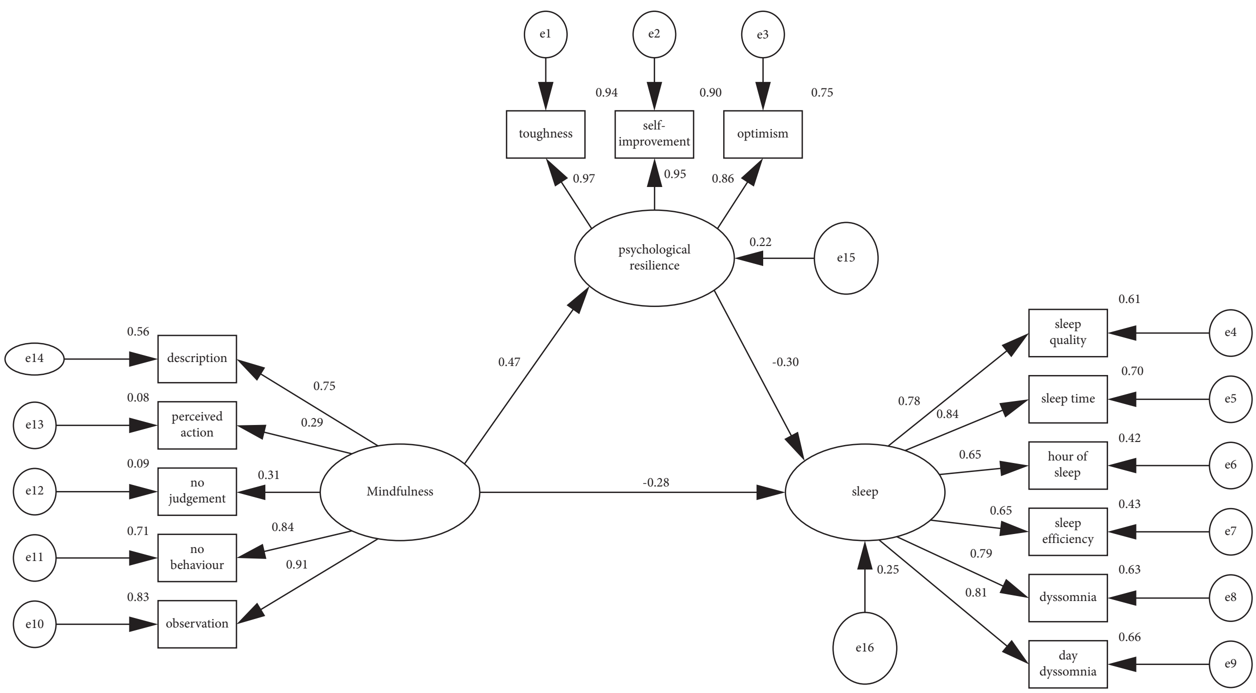

Figure 1: Antenatal diagnostic screening for maternal psychological resilience between mindfulness level and sleep quality.

understand pregnancy and prenatal diagnosis-related knowledge, establish confidence in a successful pregnancy, and then improve the negative emotions of pregnant women.

4.2. Mindfulness Levels in Pregnant Women Screened for Prenatal Diagnosis Are Low. This study showed a prenatal diagnostic screening of pregnant women with mindfulness levels at a lower level, lower than related studies [18]. The mindfulness level of pregnant women with prenatal diagnosis is at the middle level, indicating that their self-regulation and cognitive ability need to be improved. The level of mindfulness affects individuals' cognitive patterns and negative emotions caused by sleep problems. The higher the level of mindfulness, the stronger the self-regulation ability, and the more optimistic and positive they can face difficulties [19]. The level of mindfulness can be improved through learning, and long-term mindfulness practice can give practitioners peace and tranquility [20]. Mindfulness helps sleep by detecting sleep problems and not responding to any emotions or thoughts that arise. It is also necessary to explore patterns of prenatal diagnostic screening for pregnant women to improve sleep quality through mindfulness practice. Medical staff can screen pregnant women for mindfulness levels as early as possible in prenatal diagnosis and use the hospital-community and network resources to develop appropriate interventions to bring mindfulness into life and improve sleep quality through continuous learning and self-practice in prenatal diagnosis screening pregnant women.

4.3. Pregnant Women Have Poor Sleep Quality. This study showed that the median sleep quality of prenatal diagnostic screening was 6 score, and the detection rate of sleep disorders was 31.9%. The results showed that the three factors namely, sleep time, sleep disorder, and daytime dysfunction scored higher, consistent with Tan et al. [21]. The causes of sleep problems in pregnant women include fear of prenatal diagnosis screening results, increased nocturia, difficulty to find a comfortable sleeping position, physical pain, and discomfort, resulting in prolonged sleep time and sleep disorders. With the development of society, more and more professional women in the workplace need to work at high intensity while taking into account, their pregnancy [2, 22, 23]. Excessive energy into work may lead to daytime dysfunction. Therefore, we should attach great importance to sleep factors during pregnancy. Clinical medical staff should thoroughly evaluate the sleep status of pregnant women in prenatal diagnosis screening. Given the relevant influencing factors, early identification and intervention should be carried out to shorten sleep latency, control sleep disorders, and reduce the incidence of daytime sleep disorders to better improve pregnant womens sleep quality in prenatal diagnosis.

4.4. Relevant Analysis between Sleep Quality, Mindfulness Level and Psychological Resilience. Pearson correlation analysis showed that the sleep quality of pregnant women screened by prenatal diagnosis was negatively correlated with psychological resilience. Sleep quality is negatively correlated with mindfulness and positively associated with resilience. Sleep quality was negatively correlated with mindfulness levels and positively correlated with psychological resilience. This indicates that higher the mindfulness, the better the sleep quality, and higher the psychological resilience, the higher the mindfulness. The results of hierarchical regression analysis, structural equation model, and bootstrap method show that psychological resilience is the intermediary variable of the sleep quality and mindfulness level of prenatal diagnosis and screening of pregnant women and plays a partial intermediary role, accounting for 33.49% of the total effect. This indicated that psychological resilience, as a protective factor within individuals, can enhance the positive function of the mindfulness level. In the face of pregnancy-related problems, at the same mindfulness level, pregnant women with high psychological resilience levels can take a relatively more positive attitude and response way to adapt to the current state, less affecting sleep quality. On the contrary, pregnant women with poor psychological resilience are more likely to produce destructive emotions or even psychological problems and then appear sleep disorders. Consistent with the results [24], studies have shown that psychological resilience is the protective resource for the prenatal diagnosis and screening of the sleep quality of pregnant women. For pregnant women with low mindfulness levels, the mindfulness level can be improved by improving psychological resilience and sleep quality. The limit of the study is that this study is short of scientific experiments, which made the result not so solid. Further studies are needed to confirm the opinion of these reports.

4.5. Summary. In conclusion, prenatal diagnostic screening for maternal psychological resilience plays a significant mediating effect between mindfulness and sleep quality. Clinical nursing staff should pay attention to improving the psychological resilience of pregnant women in prenatal diagnosis and screening, and fully explore and utilize the integration of social resources so that pregnant women in prenatal diagnosis and screening can enhance their ability to cope with state changes, maintain good mental health, and improve the mindfulness level of pregnant women, and improve sleep quality. In this study, we only selected pregnant women with prenatal diagnosis and screening in a tertiary hospital as the research object. The sampling may be biased and cannot fully represent pregnant women with prenatal diagnosis and screening. In future studies, multi-center selection samples are needed for further exploration.

Retracted: MiR-483 Promotes Colorectal Cancer Cell Biological Progression by Directly Targeting NDRG2 through Regulation of the PI3K/AKT Signaling Pathway and Epithelial-to-Mesenchymal Transition

Journal of Healthcare Engineering

Received 1 December 2022; Accepted 1 December 2022; Published 28 December 2022

Journal of Healthcare Engineering has retracted the article titled "MiR-483 Promotes Colorectal Cancer Cell Biological Progression by Directly Targeting NDRG2 through Regulation of the PI3K/AKT Signaling Pathway and Epithelial-to-Mesenchymal Transition" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Background. Colorectal cancer is the third frequent tumor in the whole world. MiR-483, located at the 11p15.5 locus, acts as an oncogene in multiple tumors. The purpose of this study is to explore the important roles of miR-483 in colorectal cancer. *Materials and Methods*. RT-qPCR and western blot were applied to calculate the mRNA levels of miR-483 and genes. The Kaplan–Meier method was conducted to calculate the survival of patients with colorectal cancer. The proliferation and invasive abilities were measured by Methyl Thiazolyl Tetrazolium (MTT) and transwell assays. *Results*. MiR-483 was upregulated in colorectal cancer tissues, and the upregulation of miR-483 predicted poor prognosis of colorectal cancer patients. NDRG2 was a target gene of miR-483 in colorectal cancer. Furthermore, miR-483 has been reported to promote colorectal cancer cell proliferation and invasion through targeting NDRG2 by the PI3K/AKT pathway and epithelial-to-mesenchymal transition (EMT). In addition, the overexpression of miR-483 promoted xenograft growth of LOVO cells. *Conclusion*. MiR-483 promoted cell proliferation through the NDRG2/PI3K/AKT pathway and invasion-mediated EMT in colorectal cancer. In view of the multiple mechanisms of molecular immunotherapy, it is necessary to further study the relationship between miR-483 and colorectal cancer, so as to find a more direct and effective treatment method to prevent colorectal cancer.

1. Introduction

Colorectal cancer (CRC) is a type of gastrointestinal cancer that is the third frequent tumor in the whole world [1, 2]. Despite the increase of treatment modalities, the metastasis remains to be a challenge for the treatment of colorectal cancer [3]. Therefore, it is urgent to investigate the new biomarkers for the early diagnosis and metastasis of colorectal cancer.

MicroRNAs (miRNAs) are noncoding RNAs with a length of 18–25 nucleotides, which repressed gene expression through directly binding to the mRNA 3′-untranslated region (3′-UTR) at the posttranscriptional level [4, 5]. MiRNAs may act as tumor suppressors or oncogenes to regulate the tumor process including growth, differentiation, and metastasis [6, 7]. A previous study has reported several miRNAs played important roles in colorectal cancer, including miR-483 [8]. MiR-483, which has been reported to be located at the 11p15.5 locus, plays important roles in multiple tumors, including breast cancer, nasopharyngeal carcinoma, and anaplastic thyroid cancer [9–11]. Yang et al. have revealed that, in prostate cancer, miR-483 promoted cell proliferation and invasion [12]. Similarly, Tang et al. have illuminated that miR-483 promoted the proliferation, migration, and invasion and inhibited the apoptosis in hepatocellular carcinoma [13]. Even in colorectal cancer, miR-483 was overexpressed and mediated cellular proliferation by directly targeting DLC-1 [14]. Therefore, we conjectured that miR-483 may promote cell proliferation and metastasis through regulating the PI3K/AKT pathway and EMT in colorectal cancer.

N-Myc downstream-regulated gene 2 (NDRG2) belongs to the NDRG family and is a newly identified differentiation-related gene whose promoter has hypermethylation [15, 16]. NDRG2 played a vital role in multiple biological processes including cell growth, metastasis, and apoptosis [17]. Tamura et al. have indicated that loss of NDRG2 enhanced the metastasis potential in oral squamous cell carcinoma [18]. Moreover, Yamamura et al. have revealed that the suppression of NDRG2 was associated with poor prognosis in gastrointestinal cancer [19]. Even in colorectal cancer, Ali Golestan indicated that overexpression of NDRG2 promoted cell proliferation and invasion [20]. Moreover, Claire Agosta has illuminated that miR-483 promoted the migration and invasion through directly binding to NDRG2 in adrenocortical cancer [21]. Thus, we firmly believe that miR-483 may play an important role in carcinogenesis through NDRG2 in colorectal cancer. In this study, we revealed that miR-483 was upregulated in colorectal cancer and the overexpression of miR-483 predicted poor 5-year survival. MiR-483 promoted the proliferation and invasion in colorectal cancer. In addition, miR-483 promoted growth of CRC cell xenograft.

2. Materials and Methods

2.1. Sample Collection. Cancer tissue samples from 47 patients with colorectal cancer were collected from Weifang People's Hospital. Meanwhile, we also collected the 47 control tissues which were obtained from nonnecrotic colon patients. Patients were excluded if they received chemotherapy or radiation therapy before the blood was drawn. All the samples were immediately frozen in liquid nitrogen and stored at −80°C. Informed consent was obtained from all individual participants included in the study. All the specimens of this study were approved by the Ethical Committee of Weifang People's Hospital.

2.2. Cell Culture. Two human colorectal cancer cell lines (LOVO and SW480) and a normal colorectal epithelial cell line CCD-18Co were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). All the cells were cultured in the RPMI-1640 medium (Hyclone, UT, USA) with 10% fetal bovine serum (FBS), 100 U/ml penicillin, or 100 mg/ml streptomycin at 37°C in humidified air with 5% CO_2.

2.3. Cell Transfection. The miR-483 mimic and the miR-483 inhibitor, as well as their negative control (NC), were synthesized and purchased from GenePharma (Shanghai, China), which were transfected into colorectal cancer cells VOLO to up- or downregulate the expression of miR-483. The transfection was performed using Lipofectamine 2000 Reagent (Invitrogen, Carlsbad, CA) pursuant to the command of the manufacturer.

2.4. RNA Extraction and Real-Time Quantitative Polymerase Chain Reaction (RT-qPCR). For the miRNAs, total miRNAs were extracted utilizing the miRNeasy Mini Kit (Qiagen, Hilden, Germany) from tissues or cell lines. The reverse transcription was carried out to synthesize the first cDNA chain using the TaqMan miRNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, USA). Then, the qPCR was performed using the miRNA-specific TaqMan miRNA Assay Kit (Applied Biosystems) on an ABI7500 real-time PCR system (Applied Biosystems). The relative levels of miRNA were derived using the $2^{-\Delta\Delta Ct}$ method with U6 small nuclear RNA as normalization.

For the mRNAs, the TRIzol reagent (Invitrogen) was applied to extract total RNA. The Omniscript Reverse Transcription Kit (Qiagen) was utilized to synthesize the first cDNA chain from total RNAs. The qPCR was carried out using the QuantiTect SYBR Green PCR Kit (Qiagen) on a Quantitect SYBR green PCR system (Qiagen). A method was used for the mRNA quantification, which was normalized by GAPDH. We analyzed the data using the $2^{-\Delta\Delta Ct}$ method for relative quantification. The sequences of primers were as follows: miR-483 forward 5′-AGTTGGCTCACGGTTCTTTCAA-3′, reverse 5′-ATCGCCATGGCCCGCATGTCGG-3′; U6 forward 5′-GC TTCGGCAGCACATATACTAAAAT-3′, reverse 5′-CGCT TCAGAATTTGCGTGTCAT-3′; NDRG2 forward 5′-CCT CACCTC TTCCATTCC-3′, reverse 5′-TATCACCTC CACG CTCAA-3′; and GAPDH, forward 5′-CGGAGTCAACG GATTTGGTCGTAT-3′, reverse 5′-AGCCTTCTCCATGGT GGTGAAGAC-3′.

2.5. Western Blotting. Total proteins were extracted using the RIPA buffer (Beyotime, Nantong, China), and then, we tested the protein concentration by bicinchoninic acid protein assay (BCA). Equal amounts of proteins were isolated by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto a polyvinylidene fluoride (PVDF) membrane (Millipore, Boston, MA, USA). After blocking with 5% nonfat dried milk for 1h, the membrane was incubated with the primary antibody against NDRG2 (1 : 1000; ab174850, Abcam, Cambridge, USA), E-cadherin (1 : 1000; ab197751, Abcam), N-cadherin (1 : 1000; ab256744, Abcam), vimentin (1 : 1000; ab92547, Abcam), p-PI3K (1 : 1000, 17366, Cell Signaling, San Jose, CA, USA), PI3K (1 : 1000, 3821, Cell Signaling), p-AKT (1 : 1000, 5197, Cell Signaling), AKT (1 : 1000, 4685, Cell Signaling), and GAPDH (1 : 3000, Cell Signaling) at 4°C overnight. Subsequently, the membranes were incubated with the secondary HRP-conjugated antibody (Beyotime) for 2 h at room temperature. Finally, the protein signal was determined with the enhanced chemiluminescence (ECL) kit (Pharmacia Biotech, Arlington, USA).

2.6. CCK-8 Assay. The ability of cell proliferation was measured by CCK-8 assay. In brief, 300 μl cell suspension with a concentration of 80% was seeded in each well of the 96-well plates. Meanwhile, CCK-8 reagent (Dojindo, Kumamoto, Japan) was added after 24 h, 48 h, 72 h, or 96 h of culture, and the absorbance at a wavelength of 450 nm was evaluated using a Model 680 Microplate Reader (Bio-Rad, Hercules, CA).

2.7. Transwell Assay. Transwell insert (8 μm pore filters, BD Bioscience, Bedford, MA) with a Matrigel (BD Biosciences)-coated membrane was used to calculate the invasion and migration assay. Cells suspended in serum-free media were seeded to the upper chamber, while a normal RPMI-1640 medium with 15% FBS was added in the lower chamber. After incubating for about 24 h at 37°C, the invasive cells were fixed and stained by 4% paraformaldehyde and 10% crystal violet, respectively. Finally, we photographed and counted the invasive cells in five random fields under a microscope (Tokyo, Japan).

2.8. Dual-Luciferase Reporter Assay. NDRG2 was predicted to be a potential downstream target of miR-483 using TargetScan (https://www.targetscan.org). The binding sequences were mutated from 5′-AGGGCAGA-3′ to 5′-AGGCGUCA-3′ to validate whether miR-483 directly binds to NDRG2 in colorectal cancer cells. Subsequently, the wild type and the mutant 3′-UTR of NDRG2 were inserted into the dual-luciferase reporter vectors, which were designated as WT or MUT. For the luciferase assay, Lipofectamine 3000 Reagent (Invitrogen, USA) was employed to be cotransfected with the miR-483 mimic and the WT or MUT plasmid into VOLO cells. Then, the luciferase activity was measured on a dual-luciferase reporter assay system (Promega, USA).

2.9. Xenograft Tumor Formation Assay. Four-week old nude mice were purchased from Charles River Laboratories (Beijing, China). VOLO cells (5×10^6 cells) were subcutaneously injected into one side of the axillae of the nude mice. The length and the width of the xenograft tumor were evaluated and recorded every 3 days after completing the transplant tumor model. The volume of the xenografts was calculated as the square of length multiplied by the width divided by two. The experiment was terminated after culturing for 26 days, and the xenografts were incised. All animal experiments were performed in the animal laboratory center of Weifang People's Hospital and approved by the Animal Care and Use Committee of Weifang People's Hospital.

2.10. Statistical Analysis. All data are expressed as the means ± standard deviation (SD) of at least three independent experiments. Statistical analysis was performed using SPSS 16.0 software (IBM, Armonk, NY, USA). The differences between two or more groups were compared using Student's *t*-test or one-way ANOVA. The association between the expression of miR-483 and the overall survival for colorectal cancer patients were assessed by the Kaplan–Meier curve and log-rank test. Results were considered statistically significant if $P < 0.05$. Each experiment was repeated three times.

3. Results

3.1. Upregulation of MiR-483 Predicted Poor Prognosis of Colorectal Cancer. The mRNA level of miR-483 was calculated in 47 pairs of colorectal cancer and nonnecrotic colon tissues. As expected, the expression of miR-483 was higher in colorectal cancer tissues in comparison with corresponding nonnecrotic colon tissues ($P < 0.05$) (Figure 1(a)). In addition, the overexpression of miR-483 predicted poor 5-year survival in colorectal cancer ($P < 0.05$) (Figure 1(b)).

3.2. MiR-483 Promoted the Proliferation and Invasion in Colorectal Cancer Cells. The expression of miR-483 was assessed in two colorectal cancer cell lines (LOVO and SW480) and a normal colorectal epithelial cell line CCD-18Co. Similar with the findings in tissues, miR-483 was overexpressed in CCD-18Co cells compared with colorectal cancer cell lines LOVO ($P < 0.05$) and SW480 ($P < 0.05$) (Figure 2(a)). To explore the functions of miR-483 in colorectal cancer, the miR-483 mimic or the miR-483 inhibitor was transfected in LOVO cells to up- ($P < 0.01$) or down-regulate ($P < 0.05$) miR-483 (Figure 2(b)).

MTT assay revealed that the miR-483 mimic promoted cell proliferation ($P < 0.05$), while the cell proliferative ability was suppressed by the miR-483 inhibitor in LOVO cells ($P < 0.05$) (Figure 2(c)). Furthermore, transwell assay illuminated that the miR-483 mimic enhanced the cell invasive ability ($P < 0.01$) while the miR-483 inhibitor suppressed ($P < 0.05$) (Figure 2(d)). All the findings elucidated that miR-483 promoted the capacities of proliferation and invasion in colorectal cancer cell line LOVO.

3.3. MiR-483 Regulated the Expression of NDRG2 through Directly Binding to the 3′-UTR of NDRG2 mRNA. TargetScan predicted NDRG2 was a target gene of miR-483 and the binding site was located at 3′-UTR of NDRG2 mRNA. To validate miR-483 direct binding to the potential binding site of NDRG2, the binding sequences were mutated from 5′-AGGGCAGA-3′ to 5′-AGGCGUCA-3′ and then inserted into the luciferase vectors (Figure 3(a)). The luciferase reporter assay indicated that the luciferase activity of LOVO cells transfected with the wild-type NDRG2 3′-UTR was decreased by miR-483 mimic ($P < 0.05$), while the miR-483 mimic has no effect on the luciferase activity of cells transfected with mutant NDRG2 3′-UTR ($P < 0.05$) (Figure 3(b)). Furthermore, the mRNA levels of NDRG2 were measured when transfected with the miR-483 mimic or the miR-483 inhibitor in LOVO cells. As expected, the overexpression of miR-483 enhanced the mRNA level of NDRG2 ($P < 0.05$), while the knockdown of miR-483 inhibited the expression of NDRG2 in LOVO cells ($P < 0.05$) (Figure 3(c)). All the results illuminated that miR-483 regulated the expression of NDRG2 in colorectal cancer cell line LOVO.

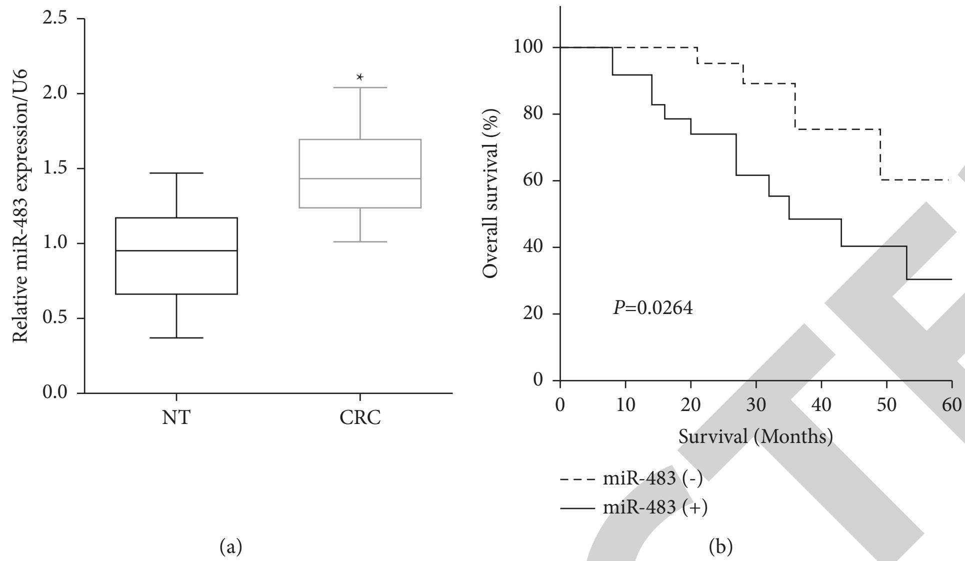

Figure 1: Upregulation of miR-483 predicted poor prognosis of colorectal cancer. (a) The expression of miR-483 was higher in colorectal cancer tissues than in the nonnecrotic colon tissues. (b) Overexpression of miR-483 predicted poor 5-year survival of colorectal cancer patients. $^*P < 0.05$. NT: normal tissues; CRC: colorectal cancer.

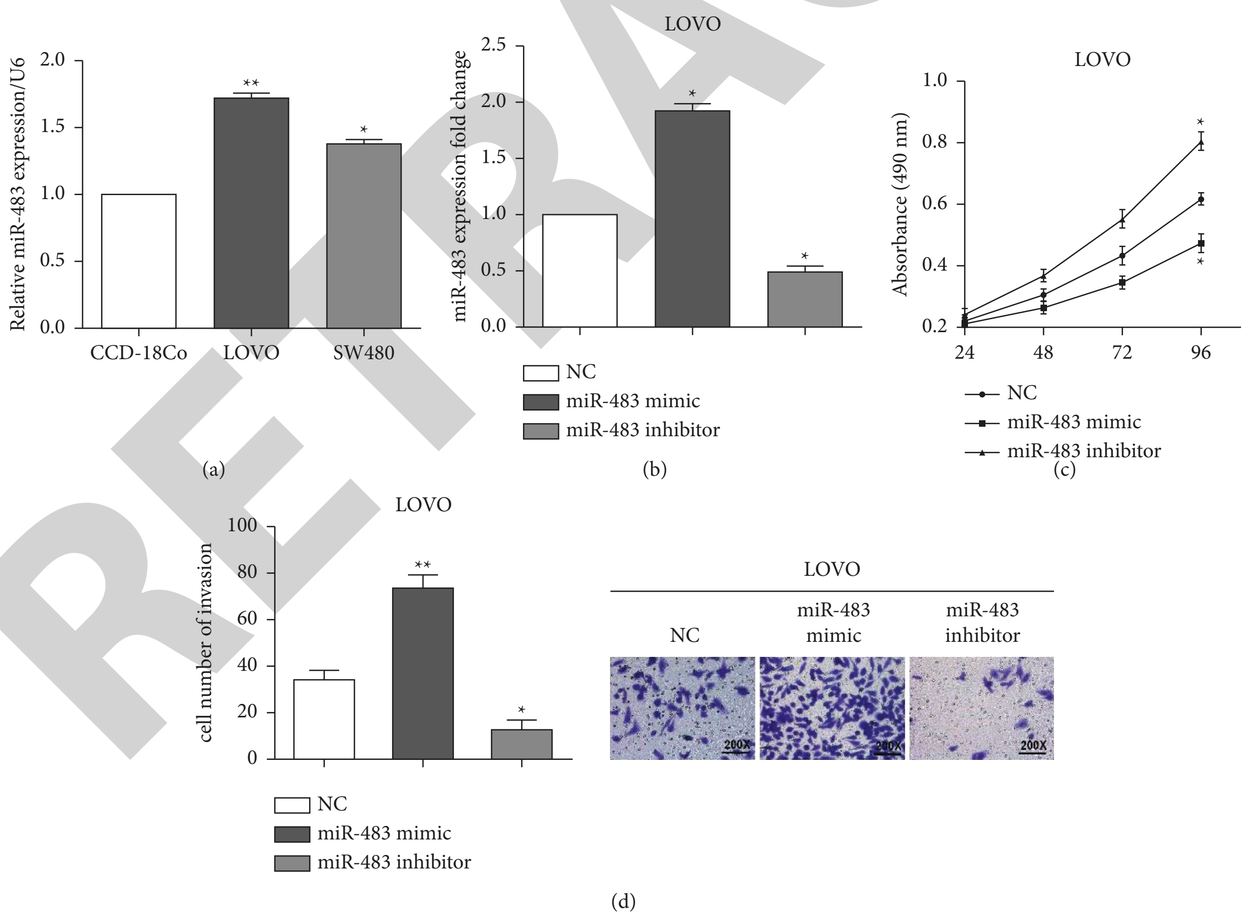

Figure 2: MiR-483 promoted the proliferation and invasion in colorectal cancer cells. (a) MiR-483 was overexpressed in CCD-18Co cells versus LOVO and SW480 cells. (b) The miR-483 mimic or the miR-483 inhibitor was transfected to up- or downregulate miR-483 in LOVO cells. (c) MTT assay revealed that the miR-483 mimic promoted the proliferation in LOVO cells. (d) The invasive ability was enhanced by the miR-483 mimic cell, while it was inhibited by the miR-483 inhibitor in LOVO cells. $^*P < 0.05$; $^{**}P < 0.01$.

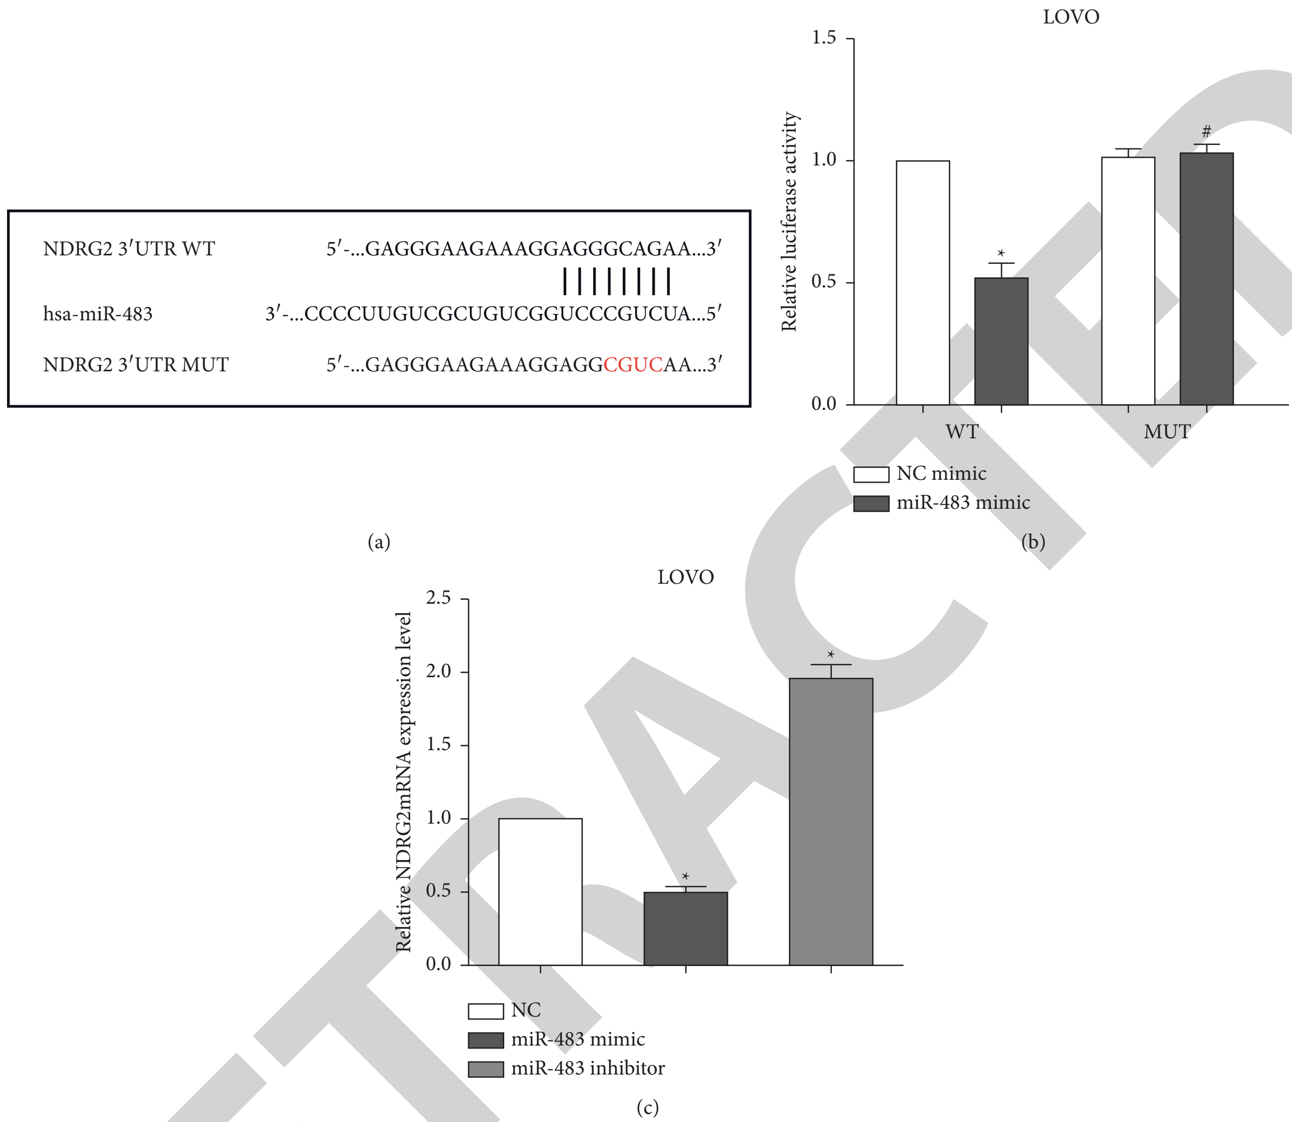

Figure 3: MiR-483 regulated the expression of NDRG2 through binding to NDRG2 mRNA 3′-UTR. (a) TargetScan predicted NDRG2 was a target gene of miR-483 and the binding site was located at the 3′-UTR of NDRG2 mRNA. (b) The luciferase reporter assay indicated that miR-483 directly targeted NDRG2 in LOVO cells. (c) Overexpression of miR-483 enhanced the mRNA level of NDRG2, while the knockdown of miR-483 inhibited the expression of NDRG2 in LOVO cells. $^*P < 0.05$; $^{\#}P < 0.05$.WT: wild type; MUT: mutant type.

3.4. MiR-483 Promoted the EMT and Activated the Phosphorylation of the PI3K/AKT Signaling Pathway. The relative mRNA level of NDRG2 was calculated, and it was found to be upregulated in nonnecrotic colon tissues in comparison with that of colorectal cancer tissues ($P < 0.05$) (Figure 4(a)). Also, the expression of NDRG2 was detected in normal colorectal epithelial cell line CCD-18Co and two human colorectal cancer cell lines LOVO and SW480. Not unfortunately, the expression of NDRG2 was lower in LOVO ($P < 0.05$) and SW480 ($P < 0.05$) cells than that in CCD-18Co cells (Figure 4(b)). Moreover, western blot was conducted to assess the expressions of EMT and PI3K pathway associated proteins in LOVO cells. We discovered that the miR-483 mimic promoted the EMT via NDRG2 by suppressing the expression of NDRG2 and N-cadherin while improving the expression of E-cadherin in LOVO cells (Figure 4(c)). Phosphorylation of PI3K and AKT promoted cell growth, proliferation, and survival [22]. As we expected, the overexpression of miR-483 enhanced the expression of p-PI3K and p-AKT in LOVO cells (Figure 4(d)), which elucidated that miR-483 activated the phosphorylation of the PI3K/AKT signaling pathway.

3.5. MiR-483 Enhanced the Xenograft Growth In Vivo. LOVO cells stably transfected with the miR-483 mimic, or control plasmid was applied to inject into the nude mice subcutaneously. The xenograft tumor volume was calculated every 3 days, and the group of transfecting the miR-483 mimic had a higher growth rate than the control group (Figure 5(a)). After dissecting the nude mice, the xenograft tumors were collected and the volumes were calculated.

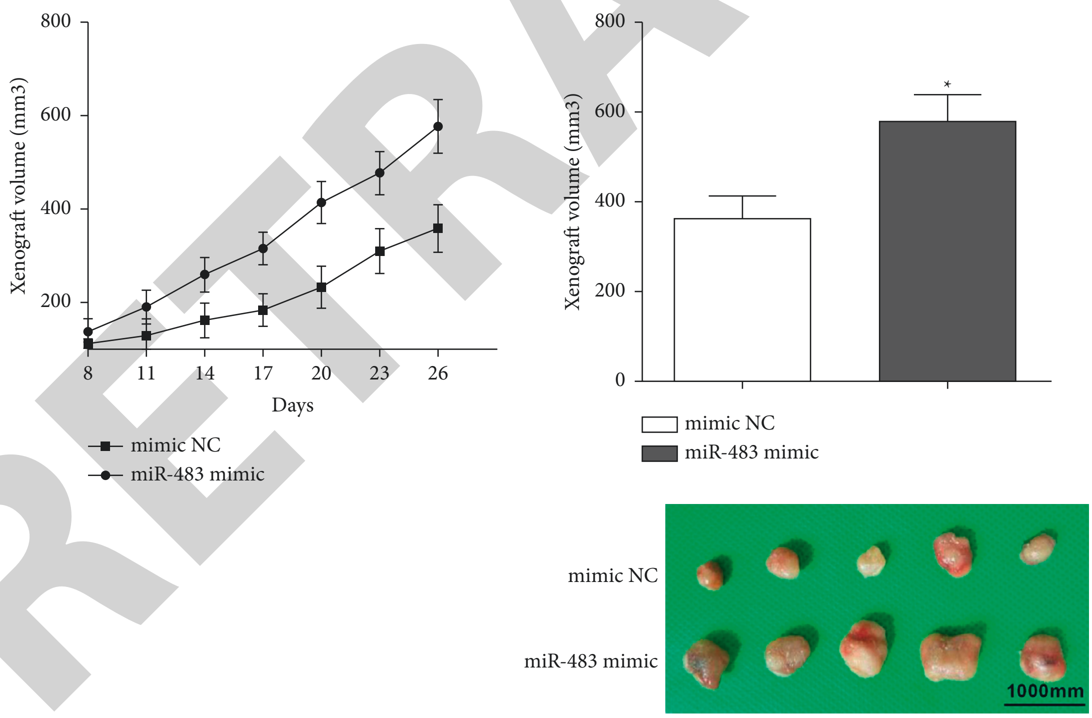
(d)

Figure 4: MiR-483 promoted the EMT and activated the phosphorylation of the PI3K/AKT signaling pathway. (a) The mRNA level of NDRG2 in nonnecrotic colon tissues was higher than that in colorectal cancer tissues. (b) NDRG2 was lowly expressed in colorectal cancer cells than normal cells. (c) Western blot illuminated that miR-483 promoted the EMT through NDRG2. (d) MiR-483 activated the PI3K/AKT pathway. $^{*}P < 0.05$. NT: normal tissues; CRC: colorectal cancer; N-Ca : N-cadherin; E-Ca : E-cadherin; and GAPDH: glyceraldehyde-phosphate dehydrogenase.



(a) (b)

Figure 5: MiR-483 enhanced the growth of xenograft in vivo. (a) MiR-483 promoted colorectal cancer growth in vivo. (b) The tumor volume of cells overexpressing miR-483 was bigger than the control group. $^{*}P < 0.05$.

Also, we discovered the tumor volumes of cells overexpressing miR-483 was bigger than that of the control group, which indicated that miR-483 mimic promoted the growth of colorectal cancer xenograft ($P < 0.05$) (Figure 5(b)).

4. Discussion

Colorectal cancer is the third frequent tumor and one of the leading causes of cancer-related death worldwide [1, 2]. The morbidity and mortality of colorectal cancer caused by metastasis are increasing rapidly [3, 23]. Therefore, it is urgent to explore the early diagnosis and metastasis of newly biomarkers for colorectal cancer.

MiRNAs repressed the protein degradation and translation through directly binding to the 3′-UTR of target mRNA at the posttranscriptional level [24]. MiR-483 which acted as a prognostic biomarker was upregulated in esophageal squamous cell carcinoma [25]. Consistent with the findings, we discovered that miR-483 was upregulated in colorectal cancer tissues in comparison with the nonnecrotic colon tissues. Moreover, miR-483 may act as a prognosis marker and the overexpression of miR-483 predicted a poor 5-year overall survival of colorectal cancer patients, which was the first time to propose the association between miR-483 and the survival of CRC. Furthermore, miR-483 played an oncogenic role and promoted cell proliferation and migration in esophageal squamous cell carcinoma [26]. In adenocarcinoma, Song et al. indicated that miR-483 promoted cell invasion and the EMT [27]. Our results were consistent with all the findings that the overexpression of miR-483 in colorectal cancer promoted cell proliferation and invasion, while the reverse was downregulation. However, miR-483 served a tumor suppressive role in glioma [28], and we speculated that miR-483 has a tissue-specific expression. In addition, we first proposed that miR-483 promoted the growth of colorectal cancer cell xenografts.

NDRG2 is a gene with promoter hypermethylation and is a newly identified differentiation-related gene [15, 16]. In esophageal cancer, NDRG2 inhibited cell proliferation, migration, invasion, and the EMT [17]. NDRG2 was a target gene of several miRNAs including miR-141b, miR-375, miR-301, and miR-650 [29–32]. Consistent with the findings of Claire Agosta in adrenocortical cancer [21], we discovered that NDRG2 was a target gene of miR-483 and miR-483 mediated the expression of NDRG2 in colorectal cancer. The expression of NDRG2 was lower in colorectal cancer tissues than in nonnecrotic colon tissues. Moreover, miR-483 promoted colorectal cancer cell proliferation, invasion, and EMT through targeting NDRG2 and activated the PI3K/AKT pathway.

5. Conclusions

MiR-483 promoted colorectal cancer cell proliferation, invasion, and EMT through directly targeting NDRG2 and activated the PI3K/AKT pathway. In addition, the overexpression of miR-483 promoted the growth of LOVO cells xenograft. Our data suggest that miR-483 is a prognostic predictor and can serve as a potential therapeutic target of colorectal cancer.

Psoriasis is a common chronic and recurrent disease in dermatology, which has a great impact on the physical and mental health of patients. Meta-analysis can evaluate the effectiveness and safety of defubao in the treatment of psoriasis vulgaris. This article observes psoriasis skin lesions treated with topical defubao and the changes in blood vessels under dermoscopy. Considering that the Apriori algorithm and the existing improved algorithm have the problems of ignoring the weight and repeatedly scanning the database, this paper proposes a matrix association rule method based on random forest weighting. This method uses the random forest algorithm to assign weights to each item in the data set, and introduces matrix theory to convert the transaction data set into a matrix form and store it, thereby improving operating efficiency. This article included 11 studies, of which 7 studies used the indicator "Researcher's Overall Assessment" (IGA) to evaluate the efficacy, 5 studies used the "Patient Overall Assessment" (PGA) as the efficacy evaluation index, and Loss Area and Severity Index (PASI) was used as an observation index to evaluate the efficacy. Seven studies conducted safety comparisons. In this paper, IGA and PGA were used as evaluation indicators. The treatment effect of the defubao group was better than the calcipotriol group and the betamethasone group. The differences were statistically significant. The effect of the Fubao treatment for 8 weeks is significantly better than that of 4 weeks and 2 weeks, and the differences are statistically different. Using PASI as the evaluation index, a descriptive study was carried out, and it was found that after 4 weeks of treatment for psoriasis vulgaris, the average PASI reduction rate of patients was higher than that of the calcipotriol group and the betamethasone group. The safety evaluation found that after 8 weeks of treatment, the incidence of adverse events in the defubao group was significantly lower than that in the calcipotriol group.

1. Introduction

How to discover these hidden and valuable relationships has always been a research hotspot in the field of data mining [1, 2]. Among them, data mining technology refers to a large number of data sets, through association rule mining, classification, aggregation and outlier detection and other methods, to find the internal relationship between the data in the data set without obvious characteristics, so as to guide people in subsequent production activities. For example, in the typical case of retail data on beer and diapers, if the decision-makers did not use data mining technology to effectively analyze the retail data, how could they find that people who bought beer would also buy diapers? Among them, in the case of beer and diapers, association rules technology is used, which is a very practical data mining technology [3–5]. This mining technology has been widely used in many fields such as store layout, consumer behavior, accident data analysis, and fraud detection [6, 7].

Psoriasis, known as "white boil" in traditional Chinese medicine, is a common chronic, inflammatory, and recurrent skin disease [8]. It is characterized by red papules or plaques with multiple layers of silvery white scales covering the limbs. Extensive side, scalp and back, severe skin lesions can spread all over the body, accompanied by varying degrees of itching [9, 10]. The disease can be seen in all races, and the prevalence varies among different regions and races. Psoriasis is clinically divided into 4 types, including vulgaris, erythroderma, pustular, and articular types, among which vulgaris is the most common, accounting for more than 97% of all patients [11]. Common TCM syndrome differentiation mainly includes blood syndrome, blood heat syndrome, blood dryness syndrome, blood deficiency syndrome and blood stasis syndrome [12]. However, psoriasis persists for a long time and the pathogenesis is complicated. Only four types cannot meet the complex and changeable clinical syndrome differentiation needs of psoriasis vulgaris. At present, our country is in a period of social transformation and rapid economic growth, and the subsequent air pollution, water pollution and increasing living pressure have laid hidden dangers for the occurrence of this disease [13]. Therefore, the need for research and treatment of this disease is more urgent than in any previous period. Modern medicine has been continuously exploring and researching the disease, and there have been a lot of research results. However, the etiology and pathogenesis of psoriasis are still unclear. Its treatment has large side effects and lacks safe, effective and satisfactory long-term curative effects. This article aims to systematically collect patients' symptoms, related factors, and analyze the distribution characteristics of pathogenic factors, combination characteristics, distribution of related factors and typical symptoms caused by pathogenic factors as comprehensively as possible, and discuss the differentiation of psoriasis vulgaris [14]. Element characteristics, using the simple, flexible, accurate, and comprehensive characteristics of syndrome elements to describe the pathogenesis of psoriasis vulgaris, provide a basis for more accurate and effective differentiation and treatment of psoriasis vulgaris [15]. In this way, the complex pathogenesis is divided into several syndrome differentiation elements of the combination of syndromes, and the precise differentiation of syndromes can be used to guide the treatment more accurately, so as to be beneficial to more in-depth research on the disease and to further improve the clinical efficacy of the disease. At present, the common indicators for evaluating the severity of psoriasis include skin lesion area and severity index, the researcher's overall assessment, the patient's overall assessment, and the target skin lesion score. The first three indicators are to observe and evaluate the overall severity of the patient. Target lesion scores are widely used to assess the severity of specific lesions in psoriasis. It includes erythema, scale, and infiltration. TLS observes specific local skin lesions. Therefore, when it is necessary to combine auxiliary examination methods to dynamically observe and record changes in diseases or skin lesions, TLS is more intuitive and comparative.

Calcipotriol has been widely used in the treatment of psoriasis, and its efficacy and safety have been recognized by doctors and patients. Local topical glucocorticoids are also the first choice for the treatment of psoriasis. Before the advent of defubao, the effect of using glucocorticoid in the morning and calcipotriol at night was significantly better than using calcipotriol or glucocorticoid alone twice a day. Topical calcipotriol and glucocorticoids have been used as classic first-line drugs for the treatment of psoriasis for several years. Calcipotriol is a vitamin D derivative, which can regulate the proliferation and differentiation of epidermal cells, as well as the production and release of proinflammatory cytokines. Local topical glucocorticoid therapy will have a wide range of biological effects, such as inhibiting the production and migration of inflammatory cells, regulating the release of cytokines (such as IL-2) and chemokines, and regulating DNA synthesis. However, external hormones alone have side effects, including skin atrophy, telangiectasia, and uneven pigmentation. Defubao is a compound preparation of betamethasone and calcipotriol, containing calcipotriol 50 μg/g and betamethasone dipropionate 0.5 mg/g. Defubao was approved by the State Food and Drug Administration for the treatment of psoriasis vulgaris. In theory, it has both calcipotriol's prokeratinocyte differentiation effect and betamethasone anti-inflammatory effect, which combines the advantages of the two drugs and complements the side effects of the two drugs. However, the effectiveness and safety of defubao still need strong evidence-based medical evidence to objectively evaluate.

2. Related Work

Many scholars have proposed binding and nonbinding association rules [16–18]. For example, they add restrictions on the number of transactions and transaction time to each item in the database to reduce the number of association rules, generate only interesting rules, generate only nonredundant rules, or use sampling to display association rules, or generate only those that meet certain requirements [19].

Relevant scholars have adopted the maximum utility value strategy, and proposed the LQS-tree storage structure, item connection and sequence connection to expand the sequence, and also provided width pruning and deep pruning to prune undesirable sequences [20]. Related scholars have proposed a four-stage MapReduce framework, which is completely based on the famous Spark platform for mining HUSP [21]. The framework provides more efficient and faster mining performance for processing large data sets. It includes four stages: initialization, mining, update, and generation. It is based on the MapReduce framework running on the Spark platform to process large data sets.

At present, most of the algorithms are mainly focused on HUSP mining in static databases, without considering streaming data. In streaming data, unlimited data appears continuously and at a high speed, which will increase the difficulty of mining. Based on this, related scholars have proposed a HUSP-UT algorithm, which is based on a data stream tree structure [22, 23]. A large number of experiments on real data sets show that HUSP-UT can effectively identify high-efficiency sequences. In addition, the article also proposes a new upper bound-sequence expansion utility. A variety of pruning strategies are further adopted [24].

In the real world, the time interval between elements is also very important. However, the existing HUSP mining algorithms cannot extract sequential patterns of this nature. The researchers took into account the utility of the elements and the time interval, and proposed a sequential pattern mining algorithm with the nature of time interval [25, 26]. In addition, four time constraints are used to process the time intervals in the sequence to extract more meaningful patterns. In addition, two upper bounds of utility are proposed, namely the upper bound of residual utility (RUUB) and the upper bound of co-occurrence utility (CUUB) to prune hopeless candidates. Under the assumption that multiple events can occur simultaneously and persist for different periods of time, considering the utility of events, a pattern mining algorithm based on high-efficiency intervals, HUIPMiner, is proposed [27, 28].

Relevant scholars believe that psoriasis is related to the five internal organs, and is most closely related to the liver [29]. The main factors are that the liver controls drainage, the blood storage in the liver, and the pathological interaction between the liver and other internal organs. Scholars used a multi-center randomized controlled method for clinical observation [30]. The treatment group was mainly given the prescription of cooling blood and detoxification, the liver-clearing and purging gunpowder was used for the blood-heat syndrome, the liver-releasing and qi-regulating medicine was used for the blood stasis syndrome, and the liver-softening detoxification was used for the blood-dry syndrome [31–33]. All were treated with medicine that was soothing to the liver and relieved depression. The improvement of DLQI scores in the treatment group was better than those in the control group. Therefore, the treatment of psoriasis from the liver theory based on Liangxue Jiedu Decoction can effectively improve the degree of skin lesions, TCM syndromes and quality of life [34, 35].

The TCM syndrome differentiation type included in the literature lacks objective and unified standardized standards. The outcome index adopts the comprehensive curative effect evaluation index, and the improvement of symptoms is based on the subjective judgment of the investigator, which makes the judgment of curative effect lack objectivity. In addition, in the trial design, most of the literature lacks long-term follow-up, which affects the combined analysis of the long-term efficacy of external use of traditional Chinese medicine in the treatment of psoriasis vulgaris. This may be related to the long treatment period of traditional Chinese medicine and the relatively difficult follow-up. A small part of the literature even lacks the description of the adverse reaction, and most of the literature lacks objective basis when describing the adverse reaction, which reduces the completeness of the data.

3. Method

3.1. Mining Based on Apriori Text Association Rules. The following introduces the related concepts of Apriori and the main algorithm process in two parts.

(1) Support: For a given data set, how often certain features are found. Support is defined as follows:

$$\text{support}(A, B) = P(A \subseteq B) \cup P(A \cap B). \tag{1}$$

Among them, A and B are itemsets.

(2) Confidence degree: It reflects the certainty of the reflection rules on the basis of frequent itemsets. The confidence is defined as follows:

$$\text{Confidence}(A, B) = P(A \cup B) \cap P(A \cap B). \tag{2}$$

(3) Frequent itemsets: Frequent itemsets find the set of data that is not less than the minimum support degree.

(4) Strong association rules: On the basis of frequent itemsets, strong association rules also meet artificially set thresholds.

Apriori's algorithm uses the candidate function to generate frequent itemsets. The function first counts the number of occurrences of each element in the itemsets (also known as support count), and finds the frequent itemsets. Then the function rescans the data set, using the iterative layer-by-layer method until there is no maximum itemset generated. The calculation process of Apriori is shown in Figure 1.

3.2. Diagnostic Model Construction Method. RNN and DBN can also achieve better experimental results in practical applications. However, these two methods still have problems in processing text data. In view of the shortcomings of the above methods, CNN, as a typical neural network, can solve the above problems well. As a feedforward network, it has outstanding performance in reducing weights and computational complexity.

The input data has a certain format, and the image itself is composed of multiple pixels, so it has certain regularity. For text data, the converted word vector is generally used as input data.

To extract the features of the input data $x(i)$, the discrete convolution formula is

$$y(n) = \prod_{i=0}^{\infty} [h(n-i+1) \bullet x(i+1)]. \tag{3}$$

Among them, $h(n-i)$ is the convolution kernel.

A filter is also called a convolution kernel. Assuming that the length of the input data is n and the size of the convolution kernel is m, the feature length after the convolution operation is $n-m+1$. However, this situation will reduce the length of the feature. CNN adopts an expansion method, that is, filling the boundary of the input data to prevent problems caused by size changes.

The feature matrix obtained by convolution has a relatively large dimension and cannot accurately describe data features. After pooling, more accurate features can be obtained, which is convenient for subsequent work.

TextCNN optimizes the standard CNN convolutional layer structure, which uses simple models to achieve excellent results in multiple data sets, achieves end-to-end classification effects, and makes it better to process text content. Compared with CNN, the network structure is simple, and the input data is one-dimensional data. The biggest feature of TextCNN is to classify text. The data are mapped to a low-dimensional space for encoding through

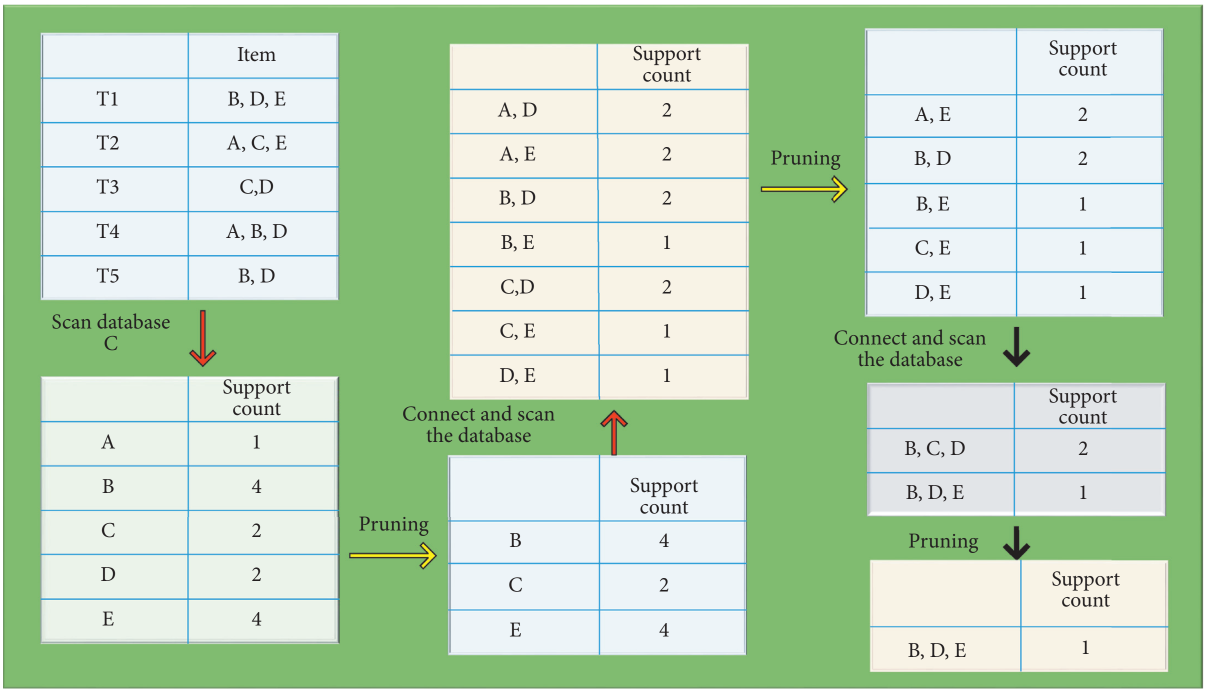

Figure 1: Apriori calculation process.

the feature extractor of the embedding layer. Figure 2 shows the architecture of the psoriasis data mining system based on association rules.

3.3. Random Forest Algorithm.

The algorithm principle is as follows:

(1) The sample is replaced with n samples randomly selected as the training set.

(2) Use the training set to construct a decision tree, and randomly extract features during the construction process.

(3) Repeat the above process to generate multiple decision trees.

(4) Integrate all decision trees to predict new data (the majority vote is generally used for classification).

The random forest algorithm can effectively weigh each feature in the data set. The main idea is to calculate the average contribution of each feature in the random forest for all trees in the random forest. The Gini index is commonly used as a measurement indicator. The process of random forest algorithm is shown in Figure 3.

Here, VIM is used for variable importance measures, and GI is used for Gini index. Taking a data set containing n features as an example, the calculation method of the j-th feature Gini index score $\mathrm{VIM}_j(\mathrm{Gini})$ is:

$$GI_m = \prod_{k=0}^{K}\prod_{k'=1}^{K}\left(p_{mk}p_{mk'}\right), \tag{4}$$

where K represents the number of categories included, and P_{mk} represents the probability of randomly sampling two samples of different categories from node m. The importance of feature X_j to node m is:

$$\mathrm{VIM}_{jm}^{Gini} + GI_l = 2GI_r + GI_m. \tag{5}$$

Here, GI_l and GI_r, respectively, represent the Gini index of the new node after branching. If the node of feature X_j in decision tree i belongs to set M, then the importance of X_j to the i-th tree is:

$$\begin{aligned}\mathrm{VIM}_{ij}^{Gini} &= \prod_{m \longrightarrow M}\left(\mathrm{VIM}_{jm}^{Gini} + GI_l + GI_r + GI_m\right),\\ \mathrm{VIM}_{j}^{Gini} &= \prod_{i=0}^{n-1}\left(\mathrm{VIM}_{ij}^{Gini} - GI_l - GI_r - GI_m\right).\end{aligned} \tag{6}$$

3.4. Design of Matrix Association Rule Algorithm Based on Random Forest Weight.

The traditional Apriori algorithm and the existing improved algorithm have problems such as low operating efficiency, and many redundant rules. In response to these problems, this section combines the random forest algorithm with matrix theory, proposes a matrix association rule algorithm based on random forest weights, and designs and implements related comparative experiments.

Due to the introduction of weights, the traditional support and confidence are no longer applicable. In addition, the transformed matrix needs to be compressed according to related properties to further obtain frequent itemsets. Therefore, this paper defines the weighted support and weighted confidence, and provides related definitions and proofs for matrix compression.

$W(X)$ is recorded as the weight of item set X, which represents the sum of the weights of all items in item set X:

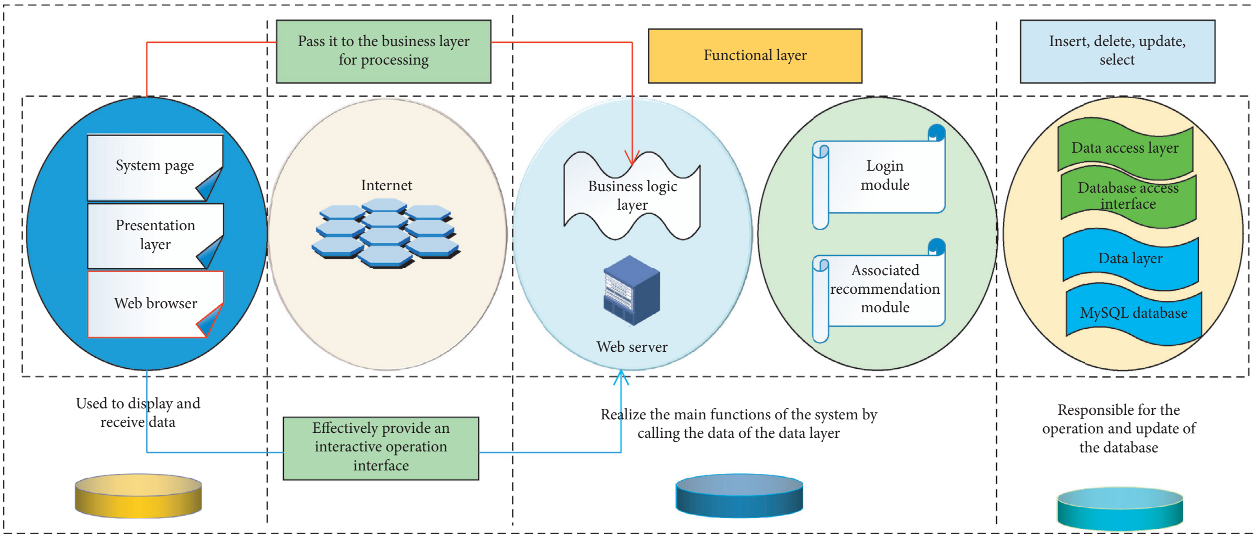

Figure 2: Architecture of psoriasis data mining system based on association rules.

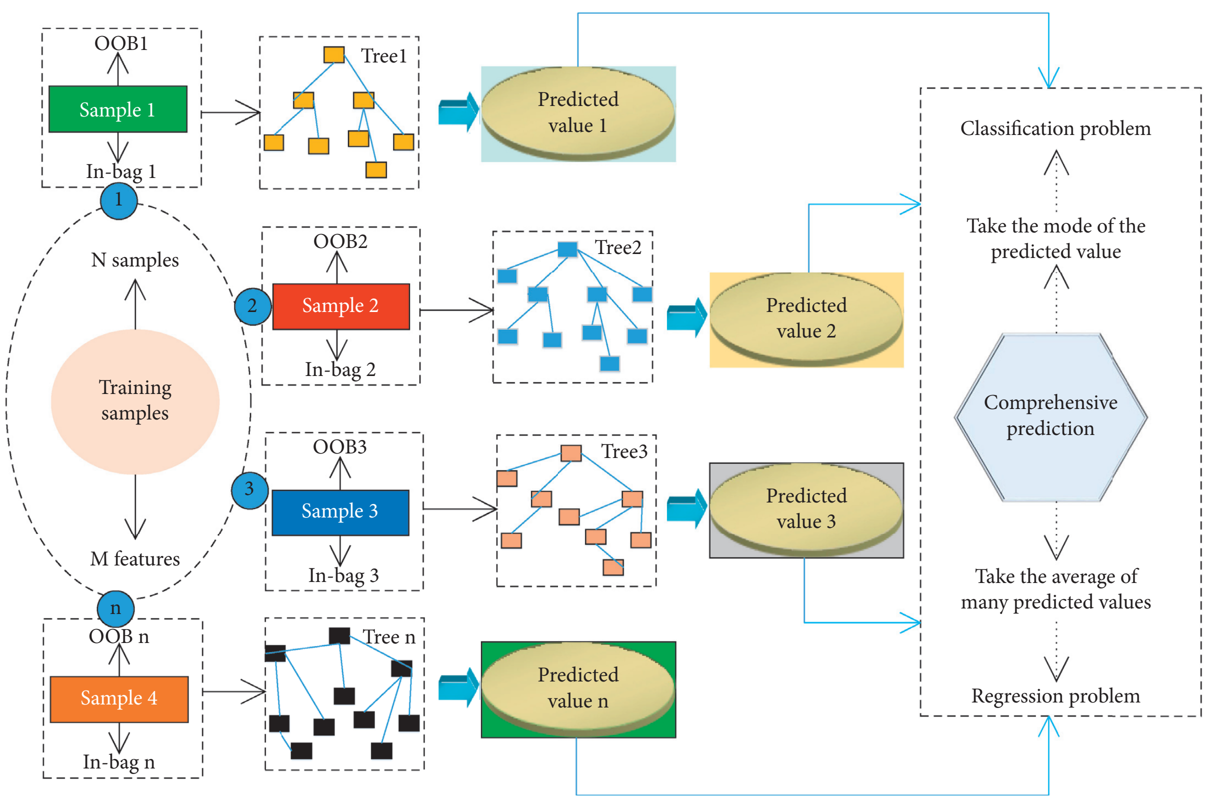

Figure 3: Random forest algorithm process.

$$W(X) = \sum_{i,I(X)} \left[W(i_j) + GI_l + GI_r + GI_m\right] \Big| \prod_{i,I(X)} W(i_j). \quad (7)$$

$WSup(X)$ is recorded as the weighted support of item set X:

$$WSup(X) = W(X) \bullet W(X) \bullet Sup(X). \quad (8)$$

If $WSup(X) > \text{minsup}$ (customized minimum weighted support), then the item set X is called a weighted frequent set. The weighted confidence of the association rule X-Y is:

$$WConf(X \mapsto Y) = WSup(X \cap Y) | WSup(X \cup Y). \quad (9)$$

Suppose there is a transaction data set $D = \{t1, t2, t3, t4, t5\}$, and its corresponding item set is I = {I1, I2, I3, I4, I5}. First, we scan the transaction data set D, and obtain the weight of each feature through the above random forest method. The conversion method is, if the j-th item exists in the i-th transaction, we set the value of the i-th row and the j-th column of the matrix to 1, otherwise set its value to 0. The transformed transaction matrix D1 is shown in Table 1.

Table 1: Transaction matrix D1.

	I1	I2	I3	I4	I5
T1	1	2	1	2	1
T2	2	1	1	1	2
T3	2	1	1	2	1
T4	1	2	2	1	2
T5	1	2	2	1	1

On the basis of the converted matrix, we add two new rows Sup and WSup, and add a new column sum_c, where sum_c is used to record the total number of items contained in each transaction, and Sup and WSup are used to record the support of different items, respectively.

We set the minimum weighted support min_wsup, compare the support number of each item recorded in the last row, if the support number of an item is not less than min_sup, it will be recorded as frequent 1 item set, otherwise the corresponding column will be deleted. If the value corresponding to an element is 0, we delete the corresponding row to obtain a new transaction matrix.

This process is repeated all the time, resulting in frequent k itemsets ($k \geq 2$). We delete the matrix column corresponding to the item Ij that appears less than k in the frequent $k-1$ item set and recalculate the sum_c column of the matrix. According to property 2, if the value of an element is less than k, we delete the corresponding row of the element in the matrix. If the value of an element is less than min_sup, we delete the column corresponding to the element.

3.5. Statistical Processing. RevMan 5.3 software was used for meta-analysis of the data. First, X2 is used to evaluate the heterogeneity between similar studies. If $P \geq 0.1$ and $I2 \leq 50\%$, it means that there is homogeneity between the studies, and the fixed effects model is used for meta-analysis; if $P < 0.05$, $I2 > 75\%$, it is considered that there is heterogeneity between the studies and the heterogeneity should be analyzed. After subgroup analysis is conducted according to the research design and different treatment options, and after eliminating the problems of the quality of the research design and different treatment options, the random effects model can be used to combine the effect size, and the research results can be explained carefully. Sensitivity analysis is performed on the heterogeneity caused by different research methods, and different model calculations are performed to evaluate the stability of the meta-analysis results. The outcome variables of this study are all two-category count data, and the odds ratio and 95% confidence interval are used as the analysis statistics. For those with insufficient data in clinical trials, only descriptive analysis will be performed.

4. Results and Discussion

4.1. Effectiveness Analysis. There are 4 randomized trials to evaluate and compare the effectiveness of defubao and betamethasone in the treatment of psoriasis vulgaris through IGA indicators. According to the course of treatment, they are divided into 3 subgroups: treatment for 2 weeks, treatment for 4 weeks, and treatment for 8 weeks. After 2, 4, and 8 weeks of treatment, the proportion of patients in the defubao group whose IGA assessment changed to "regression of skin lesions" or "very mild skin lesions" was significantly higher than that of the betamethasone group. The group had no heterogeneity in each outcome index, so fixed effects models were used for meta-analysis. The results showed that whether the treatment course was 2 weeks or 8 weeks, the treatment effect of defubao was significantly better than that of betamethasone, and the difference was statistically significant. The IGA used the IGA as an indicator to evaluate the asymmetry of the funnel chart between the defubao group and the betamethasone group at 8 weeks, and there is a publication offset in the study, as shown in Figure 4. However, in the subgroup comparing the efficacy of 4 weeks, the Cochrane Q analysis suggests that the combined data of the three groups are significantly heterogeneous, so the 4-week period is valid. The conclusions reached suggest that after 4 weeks of treatment, the treatment effect of the defubao group is better than that of the betamethasone group.

Three trials compared the effectiveness of defubao and calcipotriol (1 time/day) using IGA as an observation indicator. According to the different treatment time, they are divided into 3 subgroups and compared separately. The difference in curative effect of treatment for 2 weeks, treatment for 4 weeks, and treatment for 8 weeks is mainly compared. The 2-week curative effect subgroup and the 8-week curative effect subgroup, respectively. A fixed effects model was used for data analysis. As shown in Figure 5, the funnel graph is asymmetric, and the research has a publication offset. There is significant heterogeneity in the three groups of data compared between the four-week efficacy subgroups, and the random effects model is selected for data analysis. The results showed that the treatment with defubao was applied in 2 weeks [OR = 5.49, 95%CI (4.27, 7.05), $P < 0.001$], 4 weeks [OR = 4.67, 95%CI (3.31, 6.57), $P < 0.001$], and 8 weeks [OR = 3.44, 95% CI (2.78, 4.25), $P < 0.001$], and the effective rate of treatment was significantly better than that of calcipotriol, and the differences were statistically significant. In addition, the efficacy of defubao (1 time/day) and calcipotriol (2 times/day) was compared.

Five randomized controlled trials compared the effect of defubao and other drugs by comparing the baseline change rate of PASI before and after 8 weeks of treatment. Based on the provided clinical trial data, we conducted a descriptive analysis of the trial results, as shown in Figure 6.

4.2. Security Analysis. Six studies compared the safety issues of using defubao and calcipotriol. Three randomized experiments compared the safety difference of treatment for 4 weeks, and 3 randomized controlled experiments compared the safety difference of treatment for 8 weeks. Meta-analysis uses a fixed-effects model to compare the occurrence of adverse events. The results suggest that the defubao group was used for 4 weeks or 8 weeks. The incidence of adverse

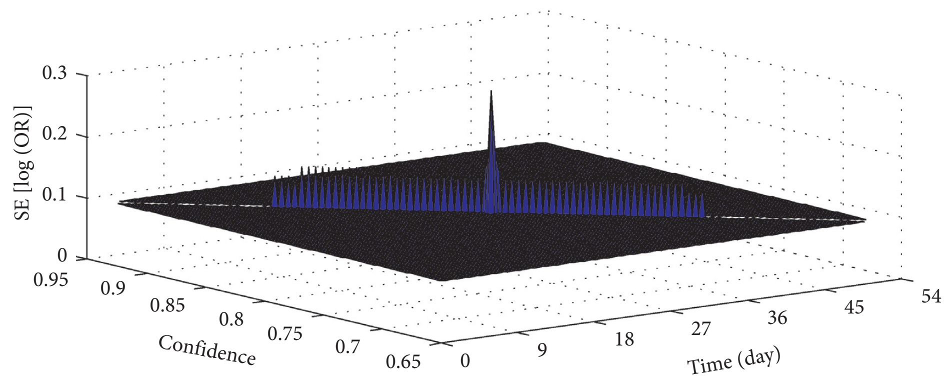

Figure 4: IGA as an indicator to evaluate the 8-week defubao group and the betamethasone group.

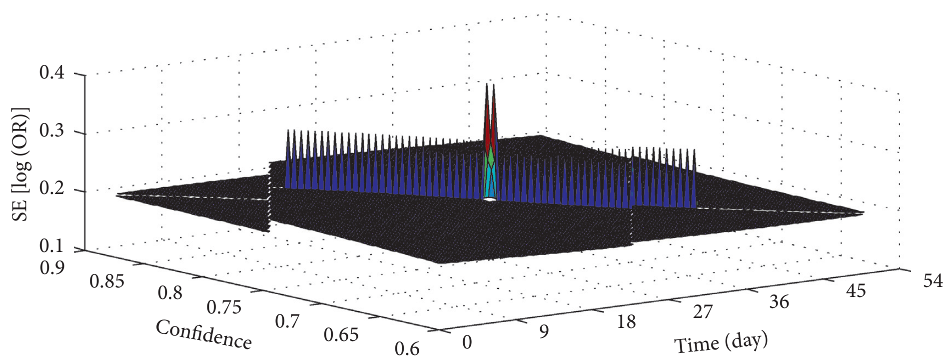

Figure 5: IGA was used to evaluate the 8-week defubao group and the calcipotriol group.

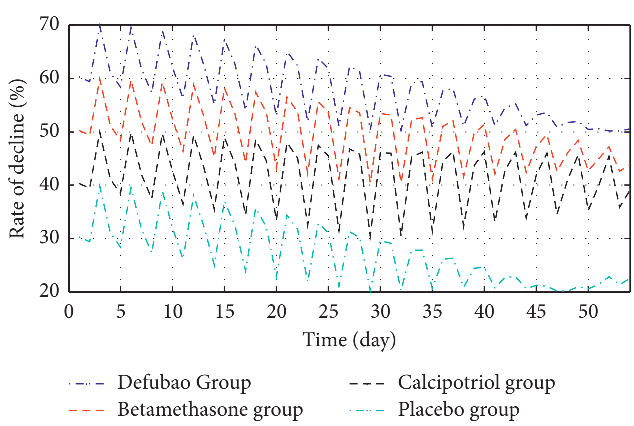

Figure 6: PASI reduction rate for 8 weeks of treatment.

events was significantly less than that of the calcipotriol group. The funnel chart shows asymmetry, and there is a publication offset in the research, as shown in Figure 7.

Four randomized controlled trials compared the safety of defubao and betamethasone for 8 weeks of treatment, that is, the proportion of at least one adverse event. The results showed that after 8 weeks of treatment with defubao and betamethasone, there was no statistical difference in the incidence of adverse reactions between the two. Two randomized controlled trials compared the incidence of adverse reactions after using Defabao and placebo for 4 weeks. Through data analysis, it was found that the proportion of adverse events in the placebo group was significantly higher than that in the defubao group. The results of different groups for 8 weeks are shown in Figure 8. In addition, the safety analysis and comparison results are shown in Table 2.

4.3. Discussion. Relevant scholars observed the changes in clinical PASI score and vascular dilatation under dermatoscope after treatment, and the relative index was used to calculate the evaluation index [36]. Many published evaluation indicators for observing curative effect are compared with the decline rate. In the initial stage of the trial design, this article consulted a large number of domestic and foreign literatures and found that even if the psoriatic skin lesions appear normal to the naked eyes, the capillaries still have different degrees of expansion under dermoscopy [37]. With drug treatment, the skin lesions of psoriasis improved, and the improvement of skin lesions reduced the release of vascular growth factors and inflammatory mediators, which in turn changed the state of intravascular microcirculation of the whole body skin, and the intravascular microcirculation of the skin surrounding the skin lesions. It will change accordingly, that is, the “normal skin data around the skin lesion” will change. The comprehensive evaluation compared the relative index algorithm and the decline rate algorithm [38]. In this experiment, the decline rate was selected as the evaluation index, the target skin lesion score (TLS) was observed to evaluate the severity of the skin lesion, and the diameter of the vascular bulb was used to evaluate the degree of vasodilation, respectively.

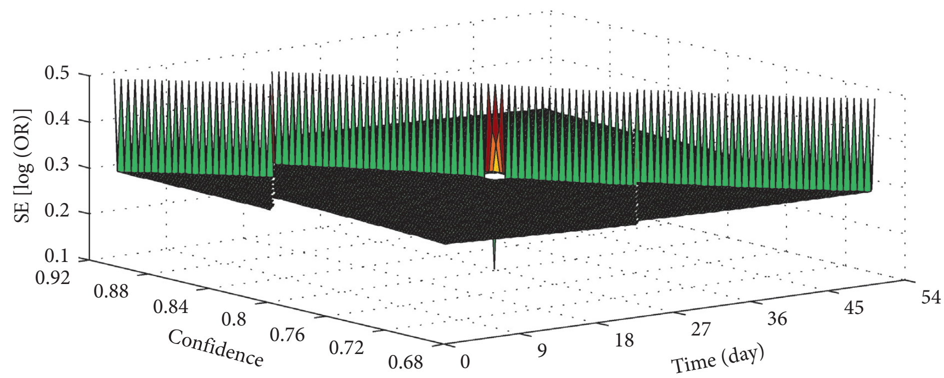

Figure 7: Safety analysis of the 8-week defubao group and the calcipotriol group.

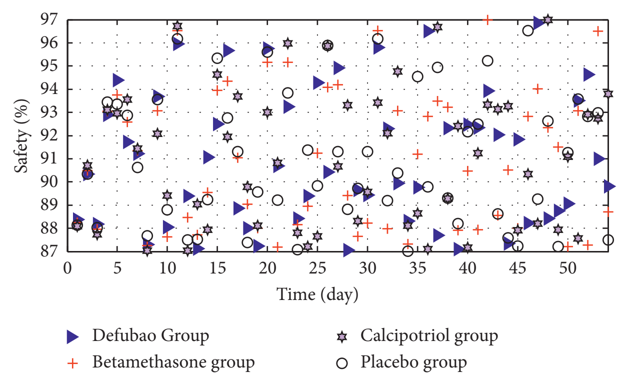

Figure 8: Safety analysis results of different groups in 8 weeks.

Table 2: Comparison results of safety analysis.

Outcome indicators	χ^2	Heterogeneity p	OR	0.95CI	Z	P
Defubao vs placebo 4 weeks	0.01	0.52	0.61	(0.41,0.89)	2.3	0.02
Defubao vs betamethasone 8 weeks	0	0.93	0.92	(0.84,1.1)	0.56	0.16
Defubao vs calcipotriol 8 weeks	0.65	0.03	0.57	(0.48,0.66)	6.4	0.011
Defubao vs calcipotriol 4 weeks	0.32	0.21	0.52	(0.42,0.61)	5.2	0

In addition, in order to be able to observe the overall condition of the skin lesions under a dermatoscopic field of view, and reduce the error caused by the difference in the observation field, the area of the psoriasis skin lesions selected in this experiment is 4–9 cm^2, which makes the data obtained more objective. However, this experiment only observed the changes in specific skin lesions of patients with psoriasis after treatment with defubao, and did not observe and evaluate the overall disease severity of the patients. In the study included in Study 1 (meta-analysis) of this article, it was found that the PASI score of patients with psoriasis vulgaris was significantly decreased after topical application of defubao. Because previous studies have found that in mouse experimental models, the inhibitory effect of steroid hormones on DNA synthesis can be observed even if they are far away from the site where steroid hormones are used [39]. In addition, the improvement of psoriasis plaques reduces the release of vascular growth factors and inflammatory mediators, and the intravascular microcirculation of the whole body skin will be improved.

The two main immunohistological changes in psoriasis are the changes in the skin microvascular system and the abnormal differentiation of the epidermis in the end-stage. The capillary loops in the dermal papilla can be seen elongated, bent and dilated. Relevant scholars have found that in the early stage of psoriasis, the skin lesions and surrounding capillaries dilate and abnormal blood flow precede the inflammatory manifestations and hyperplasia of the skin lesions [40]. With the treatment, the skin lesions improved, the plaque disappeared, and the degree of vasodilation and function also gradually recovered. The researchers compared the blood vessel diameters of scalp lesions in healthy people, patients with seborrheic dermatitis, and patients with psoriasis through dermoscopy, and found that the diameters of scalp capillaries in the seborrheic dermatitis group and the healthy group were similar [41]. There was a significant difference between the capillary diameter of the group and the former two, and the vascular bulb was significantly expanded. In recent years, the use of noninvasive examination methods to evaluate the efficacy of drugs has increasingly appeared in several skin diseases including psoriasis. After local or systemic drug treatment, the researchers evaluated the effect of the drug by evaluating the change in the diameter of the capillary globules in psoriasis or the number of capillary globules per unit field of view before and after the treatment [42].

This article compares the effectiveness and safety differences of defubao, calcipotriol, betamethasone, and placebo in the treatment of psoriasis vulgaris. Regardless of the treatment for 2 weeks, 4 weeks, or 8 weeks, compared with the calcipotriol group, the betamethasone group, or the placebo group, the efficacy of the defubao group was more significant. Topical calcipotriol and glucocorticoids are classic drugs for the treatment of psoriasis, but calcipotriol requires an alkaline environment to maintain stability, and betamethasone can be more effective in an acidic environment. The two are incompatible when mixed, and it is difficult to have both. For this reason, the researchers developed a unique and stable excipient to overcome the incompatibility barrier of the two, and finally form a formulation containing stable active ingredients. This not only gives play to the advantages of the two drugs, makes the treatment effect stronger, but also reduces the amount of topical glucocorticoids, thereby reducing the risk of hormone-related adverse reactions. This may be the reason why defubao is better than calcipotriol and betamethasone. In addition, meta-analysis found that after 4 weeks of treatment, the effective rate of the defubao group (1 times/day) was 1.72 times that of the calcipotriol group (2 times/day), which provides powerful clinical guidance for medication However, the low frequency of medication and the significant effect are more acceptable to patients. From the perspective of pharmacoeconomics, it can reduce costs and is more beneficial to patients. The study found that the incidence of adverse events in the calcipotriol group was significantly higher than that in the defubao group, while the difference in adverse events between the defubao group and the betamethasone group was not statistically significant. Moreover, it is mentioned in the literature that long-term use of defubao will not increase the risk of glucocorticoid-related adverse events compared with nonglucocorticoid topical drugs. This shows that the safety of defubao treatment is worthy of recognition.

This study found that within 8 weeks of medication, the curative effect increased with the time of medication, 8 weeks curative effect >4 weeks curative effect >2 weeks curative effect, and the difference between them was statistically significant. However, there is a lack of longer-term efficacy data. Therefore, clinical observations of a longer course of treatment are needed to determine the optimal medication time for treatment with defubao. This meta-analysis only compares the efficacy of defubao, calcipotriol and betamethasone, and does not compare with other topical drugs. This study included 11 studies, divided into multiple subgroups. When designing the study, the publication bias was tested by formulating detailed search strategies, searching literature from multiple libraries, formulating inclusion and exclusion criteria, sensitivity analysis, and making funnel charts. The number of studies included in some subgroups is small, which affects the results of heterogeneity testing. In addition, this study only retrieved Chinese and English articles, and did not retrieve research conclusions in other languages. All of the above may cause bias.

This study evaluated the efficacy of topical defubao on psoriasis vulgaris. Through clinical observation and dermoscopic observation, it was found that defubao had a significant effect on psoriasis skin lesions. The treated psoriasis plaques improved in all patients, and at the same time, the diameter of the capillary bulbs under dermoscopy gradually decreased.

However, there is a big difference between the speed and intensity of the improvement of the diameter of the capillary bulb under the dermoscopy and the clinical TLS score. After 4 weeks of treatment, the TLS score was 25/32 of "completely healed skin lesions" and "significantly improved", which reached almost 78%, while the spheroid diameter score was much lower than 10%. After 6 weeks of treatment, the target skin lesions of 26 patients had completely disappeared. Under dermoscopic imaging observations, only 5 patients returned to normal vascular diameters, while in other patients, even those whose clinical skin lesions disappeared completely, there were still significant telangiectasias.

There may be two mechanisms for the difference in results between the two. One possibility is that we have observed that the psoriasis skin lesions have subsided clinically, but there may still be slight keratinocyte proliferation or low-level growth factor secretion in the skin lesions. These small changes may continue to stimulate blood vessel formation. Another possibility is that the regulation speed of the keratinocyte proliferation cycle is faster than the speed of capillary remodeling or disappearance, the proliferation cycle of keratinocytes has returned to normal, but the expanded capillaries still exist. After treatment, some psoriasis skin lesions have dilated capillaries that can become smaller, but they cannot return to their normal size. As we all know, all clinical treatment observations are performed with standard doses within the safe range of each drug, so it cannot be excluded that increasing the dose of the drug can improve the microcirculation changes of the psoriasis skin lesions and make it possible for the dilated blood vessels to return to normal.

This article not only searched the English database, but also searched the Chinese database. The included studies are more comprehensive and involve more ethnic groups. The comparisons were made with PASI, IGA, and PGA as evaluation indicators, and the results obtained were more comprehensive and objective. The included articles are all high-quality randomized controlled trials, divided into multiple subgroups, and stratified analysis of the difference in efficacy of 2 weeks, 4 weeks, and 8 weeks of treatment.

5. Conclusion

This paper studies the classic algorithm Apriori in association rules, points out the insufficiency of this algorithm and the existing improved algorithms in dealing with unbalanced medical data sets, and then proposes a new scheme of mining association rules after balancing first to improve it. A new scheme for mining association rules that balances first and then mines is proposed. In the data balance part, aiming at the blind sampling problem of the traditional SMOTE algorithm, a balance improvement algorithm based on the combination of K-means and SMOTE is proposed. Defubao was safer than calcipotriol and placebo. The difference was statistically significant, but there was no statistical difference from betamethasone. Defubao is more advantageous than calcipotriol or betamethasone in the treatment of psoriasis vulgaris. High-quality systematic reviews provide an effective and objective choice for the choice of clinical external medications. Two randomized controlled trials were conducted to compare the efficacy of defubao in the treatment of psoriasis vulgaris in 2, 4, and 8 weeks. A fixed-effect model was used for data analysis, and the results showed that the efficacy after 4 weeks of use was better than that after 2 weeks of use [OR = 0.73, 95% CI (0.61, 0.86), $P < 0.01$]. The curative effect after 8 weeks of use was significantly better than that after 4 weeks of use [OR = 0.68, 95% CI (0.47, 0.98), $P < 0.01$]. The curative effect after 2 weeks of use was significantly weaker than that after 8 weeks of use [OR = 0.49, 95% CI (0.41, 0.58), $P < 0.01$]. After topical treatment of psoriasis skin lesions with defubao, the clinical observation showed that the skin lesions subsided and the diameter of the vascular bulb became smaller under dermatoscope, suggesting that defubao is effective in treating psoriasis vulgaris. There is a positive correlation between the target skin lesion score of a specific skin lesion in psoriasis and the diameter of the vascular bulb. As the treatment time increases, the correlation between the two increases. The reduction rate of the clinical target skin lesion score after treatment of psoriasis skin lesions is significantly greater than the reduction rate of vascular globule diameter. The microvascular healing of the skin lesions is later than the clinical cure. The observation of skin lesion vascular changes can be used to evaluate the condition of psoriasis and guide drug selection. However, this study only compared the efficacy of defubao, calcipotriol and betamethasone, and did not compare with other topical drugs. Further research is needed. In addition, there is also a lack of data to study the longer-term efficacy of defubao.

Retracted: The Exosomes Containing LINC00461 Originated from Multiple Myeloma Inhibit the Osteoblast Differentiation of Bone Mesenchymal Stem Cells via Sponging miR-324-3p

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 25 January 2023

Journal of Healthcare Engineering has retracted the article titled "The Exosomes Containing LINC00461 Originated from Multiple Myeloma Inhibit the Osteoblast Differentiation of Bone Mesenchymal Stem Cells via Sponging miR-324-3p" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Multiple myeloma is one of the hematological malignancies and inhibited osteoblast differentiation of bone marrow mesenchymal stem cells (BM-MSCs) which has been proved as a major complication of the patients with multiple myeloma. However, the pathomechanism of symptom remains unclear. Besides, several studies have indicated that LINC00461 plays an important role in the progression of multiple tumors. Hence, this study attempted to reveal the role of LINC00461 in the osteoblast differentiation of MSCs. In this study, the expression level of LINC00461 in the exosomes of multiple myeloma cells was measured, and BM-MSCs were cultured with the exosomes to observe the change of cellular phenotype. Moreover, downstream target of LINC00461 was searched and verified with dual-luciferase reporter assay, and the activation of the Wnt/β-catenin pathway was also observed by Western blot. The results showed that the isolated BMSCs exhibited special biomarkers of MSCs. LINC00461 was significantly upregulated in the exosomes originated multiple myeloma cells, and increased LINC00461 significantly impeded the osteoblast differentiation of MSCs. Moreover, LINC00461 could significantly suppress the activation of the Wnt/β-catenin pathway in MSCs. In conclusion, this study suggested that LINC00461 in exosomes of multiple myeloma could reduce the activity of the Wnt/β-catenin pathway to inhibit the osteoblast differentiation of BM-MSCs via targeting miR-324-3p.

1. Introduction

Multiple myeloma is the most dangerous malignant hematological diseases with high morbidity. Statically, more than 100000 people have been diagnosed with multiple myeloma, and approximately 2% cancer-related death in the world is caused by this disease each year [1, 2]. At present, even with the current therapeutic strategies, including radiotherapy, chemotherapy, and drug intervention, the prognosis of the patients with multiple myeloma remains unsatisfactory [3]. According the recent study, the 5-year survival rate of the multiple myeloma is less than 40% [4]. Therefore, investigating more effective intervention techniques for multiple myeloma are urgent.

The failure of osteoblast differentiation is a major reason causing the bone-related complications of the patients with multiple myeloma, such as osteoporosis and osteodynia, which is also related with the malignant progression and of multiple myeloma [5]. The osteoblast differentiation of human mesenchymal stromal cells (hMSCs) serves as an important role in maintaining the stability of skeletal internal environment [6]. Recently, increasing studies have indicated that multiple myeloma cells can remarkably inhibit the differentiation of MSCs, and the intervention on osteoblast differentiation of MSCs has also been confirmed as a promising strategy for alleviating the poor prognosis of the patients with multiple myeloma [7, 8]. Several studies have indicated the aberrant expression of some noncoding RNAs, such as long noncoding RNA (lncRNA) and micro-RNA (miRNA). lncRNA consist of almost 200 ribonucleic acids, and miRNA contains approximately 22 ribonucleic acids [8, 9]. lncRNA and miRNA involve the progression of cellular development and differentiation, and lager studies in recent ten years have illustrated that those aberrant noncoding RNAs involve the formation and development of multiple diseases [8, 10].

LINC00461 has been confirmed as a tumor promoter involving the malignant progressions of many cancer cells [11]. However, few studies have revealed the functions of LINC00461 in multiple myeloma. Thus, this study attempted to investigate the role of LINC00461 in multiple myeloma cells and then reveal the molecular mechanism of LINC00461 on osteoblast differentiation of BM-MSCs.

2. Materials and Methods

2.1. BM-MSCs Isolation and Osteogenic Differentiation. This study was approved by the hospital ethic committee, and the human-related experiments were performed following the Declaration of Helsinki protocol. The primary CD 138$^+$ BM cells were isolated from mononuclear cells of the patients and normal donors. The BM-MSCs obtained from the patients and health donors were cultured with Dulbecco's modified Eagle medium (DMEM) with 20% fetal bovine serum (FBS).

After cell attachment, BM-MSCs were cultured with the osteogenic induction medium (full culture medium containing 10^{-2} M β-sodium glycerophosphate, 50 mg/mL L-ascorbic acid, and 10^{-7} M dexamethasone) to induce the progression of osteoblast differentiation. After culture for 21 days, BM-MSCs were strained with alizarin red S (Beyotime), and then, the osteoblast mineralization in three random microscopic regions was imaged and quantified with Image-Pro Plus 6.0 software. Finally, the relative mineralized regions were calculated.

2.2. Cell Culture and Translation. Human normal plasma cell line (nPCs) and human myeloma cell lines including H929 and U266 cell lines purchased from Tongpai Biotechnology Co., Ltd (Shanghai, China), and the cells were cultured with the 1640 medium containing 10% FBS. All cells were cultured in an incubator with 5% CO_2 and 37°C. The cells subculture was performed when the confluence of the cells was at 90%.

The cell transfection was performed when cellular confluence was at 70%. In brief, 4 μg of DNA or 100 pmol RNA was incubated with 250 μl serum-free mediums for 5 min and then was mixed and incubated with isometric serum-free containing 10 μl Lipofectamine 2000 at 25°C for 20 min. Finally, the mixtures were added into each well, and the cells were further incubated for 24 hours.

2.3. Exosomes Isolation. U266 cells were cultured with FBS-free 1640 medium, and the culture medium was collected and centrifuged at 800 g for 5 min, followed by 3000 g for 10 min and 10000 g for 60. After that, total exosome isolation reagent (Cat#: 4478359; Thermo Fisher Scientific) was used for isolation of exosomes from the supernatants. Afterward, exosomes were harvested from the pellets and resuspended in PBS. Then, 0.22 μm pore size polyvinylidene difluoride (PVDF) membrane filters (Cat#: GVWP04700; Millipore Sigma) were used to filter any remaining cells or debris. The concentration of exosome was quantified through the BCA kit.

2.4. Cells Differentiation and Observation. The MSCs were cultured and induced with osteogenic differentiation medium, including alpha-minimum essential medium containing 10% FBS, 2 mM L-glutamine, 100 mM dexamethasone, 0.2 mM L-ascorbic acid, and 10 mM β-glycerophosphate. The osteogenic differentiation of BM-MSC cells were observed after alizarin red staining. In brief, the MSCs were fixed with 1% formaldehyde for 15 min after inducing with osteogenic differentiation medium, and then, the cells were rinsed with double distilled water. After that, the cells were stained with 2% alizarin red S solution (pH = 4.2, Shanghai Zeye Biotechnology Co., Ltd, Shanghai, China) for 10 min. Finally, after rinsing with double distilled water for three times, the cells were imaged and then quantified with decalcification solution at 405 nm.

2.5. qRT-PCR. For RNA extraction, the total RNAs of the cells were isolated with TRIzol reagent. The total RNAs were transcribed as cDNA by a PrimeScript® RT reagent Kit (Thermo Fisher, Massachusetts, the USA). The reaction system including primers, cDNA, dNTPs, and Taq DNA polymerase were prepared according the instruction of the qRT-PCR kit (Sigma-Aldrich, Missouri, USA). After that, qRT-PCR was performed according to the following program: denaturation at 95°C for 3 min, followed by amplification for 40 cycles at 95°C for 12 s and at 53°C for 40s and 70°C for 30s. The relative levels of miRNA or mRNA were calculated with the $2^{-(\Delta\Delta Ct)}$ method. The sequences of the primers are given in Table 1.

2.6. Western Blot. The total proteins of the cells were extracted with RIPA buffer on the ice, and then, the concentration of the extracts was measured with the BCA kit. The protein was added with loading buffer and then boiled at 100°C for 5 min. After that, 30 μL of the symbol was separated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and then, the proteins in the gels were transferred on the polyvinylidene difluoride membranes by the wet transfer method. The membranes were blocked with 5% fat-free milk at 4°C for 2 hours and then were incubated with the related primary antibodies at 4°C overnight. Subsequently, the membranes were washed with TBST for three times, and then, the membranes were incubated with the second antibodies. Finally, the expressions of the related proteins were observed with a chemiluminescence detection system.

2.7. Dual-Luciferase Reporter Gene Assay. The binding sites of LINC00461 and miR-324-3p were obtained from the NCBI database (https://www.ncbi.nlm.nih.gov/) and used for synthetizing the mutant sequences of LINC00461. The mutant type and wild type of LINC00461 were, respectively, cotransfected with miR-324-3p mimics or the miR-NC into

Table 1: Primer sequences of LINC00461, miR-324-3p, and U6.

Name of primer	Sequences
LINC00461-F	5′-GCGTGGACTACTCTGATG-3′
LINC00461-R	5′-CCAAGTGCTTACTGTCT-3′
miR-324-3p-F	5′-ATTAGCCCACTGCCCCAGGT-3′
miR-324-3p-R	5′-CCCACTGCCCCAGGTGCTGCTGG-3′
U6-F	5′-CTCGCTTCGGCAGCACA-3′
U6-R	5′-AACGCTTCACGAATTTGCGT-3′

HEK-293T for 48 hours. After that, a dual-luciferase reporter assay system was used to observe the luciferase activity of HEK-293T.

2.8. Data Analysis. The experiments in this study were performed 3 times, independently. The data analysis was performed with SPSS 20.0 with the chi-squared test or ANOVA with Tukey's post hoc-test and then were graphed with GraphPad Prism 8.0. Moreover, $P < 0.05$ meant that the statistically significance existed in two groups.

3. Results

3.1. LINC00461 Was Upregulated in the Exosomes of Multiple Myeloma Cells. To analyze the role of LINC00461 in multiple myeloma cells, the expression levels of LINC00461 in cells and pathological symbol were measured with qRT-PCR. The result showed that LINC00461 was significantly upregulated in multiple myeloma cells, compared with the normal cells (Figure 1(a), $P < 0.01$). Moreover, the increased LINC00461 was also found in the exosomes originated from multiple myeloma cells (Figure 1(b), $P < 0.01$). Those observations suggested that LINC00461 may involve the progression of multiple myeloma and was abundant in the exosomes of multiple myeloma cells.

3.2. The Exosomes of Multiple Myeloma Cells and LINC00461 Inhibited the Osteoblast Differentiation of MSCs. To investigate the mechanism of multiple myeloma cells on blocking the osteoblast differentiation of MSCs, the exosomes originated from MSCs were used to culture MSCs cells. The results showed that compared with normal MSCs, the expression levels of RUNX2 and ALP were downregulated, significantly (Figures 2(a)–2(c), $P < 0.01$). Moreover, compared with the cells transfected with negative control of LINC00461, MSCs transfected with LINC00461-expressed vectors exhibited poor progression of osteoblast differentiation (Figure 2(d), $P < 0.01$). Those observations suggested that LINC00461 was the main substance in the exosomes, which could restrain the osteoblast differentiation of MSCs.

3.3. MiR-324-3p Was a Downstream Target of LINC00461. To reveal the regulation mechanism of LINC00461 in development of multiple myeloma, the downstream targets of LINC00461 were searched and matched with TargetScan, an online database. The results showed that miR-324-3p was a potential downstream target of LINC00461 (Figure 3(a), $P < 0.01$). The binding effect of LINC00461 and miR-324-3p was verified by dual-luciferase reporter assay, and the results showed that LINC00461 could directly target 3′-UTR of miR-324-3p. Moreover, the expression level of mi-485-5p was also detected with qRT-PCR. The results showed that miR-324-3p was significantly downregulated in MSCs after transfecting with LINC00461-expressed vectors (Figure 3(b), $P < 0.05$). Those observations suggested that miR-324-3p was a downstream target of LINC00461, and miR-324-3p also involved in the progression of multiple myeloma.

3.4. MiR-324-3p Reversed the Effect of LINC00461 on the Osteoblast Differentiation of the MSCs. To further confirm whether miR-324-3p is involved in the regulation of LINC00461 on osteoblast differentiation of MSCs and proosteocytic cells, the miR-324-3p inhibitors and miR-324-3p mimics were cotransfected into cells. The results showed that compared with LINC00461-negative cells, the levels of RUNX2 and ALP in MSCs cotransfected with LINC00461-expressed vectors and miR-324-3p mimics were reversed, partly (Figures 4(a)–4(c), $P < 0.01$). Moreover, the inhibited osteoblast differentiation of MSCs treated with exosomes of multiple myeloma cells was remarkably reversed after transfecting with miR-324-3p mimics (Figure 4(d), $P < 0.01$). Those observations supported that LINC00461 could inhibit the osteoblast differentiation of MSCs and proosteocytic cells via targeting miR-324-3p.

3.5. LINC00461 Reduced the Activity of Wnt/β-Catenin Pathways via Targeting miR-324-3p. To delve the regulation mechanism of LINC00461 in the progression of multiple myeloma, the activities of the Wnt/β-catenin pathway were observed by Western blot. The study showed that Wnt and β-catenin were remarkably downregulated in MSCs after transfecting with LINC00461-expressed vectors (Figure 5, $P < 0.01$). Moreover, to further investigate whether miR-324-3p was involved in the regulation of miR-324-3p on multiple myeloma cells, the LINC00461-expressed vectors and miR-324-3p mimics were cotransfected into MSCs, and Western blot showed that the effect of LINC00461 on multiple myeloma could be reversed by increased miR-324-3p (Figure 5, $P < 0.01$). Those observations suggested that LINC00461 could inactivate the Wnt/β-catenin pathway via targeting miR-324-3p.

4. Discussion

Multiple myeloma is still a malignant plasma cell disorder, which seriously threatens the health of people, and several studies have indicated that the suppressed osteoblast differentiation of the MSCs induced by multiple myeloma can promote the progression of bone-related disease [12]. lncRNA and miRNA involve in the life activities of cells, and the aberrant expression of those noncoding RNA may serve as a key biomarker and drug target reference for clinical treatment [13]. This study proved the relationship of LINC00461 and multiple myeloma and the revealed the regulation mechanism of LINC00461 on osteoblast differentiation of the MSCs.

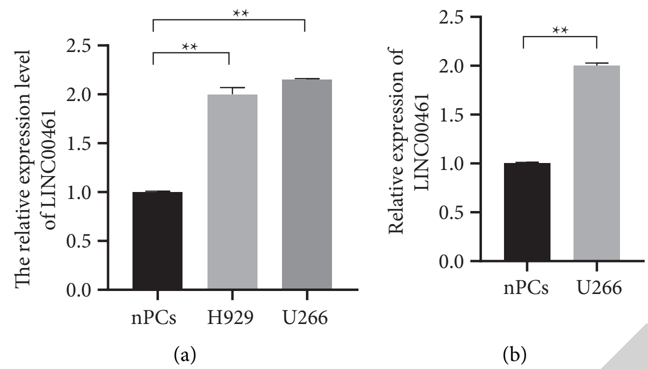

Figure 1: LINC00461 significantly upregulated in the multiple myeloma cells and their exosomes. (a) The relative expression level of LINC00461 in normal and multiple myeloma cell lines. (b) The relative expression level of LINC00461 in the exosomes originated from nPCs and U266.

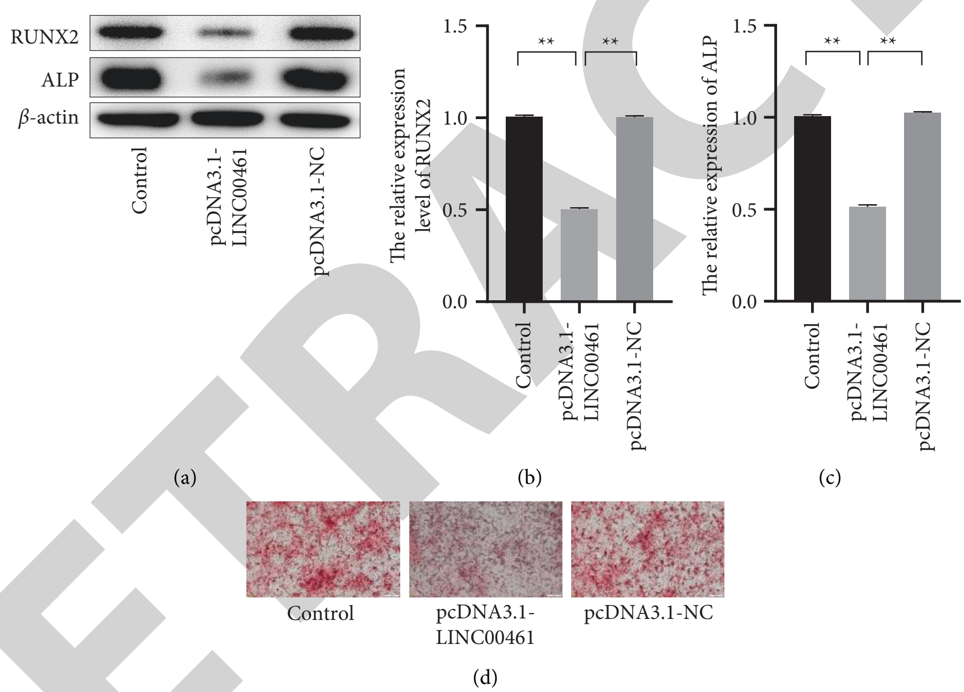

Figure 2: LINC00461 inhibits the osteoblast differentiation of MSCs. (a)–(c) The relative expression levels of RUNX2 and ALP measured with Western blot. (d) The osteoblast differentiation of MSCs observed by alizarin red staining.

lncRNA disorder is closely related with the progression of multiple myeloma [14]. In this study, it was found that LINC00461 was significantly upregulated in the multiple myeloma cells and their exosomes. Several studies have indicated that LINC0046 plays a tumor promoter role in some cancer cells and involves the multiple malignant behaviors of the tumor cell, including drug resistance, proliferation, and migration [15]. Qu et al. confirmed that LINC00461 is extremely upregulated in the rectal cancer cells and could decrease the sensitivity of tumor cells on cisplatin via mediating the miR-593-5p/CCND1 pathway [11]. The failure of osteoblast differentiation induced by multiple myeloma has been identified as a major reason leading the poor prognosis of the patients [16]. Increased RUNX2 and ALP have been confirmed as the biomarker events for the differentiation of BMSCs [17]. This study also found that the exosomes originated from multiple myeloma cells or upregulation of LINC00461 could obviously inhibit expression of RUNX2 and ALP. Exosomes, the nanometre-sized membranous vesicles with a diameter of about 30–100 nm, are secreted through the endocytic pathway [18]. The exosomes containing some cancerogenic factors can be released by tumor cells and then may promote angiogenesis and stromal remodelling. Liu et al. indicated that the exosomes derived from multiple myeloma could effectively block the differentiation of BMSCs [19]. Therefore, those study suggested that LINC00461 silence induced the differentiation of osteoblast.

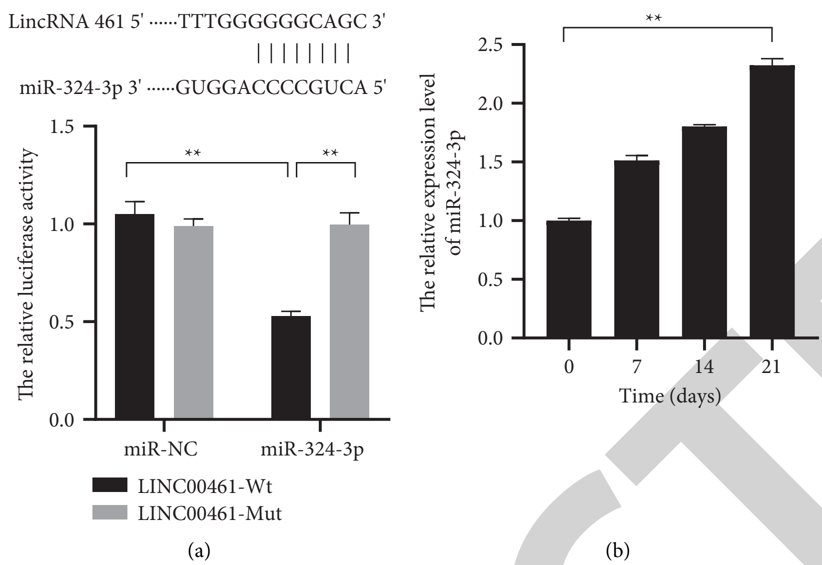

FIGURE 3: MiR-324-3p was a target of LINC00461, and miR-324-3p was related with osteoblast differentiation of MSCs. (a) The binding effect of LINC00461 and miR-324-3p observed by dual-luciferase assay. (b) Increased miR-324-3p observed in MSCs during the osteoblast differentiation.

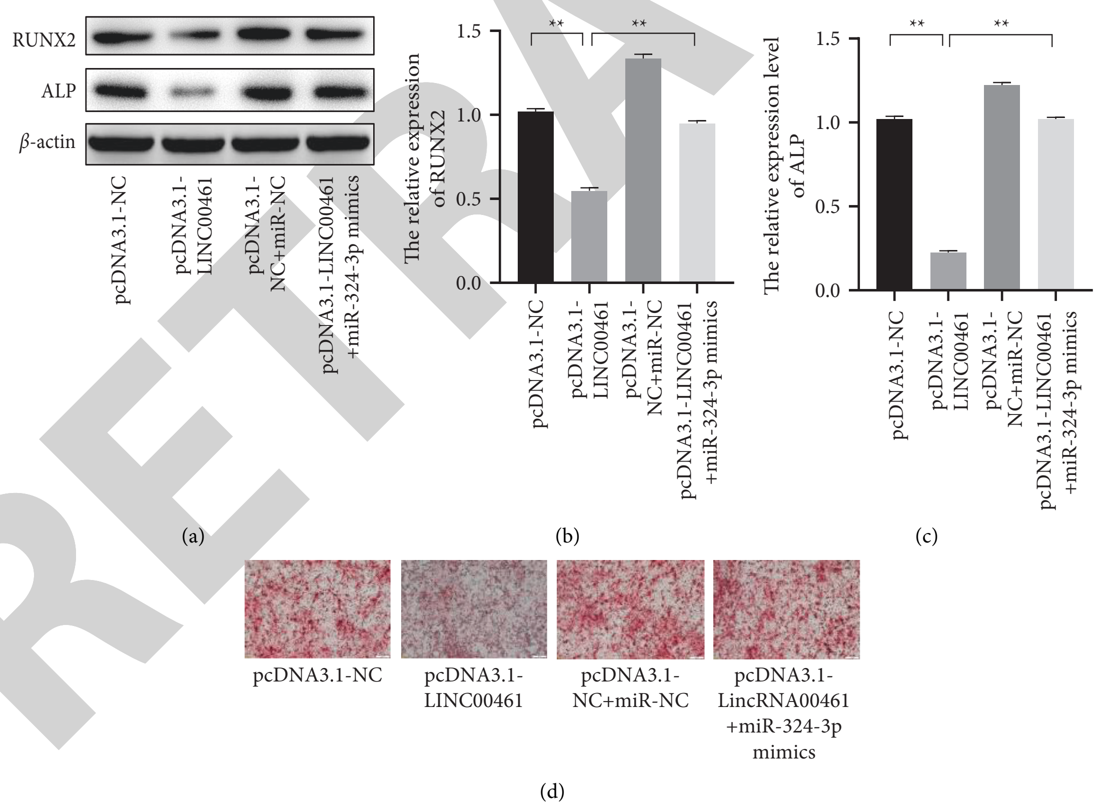

FIGURE 4: LINC00461 inhibits the osteoblast differentiation of MSCs via targeting miR-324-3p. (a)–(c) The relative expression levels of RUNX2 and ALP measured with Western blot. (d) The osteoblast differentiation of MSCs observed by alizarin red staining.

lncRNAs are characterized by regulating the cellular activities via serving as a molecular sponge to specially combine with the related mRNAs and miRNAs. Dong et al. indicated that LINC00461 promotes the proliferation and migration via regulating miR-30a-5p/integrin β3 axis [20]. The studies have indicated that miR-324-3p serves as a tumor inhibitor to impede the progression of some cancer cells. Zhao et al. observed that miR-324-3p was remarkably downregulated in thyroid cancer, and increased miR-324-3p could effectively block the

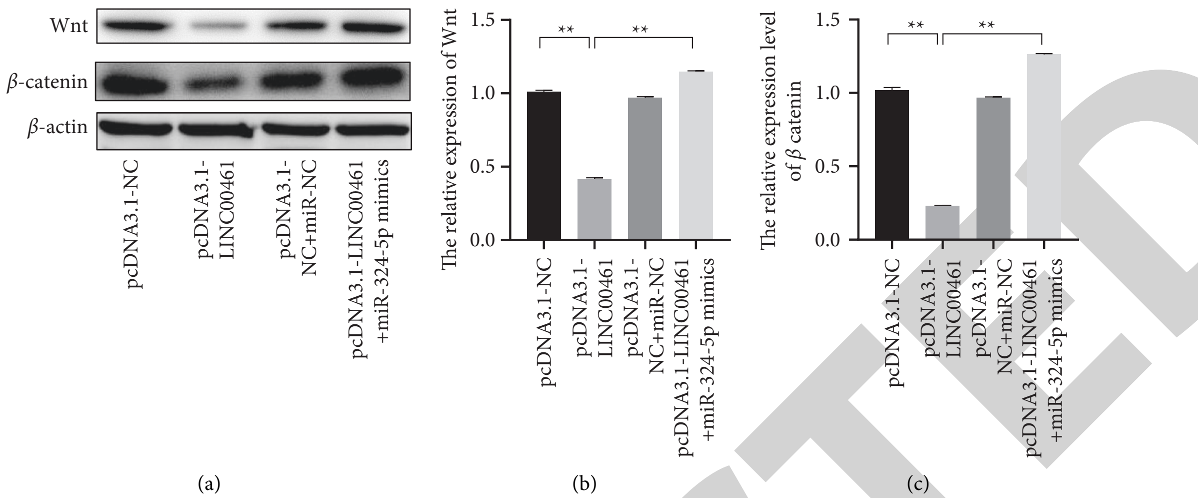

Figure 5: LINC00461 inhibits Wnt/β-catenin via targeting miR-324-3p. (a)–(c) The expression levels of Wnt and β-catenin measured by Western blot.

progression of hemangioma via targeting PDRG1 [21]. In this study, it was found that LINC00461 could directly target the 3′-UTR of miR-324-3p. It was also found that miR-324-5p was downregulated in the MSCs cells transfected with LINC00461-expressed vectors, and miR-324-3p could partly reverse the effect of LINC00461 on the osteoblast differentiation of MSCs. Kocijan et al. [22] confirmed that the expression of miR-324-3p was correlated with formation and development of the patients with postmenopausal osteoporosis. Moreover, the study also confirmed that miR-324-3p upregulation could partly reverse the effect of LINC00461 on osteoblast differentiation of MSCs. Those proofs suggested that LINC00461 in the exosomes originated from multiple myeloma cells could impede the osteoblast differentiation of MSCs via targeting miR-324-5p.

Cell differentiation involves the changes of multiple signaling pathways, and increasing studies have indicated that the activation of the Wnt/β-catenin pathway is responsible for osteoblast differentiation [23]. The study has indicated that the antagonists produced and secreted by multiple myeloma cells may block the progression of osteoblast differentiation via inactivating the Wnt/β-catenin pathway in MSCs [24]. In this study, it was found that the expression levels of Wnt and β-catenin in MSCs were obviously downregulated after treating with the exosomes of multiple myeloma cells and LINC00461-expressed vectors, suggesting that LINC00461 regulates the osteoblast differentiation of MSCs via inactivating the Wnt/β-catenin pathway. Moreover, it was also observed that increased miR-324-3pcould partly reverse the inactivated Wnt/β-catenin pathway [25]. Razny et al. indicated that miR-324-3p was significantly downregulated in the progression of osteoblast differentiation, which may be related with the activation of the Wnt/β-catenin pathway [26]. Thus, those proofs suggested that LINC00461 could inactivate the Wnt/β-catenin pathway to suppress the osteoblast differentiation of MSCs via targeting miR-324-3p.

Retracted: Targeting AraC-Resistant Acute Myeloid Leukemia by Dual Inhibition of CDK9 and Bcl-2: A Systematic Review and Meta-Analysis

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

In addition, our investigation has also shown that one or more of the following human-subject reporting requirements has not been met in this article: ethical approval by an Institutional Review Board (IRB) committee or equivalent, patient/participant consent to participate, and/or agreement to publish patient/participant details (where relevant).

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

Purpose. This study aims to determine the influence of targeting araC-resistant acute myeloid leukemia by dual inhibition cyclin-dependent protein kinase (CDK9) and B-cell lymphoma-2 (Bcl-2). *Method.* The c-Myc inhibitor 10058-F4 and the CDK9 inhibitor AZD4573 were used to determine the cell cycle arrest and apoptosis. *Results.* 10058-F4 reduces c-Myc protein levels and suppresses HepG2 cell proliferation, possibly by upregulating cyclin-dependent kinase (CDK) inhibitors, p21WAF1, and reducing intracellular alpha-fetal protein (AFP) levels. *Conclusion.* The combination of AZD4573 and 10058-F4 has a synergistic anti-araC-resistant AML activity, providing a solid database for the aforementioned scientific hypothesis.

1. Introduction

Hematopoietic stem cells can self-renew and differentiate, and their control regulates their proliferation speed [1, 2]. When hematopoietic stem cells show malignant proliferation, leukemic cells are characterized by abnormal proliferation, impaired differentiation, and blocked apoptosis. The proliferation and accumulation of leukemic cells are substantially held in the bone marrow and other hematopoietic tissues and proceed to infiltration in other body tissues and organs, thus affecting the normal physiological function of the human body. Common clinical symptoms of leukemia are various anemic blood pictures, uncertain bleeding, common infections and body fever, and enlargement of vital body organs, including liver, spleen, lymph adenomegaly, and skeletal pain [3–6]. Acute myeloid leukemia (AML) is a cancer of blood cell myeloid cell lines defined by the rapid growth of abnormal leukocytes, accumulating in the patient's bone marrow and interfering with the normal blood cells production, and its incidence increases with age [7–10]. In our country, 3-4 people develop leukemia per 100,000 people. Leukemia ranks sixth among female malignancies, seventh among men, and first among children and adults under 35. Therefore, it is urgent to develop more effective treatment strategies to enhance the therapeutic effect of leukemia and reduce mortality. Currently, the primary treatment of AML is "7 + 3" therapy combined with HSCT [11]. Although most patients can achieve complete remission after chemotherapy, most of these patients will relapse with complications. In addition, approximately two-thirds of older patients (over 60 years old) with AML are refractory to standard chemotherapy and have a poor prognosis [12]. Currently, the five-year overall survival in adult AML is only about 25% and about 65% in pediatric patients. Therefore, it is of great scientific and clinical importance to find new AML therapies, develop new therapeutic strategies to prolong the survival rate of AML patients, and ultimately improve their cure rates.

2. Method

The Bcl-2 protein family comprises antiapoptotic proteins (Bcl-2, Bcl-xL, Mcl-1, Bcl-w etc.) and proapoptotic proteins (Bim, Bak, Bad, Bax, etc.), and the two classes of protein ratios determine cell survival or cell death [13, 14]. The aberrant expression of antiapoptotic Bcl-2 family proteins is firmly linked with chemoresistance and poor prognosis [15]. 10058-F4 is a c-Myc inhibitor that explicitly inhibits c-Myc-

Max interactions and prevents the transcriptional activation of c-Myc target gene expression [16–19]. 10058-F4 can promote caspase-3-dependent apoptosis and regulate autophagy. 10058-F4 inhibited leukemic cell growth and inhibited Myc and Max dimerization. Cell cycle arrest and apoptosis were induced by 10058-F4 in AML cells. AML cells stalled by 10058-F4 in the cell cycle phase of G0/G1 downregulated the expression of c-Myc and upregulation of CDK inhibitors, including p21 and p27 [20].

3. Results

Meanwhile, the apoptosis was induced by 10,058-F4 performing mitochondrial pathway activation, and downregulation of Bcl-2, upregulation of Bax, cytochrome C release within the cytosol, and cleavage of caspase 3, 7, and 9 were observed. In addition, bone marrow cell differentiation is also induced by10058-F4, perhaps by activating multiple transcription factors. Similarly, 10058-F4 acts on primary AML cells to cause apoptosis and differentiation. 10058-F4 reduces c-Myc protein levels and suppresses HepG2 cell proliferation, possibly by upregulating cyclin-dependent kinase (CDK) inhibitors, p21WAF1, and reducing intracellular-alpha-fetal protein (AFP) levels [21]. The human telomerase reverse transcriptase (hTERT) downregulated at the transcriptional level by the treatment of 10058-F4. Besides inhibiting He 2 cell proliferation, HepG8-F4 is used to enhancing its sensitivity and responsiveness against conventional chemotherapeutics, including doxorubicin, 5-fluorouracil (5-FU), and cisplatin. It has also been shown that Mcl-1 causes the tolerance of tumor stem cells to chemotherapeutic agents by enhancing mitochondrial oxidative phosphorylation [22].

Moreover, Bcl-2 was also overexpressed in human AML stem cells, and inhibition of Bcl-2 selectively eradicated quiescent AML stem cells by inhibiting mitochondrial oxidative phosphorylation [23–25]. The above studies suggest that targeting both Bcl-2 and Mcl-1 induces apoptosis through the mitochondrial pathway. On the other hand, it inhibits mitochondrial oxidative phosphorylation while killing AML primary cells and stem cells [26]. Our previous work demonstrated that the FLT3 inhibitors midostaurin and gilteritinib can downregulate Mcl-1 and synergy with anti-F LT 3 mutation-positive AML activity with ABT-199 [27]. Still, studies of their combined application on AML stem cell killing activity are lacking.

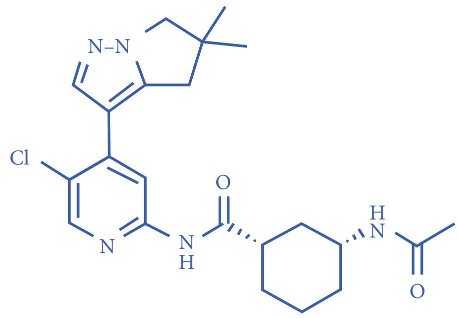
CDK is a cyclin-dependent kinase that functions to activate the phosphorylation of downstream cell cycle-associated proteins while regulating its activity itself, influenced by phosphorylation and nonphosphorylation [28]. Its activity control points are mainly summarized as follows: (1) the concentration of cyclin because CDK needs to bind to some cyclins to produce activity; (2) CDK phosphorylation sites; (3) the regulation of CDK repressors, such as CDK repressor CKI; and (4) the control of protein catalytic factors.

AZD4573 is a potent CDK9 inhibitor with high selectivity. Scheme 1

In cells, the short-term treatment of AZD4573 can decrease intracellular pSer2-RNAPII (concentration and time correlation), with the activation of caspase 3 and apoptosis in most hematologic blood cancer cell lines. In various human blood cancer cells, AZD4573 induced rapid caspase activation (6 h) and lost survival viability (24 h), with little effect on solid tumors. Cyclin-dependent kinases (CDK) are a wide range of key proteins that perform cellular activities and function, including cell division and transcription. Dysregulation is identified as an important tumorigenesis driver. Additionally, the role of CDK in cancer and its involvement in the transcriptional process has been demonstrated recently. In most cancers, CDKs openly used as vital transcriptional regulators (e.g., CDK9) for consistent production of short-lived gene products that support cell survival [29]. Therefore, CDK9 pathway dysregulation is seen in various malignancies, making it a key anticancer target [30]. This approach has been used to initiate the discovery of CDK9 inhibitors by conducting human clinical trials [31].

Protein kinases are an important name in the CDK9 inhibitors list. These are the large family of enzymes and are responsible for the regulation of most eukaryotic cellular functioning and regulate cell signaling pathways by protein phosphorylation. This process is responsible for enzymes activation or inhibition, increasing protein-protein interactions, alteration of cellular localization, or generation of protein recruitment sites. Regulation of protein kinases itself is generated by various transcriptional and posttranslational modifications. The overall outcome of the whole process is the regulation of cellular functioning, including proliferation, apoptosis, and differentiation. The encoding of the human genome includes more than 500 genes of protein kinase. Because of its key function, dysregulation of protein kinase due to gene mutations or lack of negative regulators is associated with many pathological diseases (e.g., cancer and inflammatory diseases). A protein-dependent kinase (CDK) is a serine (Ser)/threonine (Thr) protein kinase activated by the regulatory cyclin. The encoding of 20 CDK (numbers 1–20) of the human genome belongs to the CDK and CDK-like clades of the CMGC. CMGC is a subfamily of human cell kinases, such as cyclin-dependent, glycogen synthase, mitogen-activated, and CDC-like kinases.

CDK and its cyclin partners perform their particular roles in many cellular functioning, including cell division and cell transcription, responding to intracellular and extracellular cell signaling. The structure of CDK protein is a double-leaf, and the active site is sandwiched between the (amino) N-terminal lobe, particularly comprising sheet B and the (carboxyl) C-terminal lobe of the helix. The CDK regulation is initiated by cyclin subunits binding, which is itself regulated by formation and degradation, and the phosphorylation of the conserved residues in the T-and glycine (G) rich loop structures of CDK. Due to the evolutionary connection and key functional roles, CDKs can be categorized into two major groups: CDKs that are responsible for the cell cycle regulation, including CDKs 1–7 and 14–18, and CDKs for transcription regulation, including CDKs 7–13 and 18–20. Due to these central regulatory activities, dysregulation of CDK is closely linked to human



Scheme 1: Chemical structure of AZD4573. AZD4573 is a novel and selective inhibitor of CDK9, exhibiting rapid cell-death induction in most hematologic blood cancer cell lines.

cancers or malignancies. This is especially true of CDK9, where CDK9 is a key transcriptional regulator in which cancer cells openly utilize to continuously produce short-lived proteins that sustain survival. During transcription elongation, a component called P-TEFb is a major target of DRB. A protein obtained from the human immunodeficiency virus 1 (HIV1), called the transcriptional transactivator (TAT), performs a vital role in HIV1 viral transcription by creating a complex containing P-TEF.

Based on the above literature analysis and preliminary research basis, we propose the scientific hypothesis of this project (Figure 1). In araC-resistant AML, applying AZD4573 and 10058F4 to downregulate c-Myc and Mcl-1 to inhibit Bcl-2 simultaneously and, on the other hand, to induce apoptosis by the activation of the endogenous apoptotic pathway. We demonstrated in our previous work that the combination of AZD4573 and 10058-F4 has a synergistic anti-araC-resistant AML activity, providing a solid database for the aforementioned scientific hypothesis.

For a comprehensive validation of the above hypothesis, this study will focus on addressing three key scientific issues: ① in araC-resistant AML, AZD4573 downregulated c-Myc and Mcl-1. Thus the molecular mechanism of inducing apoptosis in AML cells in coordination with 10058-F4;② effects of AZD4573 and 10058-F4 on the energy metabolism of Arac-resistant AML cells further illustrate the molecular mechanism of the AZD4573 and 10058-F4 synergy against araC-resistant AML;③ the in vivo activity of the combination of AZD4573 and 10058-F4 and the effects on araC-resistant AML cells.

4. Discussion

Cells in the human blood are all derived from pluripotent HSCs in the bone marrow. Pluripotent hematopoietic SCs differentiate into myeloid progenitors, and after a series of differentiation maturation processes, myeloid progenitors eventually become erythrocytes, granulocytes, monocytes, and platelets, while lymphoid progenitors differentiate into lymphocytes and plasma cells [32–35]. Each blood cell has important and unique physiological functions, and blood cell abnormalities can lead to the occurrence of disease. Leukemia is triggered if blood cell precursor cells arrest and proliferate malignantly. Leukemic cells are able to inhibit the generation of normal blood cells and infiltrate other

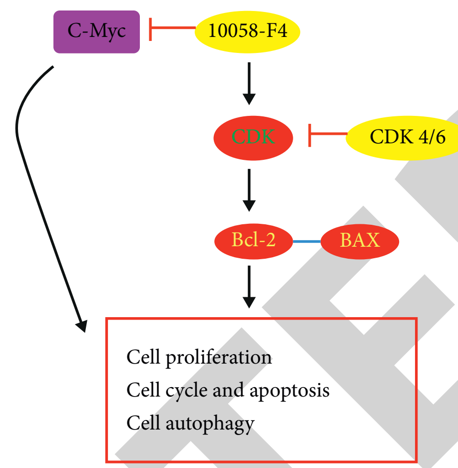


Figure 1: In araC-resistant AML, we apply AZD4573 and 10058F4 to downregulate c-Myc to inhibit Bcl-2 and affect the cell proliferation, cell cycle and apoptosis, and cell autophagy.

healthy tissues and organs, causing hematopoietic dysfunction. The clinical manifestations of patients with leukemia are usually anemia, easy fatigue, fever, bleeding points, pain in limbs, infection, hepatic manifestations, and splenomegaly. The exact etiology of leukemia is currently unclear, with smoking, ionizing radiation, exposure to certain chemical reagents, viruses, and genetic factors being possible triggers of leukemia. About 75,000 new leukemia patients occur in China every year, while 53,000 individuals die of leukemia every year. In the past two years, the incidence of leukemia in China has been on the rise.

Leukemia can be categorized into acute leukemia and chronic leukemia according to the fast and slow course of the disease. Abnormal proliferating cells of acute leukemia are not mature and make rapid clinical progress; blood cells with abnormal proliferation of chronic leukemia develop more mature but do not have the anti-infection ability of normal leukocytes, and the clinical progress is slow. Leukemia can be divided into myeloid leukemia and lymphoid leukemia according to the origin of the onset cell. By combining the incidence rate with the cellular source, leukemia can be divided into four types, as shown in Table 1:

Acute myeloid leukemia (AML) is a highly malignant hematological disease with abnormal proliferation, blocked differentiation, and high cell heterogeneity. Routine treatment of AML is divided into two stages. The first stage is the induced remission phase, and the primary aim is to reduce the number of AML main cells to achieve complete remission, where AML cells are not detectable in both the bone marrow and peripheral blood, and healthy blood cells return to normal levels. Commonly used drugs are cytarabine (cytarabine, araC) and anthracyclines such as daunorubicin (daunorubicin, DNR), idarubicin, and mitoxantrone. The conventional chemotherapy regimen was a 7-day continuous intravenous infusion of standard-dose cytarabine (100–200 mg/m2/d) plus daunorubicin continuous intravenous infusion (60–90 mg/m 2/d), also known as "7 + 3" therapy.

The second stage of AML treatment is the postremission treatment. A small number of undetectable AML cells will

Table 1: The classification of leukemia.

Number	Disease	Popular
1	Acute lymphoid leukemia	Children aged 3–7 years; is relatively rare in adults
2	Acute myeloid leukemia	67–70 years old, especially the elderly over 65; is rare before 45 years old
3	Chronic lymphoid leukemia	Frequently occurring in adults, occasionally in adolescents; it is extremely rare in children
4	Chronic myeloid leukemia	Extremely rare among children with a median age of onset over 70 years

still exist in vivo after complete remission. Without further treatment, AML will relapse within weeks to months. There are two strategies after remission: the first is consolidation therapy, which refers to the same or higher intensity of chemotherapy with chemotherapeutic drugs without cross-resistance as the chemotherapeutic drugs used for inducing remission therapy. Suitable for AML patients under 60 years of age, who are highly tolerated and can continue to receive 2–4 cycles of araC after remission. The other is to find a suitable bone marrow donor for bone marrow transplantation. Patients need a feasibility and risk assessment to decide on a bone marrow transplant. Bone marrow transplant patients need to remove AML cells before bone marrow transplantation, and not all patients can withstand this treatment, and there is a certain risk of surgical failure. Patients with AML may still relapse even with the most effective after remission therapy. Although most patients can achieve complete remission after chemotherapy, most of these patients will relapse with complications. In addition, approximately two-thirds of older patients (over 60 years old) with AML are refractory to standard chemotherapy and have a poor prognosis. Currently, the five-year overall survival in adult AML is only about 25% and about 65% in pediatric patients. Therefore, it is of great scientific and clinical importance to find new AML therapies, develop new therapeutic strategies to prolong survival in AML patients, and ultimately improve their cure rates.

Acute myeloid leukemia (AML) is initiated by the abnormal myeloblasts accumulation, primarily in the bone marrow, which leads to bone marrow failure and finally causes death [36–39]. Involvement of peripheral blood is frequent in AML, while infiltration of vital body organs (most ominous, brain and/or lungs) is quite rare; the most common sign in AML patients is high blood cell count (e. g., >50,000/L). Granulocytic sarcoma (GS), also referred to as AML, that confined to bone marrow or blood does not progress to organs. GC usually developed involvement of bone marrow within 1 year time and is generally treated as myeloid-involved acute myeloid leukemia. The 2016 World Health Organization (WHO) criteria for acute myeloid leukemia define at least 20 percent of bone marrow (or blood) cells (MFCs). The exception to the 220% standard was CBF acute myeloid leukemia including cytogenetic abnormalities (t [8; 21], or inv [16], or t [16; 16]), NPM1 mutant AML, or acute promyelocyte leukemia; in each case, the diagnosis of acute myeloid leukemia was not dependent of % of blast seen. Occasionally myeloid blasts may also have T-cell or B-cell markers for the identification or may have distinct myeloid and lymphoid populations [40–43]. These AML cases are identified as "mixed phenotypic acute leukemia." It is still unclear whether it requires simultaneous treatment as acute myeloid leukemia, lymphoblastic leukemia, or both. Treatment dependence is based on the extent to which the myeloid or lymphatic component is dominant. Cases with fibroblasts of over 20% but lack markers are called acute undifferentiated leukemia, often treated as acute myeloid leukemia.

The prognosis of AML patients ranges from the death of treatment to within days, i.e., treatment-related mortality to cure it, possibly. The main reason for patients is treatment resistance and often presents as relapse after remission rather than a TRM with decreasing incidence even in older patients. Knowledge of the various premutational states of gene therapy improves our ability to assign initial treatments. More importantly, whether ostensibly patients have measurable residual disease in time in remission should affect subsequent management. The US Food and Drug Administration has approved several new drugs, discussing their role in treatment.

Based on data that indicate predictive covariates, the following factors are more important than the difference in acute myeloid leukemia—MDS disease, and some centers treated patients with blast number >10% as acute myeloid leukemia, even if they were treated by the WHO as a blast number of more than 2. From a biological perspective, the pattern of acute myeloid leukemia mutations occurring after previous hematological disorders (e. g., myeloid marrow dysplasia) is generally more similar to that found in MDS than primary (new) acute myeloid leukemia.

As research advances, many new therapies have been constantly proposed and applied to clinical experiments, such as small-molecule inhibitor-targeted therapies, immunotherapy. Among them, small-molecule inhibitor-targeted treatment is even more popular and highly concerned. Small molecule inhibitor-targeted treatment mainly suppresses cell growth, proliferation, and survival by targeting relevant cell signaling pathways (for example, kinase pathway, apoptosis pathway, DNA damage repair-related pathway) to achieve the effect of treating AML [44–47]. At present, the research of such new therapies has also achieved gratifying results. In recent years, the FDA has successively approved multiple small-molecule targeting inhibitors to treat AML, such as the Bcl-2-selective inhibitor venetoclax, the FLT-3 inhibitor midostaurin and gilteritinib [48].

Traditionally, new drugs have been tested in newly diagnosed cases of acute myeloid leukemia with relapse or at risk of disadvantage [12, 49–51]. One possibility is on the MRD setting. This practice may tend to abandon these drugs, but in less advanced diseases, they may act better. However, the registration of many new drug trials is limited to morphological relapse (>5% fibroblasts) [52]. The response rate to new therapeutics may be higher if tested in MRD cases, and MRD is the only evidence of disease. It is the rationale for relapse that the predictive value of positive MRD trials is very high, particularly in individuals taking pretreatment of ELN 2017 year confrontation, the interval between MRD emergence and morphological relapse is usually short (<1 year), and the side effects of "targeted" therapy are generally limited, thus creating a favorable risk ratio when used for the MRD treatment. It is most likely that more targeted therapies for MRD will follow in the next few years. In recent years, it has also been seen to detect recurrence by bone marrow morphological evaluation of technical partial replacement criteria based on MRD; it seems that when MFC results are negative, the morphology of the cell will inevitably present with <5% of fibroblasts, which is below the morphological recurrence threshold. When the identical drug treatment is used to treat MRD relapse only and morphological degeneration, AML patients who only treat MRD will compare outcomes. It will also allow testing the very plausible yet unproven hypothesis that reduced MRD will generate better results. The next step will allow the piloting of new therapeutics with MRD negative cases but having a high risk of recurrence based on the pretreatment markers.

Finally, we may have overestimated our knowledge of targeted therapeutic targets. We note that the above beneficial effects of sorafenib, commonly considered as FLT 3 inhibitors, and, by adding to 7 + 3, appear to be the same in the population, regardless of whether they have FLT3 ITD or not. Therefore, there may have potential value once the outcome of targeted therapy. However, the limit is that there are not enough solid data that support the opinion, which suggest us to conduct further experiments to confirm this.

Retracted: Analysis on Value of Applying Serum miR-144 and miR-221 Levels in Diagnosing Atherosclerosis

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 30 January 2023

Journal of Healthcare Engineering has retracted the article titled "Analysis on Value of Applying Serum miR-144 and miR-221 Levels in Diagnosing Atherosclerosis" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Objective. To explore the value of serum miR-144 and miR-221 in diagnosing atherosclerosis (AS). *Methods*. The clinical data of 52 AS patients treated in the department of cardiovascular medicine of our hospital from August 2019 to August 2020 were retrospectively analyzed, and 53 healthy persons were selected from the physical examination center at the same period as the control group. By measuring the indicators including the serum vascular endothelial growth factor (VEGF), superoxide dismutase (SOD), miR-144, and miR-221 in patients of both groups, their value of diagnosing AS was analyzed. *Results*. Compared with the control group, the AS group obtained significantly higher serum miR-221 and miR-144 expression levels ($P < 0.001$), significantly higher mean serum homocysteine (Hcy) level value ($P < 0.001$), lower mean serum SOD level ($P < 0.001$), and significantly higher level values of serum VEGF, nuclear factor-kappaB (NF-kB), and transforming growth factor-β (TGF-β) ($P < 0.001$), and the area under ROC curve, sensitivity, and specificity of combining miR-221 with miR-144 were significantly higher than those of single diagnosis. *Conclusion*. Serum miR-221 and miR-144 expression levels are increased in AS patients, and combining the two indicators in diagnosis is more accurate and can provide an accurate basis for diagnosis and condition assessment of AS.

1. Introduction

Atherosclerosis (AS) is a slowly progressive cerebrovascular disease. Research and investigations have revealed that [1, 2] approximately 20 million people worldwide die from the disease each year, which is an important cause of diseases including angina, coronary heart disease, and sudden cardiac death, as well as a leading cause of death in the elderly population. Although the fatality rate of AS shows a decreasing trend with modern medical treatment technology advancing day by day, its incidence rate is still increasing. Traditionally, AS is assessed mainly by imaging methods such as ultrasound vascular examination or X-ray, but quantitative indexes of assessment are lacking. According to the research finding [3], the incidence of AS is closely related to vascular inflammation, cell proliferation and apoptosis, and lipid metabolism, which is a complex and slow process. Recently, with the intensive research on exosomes, it has been found that exosomes can act as an important medium of intercellular communication and plays a major role in the occurrence and progression of AS. Micro-RNAs (miRNAs), stably present in various body fluids as the biomarker for various types of diseases, involve in the formation of AS as the key signaling and molecular regulator (Figure 1) [4–6]. miR-144 is structurally highly conserved and involves in the occurrence and progression of cancer, and cardiovascular diseases. Foreign scholars have confirmed [7] the down-regulation of miR-144 in plasma of patients with medullary carcinoma of thyroid, which in turn led to the development and progression of thyroid cancer; other studies have proved that [8] miR-144 played the role of cancer suppressor gene in cervical cancer, which provided a new direction in the later diagnosis and treatment for cardiovascular diseases. It has been proved that miR-211 is expressed abnormally in patients with epithelial ovarian cancer and closely related to the processes such as incidence, invasion, and metastasis of such disease [9, 10]. Currently, the diagnostic efficacy of miR-144 and miR-221 in AS is rarely studied, and therefore, it was

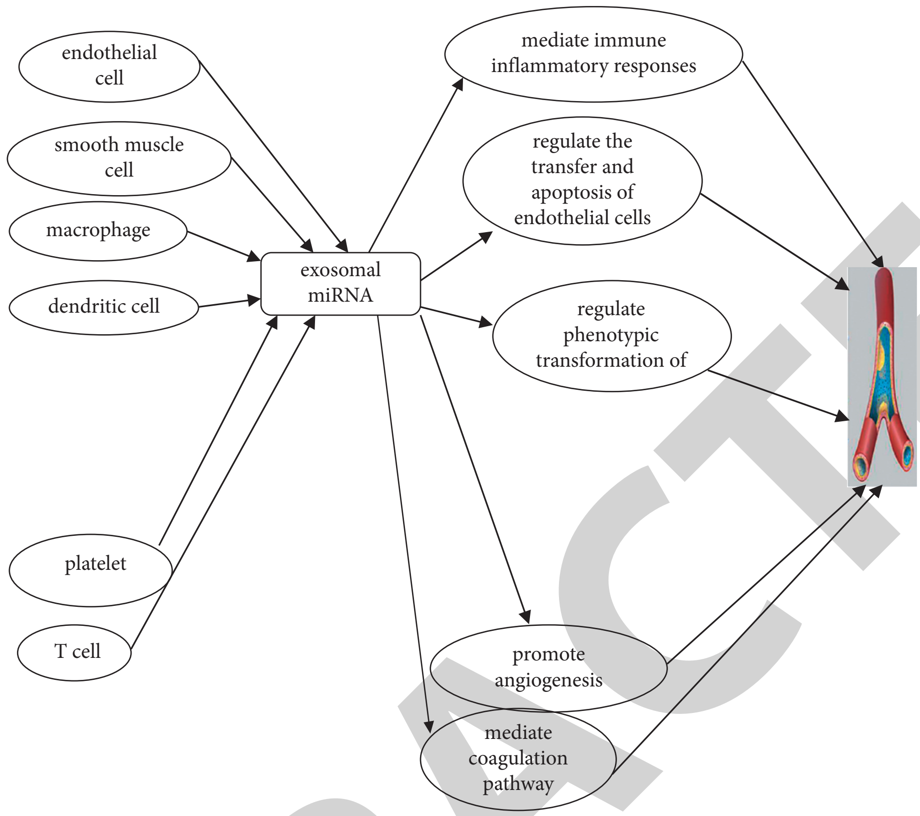

Figure 1: Effect of exosomal miRNA on AS progression.

analyzed herein to prevent and treat relevant cardiovascular diseases by target regulating miR-144 and miR-221 expression levels.

2. Data and Methods

2.1. General Information. The study was reviewed and approved by the hospital ethics committee. The clinical data of 52 AS patients treated in the department of cardiovascular medicine of our hospital (08.2019–08.2019) were selected for the retrospective study, and 52 healthy persons were screened from the physical examination center at the same period as the control group. Patients in the AS group met the diagnosis criteria of the disease, namely, abnormal blood lipid indexes and vascular stenosis lesions found in arteriography, and their clinical manifestations included angina, arrhythmia, headache, and fainting. Those with heart failure, angina, heart disease, hypertension, kidney function obstacle, and other cardiovascular diseases were excluded. Under the condition that all subjects signed the informed consent and agreed to join the study, the retrospective analysis and physical examination were conducted to all enrolled subjects, and their gender, age, BMI values, and other indicators were recorded.

2.2. Index Detection

2.2.1. Detection of miR-221 and miR-144 Level Values. The subjects fasted for more than 10 h. Before blood drawing, relevant instruments were prepared as required. The patients took the sitting position, with an arm extended straight on the table and the tourniquet tied at the upper arm; they were instructed to repeatedly make a fist to fill the vein, a cotton stick moistened with iodophor was used to make a ring disinfection treatment at the site for venipuncture with a syringe to collect 10 ml of venous blood, blood was placed in a procoagulant containing blood collection tube, and after centrifugation at 3,500 r/min for 10 min in an intelligent high-performance centrifuge (Beckman Coulter China branch; model: Avanti JXN-30/26), the serum from the upper layer was collected for relevant index detection [11, 12].

The extraction of RNA in serum was conducted according to the specification of blood RNA extraction kit (Shanghai GenePharma Co., Ltd.). The extracted RNA was collected and reversely transcribed into cDNA with the genome removal reverse transcription kit (Shanghai Ruifen Biotechnology Co., Ltd.). The expression levels of serum miR-221 and miR-144 were detected by the real-time fluorescent quantitative PCR method.

2.2.2. Detection of Serum Superoxide Dismutase (SOD) and Homocysteine (Hcy) Levels. The level values of serum SOD and Hcy were detected with the automatic biochemical analyzer (Shanghai Huanxi Medical Device Co., Ltd.; model: LW C200E).

2.2.3. Detection of Vascular Endothelial Growth Factor (VEGF), Nuclear Factor-Kappa B (NF-kB), and Transforming Growth Factor-β (TGF-β) Levels. The cytokine levels were detected by enzyme-linked immunosorbent assay (ELISA), the VEGF and NF-kB kits were purchased from Shanghai Zhen Ke Biological Technology Co., Ltd., the FGF-β kits were purchased from Shanghai Win-Win Biotechnology Co., Ltd., and all operations were carried out according to the kit instructions.

2.3. Statistical Processing. The statistical analysis and processing of experimental data were conducted with SPSS 21.0 software, the picture drawing software was GraphPad Prism 7 (GraphPad Software, San Diego, USA), the diagnosis value was analyzed by the Mann–Whitney U test, and the area under receiver operating characteristic curve (ROC curve), the measurement data examined by the t-test and expressed by ($\overline{x} \pm s$), and differences were considered statistically significant at $P < 0.05$.

3. Results

3.1. Between-Group Comparison of Basic Clinical Information. Other than various blood lipid indicators, no obvious between-group differences in the gender ratio, mean age, BMI value, smoking history, and drinking history were observed ($P < 0.05$), as given in Table 1.

3.2. Between-Group Comparison of Serum miR-221 and miR-144 Levels. Compared with the control group, the AS group had significantly higher miR-221 expression level and significantly lower miR-144 expression level ($P < 0.001$), as shown in Figure 2.

3.3. Between-Group Comparison of Serum SOD and Hcy Level Values. Compared with the control group, the AS group presented significantly higher mean serum Hcy level values ($P < 0.001$) and significantly lower mean serum SOD level values ($P < 0.001$), as shown in Figure 3.

3.4. Between-Group Comparison of Serum VEGF, NF-kB, and TGF-β Level Values. The serum VEGF, NF-kB, and TGF-β level values were significantly higher in the AS group than in the control group ($P < 0.001$), as given in Table 2.

3.5. Diagnosis Value of Serum miR-221 and miR-144 Levels for AS. The areas under the ROC curves of serum miR-221 and miR-144 levels for the diagnosis of AS was 0.670 and 0.613, respectively, and the area under the ROC curve of combined diagnosis was 0.858 (Table 3 and Figures 4–6).

4. Discussion

AS will cause arterial wall thickening, vessel stenosis, and vascular elasticity decrease, which is the main pathological basis of coronary heart disease, cerebral infarction, and peripheral ischemic vascular disease [13] and chronic inflammatory disease triggered by various factors. Since the early symptoms of the disease are not obvious, most patients have entered middle and late stages when diagnosed, seriously affecting the prognosis. Intravascular ultrasound (IVUS) examination is a common method for the diagnosis of AS [14–16], but it cannot accurately obtain the internal fine structure of local plaques, has less significance for identifying their vulnerability, and is an invasive tomographic technique [17]. On people's deeper exploration of serum biology, it is found that inflammation extends through the whole occurrence and progression process of AS, a long-term formed and progressed chronic inflammatory response, while serum marker levels are relatively stable and less affected by other factors, presenting higher sensitivity and specificity. Studies have shown that multiple cell-derived exosomal miRNAs are involved in this inflammatory process [18], exacerbating the disease progression of AS by causing inflammatory responses in its targeted cells and then leading to the formation of endothelial cell insufficiency, monocyte adhesion, foam cell, and vascular remodeling in the arterial wall. Among them, miR-221 accelerates the progression of AS by participating in the inflammatory response, activating its target genes, and causing dysfunction of the vascular endothelial membrane in patients. In the study conducted by foreign scholars [19] on a rat model of inflammation caused by chronic intake of sucrose, by detecting the exosomes in rats' blood, it was found that their miR-221 expression in plasma was significantly elevated, from which it could be speculated that miR-221 in plasma exosomes might be involved in the inflammatory response. Another study also found [20] that upregulated miR-221 expression could inhibit the cell cycle regulator p27kip1 in vascular smooth muscle cells, thereby mediating vascular calcification to cause atherosclerosis and stenosis. In this study, by detecting the expression levels of serum miR-221 in AS patients and in healthy persons, it was found that the miR-221 expression level was significantly higher in AS patients ($P < 0.001$), which was proved in the study by Elbaek et al. [21].

As an evolutionarily highly conserved miRNA, miR-144 is mapped on chromosome 17 in humans and exists as a miR-144/miR-451 gene cluster [22]. miR-144 levels in tissues are also of a great value in the diagnosis and prognosis evaluation of malignant tumors, and its clinical utility has been demonstrated in diseases such as breast cancer, oral squamous cell cancer, and colon cancer cancer [23]. Studies have found that [24] miR-144 is highly expressed in cardiomyocytes, and its high expression level can promote myocardial oxidative stress, thereby inducing myocardial injury related diseases, and its key role in the occurrence and progression of cardiovascular diseases have been confirmed by several foreign clinical trials. In this study, it was found that the serum miR-144 expression level in AS patients was significantly higher than that in the healthy group, and Lu et al. [25] in their study found that miR-144 expression in AS plaques and vascular smooth muscle cells (VSMCs) would gradually elevate as the disease progressed, presumably due to the imbalance of methylation and demethylation systems in vivo causing increased methylation of the miR-144 promoter.

An ideal serum marker shall have high specificity and sensitivity. In this study, miR-144 was found to be under

Table 1: Between-group comparison of basic clinical information (n (%), $\bar{x} \pm s$).

Item	AS group ($n = 52$)	Control group ($n = 53$)	X^2/t	P
Gender			0.094	0.759
Male	30 (57.69%)	29 (54.72%)		
Female	22 (42.31%)	24 (45.28%)		
Mean age ($\bar{x} \pm s$, years)	64.37 ± 3.26	64.42 ± 3.31	0.078	0.938
BMI ($\bar{x} \pm s$, kg/m^2)	21.19 ± 1.02	21.23 ± 1.04	0.199	0.843
Smoking history	29 (55.77%)	31 (58.83%)	0.079	0.778
Drinking history	32 (61.54%)	28 (52.83%)	0.813	0.367
Total cholesterol ($\bar{x} \pm s$, mmol/L)	5.22 ± 0.47	3.52 ± 0.46	18.731	<0.001
Triacylglycerol ($\bar{x} \pm s$, mmol/L)	1.62 ± 0.46	0.84 ± 0.21	11.212	<0.001
LDL-C ($\bar{x} \pm s$, mmol/L)	3.56 ± 0.35	2.26 ± 0.17	24.280	<0.001
HDL-C ($\bar{x} \pm s$, mmol/L)	1.12 ± 0.31	1.34 ± 0.23	4.135	<0.001

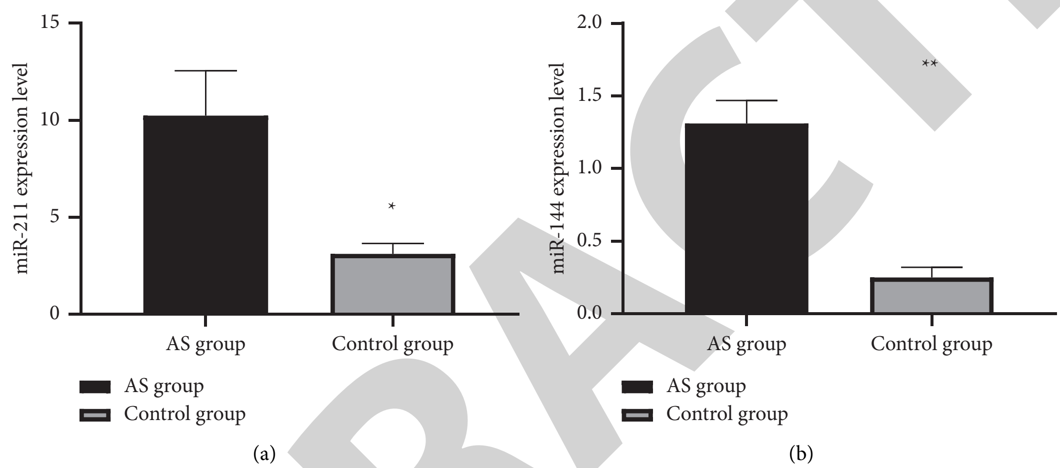

Figure 2: Between-group comparison of serum miR-221 and miR-144 levels ($\bar{x} \pm s$). (a) The between-group comparison of miR-221 expression levels. The horizontal axis denotes the AS group and control group, and the vertical axis denotes the level. The miR-221 expression level of the AS group and control group was 10.24 ± 2.31 and 3.12 ± 0.54, respectively, and * indicates the significant between-group difference in the miR-221 expression levels ($t = 21.841$, $P < 0.001$). (b) The between-group comparison of miR-144 expression levels. The horizontal axis denotes the AS group and control group, and the vertical axis denotes the level. The miR-144 expression level of the AS group and control group was 1.31 ± 0.16 and 0.25 ± 0.07, respectively, and ** indicates the significant between-group difference in the miR-144 expression levels ($t = 44.122$, $P < 0.001$).

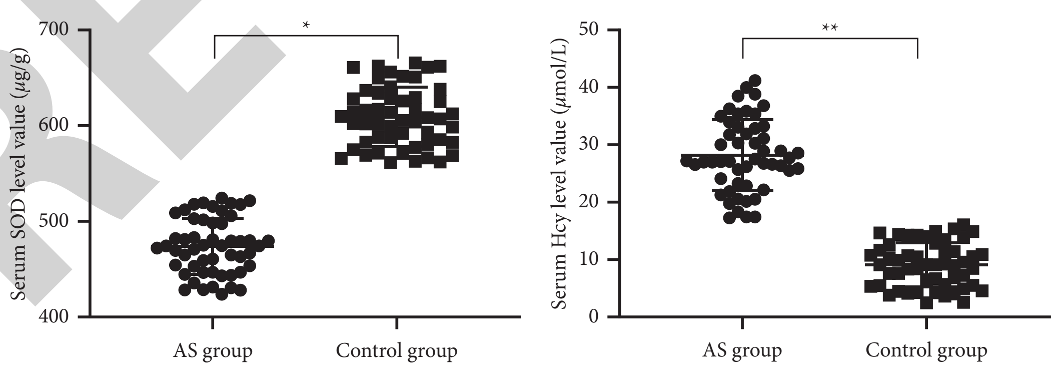

Figure 3: Between-group comparison of serum SOD and Hcy level values ($\bar{x} \pm s$). (a) The between-group comparison of serum SOD level values. The horizontal axis denotes the AS group and control group, and the vertical axis denotes the value (μg/g). The mean serum SOD level values of the AS group and control group were (477.30 ± 31.19) and (606.65 ± 32.00), respectively, and * indicates the significant between-group difference in mean serum SOD level values ($t = 20.970$, $P < 0.001$). (b) The between-group comparison of serum Hcy level values. The horizontal axis denotes the AS group and control group, and the vertical axis denotes the value (μmol/L). The mean serum Hcy level values of the AS group and control group were (28.17 ± 6.20) and (9.09 ± 3.85), respectively, and ** indicates the significant between-group difference in mean serum Hcy level values ($t = 18.983$, $P < 0.001$).

Table 2: Between-group comparison of serum VEGF, NF-kB, and TGF-β level values ($\bar{x} \pm s$).

Group	n	VEGF (pg/ml)	NF-kB (ng/L)	TGF-β (ng/L)
AS group	52	432.25 ± 35.64	1.69 ± 0.36	257.83 ± 5.27
Control group	53	142.56 ± 24.26	1.04 ± 0.29	67.48 ± 4.58
T		48.770	10.198	197.662
P		<0.001	<0.001	<0.001

Table 3: Diagnosis value of serum miR-221 and miR-144 levels for AS.

Indicator	Area under ROC curve	Positive rate (%)	95% CI	Sensitivity (%)	Specificity (%)
miR-221	0.670	24.76	0.566–0.774	86.75	81.26
miR-144	0.613	21.90	0.505–0.721	79.25	74.27
miR-221 + miR-144	0.858	43.81	0.781–0.935	93.25	85.37

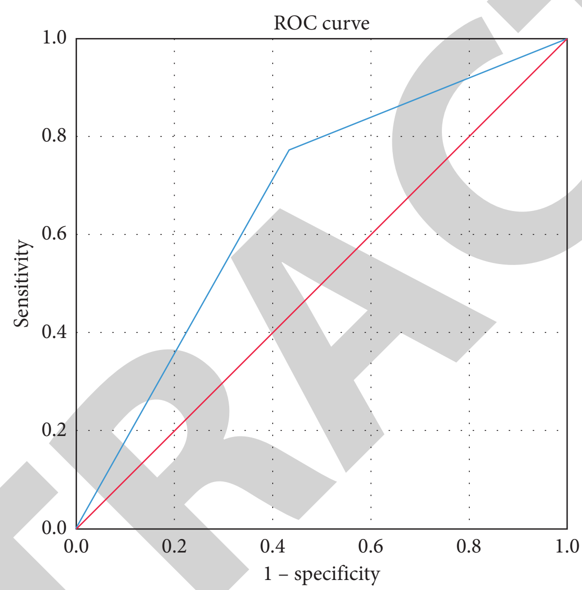

Figure 4: ROC curve of diagnosing AS with serum miR-221 expression level.

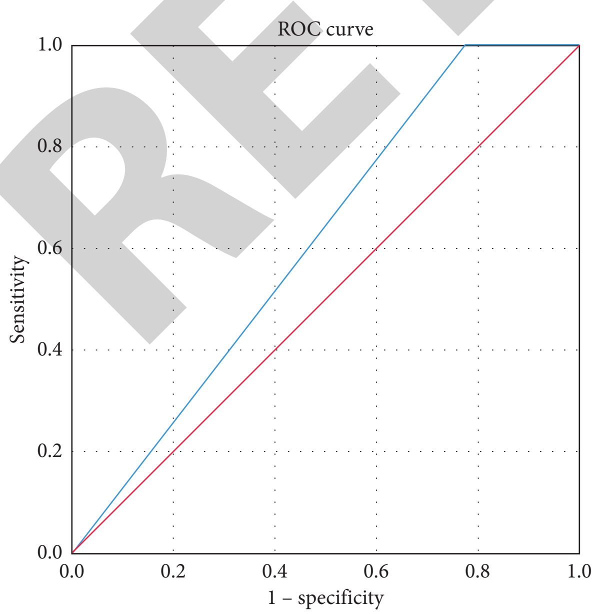

Figure 5: ROC curve of diagnosing AS with serum miR-144 expression level.

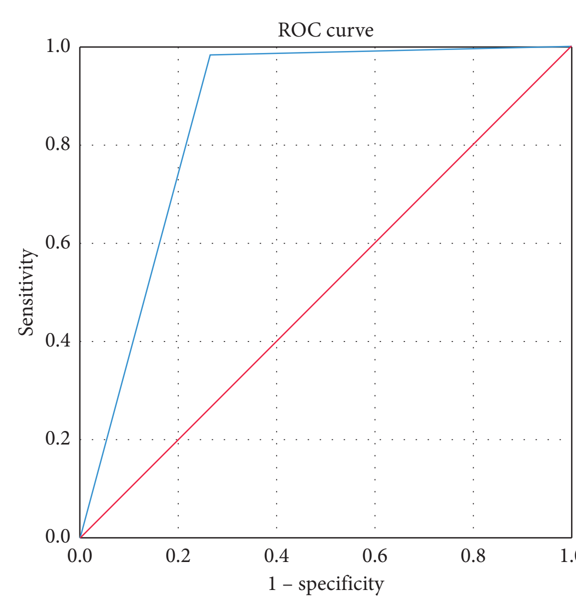

Figure 6: ROC curve of diagnosing AS with miR-221 + miR-144 expression level.

expressed in the serum of AS patients, and its area under the ROC curve for the diagnosis of AS was 0.613, whereas miR-221 had an area under the ROC curve of 0.670, which was higher than that of miR-144. But considering the low specificity of miR-144 in the diagnosis of AS, miR-221 was adopted for combined diagnosis, and as a result, the combination could improve the specificity and sensitivity of miR-144 for the diagnosis of AS, with an area under the ROC curve of 0.858. Deficiency of this study is that the small number of cases selected and the failure to consider the effect of disease type and stage on the results of the study are prone to bias of conclusions.

In conclusion, both miR-144 and miR-221 participate in the occurrence and progression of AS, and the combination of the two has a higher diagnosis value and can provide a new direction for the clinical diagnosis of AS.

Population at risk can benefit greatly from remote health monitoring because it allows for early detection and treatment. Because of recent advances in Internet-of-Things (IoT) paradigms, such monitoring systems are now available everywhere. Due to the essential nature of the patients being monitored, these systems demand a high level of quality in aspects such as availability and accuracy. In health applications, where a lot of data are accessible, deep learning algorithms have the potential to perform well. In this paper, we develop a deep learning architecture called the convolutional neural network (CNN), which we examine in this study to see if it can be implemented. The study uses the IoT system with a centralised cloud server, where it is considered as an ideal input data acquisition module. The study uses cloud computing resources by distributing CNN operations to the servers with outsourced fitness functions to be performed at the edge. The results of the simulation show that the proposed method achieves a higher rate of classifying the input instances from the data acquisition tools than other methods. From the results, it is seen that the proposed CNN achieves an average accurate rate of 99.6% on training datasets and 86.3% on testing datasets.

1. Introduction

Data collection has become much easier, thanks to the rise of smart Internet-of-Things (IoT) devices and sensors. However, the analysis and utilization of data still face challenges associated with incorrect feature extraction. When faced with these difficulties, researchers and specialists began looking for optimal solutions that allow extraction of most possible data from a given dataset. Our ability to learn more about our surroundings has improved since the invention of AI in the late twentieth century.

Ongoing advancements in artificial intelligence (AI) have been implemented in numerous industries, including the education and medical field. According to numerous studies [1–3], AI has shown the ability to outperform humans and information systems at most cases [4–8]. It is a mechanical, electrical, and chemical organism that constitutes the human body [5]. Electrocardiogram (ECG) signals are a biophysical indicator of the electrical activity of the heart. It shows how the beating of the heart changes over time [9–13]. Automated systems have a difficult time spotting anomaly. External noise and the body response to different physical conditions are examples of this [6–8].

To our knowledge, convolutional neural network (CNN) works well with ECG recordings from the data acquisition IoT devices. Appropriate ECG signal processing with the CNN learns features using patient needs with abnormalities in arrhythmia and heart failure [14–16].

In this paper, we develop the convolutional neural network (CNN) architecture, which we examine in this study to see if it can be implemented. The study uses the IoT system with a centralised cloud server, where it is considered as an ideal input data acquisition module.

The main contribution of the work involves the following:

(i) The authors develop a sparse CNN with autoencoding properties in order to improve the accuracy of classification.

(ii) The speed and reliability of IoT systems are heavily dependent on the speed and reliability of the internet connection used. Smart gateway devices lack the processing power to execute CNN methodologies.

(iii) The study uses cloud computing resources by distributing CNN operations to the servers with outsourced fitness functions to be performed at the edge. It is therefore enabling improved system availability by making decisions at the local level.

(iv) An ECG classification using input IoT data acquisition modules is evaluated in terms of response time and accuracy in a real-world case study.

2. Background

Each of the six waves in the ECG waveform is separated into two waves, two segments, and one complicated wave. During the initial electrical activity of the human heart, which is known as the PR interval, the right atrium chamber depolarizes, causing deoxygenated blood to exit via the vena cava into the right ventricle. It is at this point that two distinct pumping mechanisms kick into high gear: one to move deoxygenated blood to the lungs for oxygenation and the other to move oxygenated blood throughout the remaining part of the body. To begin another heartbeat cycle, the heart ventricles must be repolarized during the QT interval including the QRS complex, the ST segment, and the *T*-wave.

Some of the most critical and subtle ECG signals may be missed by commonly used applications that only count the number of beats per second and ignore the ECG signal pattern morphology that changes without altering the cycle normal time. A great deal of effort has gone into figuring out how to get useful information out of such sensitive medical records. Several methods utilizing the feature extraction based on features, feature combinations, or a selection of features were presented [17]. Time-frequency analysis of ECG signals can be done using wavelet transforms developed by the authors in [18]. In this paper, ECG classification using a CNN is presented to address these shortcomings. CNNs are a type of hierarchical artificial neural networks (ANNs) [19, 20] that use downsampling and convolutional layers to alternately mimic the human visual cortex cells.

3. Proposed Method

Figure 1 shows an autoencoder with the hidden layer for learning features from the input x if there are data $x = \{x_1, x_2, x_3, x_4, x_5\}$ available. All three layers are referred to as input, hidden, or reconstitution layers. The input layers are connected directly with layer 2 or hidden layers, where it performs various operations of autoencoding, and then layer 3 performs the process of providing the outputs of the hidden layers.

The goal of the reconstitution layer is to minimize the error between the layers. The hidden layer can be thought of as a different way to represent data because the essential characteristics of the data can be extracted from it.

Autoencoder networks are actually designed to learn the activation function $h_{W,b}(x) \approx x$. The limited neurons in the hidden layer extract the hidden features. As an example, 1024 neurons can be used to process a 32×32 matrix image. In a similar way to PCA and other dimension reduction methods, this is what this does. However, the hidden layer contains only a few neurons. According to this constraint, any network can be made to become sparse if the activation value of each hidden layer j^{th} neuron is a_j.

$$\rho_j = \frac{1}{m}\sum_{i=1}^{m} a_j x_i, \tag{1}$$

where m is the input layer neurons and ρ_j is the sparse constraint constant (like 0.05).

The study uses the KL distance function to optimise ρ_j when solving the hidden layer.

$$\mathrm{KL}\left(\rho\rho_j\right) = \rho \log\frac{\rho}{\rho_j} + (1-\rho)\log\frac{1-\rho}{1-\rho_j}. \tag{2}$$

CNNs use a spatiotemporal convolution kernel to specify the feature map in their convolution layer. Each feature map output of the last subsampling layer l consists of the bias term b_j^{ℓ} and convolution kernel W_{ij}^{ℓ} only if there exist input feature maps N_{in}. The formula for estimating the feature map X_j^{ℓ} of output j is as follows:

$$X_j^{\ell} = f\left(\sum_{i=1}^{N_{in}} \alpha_{ij}\left(X_i^{\ell-1} * W_{ij}^{\ell}\right) + b_j^{\ell}\right). \tag{3}$$

Additionally, it must adhere to the following rules:

$$\begin{gathered}\sum_i \alpha_{ij} = 1,\\ 0 \le \alpha_{ij} \le 1.\end{gathered} \tag{4}$$

Backpropagation begins with determining how each subsampling layer (l) is connected to its next convolution layer, and this must be done before we can begin the process, so as to conduct backward the next layer residual $\delta^{\ell+1}$. To determine the feature map of the j^{th} residual (δ_j^{ℓ}) layer, we can apply the gradient descent method. Suppose the layer activation function f which is the derivative of $f'(z_j^{\ell})$ has the input z_j^{ℓ}. The formula for the calculation is as follows:

$$\delta_j^{\ell} = f'\left(z_j^{\ell}\right) \cdot \operatorname{conv2}\left(\delta_j^{\ell+1}, \operatorname{rot180}\left(W_j^{\ell+1}\right)\right). \tag{5}$$

In the above process, the convolution kernel conv2 $(\cdot)$ must be rotated in order to perform cross-correlation calculations.

The sparse constraint is imposed on the output of the sparse autoencoder neural network. However, in this case, the input is limited to a sparse set of values. These two modes of operation are distinct, but they accomplish the same thing. Features can be extracted from input data using sparse autoencoder neural networks. Spatiotemporal convolution is a major change in this framework because all of the previous layer input feature maps are used as inputs for each output feature map. Due to the sparse constraints, the feature maps can be fed to the output map, and this is limited extremely.

3.1. Event Recognition Using the CNN. In the above framework, we feed the CNN seven consecutive 64×64-pixel frames in order to capture ECG data encoded in the input image frame, with the current image frame serving as the centre of attention. Assume that each frame in the input set is a 64×64 greyscale image with the same dimensions. Scaling is required if the dimensions are different from one another.

Convolution kernels of the form $7 \times 5 \times 5$ can be used by the C1 layer to obtain 36 feature maps to extract 36 different features from the input frames. As complicated as action event classification is, the 36 feature maps are perfectly capable of classifying the simple action. On the contrary, the convolution kernel is 5×5 in the space dimension. In other words, each C1 layer feature map is linked to all seven 5×5 image blocks. The C1 layer produces 36 number of 60×60-pixel feature maps as a result.

It is a sampling layer, the S1 layer. Accordingly, the C1 layer feature maps are rescaled to improve the CNN resilience to scale changes and minor deformations. The subsampling layer scaling factor cannot be too large.

4. Results and Discussion

In this section, the entire simulation is conducted in the Python environment to study the effectiveness of the proposed model. Table 1 shows the proposed CNN which is compared with existing image classification models such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7, the parameters of which are given in Table 1.

The proposed CNN is compared with existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7 in terms of various performance metrics including accuracy, precision, recall, *F*-measure, and percentage error. Moreover, the running time of the proposed method is tested on training and testing times.

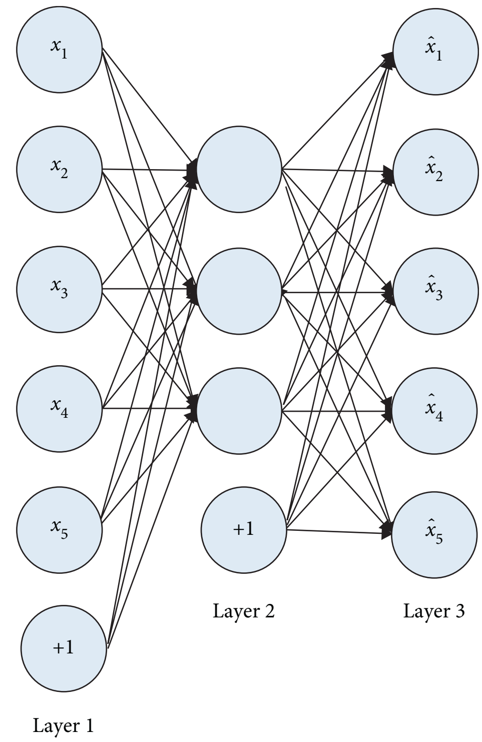

Figure 1: Sparse CNN of autoencoding type.

Table 1: Deep learning parameters.

Model	Parameters
VGG-16	138 million
ResNet-50	25 million
Inception V3	24 million
EfficientNetB0	5.3 million
EfficientNetB7	66 million
Proposed CNN	60,000

Table 2 shows the results of accuracy between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7. The results of the simulation are conducted on both training and testing stages. The results of accuracy show that, at the time of training, the study has more accuracy than at the testing stage. Moreover, it is seen that the proposed CNN has higher classification accuracy than other methods.

Table 3 shows the results of run time between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7. The results of the simulation are conducted on both training and testing stages. The results of run time show that, at the testing stage, it has higher run time than the training stage. Moreover, it is seen that the proposed CNN has reduced run times than other methods.

Figure 2 shows the results of precision between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and

Table 2: Accuracy (%) of training and testing.

Model	Accuracy with training datasets	Accuracy with testing datasets
VGG-16	75.0	74.5
ResNet-50	87.0	76.3
Inception V3	90.7	77.15
EfficientNetB0	93.8	78.8
EfficientNetB7	94.9	84.4
Proposed CNN	99.6	86.3

Table 3: Running time (ms) of training and testing.

Model	Running time with training datasets	Running time with testing datasets
VGG-16	352,628	793,412
ResNet-50	38,797	117,167
Inception V3	15,652	97,854
EfficientNetB0	10,422	79,485
EfficientNetB7	5252	43,685
Proposed CNN	4556	42,965

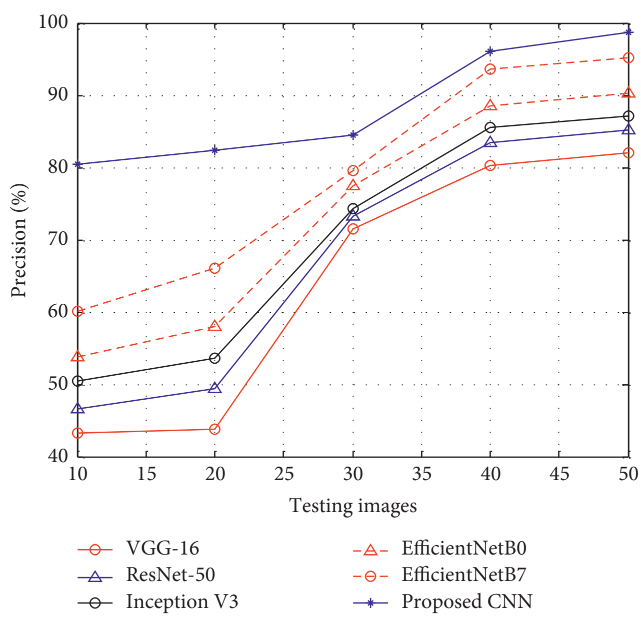

Figure 2: Precision.

EfficientNetB7. The results of precision show that, at the time of the testing stage, the proposed CNN has higher precision rate than other methods.

Figure 3 shows the results of recall between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7. The results of recall show that, at the time of the testing stage, the proposed CNN has higher recall rate than other methods.

Figure 4 shows the results of *F*-measure between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7. The results of *F*-measure show that, at the time of the testing stage, the proposed CNN has higher *F*-measure rate than other methods.

Figure 5 shows the results of MAE between the proposed CNN and existing methods such as VGG-16, ResNet-50, Inception V3, EfficientNetB0, and EfficientNetB7. The results of MAE show that, at the time of the testing stage, the proposed CNN has reduced MAE than other methods.

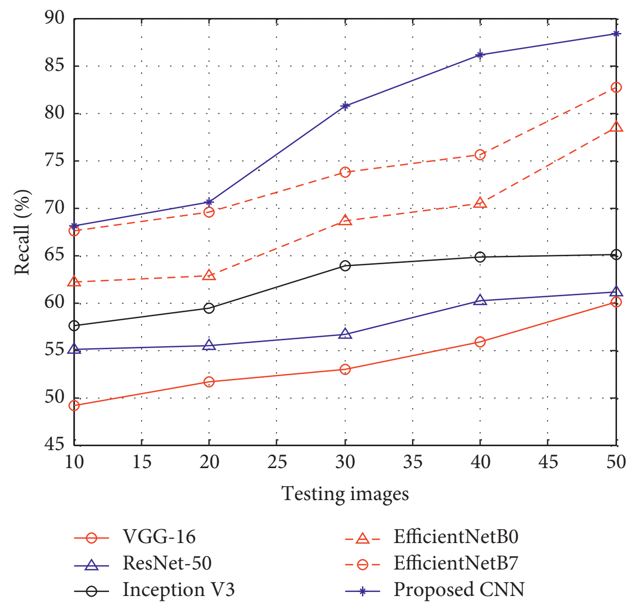

Figure 3: Recall.

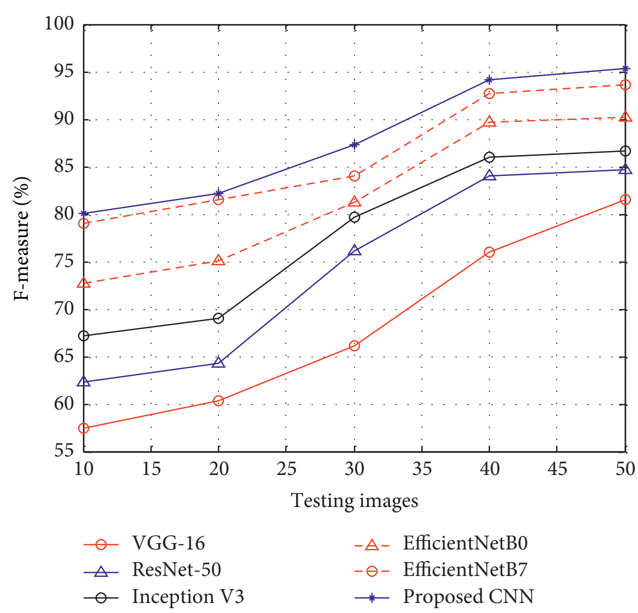

Figure 4: F-measure.

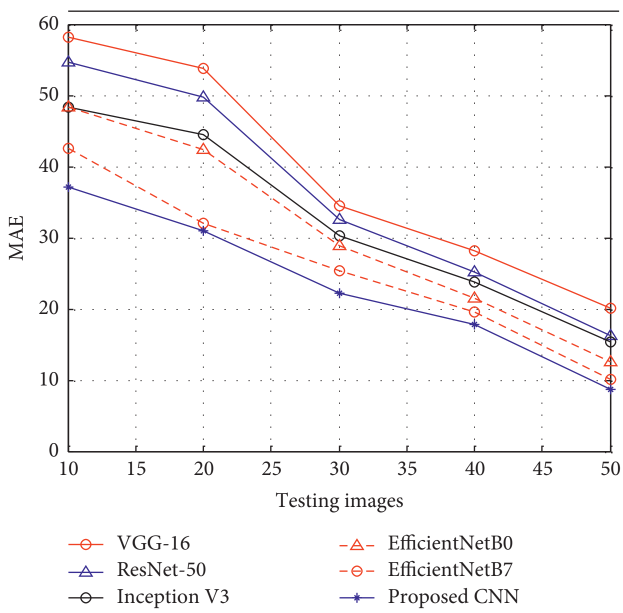

Figure 5: MAE.

5. Conclusions

In this paper, CNN examines the input signal from the IoT devices, where ECG data are classified to detect the presence of arrhythmia and heart failure from the image dataset. The classification of the dataset on two different heartbeat signals enables faster training and testing packages. The utilization of cloud resources to perform the CNN classification shows fastest classification process without lags. The simulation is conducted to test the efficacy of the CNN against ECG image datasets. The simulation shows that the proposed CNN classifies well the instances than other existing methods. The results of the simulation show an improved accuracy rate of 98% than image ECG classification models. In the future, federated learning can be used to examine the multimodal signals for the purpose of improved classification of instances in case of arrhythmia and heart failure.

Data Availability

The datasets used and/or analyzed during the current study are available from the corresponding author upon reasonable request.

Conflicts of Interest

The authors declare no conflicts of interest.

A rising proportion of older people has more demand on services including hospitals, retirement homes, and assisted living facilities. Regaining control of this population's expectations will pose new difficulties for lawmakers, medical professionals, and the society at large. Smart technology can help older people to have independent and fulfilling lives while still living safely and securely in the community. In the last several decades, the number of sectors using robots has risen. Comrade robots have made their appearance in old human life, with the most recent notable appearance being in their care. The number of elderly individuals is increasing dramatically throughout the globe. The source of the story is the use of robots to help elderly people with day-to-day activities. Speech data and facial recognition model are done with AI model. Here, with the Comrade robotic model, elder people's healthcare system is designed with better analysis state. The aim is to put in place a simple robotic buddy to determine the health of the old person via a headband that has been given to them. Comrade robot may do things like senior citizens home automation, home equipment control, safety, and wellbeing sensing, and, in emergency situation, routine duties like navigating in the outside world. The fear that robotics and artificial intelligence would eventually eliminate most of the jobs is increasing. It is anticipated that, in order to survive and stay relevant in the constantly shifting environment of work, workers of the future will need to be creative and versatile and prepared to identify new business possibilities and change industry to meet challenges of the world. According to the research, reflective practice, time management, communicating, and collaboration are important in fostering creativity.

1. Introduction

Technology is a trend that affects human existence in every part of the world. Robots are an exciting example of what the future of technology holds. Robotics has enhanced human life and industry significantly, thanks to the technology [1]. Adults with autism are already a regular thing in many industries, including healthcare, military service, and domestic assistance. The global population is growing, therefore making the requirements of this demographic an increasingly significant issue for health providers, government officials, caretakers, and families. Due to these reasons, buddy robots (which serve as aids to elderly people) are often seen as having an authoritarian function in helping individuals do their caring duties without assistance. An increased old population is often brought up as a method of dealing with the rising number of senior persons. Actually, robots are becoming more prevalent in the senior care sector. We should have been aware of certain ethical issues that have recently been brought to light as a result of these advances. Artificial intelligence approaches are applicable for various fields of utility. Digital smart systems, medical data analysis, healthcare system, and other applications are possible with AI model. Specifically, disease diagnosis with deep learning, radiology model with ML, automatic systems, and so forth are the most utilized healthcare systems of AI.

A rising need for new technology has emerged for older adults because of the greying of our current generation. The primary reasons in favour of this are that there are too few hospital workers and many individuals want to live as independently as possible rather than be placed in an institution [2]. Additionally, we will need an adequate supply of healthcare professionals together with the use of cutting-edge technology. Robotics is playing a significant role in helping older people these days. A household use robot that is particularly intended for use at home may be regarded as a level of service robot. The business of making robots specifically for the house is expanding from scientific and commercial standpoints. In order for Comrade robot to be the most effective in the house, it should be able to carry out several activities such as home monitoring, gadget management, personal assistance, and entertaining. When more and more robots are developed to engage with a human being to give the sort of care that is often provided by a licensed therapist, the lack of healthcare and the standard of living for the elderly will both improve [3]. Designing a providing assurance "robotic arm" to supervise the old person is the method being used. The overall aim is to create a low rental Comradeship robot to assist an elderly person with daily home automation.

In the end, the house robot could traverse the usual home settings without any human assistance, carrying out duties such as senior citizens monitoring devices, home gadget management, and security and stability sensing, as well as in the case of an attack. This document has two distinct sections. One is a Comrade robot, while the other is a health monitoring band. A Comrade robot does so in the form of "making itself helpful"; that is, it is capable of assisting people in a household setting. The old person is constantly being kept under constant supervision by the Comrade robot [4]. With the sensors incorporated in the design, the leaving comments industrial vehicle ensures both safe and secure environment in the family environment. Trespassers, gas leaks, and fire are all on the list. In the creative and emotional realm, Comrade robots and emotional synthetic avatars have now been created for graduate training. It may be difficult to extract a ministry of planning from both materials; therefore, teams that want to build Comrade robots must create their own website from scratch. Of course, there are many representations of structure for Comrade robot, but it is also tough to locate how the actual ones operate. Most articles concern themselves with how well an overall behavior performs, with little emphasis on the detailed architecture needed for replication.

This article, covering the themes of the first twenty months of exercises of RoboCare, explains the kind of programs the group has done so far and the subjects in which they have focused. The RoboCare program is dedicated to creating distributed applications where programming and autonomous agents all work together to accomplish an overall objective, which is to provide a supply of services that are ready for use in settings where people may need help and direction. While we are also interested in supporting endangered elderly individuals to enjoy an inclusive environment in their own homes, our primary focus is on bringing the concept to market [5]. According to recent data, Europe and Japan are gradually growing older. In order to increase public attention to this matter of "independence" and "ageing at home," new ways of supporting the seniors and persons with disabilities have been created.

This is why when it comes to RoboCare, most of the study deals with two potential situations, which are referred to as the RoboCare Household Atmosphere and the Quality of Life Institution setting [6]. Robotic frameworks, wearable devices, activity monitoring in complicated settings, and human relationships are the main components of strong reliance for the future of robotic care. Here we will give the reader a short summary of the key findings that we have discovered so far and many lessons we have learnt from those efforts to custom-tailor AI for assisted living. Remote sensing data-based applications, image processing, video and audio recognition system, security system, and so forth are the applications of this research field. The major objective is to improve the performance state of medical data analysis and the robot model construction with efficient analysis is designed. This research contributes to improving the robot technology and availability of AI in medical healthcare system. Comrade robot model with AI utility helps to obtain a better performance result.

The remainder of the paper is organized as follows. Section 2 analyzes various review papers related to the topic. The overview of robot model is studied in Section 3. The module performance and architecture of Comrade robot are described in Section 4. Section 5 analyzes the AI technology in the healthcare system. Specifically, the elder healthcare system is designed. Section 6 presents the methodology, and Section 7 evaluates the analyzed performances result. Section 8 concludes the proposed work.

2. Review of Literature

Lifespans across the globe are rising, and therefore the percentage of the people in retirement ages is growing (Moyle et al. [6]). As visual acuity in older adults diminishes, this necessitates the provision of more services and has a larger impact on budgets for healthcare provision. The older population needs more research to help them retain emotional human fellow. Robotic technology may be used to assist both rehabilitative and sociable robots in relieving strain on social care facilities. Large data processing, overlapping issue, and feature set analysis difficulties are the major problem of conventional work.

You may also look into Comradeship robotics, which are little robots that are made to look and behave like animals (Pu et al [4]). They aid creatures during rodent therapy by decreasing the dangers for the mammals individually. In general, Schrödinger, the mechanical seal, is a famous example. The advantages of getting to know Paro, a simulated nursing care Comrade for elderly people, include decreased irritation as well as depressive disorder in cognitive impairment, better immune responses, less burden on care providers, and enhanced affect and information exchange among both elderly people and their day care providers. Furthermore, paracetamol may help to minimize the need for hallucinogenic and analgesia medications and may help to lower cholesterol levels.

The authors in [7] and others examine the main methodologies, including designation as well as learning algorithms, which are essential in the development of developing quantum computing, as well as designation and learning algorithms, and computational efficiency that are applicable in the field of growing artificial intelligence and intricate their use [8–10]. Research methods employed in data security, personal computing, and cloud services provide better findings, as diverse assessment criteria are taken into consideration.

The impact of robot animals upon autonomous older adults was examined in a clinical trial (Abubshait et al. [11]), and also the researchers reported that robotic dogs may offer social enjoyment and relationships. While practical assistance was very attractive, the fact that the robot looked and felt more like a human created a conflict. People preferred soft fur and recommended play elements, such as plush toys, as potential improvements for the Comrade robots that are presently available. When new, brightly colored, child-oriented dogs were used, this restricted the kind of impressions respondents might create. Note that although older persons and individuals with memory are incorporated throughout Comrade robot creation, they are seldom, if ever, offered the opportunity to be engaged. Interaction typically happens in the project design whenever healthcare services are engaged.

It was recommended that the construction of something like an everyone around collapse detection technique be undertaken (Celis et al. [12]). Utilizing just one aeration rate, an innovative wearable gadget for the detection of falls was created. Ubiquitous computing Remote Monitoring for the Old capable of detecting an individual's fall as maintaining the health of the patients. An Intelligent Home Security System based on GSM and ARM Architectural design: Industrial robots have lately been created utilizing a range of technologies, including the Web, wireless communications, wirelessly, and speech recognition.

3. General Overview of Robots

The word robot was originally derived from the Czech word robot, which means forced labor. Karel Capek, the Czech writer, introduced the term robot in his play "R.U.R." Capek used the term robotic in a series called "Rossum's Universal Robots" that premiered in Prague in 1921. The robots in R.U.R were built by man, and they were supposed to work for humanity. Thus, from generations to generations, human people have made use of robots to do various jobs. However, there is just no generally accepted definition for robots [11]. Despite this disagreement, the University of the Robot Society still sees a robot as a multipurpose fully programmable tool that is used to transfer credible commitments, tools, or optical disks in various ways using preprogrammed movements. This concept differentiates robots from other automated machines, because they are programmable. A robot may be described as an upgradeable, complex nervous, sentient, and transportable machine that uses energy to do work. Regardless of its form and size, a robot has seven major elements. This collaboration serves a particular goal. Figure 1 depicts the parts of a robot.

3.1. Controller. The commander is in charge of coordinating the robot's movements. The operational environment refers to the area within which a robot may operate [13]. The microcontroller is also in charge of collecting input first from surrounding environment via the use of its sensing.

3.2. Power Conversion Unit. The fusion reactor supplies the robot's controls. Electricity, combustible materials, and battery storage are all commonplace power stations in robots [14]. Most of the electricity that is provided to a building comes from the grid, and, in order to power the building, the system uses an AC/DC electrical power converter to change the AC electricity into DC electricity.

3.3. Manipulator. The robotics have had the capacity to pick up, alter, and blow things up. The robot's manipulation imitates outstretched arm of something like a human individual. Manipulators typically refer to the joints connecting the arms with the upper arms, elbows, and wrists. Joints tend to be either rotational or sliding [4]. Reaction kinetics refer to the way wherein the joints are arranged to define the potential stepper motor.

3.4. End Effector. The final part of the system, which connects to the input device, is known as the manipulation link. The instrument handle's link is known as an actuation. It imitates the mechanical arm, mimicking the results obtained.

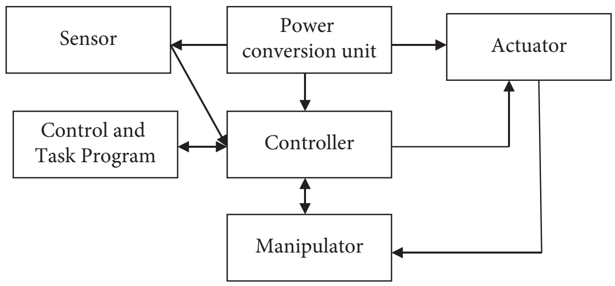

Figure 1: Components of a robot.

3.5. Sensors. Robots may now have the sensor take a specific measurements of the surroundings, with the sensing' data helping to shape the robot's behaviors. To guarantee the robot's security, this is often done. Devices utilize a robot to respond to environmental variations.

3.6. Actuator. In most of the robots, the actuators are often known as the muscles of the robot. The conversion takes place by using the energy that drives your robot's mobility.

3.7. Control and Task Program. A collection of commands from the manufacturers of the robot's controller are known as the management plan, while a sequence of questions typically supplied by the user are called the task programme [15]. To accomplish a particular job, the manipulator must carry out the movements task programmed by the task programme.

4. Architecture of Comrade Robot

To develop up with a proper Comrade robot structure, we also must research the many needs that Comrade robots may have. Just one "perfect" Comrade robot might fulfill all these criteria. Meanwhile, theoretically speaking, the need of a Comrade robot does not quite apply; in reality, one is still required [16]. The specifications for a given robot rely on a variety of different variables, including the kind of intended application and also the particular hardware components that are required. Here we provide a comprehensive list of all potential criteria an engineer should consider while designing a generic structure. The main task of the Comrade robot is to sense the environment around it, including hearing, seeing, and touching. Intercultural competence calls for synchronizing data; thus, various kinds of data need attention. In addition, inputs processing may be programmed to target specific sensor data, in response to predictions from a mixing process. Significance must be verified on every piece of data received, and all information collected must also be classified before it can be kept.

The Comrade robot was able to have a classroom discussion with the user. What this implies is not just to create effective sentences and also to take fundamental principles of communicating into consideration [17]. A Comrade robot should constantly be likely to preserve the dialogue flowing in order to sustain a strong connection. The usage of live interaction also incorporates elements like this; for instance, in order to prevent boring or misunderstanding the user, lengthy pauses should not be present in a discussion. It should be able to communicate across all modalities and should do so in a logical and reasonable manner. Speech would overlap with proper lip motions, which have been prioritized about the present face animations and the robot dealing with the lips both of it. We illustrate the construction of a Comrade robot in Figure 2 and address the specifications outlined above. However, observe that perhaps the design is abstracted from the specifics of various kinds of friend robotics, allowing its application to diverse kinds of robot Comrades. We are emphasizing again here that it was for a Comrade robot that also has an "overall" personality; nevertheless, you may build various parts without putting any content into them. Initial set of data processing uses dialogue engine and reasoning engine. Depending on the goals, rules, memory unit, and emotion recognitions are taken with heuristics approach. After that, the input and output processing states are determined with facial recognition with animation approach. Dataset uses source from camera, sound, and so forth and the speech recognition and facial recognition data are synchronized. With the low-level behavior, the animation controls are processed. Here this conflict scheduler, the performance of output state is determined.

5. AI and Robotic Technology in Elder Healthcare

By building a framework that incorporates current state-of-the-art AI technologies from an off way, RoboCare aims to help service providers fully appreciate the kind of assistance resources available [18]. The difficult part is to find out whether the methods listed above might help create educational software parts that can be purchased off market. Robotic systems now provide us the ability to create robotic system with very accurate survival skills. We have effectively implemented these systems in both the home and hospital facility settings thanks to a variety of methods.

The professional diagnosis and management Comrade robot is able to provide guidance on prevention and prognosis by collecting data like clinical findings, a client's medical records, and previous medical instances. The robot was created by the robotics and artificial intelligence, that is, related to clinical texts, two million clinical data, and many individual instances [19–22]. The hospital is conducting a pilot programme in which people participate to evaluate the robot. When interacting with a client all through physical diagnosis, the robot "pays attention" to the dialogue and takes the sensor readings along with source information to help the clinician diagnose and prescribe medication [19]. The clinician then collects information to interact with the clinician. It is anticipated that the robot would assist doctors to come to a conclusion about the cause of the patient's symptoms quicker and cut down on mistakes.

The Health System Mechanism, shown in Figure 3, is made up of several AI industrial robots. To arrive at a prognosis, the speech based EHR system and image natural antibiotic are both utilized. Comrade proposes a diagnosis and therapy in which all relevant information is collected.

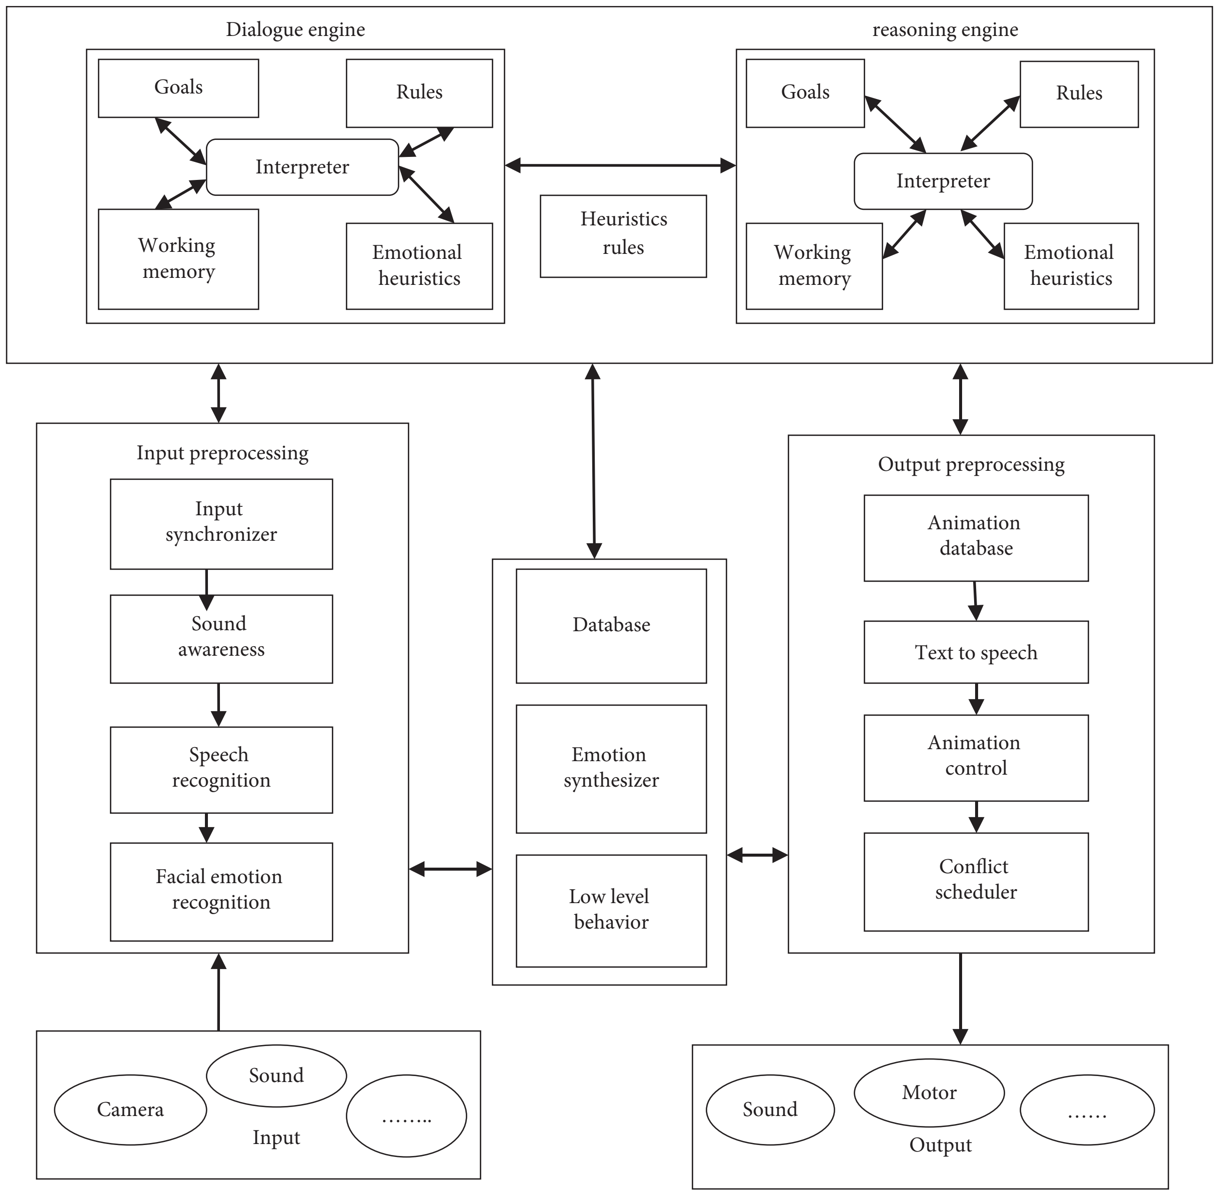

Figure 2: Architecture of Comrade robot.

Thanks to advancements in technology, it is now possible to provide ambient independent living solutions to help seniors in their dwellings [23]. The multidisciplinary approach that is required for robotics technology problems includes knowledge from fields like building, fashion, psychological, law, and ethics, as well as technology, computer programming, science, and medicine. In order to benefit everyone, robots and information and communication technology (ICT) must be made accessible across the populace at school, in hospitals, in home languages, and in smart neighborhoods. A high degree of acceptance and usefulness for the users may be achieved by integrating these approaches in the development of the surroundings.

Some basic suggestions for social order, together with technological and legal troubles, may be discovered through the applying load with actual customers in some kind of a contemporary context.

5.1. Society Centered Design. Robotic technologies should be planned, manufactured, and deployed to assist people in the day-to-day tasks in a societal architecture. The intelligent machines must be able to go from a user-centered design process to a social system design process, at which development process is properly considered and is further integrated with the society's requirements [24]. Many of the ideas shown in the previous sections included users throughout the whole development process, starting with the study of end-users' requirements and leading all the way through the assessment of the prototype system for valuable suggestions.

5.2. Stakeholder Readiness. It is also essential to consider the speed to market in evaluating integrated services. That level of readiness indicates how soon the individuals and

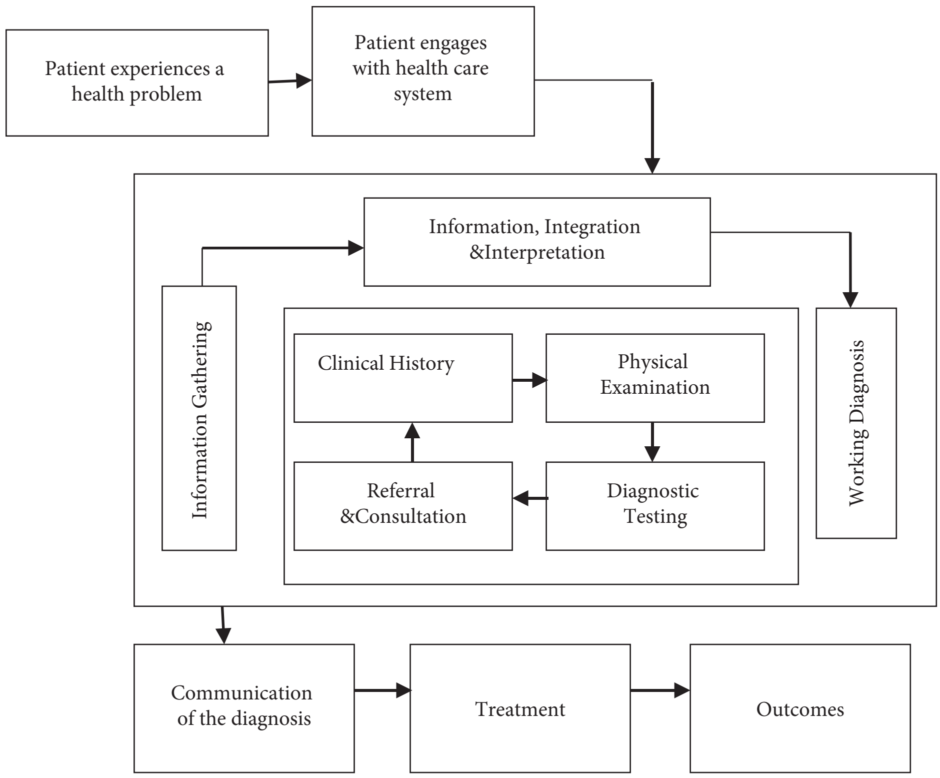

Figure 3: AI robotic systems in elder healthcare process.

organizations are prepared to take and spread the technologies. The gap among study and implementation is the only problem with this topic.

5.3. Low Cost. Considering that personalized robotics are meant to be used by the individual, the price must be in line with their financial capability, in place to encourage for broad service usage. Robotic alternatives incur a reduced cost for the sake of a costing system [25]: they are costly owing to the increased components they employ, but then on the other hand they are less costly for the public health system. Cloud automation solution models may enable a new breed of personalized robots for businesses.

5.4. Customizability, Flexibility, and Modularity. The requirements of the users will fluctuate. Having provided component services, it is essential to offer one that can respond to customer requirements and competences that vary.

5.5. Robustness, Dependability, Safety, and Security. Because the test equipment is expected to engage with those who are vulnerable and aged, it must have been secure and dependable.

5.6. Autonomy. Robotics institutions are expected to move independently and make choices based on the needs of consumers. They ought to be capable of identifying errors that users have made or they have made and make corrections on their own when required.

5.7. Social Informatics of Knowledge Embodiment. Our study has significance that are present in the system; it is applied to other comparable systems. Nonetheless, in order to validate our results, further research with healthcare practitioners in the field is required [26]. In our research of AI-infused autonomous vehicles, we disregarded electronic archives, too. The usage of other things, like computers, may be affected by AI industrial robotics; however, in our research paper, we have not seen this. The possibility of further study includes research that compares cognitive manifestation in various entities in order to learn about how they support or replace one another. Lastly, we have not investigated the nature of senior executives' interest in, or usage of, AI machines. Understanding the four forms of information embodiment as a generative framework for finding motivators may be the most useful. Mechanistic explanation of cognitive immersion should rely on knowing the motive.

From a social bioinformatics viewpoint, AI technology is relevant in the context. It is vital to understand the socio-spatial relationships AI has with people in order to fully comprehend its true worth. STIN analytic approach is particularly helpful, since it offers a paradigm for incorporating various social actors' perspectives while considering technologies [20]. An excellent illustration of our findings is that, in contrast to the robots that were intended to make people's job and emphasizing, the AI humanoid systems that operate as rivals and magisters encounter greater opposition from economic systems than those that work as collaboration and guild mates. This STIN study also showed that the automation technologies supplier has a minimal but nonetheless significant impact on the market.

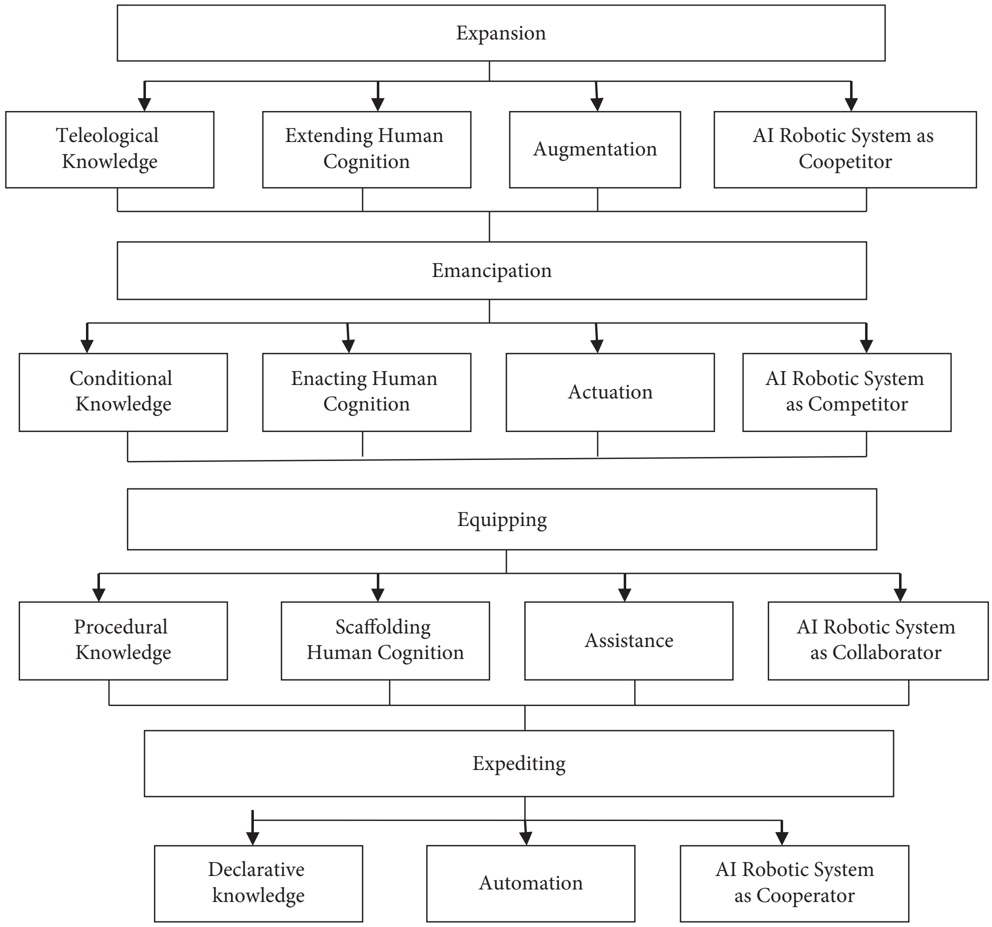

Figure 4: Overview of social informatics of knowledge embodiment.

Requiring timely deployment of AI mobile robots for skilled employees, the supplier highlighted the technologies' complimentary and nonconfrontational character to help people gain confidence. This research confirms that our awareness of the use of AI industrial robotics in intellectual work requires a social information systems viewpoint.

By using powerful computers like AI robotic systems, researchers are showing that they can behave as an independent social actor in addition to just being a tool for humans. When humans and robots interact more naturally and intuitively, the difference between the humanity and the machine may become obsolete. Further refinement of the notion of interconnections in social bioinformatics as interpersonal relations and living organism connection converge may be required in order to help more people have social networks [8]. A manifestation of information changes understanding labor, and the introduction of new privacy practices is probable. Since making scientific have yet to comprehend the consequences of artificial intelligence, it is possible that the necessary training activities may need new methods of collecting, analyzing, and displaying data at employment. Social and community customers frequently need to work with machines, as well. Because of the resulting shift in the organization, in other words, the dissemination of materials is most likely to be caused.

Figure 4 shows major module utilizing expansion, emancipation, equipping, and expediting. Speech data with knowledge analysis, human cognition, augmentation, and AI robot are analyzed in expansion set. Actuation and competitor design of emancipation is determined. Assistance and automation model uses the procedural knowledge and final declaration.

6. Methodology

Robotic systems that utilize the making plans, observation, concurrence, and successive cognitive orientations review process acquire questionnaire questions from guardians and carry out the intellectual orienting examination control and experimental group. The robot then engages in a discussion with the user and gathers feedback. When the robot has finished evaluating the responses, it reports back to those same caregivers with the results [25]. This section describes the cognitive assessment method and the communication mechanisms platform. Our Friend Robotic, a 3D-printed desk device, is fitted with a cognition assessment process. The capacitive touch screen is linked to an ARM-based microcomputer executing Android platform, and the interaction is shown on it. In addition to having a 3D camera, this robot is equipped with a vision circuit composed of an RGB-D camera for image recognition and four loudspeakers that help with sound localization. We have also included voice and physical movement detection in our robot arm, as can be seen in Figure 5. The cognitive orientation assessment method has seven critical features: a development tool, inquiry and response creation, agreement between two parties, excessive screen, Internet computer vision, answer appraisal, and intelligence score [15]. An online dataset and native databases are required for the relational database. In the public cloud, Q&A worksheets containing users' accounts and summaries of memory score are stored, along with cognitive orientations evaluations. These may be revised and checked by a caretaker. The personal dataset provides the user's focus strategy, test timetables, and Q&A answers.

6.1. Modeling and Formulations of Comrade Robots. The study of bending moment enables one to approach performs of large masses. According to the current motion, one may see the position, orientations, and higher incidence as having evolved through time. Dynamics in robotics are used to build up basic equations of controls, with the dynamic transfer function for deceivers acting as the explanation governing motion. Torque is the mechanism that is responsible for producing the dynamic movement of both manipulating arms in a robot's arm [24]. Dynamic modeling is involved in the development of the differential equations of the manipulation as a function of something like the displacements acting on it. In dynamic modeling, the robotics manipulator's components are constrained to a set of forces and; as a result, the locations, velocities, and deceleration are determined:

(i) People who have torque needed to achieve certain end-effector movements are all determined by this calculation (the direct dynamic problem)
(ii) The elastic scattering issue is modeled mathematically, and there are a variety of control methods which use the model
(iii) It enables the calculation of the real manipulation to be done using a control scheme

Lagrange's integrated model may be used to construct Euler equations and manipulate Lagrange's movement. Joint characteristics and characteristics of the manipulation define the motion.

A communication model with overall energy K and gravitational potential V is shown as follows. Lagrange refers to

$$L(q, \dot{q}) = K(q, \dot{q}) - \mathrm{V}(q). \tag{1}$$

It is a simple procedure using the Lagrangian differential equation derived.

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}} - \frac{\partial L}{\partial q} = \mathrm{Q}_i. \tag{2}$$

The general force that corresponds to the generalized coordinate q_i is referred to as Q_i. Connection I has kinetic and potential energy provided.

$$\begin{aligned} K_i &= \frac{1}{2}\,\mathrm{trace}\left[\sum_{j=1}^{i}\sum_{k=1}^{i}\frac{\partial T}{\partial \mathrm{Q}_i}J_i\frac{\partial T}{\partial q_k}\dot{q}_j\dot{q}_k\right], \\ V_i &= -m_i g^T T_I r^{-(i)}. \end{aligned} \tag{3}$$

A second-order linear evolution equation may be used to describe the Lagrangian equations of motion for the n-th links manipulators.

$$\sum_{j=1}^{n} B_{ij}\ddot{q}_j + \sum_{j=1}^{n}\sum_{K=1}^{n} C_{ijk}\dot{q}_j\dot{q}_j + g_i = \mathrm{Q}_i, \tag{4}$$

where

$$\begin{aligned} B_{ij} &= \sum_{k=\max(i,j)}^{n}\mathrm{trace}\left[\frac{\partial T_k}{\partial q_i}J_k\frac{\partial T_k}{\partial q_i}^{T}\right], \\ C_{ijk} &= \sum_{k=\max(i,j,k)}^{n}\mathrm{trace}\left[\frac{\partial T_h}{\partial q_i}J_n\frac{\partial^2 T_h}{\partial q_i \partial q_k}^{T}\right], \\ g_i &= \sum_{k=1}^{i} m_i g^T \frac{\partial T_k}{\partial q_{ki}} r^{-(i)}. \end{aligned} \tag{5}$$

6.2. Evaluation Process. Google has published a new open software speech recognition processing framework, known as SyntaxNet, to the public. Syntax Net's main purpose is to find out the words and phrases, and each word is clearly shown in phrase. A parser is capable of determining the morphological purpose of any single phrase, including conjunctions, in the phrase. In addition to providing an also before the model named Parse McParseface, Goggling also offers a grammar models, known as Parsey McParseface, that is developed. No matter how complicated the root of a phrase may be, SyntaxNet is able to recognize it [15]. It is able to trace out the connection between the word meaning and each individual word in the phrase. This study aimed to use SyntaxNet, so that the customer's voice communication may be processed genuinely. To illustrate, a phrase will be spoken, at which point the voice activation component will transform textual content, which is then processed by SyntaxNet for deeper comprehension. To put a POS on a word, SyntaxNet examines the whole phrase as well as the word's semantics. Similarly, since SyntaxNet can correctly predict the calculated value used when a machine evaluates the provided response with the right answer, assessing answers that utilize math is quite simple. The capabilities of SyntaxNet may also be utilized to detect whether there is negativity in the word but when the phrase has a pejorative perception.

The programming language we use to describe paragraph characteristics is called SyntaxNet. Step one is answering the question, and step two is evaluating the response. Next, the input is examined and processed using SyntaxNet to identify both user responses and right answers. Long computational network and right answer structure are created from the interpreted results. Those trees stand for the concept of a "pos" and how words relate to one other [26].

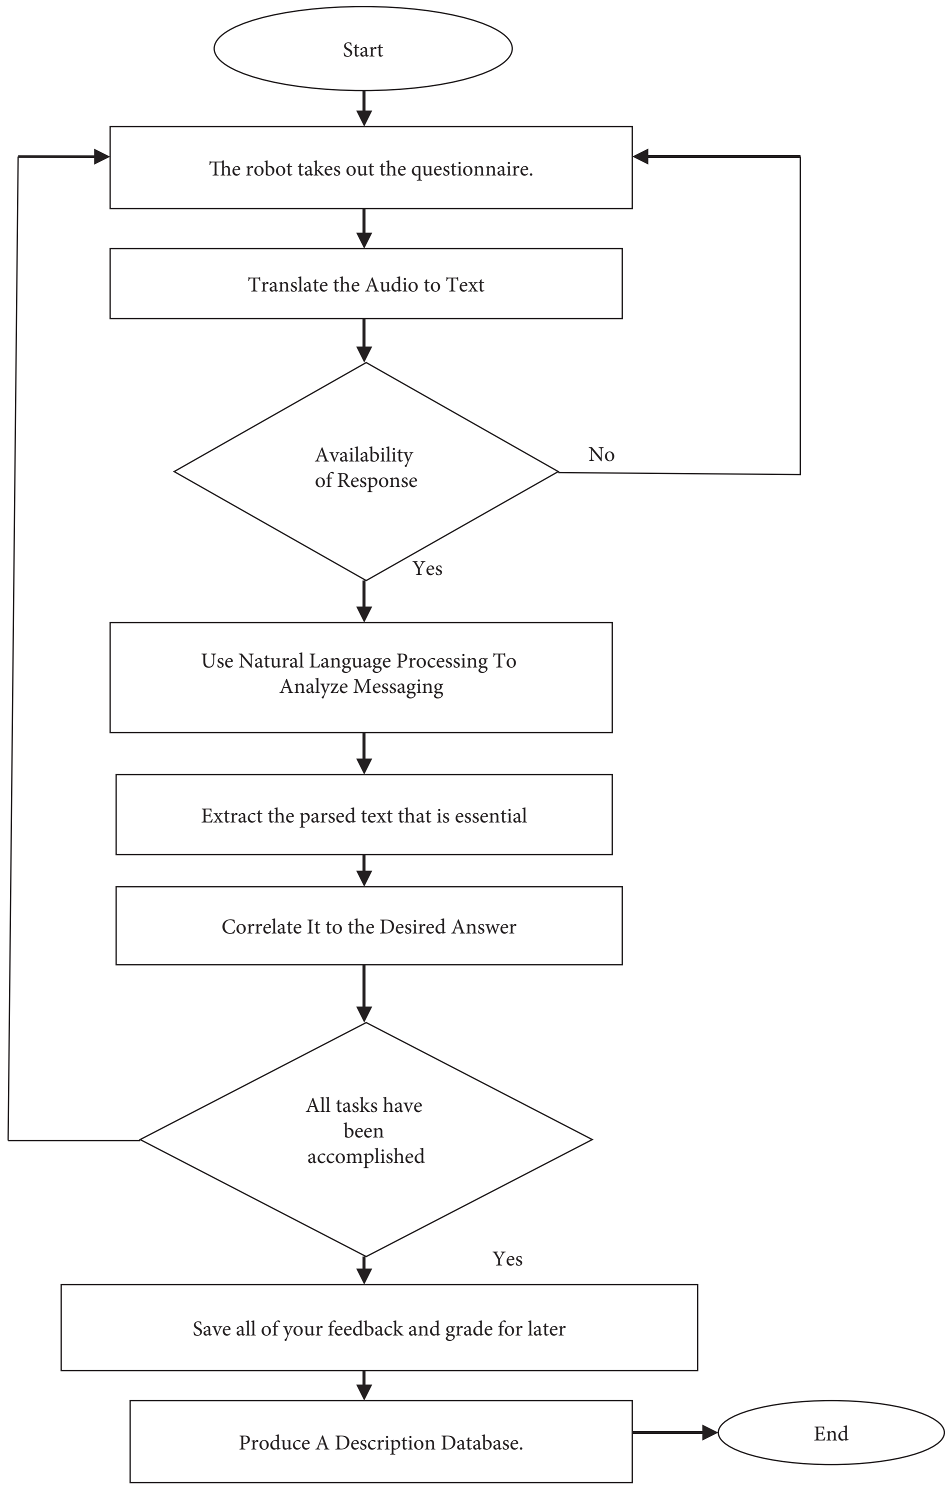

Figure 5: Cognitive assessment of Comrade robot for elder healthcare.

The second step in the algorithm is to connect two trees, and the saplings are compared using a mating Canadian land. A compatibility score is given for these tree trunks, depending on their resemblance. The robot gives a score of 1 to a right answer tree and a score of 0 to an erroneous solution tree. A partial number may be given if the answer matches both trees; however, the progress and achievement are used to evaluate the two trees. To determine the user's cognitive score, the participant's characteristics and a caregiver-determined criterion are utilized.

Recognition state of robot has various questionnaires, which translates the audio data to text data. Depending on the availability of given response, the NLP is performed and messages are taken with NLP analysis model. The parsed text is extracted with the feature set of given database. These correlated results are analyzed and desired answers are taken for the task accomplishment. Feedbacks are saved; then the respective description database assessment result is produced.

7. Result and Discussion

The robots were selected based on the category of robotic systems for old, meaning they may help elderly individuals feel more at ease with one another. The many robots attempted to encompass several diverse settings linked to ageing, such as healthcare, recreation, and commercial work [24]. There were three types of robots: Comrades, service, and factory. The researchers checked all of the materials that the groups debated about which robot should best suit each particular task and put it to the blackboard. We should also point out that respondents were not encouraged to do so, and they did not identify a robot for every activity. A second advantage of having several robots on hand is that they may choose to do multiple activities with each one. In order to prevent pressuring individuals while being indecisive, the course designed was used in this phase.

The data gathered from the activities performed by the respondents were studied by the psychologist from this research. The behaviors generated from the chalkboard and or the edited version of the meetings originated from two separate sources. The whole group meeting was recorded and mapped onto the blackboard with the included assignments [17]. Participants developed 85 activities that included a majority over and over again. The main objective of this study would be to provide light on a variety of activities, and thus the researchers focused on just the activities that were being performed on a regular basis. Thus, only 75 quasi tasks were actually and categorized to collect data. A structure for ageing in place was created so that groups of actions may be classified thus according to both purpose and environment.

Basic Activities of Daily Living. This would be the minimum set of fundamental tasks a person should have been able to do while living on their own (e.g., bathing).

Instrumental Activities of Daily Living. The capacity to carry out effective instrument tasks is an important part of enjoyable life (e.g., managing a medication regimen).

Enhanced Activities of Daily Living. Independence includes time for interests, social interaction, and personal development. It also incorporates interests, social interaction, and personal growth that extend beyond functional needs. These are obligations that go hand in hand with large and important tasks (e.g., buying groceries).

Social Activities. Those practices are intended to promote social connectedness, such as maintaining connections through talking with people. This component was incorporated to the structure for elderly people with robot as per the suggestions gathering of data.

Table 1: Number of activities yield by older adults.

S. no.	Name of the activity	Number of activities
1	IADL	29
2	BADL	20
3	EADL	13
4	SA	13

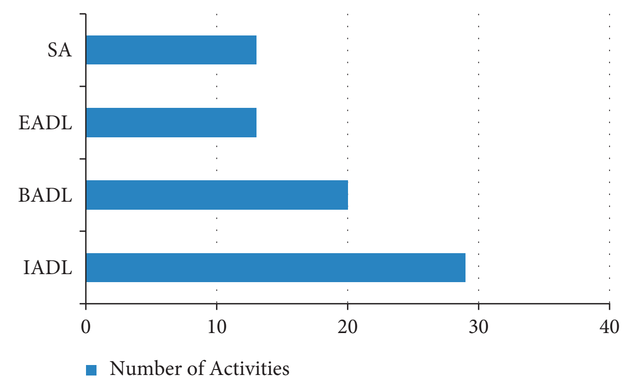

Figure 6: Number of activities yielded by older adults.

7.1. Activities for Ageing in Place with Robots. Table 1 and Figure 6 show that older adults do the same activities every day; they refer to around 29 different daily tasks and use the term Instrumental Activities of Daily Living (20), followed by Basic Activities of Daily Living (or BADL) and then the terms Enhanced Activities of Daily Living (or EADL) and Social Activities (or SA).

7.2. Chosen Robots according to the Different Types of Activities. Table 2 and Figure 7 show that Paro (50%), Pleo (47%), and Emys (55%) are the robots selected by the majority of participants in IADL; Paro (49%), Pleo (42%), and Emys (48%) are the robots chosen by the majority of participants in BADL; and Paro (37%), Pleo (36%), and Emys (32%) are the robots chosen by participants in EADL.

7.3. Accuracy Response of Robots (Comrade and Service) with Different Activities. The activity of ageing in robot model is analyzed with the name and respective value of activity. Different types of activities are evaluated with robot model. The performance states and graph model of Paro, Pleo, and Emys Comrade robots are obtained. Depending on the service type, the accuracy response is obtained and activities of IADL, BADL, EADL, and SA are obtained with two different states. Table 3 and Figure 8 describe that, in IADL, Comrade robot gives highest accuracy response with percentage of 99% compared to service robot;, in BADL, Comrade robot gives highest accuracy response with percentage of 99% compared to service robot; and, in IADL, Comrade robot gives highest accuracy response with percentage of 92% compared to service robot; in EADL, Comrade gives highest accuracy response with percentage of 77% compared to service robot; and, in SA, Comrade robot gives accuracy response with percentage of 64%.

Table 2: Chosen robots according to the different types of activities.

Robot	Activity			
	IADL (%)	BADL (%)	EADL (%)	SA (%)
Paro (Comrade)	50	49	37	12
Pleo (Comrade)	47	42	36	13
Emys (Comrade)	55	48	32	11

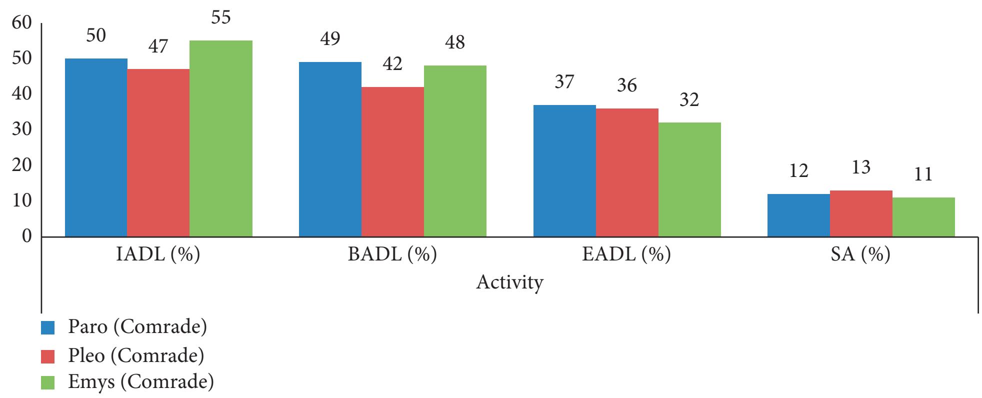

Figure 7: Chosen robots according to the different types of activities.

Table 3: Accuracy response of robots with different activities.

Activity	Accuracy response	
	Comrade robot	Service robot
IADL	99	91
BADL	92	88
EADL	77	23
SA	64	65

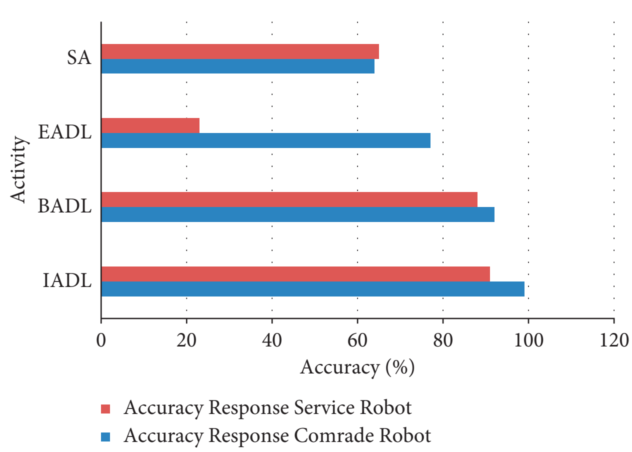

Figure 8: Accuracy response of robots with different activities.

8. Conclusion

Artificial intelligence is a rapidly expanding area of research, which has implications in many sectors, such as medical services, and to provide pharmaceutical aid. It is well established that the area of healthcare is a dynamic market for AI. In this article, a robotics framework is created which uses human messages between a human and a robot to carry out cognitive orientation evaluation. SyntaxNet, which enables the robots to comprehend programming knowledge naturally, helped carry out natural language processing. The Comrade robot was created from the ground up to handle this entire ecosystem. We do not need outside assistance in order to conduct a cognitive orientation evaluation, since the system is capable of doing it. This research sought to elicit tasks where a certain robot aids with increasing the quality of life (QoL) and assisting with an autonomous, healthy ageing. This research presents occupations that are an important component of the lives of older people in all the secondary classrooms. This study demonstrates that it is possible to use technologies with an eye on improving the quality of life for older people. At a profound level, elderly people need robots to do more complex tasks. In the future, the research work may be adopted with big data analysis, image processing, and statistical analysis reviewed with comparative analysis of machine learning approach.

Retraction

Retracted: LncRNA MAGI2-AS3 Suppresses the Proliferation and Invasion of Cervical Cancer by Sponging MiR-15b

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 30 January 2023

Journal of Healthcare Engineering has retracted the article titled "LncRNA MAGI2-AS3 Suppresses the Proliferation and Invasion of Cervical Cancer by Sponging MiR-15b" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Background. Cervical cancer is the leading cause of cancer deaths among women, and more than 85% of cervical cancer deaths occur in low and middle-income countries. The purpose of this study is to investigate the functions of MAGI2-AS3 and miR-15b in cervical cancer. *Materials and Methods*. The mRNA levels of MAGI2-AS3, miR-15b, and CCNE1 were evaluated using RT-qPCR assay. Dual-luciferase reporter gene assay was used to confirm whether miR-15b binds to CCNE1. *Results*. LncRNA MAGI2-AS3 was downregulated, while miR-15b was upregulated in cervical cancer. Cervical cancer patients with low expression of MAGI2-AS3 have a poor prognosis. Upregulation of MAGI2-AS3 inhibited proliferative and invasive abilities of HeLa cells via regulating the expression of miRNA-15b. MiR-15b inhibitor suppressed cell proliferation and invasion. CCNE1 was a direct target gene of miR-15b, which binds to the 3'-UTR of its mRNA. MiR-15b partially reversed the inhibitory effect of overexpression of MAGI2-AS3 on the proliferation and invasion of HeLa cells. MAGI2-AS3 mediated the expression of CCNE1 in HeLa cells. *Conclusion*. LncRNA MAGI2-AS3 inhibits the proliferation and invasion of cervical cancer cells via the miRNA-15/CCNE1 axis. Our results illustrates that MAGI2-AS3 can be used as a useful clinical predictor for early diagnosis and prognosis assessment of cervical cancer.

1. Introduction

Cervical cancer (CC) is the fourth most commonly diagnosed cancer in women and one of the most common cancers in the world. There were approximately 570,000 new cases worldwide in 2018, and 311,000 died of cervical cancer [1, 2]. There are two main types of cervical cancer: cervical squamous cell carcinoma (CSCC), which accounts for approximately 80% to 85% of cervical cancer cases, and the remainder are cervical adenocarcinoma (CAC) [3]. Although treatments such as chemotherapy, radiation, and surgical resection have improved the prognosis of early-stage cervical cancer, the metastasis and recurrence of cervical cancer are the cause of most deaths [4]. Thus, it is urgent to investigate the biomarkers related to cervical cancer metastasis.

Long non-coding RNAs (lncRNAs) belong to noncoding RNAs that are greater than 200 nucleotides in length [5]. Increasing evidence has proven that lncRNAs were involved in range of biological processes, including differentiation, tumorigenesis, and metastasis [6]. For instance, lncRNA-H19 activated the CDC42/PAK1 pathway to promote cell proliferation, migration, and invasion by targeting miR-15b in hepatocellular carcinoma [7]. Long noncoding RNA DSCAM-AS1 contributed to tumorigenesis to enhance cell proliferation, migration, and invasion ability in cervical cancer [8]. LncRNA MAGI2-AS3 suppressed cell viability and migration via miR-374b/SMG1 signaling pathway in hepatocellular carcinoma [9]. In addition, MAGI2-AS3 inhibited cell proliferation and invasion through miRNA-23a-3p/PTEN axis in non-small cell lung carcinoma [10]. Therefore, exploring the mechanism of action of lncRNA

MAGI2-AS3 may provide new ideas for the clinical treatment of cervical cancer.

LncRNAs always regulate cell progression via spongy micro-RNAs [11]. Micro-RNAs (miRNAs) are short noncoding RNAs with a length of approximately 22–25 nucleotides [12]. MiRNAs functioned as regulators in tumorigenesis by cleaving mRNA and suppressing translation [13]. MiR-15b enhanced cell cycle from G1 phase to S phase and reduced cell apoptosis in the treatment of renal cell carcinoma with sunitinib [14]. However, miR-15b represses cell proliferation, migration, invasion, senescence, and apoptosis of ovarian cancer [15].

The cyclin E1 (CCNE1) belongs to the highly conserved cyclin family, whose members are characterized by a dramatic periodicity in protein abundance through the cell cycle [16]. CCNE1, acted as a regulator of CDK kinases, whose activity is required for cell cycle G1/S transition [17]. Overexpression of CCNE1 has been observed in many tumors, which can lead to chromosome instability, and thus may contribute to tumorigenesis. In this study, we found that upregulation of MAGI2-AS3 inhibited the proliferative and invasive abilities of HeLa cells via regulating the expression of miRNA-15b. LncRNA MAGI2-AS3 inhibited cell proliferation and invasion of cervical cancer via the miRNA-23a-3p/PTEN axis.

2. Materials and Methods

2.1. Clinical Samples. During 2015 to 2018, we collected 47 cervical cancer patients from Shandong Provincial Hospital Affiliated to Shandong First Medical University and obtained pairs of cervical cancer tissues and corresponding normal tissues. The excised tissue samples are frozen in liquid nitrogen, followed by cryopreservation. All patients did not receive any therapy before surgery. Our study was approved by the Ethics Committee of Shandong Provincial Hospital Affiliated to Shandong First Medical University, and all patients signed written informed consent.

2.2. Cell Culture and Transfection. A normal cervix epithelial Ect1/E6E7 cell and three cervical cancer cell lines HeLa, SiHa, and CaSki were obtained from American Tissue Culture Collection (ATCC, USA). All cells were cultured in RPMI-1640 (Hyclone, USA) containing 10% fetal bovine serum (FBS) in a humidified atmosphere with 5% CO_2 at 37 °C.

MAGI2-AS3 overexpression vector (pEX-MAGI2-AS3) and the control vector were purchased from Ribobio (Guangzhou, China). The miR-15b mimic, miR-15b inhibitor, and the corresponding controls (NC) were synthesized by GenePharma (Shanghai, China). Lipofectamine 2000 (Invitrogen Life Technology) was used to transfect pEX-MAGI2-AS3, miR-15b mimic, and miR-15b inhibitor into HeLa cells. All cells were harvested at 48 h after transfection.

2.3. RNA Extraction and Real-Time Quantitative Polymerase Chain Reaction (RT-qPCR). The TRIzol reagent (Invitrogen Life Technology) was used to isolate total RNA from HCC tissues or cells. The RT-PCR kit (Takara, Dalian, China) or Hairpin-it miRNA qPCR quantitation kit (GenePharma) was used to perform the reverse-transcription and synthesize the first cDNA chain. The SYBR Green-based PCR kit (TAKARA Biotechnology, Dalian, China) was conducted to carry out the qPCR in an iQ5 Multicolor real-time PCR detection system (Bio-Rad Laboratories, Hercules, CA). The primers were MAGI2-AS3: forward, 5′-CACCTTGCTTGACAACTTGA-3’ and reverse, 5′-CATTACAGCTCGGCTACTGC-3’; glyceraldehyde 3-phosphate dehydrogenase (GAPDH): forward, 5′-ACCACAGTCCATGCCATCAC-3′ and reverse, 5′-TCCACCACCCTGTTGCTGTA-3’; miR-15b: forward, 5′-CTCAACTGGTGTCGTGGAGTCGGCAATTCAGTT-GAGTGTAA-3′ and reverse, 5′-ACACTCCAGCTGGGT-TAGCAGCACATC-3’; U6: forward, 5′-ATTGGAACGATACAGAGAAGATT-3′ and reverse, 5′-GGAACGCTTCACGAATTTG-3’.

2.4. Transwell Assay. Cell invasion assay was carried out using Transwell inserts (Corning, Blacksburg, VA, USA) with a filter of 8 μm pores (BD Biosciences, San Diego, CA) according to the manufacturers' instructions. The upper chamber was added 200 μl medium containing 5×10^5 cells without serum, and the lower chamber was filled with 600 μl medium with 20% FBS. After 24 h of incubation, the invaded cells were fixed and stained with methanol and crystal violet. A light microscope (Olympus Corporation, Tokyo, Japan) was used to count the number of the invading cells.

2.5. Cell Counting Kit-8 (CCK-8). Cell counting kit-8 (CCK-8; Dojindo Laboratories, Kumamoto, Japan) was conducted to evaluate cell proliferation following manufacturer's instructions. Each well was added with 10 μl CCK-8 solution, and then the absorbance was measured using a spectrophotometer (Thermo Fisher Scientific, MA, USA).

2.6. Luciferase Reporter Assay. StarBase v2.0 (http://starbase.sysu.edu.cn/) software predicted the putative miRNA binding sites in the MAGI2-AS3 sequences. HeLa cells were seeded in 6-well plates. The wild-type (WT) or mutant (MUT) MAGI2-AS3 binding sites and the miR-15b mimic or NC (GenePharma Biotechnology, Shanghai, China) were cotransfected in HeLa cells using Lipofectamine 2000 according to the manufacturer's instructions. Cells were harvested 48 h after transfection, and assayed using a luciferase reporter assay system (Promega, Madison, WI, USA) according to the manufacturer's instructions.

2.7. Statistical Analysis. GraphPad Prism software, version 5.0 (GraphPad Software, La Jolla, CA) was used to perform the statistical analyses. The data are expressed as the mean ± standard deviation (SD). The difference between two or more groups was compared by Student's *t*-test and a one-way analysis of variance. Spearman's correlation analysis was used to assess the relationships between MAGI2-AS3 and miR-15b. $P < 0.05$ is considered to be of statistical significances. Results were from at least three independent experiments.

3. Results

3.1. MAGI2-As3 Expresses Low Expression in Cervical Cancer. RT-qPCR was conducted to measure the expression of MAGI2-AS3 in tissues and cell lines. As expected, the expression of MAGI2-AS3 in cervical cancer tissues was lower than that of matched adjacent normal tissues (Figure 1(a)). Moreover, MAGI2-AS3 has been found to be downregulated in cervical cancer patients at III-IV stage compared with the I-II stage (Figure 1(b)). Similarly, the expression of MAGI2-AS3 was lower in cervical cancer cell lines HeLa, SiHa, and CaSki than the normal cervix epithelial Ect1/E6E7 cells (Figure 1(c)). Kaplan–Meier curve was employed to evaluate the overall survival of cervical cancer patients, indicating that downregulation of MAGI2-AS3 predicted a worse prognosis (Figure 1(d)).

3.2. Overexpression of MAGI2-As3 Suppresses the Proliferative and Invasive Abilities in HeLa Cells. The transfection efficacy of pEX-MAGI2-AS3 transfected in HeLa cells was determined by RT-qPCR assay (Figure 2(a)). CCK-8 and transwell assays were applied to assess the cell proliferative and invasive capacities. Cell proliferation was inhibited by transfecting with pEX-MAGI2-AS3 in comparison with negative control (Figure 2(b)). Similarly, the invasive ability of HeLa cells was attenuated by overexpressing MAGI2-AS3 (Figure 2(c)).

3.3. MAGI2-As3 Sponges MiRNA-15b as a ceRNA. The expression of miR-15b was calculated after altering MAGI2-AS3, and we are surprised to discover that the expression of miR-15b was reduced when overexpression of MAGI2-AS3 in HeLa cells (Figure 3(a)). The expression of miR-15b was increased in HeLa, SiHa, and CaSki cells versus normal cervix epithelial cell Ect1/E6E7 (Figure 3(b)). Likewise, the expression of miR-15b was also measured, and we found that miRNA-15b was upregulated in cervical cancer tissues compared with the paracancerous tissue samples (Figure 3(c)). Due to the expression of MAGI2-AS3 and miR-15b in cervical cancer tissues, the correlation analysis was measured. Not unfortunately, it has a negative correlation between the mRNA level of MAGI2-AS3 and miR-15b in cervical cancer tissues (Figure 3(d)). Thus, all the results demonstrated that MAGI2-AS3 sponged miRNA-15b and negatively regulated its expression in cervical cancer.

3.4. Knockdown of MiR-15b Suppresses the Proliferation and Invasion in HeLa Cells. To investigate the functions of miR-15b, the expression of miR-15b was reduced by miR-15b inhibitor ($P < 0.05$) (Figure 4(a)). Cell proliferation was inhibited after miR-15b was knocked down compared with the negative control ($P < 0.05$) (Figure 4(b)). Similarly, miR-15b inhibitor reduced the invasive ability of HeLa cells ($P < 0.05$) (Figure 4(c)). All the findings suggested that silencing miR-15b suppressed HeLa cell proliferation and invasion.

3.5. MiR-15b Restores the Inhibitory Effect of MAGI2-As3 on HeLa Cells. In order to find out whether miR-15b has an effect on the function of MAGI2-AS3, miR-15b mimics were transfected into MAGI2-AS3 overexpressing HeLa cells, and the transfection efficiency was calculated by RT-qPCR ($P < 0.05$) (Figure 5(a)). CCK-8 results demonstrated that retransfection of miR-15b mimic enhanced cell viability versus only transfected pEX-MAGI2-AS3 group ($P < 0.05$) (Figure 5(b)). Moreover, HeLa cells cotransfected with miR-15b mimic and pEX-MAGI2-AS3 cause a great increase of cell invasion compared with pEX-MAGI2-AS3 group ($P < 0.05$) (Figure 5(c)). The results revealed that miR-15b restored the inhibitory effect of MAGI2-AS3 on the proliferation and invasion in HeLa cells.

3.6. CCNE1 Is a Direct Target of MiR-15b. Next, we designed to explore how MAGI2-AS3 and miR-15b were involved in the cervical cancer progression. TargetScan analysis showed that there was an evolutionarily conserved miR-15b binding site in the 3'-UTR of CCNE1 mRNA (Figure 6(a)). Subsequently, the luciferase reporter assay indicated that the luciferase activity of wild-type CCNE1 was decreased. Meanwhile, miR-15b mimic does not alter the luciferase activity of the mutant CCNE1, which demonstrated specific binding of CCNE1 3'-UTR to miR-15b (Figure 6(b)). Furthermore, the expression of CCNE1 was reduced after transfection with miR-15b inhibitor (Figure 6(c)). In addition, the expression of CCNE1 was increased by knockdown of MAGI2-AS3, while it was decreased by overexpressing MAGI2-AS3 (Figure 6(d)). All results exhibit that CCNE1 is a target gene of miR-15b, and its expression is mediated by MAGI2-AS3.

4. Discussion

Increasing evidence indicated that lncRNAs played vital functions in the progression of cervical cancer [18,19]. For instance, lncRNA-CTS promoted metastasis and epithelial-to-mesenchymal transition through regulating miR-505/ZEB2 axis in cervical cancer [20]. Long noncoding RNA ZNF667-AS1 inhibited tumor invasion by counteracting downregulation of micro-RNA-93-3p-dependent PEG3 in cervical cancer [21]. In our study, we discovered that MAGI2-AS3 was low expressed in cervical tissues. Also, through comparing the expression of MAGI2-AS3 in different stage, we found that the expression of MAGI2-AS3 was lower in III-IV stages than I-II stages. The overall survival of cervical cancer patients were calculated and compared its relationship with the expression of MAGI2-AS3. The results indicated that low expression of MAGI2-AS3 was associated with poor prognosis. Previous studies demonstrated that MAGI2-AS3 played tumor suppressive roles in high-grade serous ovarian carcinoma and breast cancer [22,23]. Consistent with the previous studies, we discovered that upregulation of MAGI2-AS3 suppressed cell proliferation and invasion in HeLa cells. However, MAGI2-AS3 promoted progression of gastric cancer and colorectal cancer [24,25]; thus, we conjectured that MAGI2-AS3 might have tissue specificity.

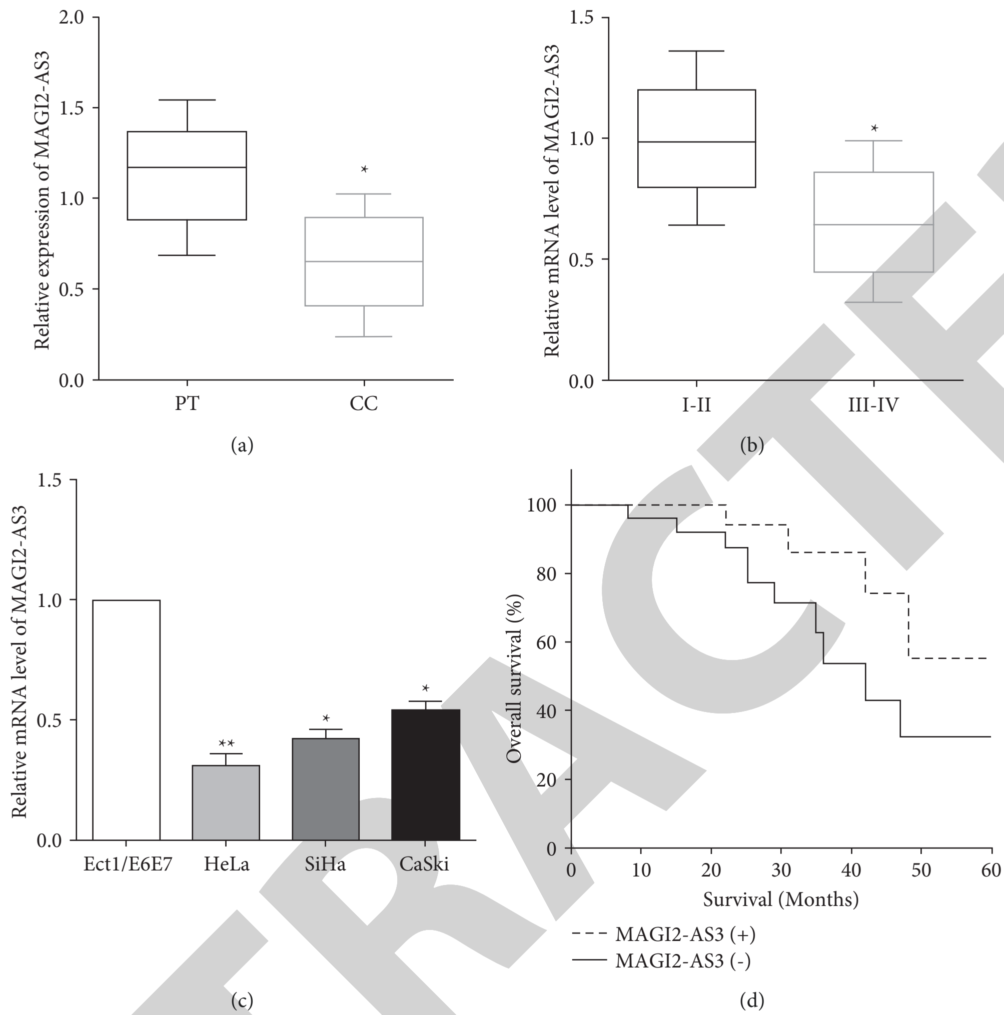

Figure 1: MAGI2-AS3 exhibits low expression in cervical cancer (a) MAGI2-AS3 has a lower expression in cervical cancer tissues than matched adjacent normal tissues. (b) MAGI2-AS3 was downregulated in cervical cancer patients at III-IV stage compared with the I-II stage. (c) MAGI2-AS3 expression was lower in cervical cancer cell lines than the normal cervix epithelial cells. (d) Kaplan–Meier curve indicated that downregulation of MAGI2-AS3 predicted a worse prognosis.

LncRNAs often acted as the endogenous competitive RNA (ceRNAs) of miRNA. LncRNA MAGI2-AS3 inhibited cell invasion and migration via sponging microRNA-374a [26]. Similarly, the spongy of MAGI2-AS3 miR-15b inhibited the progression of bladder cancer [27]. In this study, we discovered that overexpression of MAGI2-AS3 reduced the expression of miR-15b. Evidence showed that miR-15b promoted cell proliferation and invasion by targeting AXIN2 in liver cancer [28]. However, the expression of miR-15b inhibited tumor progression via directly targeting MYCN in neuroblastoma [29]. But the expression of miR-15b in cervical cancer is unknown; thus, we conducted RT-qPCR to assess miR-15b. We found that the expression of miR-15b was higher in cervical cancer cells and tissues. Moreover, the expression of MAGI2-AS3 has a negative connection with miR-15b in cervical cancer tissues. However, we have no evidence to prove whether MAGI2-AS3 and miR-15b directly bind, which was a limitation in this study. Next, the functional tests were performed after knockdown miR-15b in HeLa cells. We discovered that miR-15b inhibitor can impair cell proliferation and invasion of HeLa cells. Furthermore, miR-15b partially reversed the promotive functions of MAGI2-AS3 on HeLa cell viability and invasion. MiR-15b regulates cell differentiation and survival by targeting CCNE1 in APL cells [30]. Consistent with the above findings, miR-15b was confirmed to be directly binding to the 3’UTR of CCNE1 by luciferase report assay. The expression of CCNE1 was suppressed by upregulating miR-15b in HeLa cells. Meanwhile, overexpression of MAGI2-AS3 enhanced the expression of CCNE1, and low expression of MAGI2-AS3 reduced the expression of CCNE1. Thus, we proposed that MAGI2-AS3 enhanced cervical cancer cell proliferation and invasion via regulating the miR-15b/CCNE1 axis.

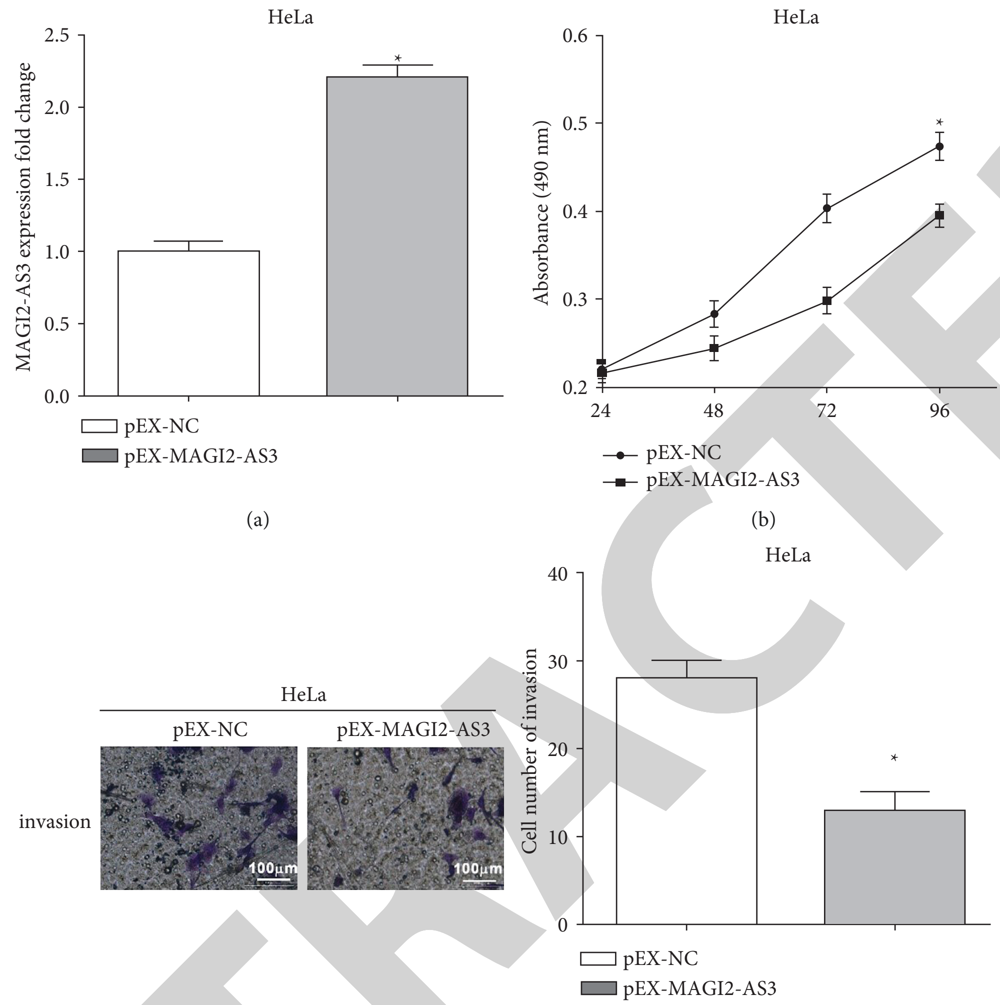

Figure 2: Overexpression of MAGI2-AS3 suppresses the proliferative and invasive abilities in HeLa cells (a) The transfection efficacy of transfection of pEX-MAGI2-AS3 in HeLa cells using RT-qPCR assay. (b) Cell proliferation was inhibited by transfecting with pEX-MAGI2-AS3 in comparison with negative control. (c) The invasive ability of HeLa cells was attenuated by the overexpression of MAGI2-AS3.

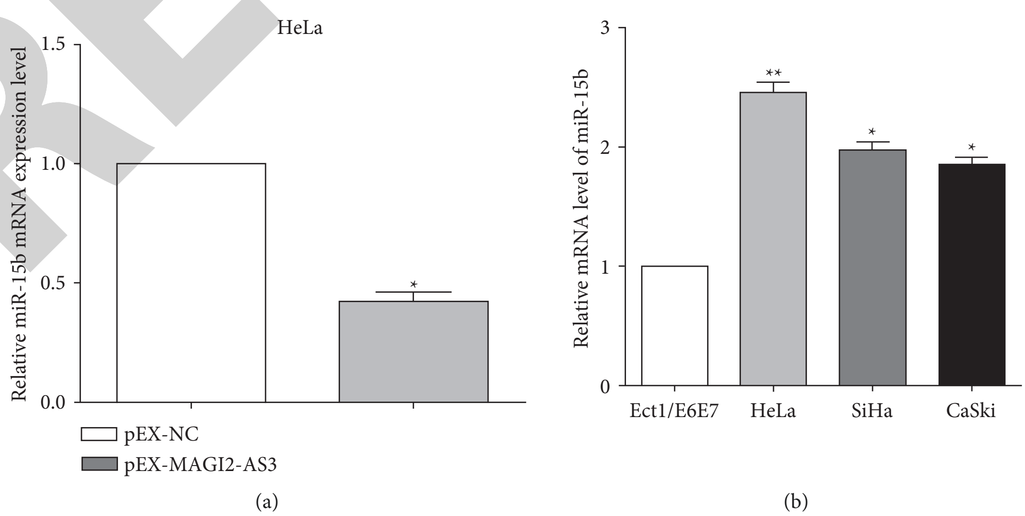

Figure 3: Continued.

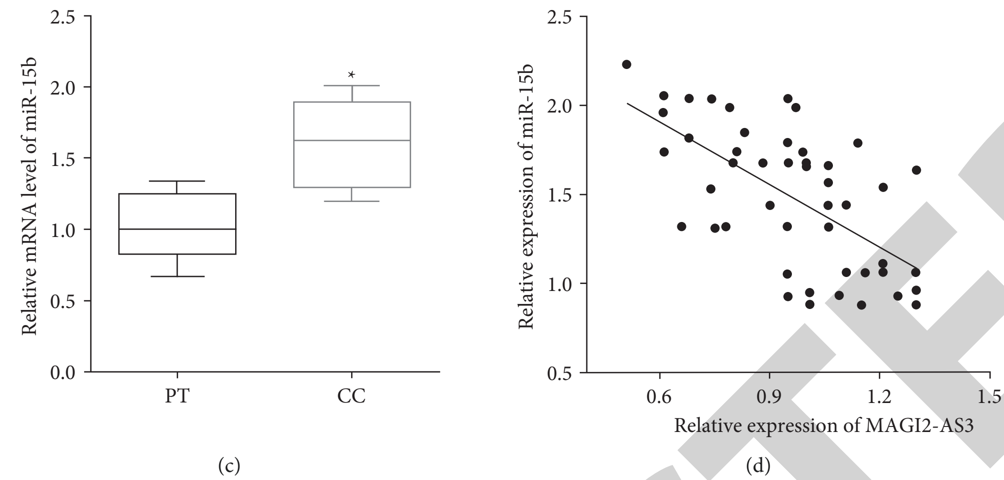

Figure 3: MAGI2-AS3 sponges miRNA-15b as a ceRNA. (a) The expression of miR-15b was reduced when overexpression of MAGI2-AS3 in HeLa cells. (b) The expression of miR-15b was increased in cervical cancer cells versus normal cervix epithelial cell. (c) MiRNA-15b was upregulated in cervical cancer tissues compared with the paracancerous tissue samples. (d) It has a negative correlation between the mRNA level of MAGI2-AS3 and miR-15b in cervical cancer tissues.

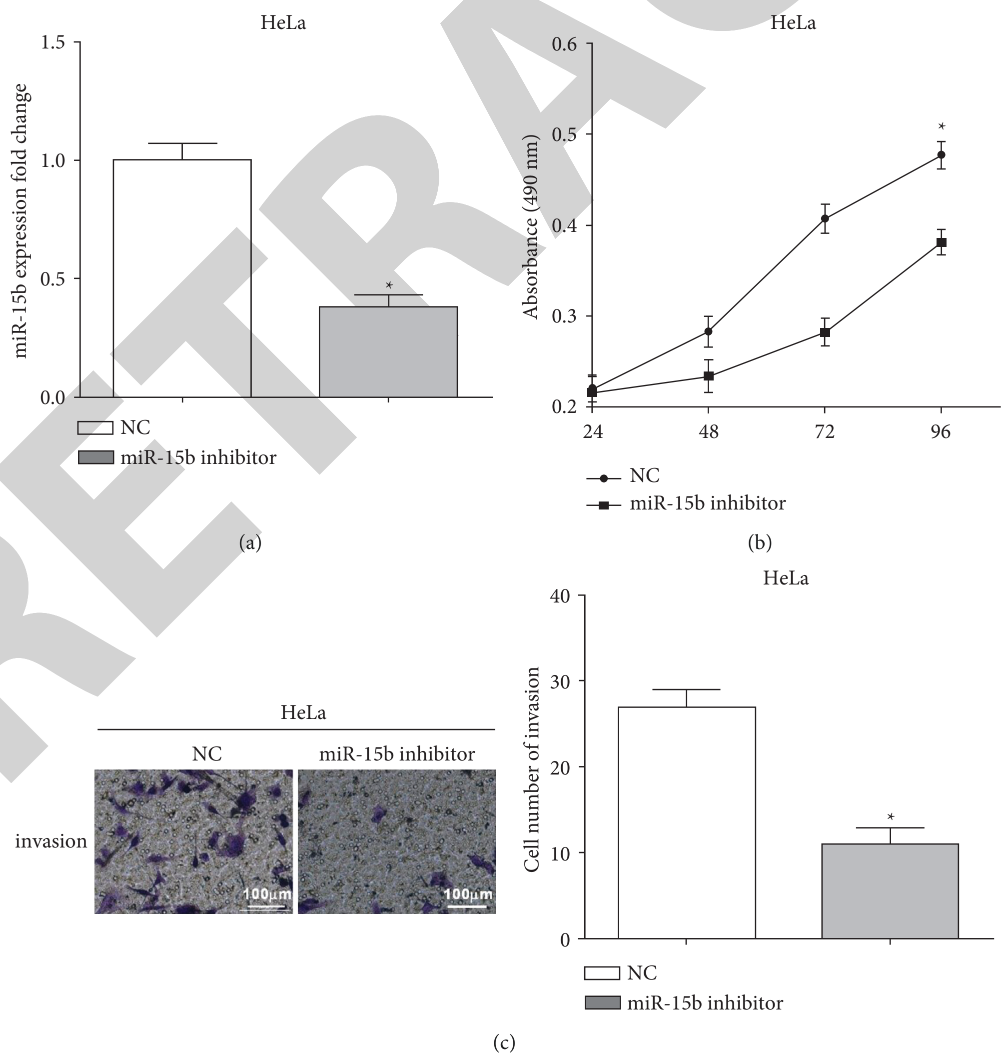

Figure 4: Knockdown of miR-15b suppresses the proliferation and invasion in HeLa cells. (a) The expression of miR-15b was reduced by miR-15b inhibitor. (b) Cell proliferation was inhibited after knockdown miR-15b. (c) MiR-15b inhibitor reduced the invasive ability in HeLa cells.

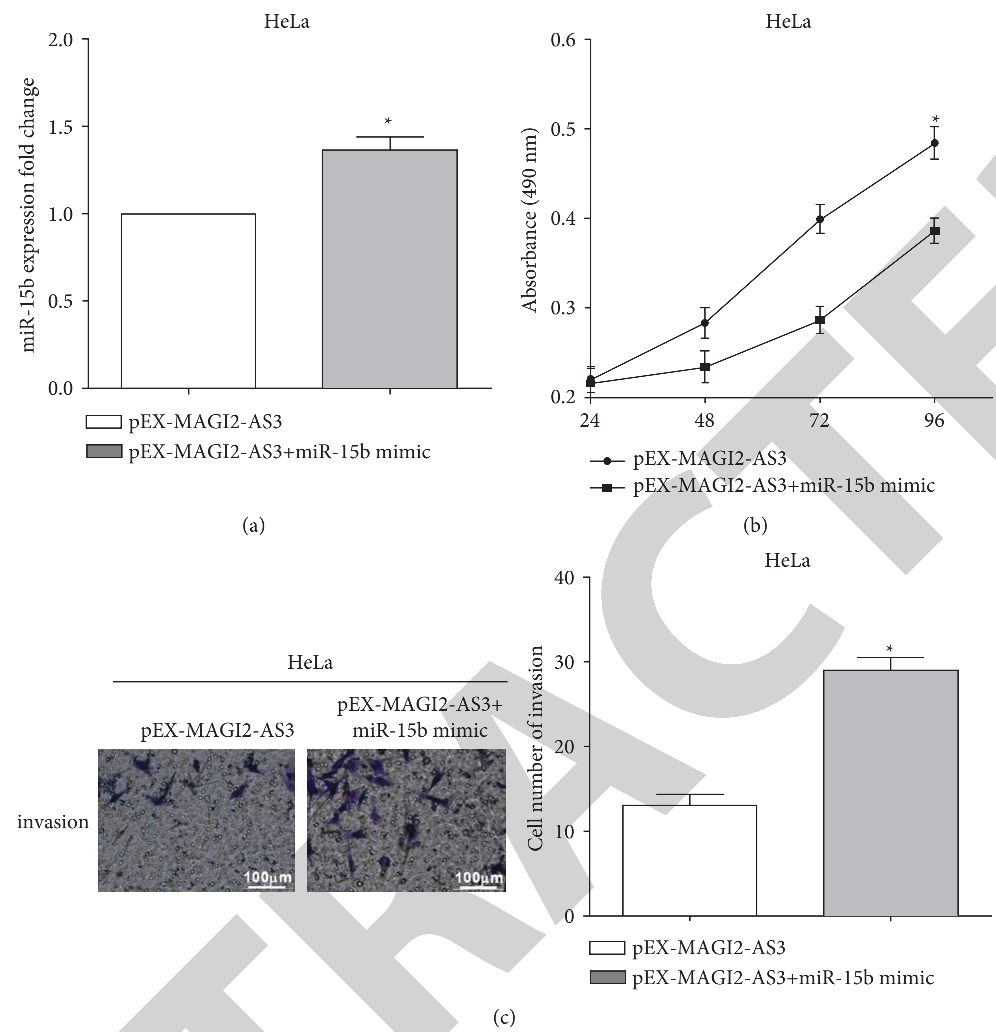

Figure 5: MiR-15b restores the inhibitory effect of MAGI2-AS3 on HeLa cells. (a) MiR-15b mimics were transfected into MAGI2-AS3 overexpressing HeLa cells. (b) Retransfection of miR-15b mimic enhanced cell viability. (c) Cotransfected with miR-15b mimic and pEX-MAGI2-AS3 cause a great increase of cell invasion compared with pEX-MAGI2-AS3 group.

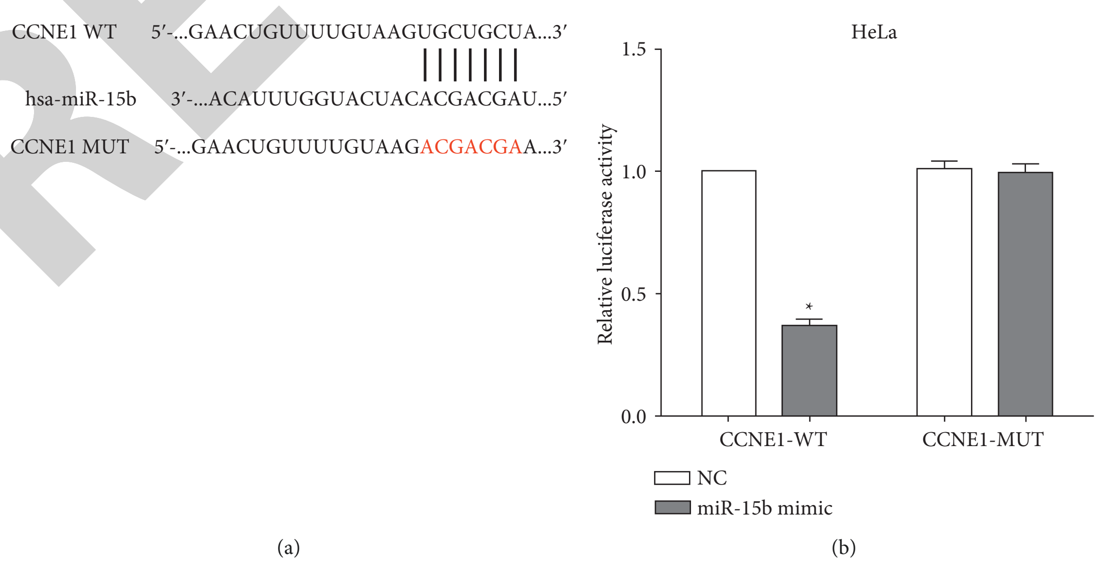

Figure 6: Continued.

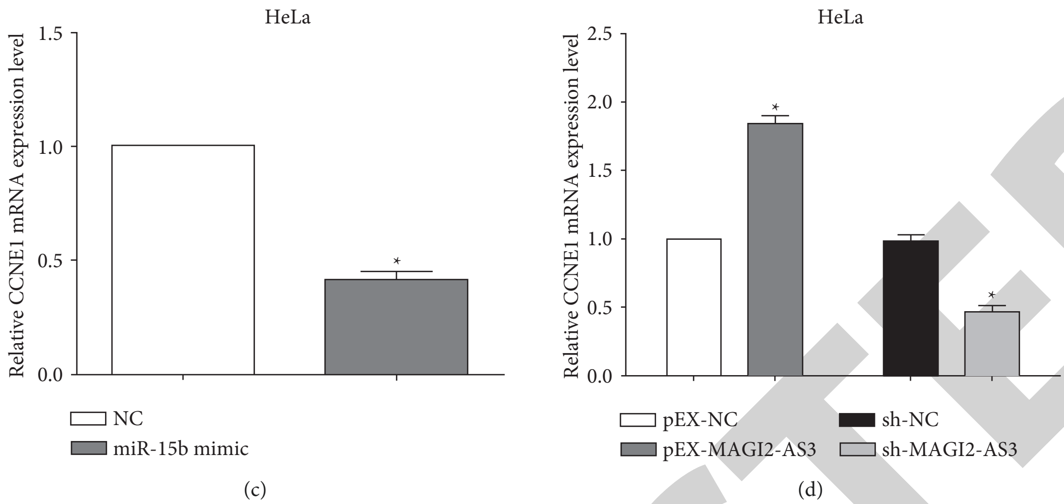

Figure 6: CCNE1 is a direct target of miR-15b. (a) TargetScan analysis showed that there was an evolutionarily conserved miR-15b binding site in the 3'-UTR of CCNE1 mRNA. (b) Luciferase reporter assay indicated that CCNE1 3'-UTR bound specifically to miR-15b. (c) The expression of CCNE1 was reduced after transfecting miR-15b inhibitor. (d) The expression of CCNE1 was increased by knockdown of MAGI2-AS3, while it was decreased by overexpressing MAGI2-AS3.

5. Conclusion

We found that MAGI2-AS3 inhibited the growth and invasion of cervical cancer by regulating the miR-15b/CCNE1 pathway. The findings of this study provide new insights into how MAGI2-AS3 could be an effective target for the diagnosis of cervical cancer. However, it is not enough to support the clinical application of MAGI2-AS3, and more research is urgently needed.

Retraction

Retracted: Investigation on the Effect of Graded Emergency Nursing Group under the Assistance of Multidisciplinary First Aid Knowledge Internet-Based Approach on the First Aid of Acute Myocardial Infarction

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 26 January 2023

Journal of Healthcare Engineering has retracted the article titled "Investigation on the Effect of Graded Emergency Nursing Group under the Assistance of Multidisciplinary First Aid Knowledge Internet-Based Approach on the First Aid of Acute Myocardial Infarction" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Objective. To analyze the effect of a graded emergency nursing group under the assistance of multidisciplinary first aid knowledge Internet-based approach on the first aid of acute myocardial infarction (AMI). *Methods*. The clinical data of 90 AMI patients treated in our hospital from March 2019 to March 2020 were selected for the retrospective analysis, and the patients were divided into the observation group and the routine group according to the first aid order, with 45 cases each. The patients in the routine group received the conventional first aid measures, and the graded emergency nursing group mode with the help of multidisciplinary first aid knowledge Internet-based approach was adopted for those in the observation group so as to compare the prognosis, nursing satisfaction scores, etc., between the two groups. *Results*. Compared with the routine group, patients in the observation group obtained significantly lower various fast reaction indicators and quality of life score ($P < 0.001$), higher nursing satisfaction score ($P < 0.001$), lower total complication rate ($P < 0.05$), higher successful rescue rate ($P < 0.05$), and lower AMI recurrence rate and PCI reuse rate ($P < 0.05$). *Conclusion*. Rescue measures by the graded emergency nursing group with the help of multidisciplinary first aid knowledge Internet-based approach are a reliable method for improving AMI patients, and such strategy greatly promotes patients' quality of life and reduces the PCI reuse rate. Further research will be conducive to establishing a better solution for AMI patients.

1. Introduction

Acute myocardial infarction (AMI), the myocardial ischemic necrosis resulting from the blockage of coronary arteries, is a common critical illness with the characteristics such as rapid disease progression, poor clinical prognosis, and high mortality [1, 2]. Early reperfusion is the key to rescuing patients, and studies have found that [3] the case fatality rate reaches 6% in those who received reperfusion with onset >6 h and decreases to 2% in those who received reperfusion with onset <1 h, indicating that prompt rescue is significant in reducing the mortality of AMI patients [4, 5]. Routine first aid processes are cumbersome and significantly delay the rescue time, so optimization is necessary [6, 7]. For patients with critical, urgent, and complex condition, instead of single department working alone, multiple departments must jointly carry out first aid by the way of consultation to exploit their advantages to the full, thereby taking effective first aid measures with the shortest time and improving the success rate of first aid to the greatest extent through close cooperation. With the help of the modern Internet assistance model, an emergency network consisting of the emergency center, clinic, community medical service, primary hospital, and ambulance is connected, thus helping rescue staff to drive out to the emergency scene precisely and quickly and greatly reducing the time from patients' onset to admission. The treatment effect has been proved in the first aid of severe craniocerebral trauma and chest pain [8]. In addition, investigations found that triage and first aid for patients with different degrees of critical diseases can maximize the first aid efficiency of nurses at different grades and that the implementation of graded first aid nursing in the rescue process can effectively shorten the rescue time, which has been confirmed in the rescue of patients with abdominal trauma accompanied by hemorrhagic shock [9]. At present, there are fewer reports about the graded emergency nursing group with the help of multidisciplinary first aid knowledge Internet-based approach in the first aid of AMI, and the following study was carried out on the basis of the background.

2. Materials and Methods

2.1. General Data. The clinical data of 90 AMI patients treated in our hospital from March 2019 to March 2020 were selected for the retrospective analysis, and the patients were divided into the observation group and the routine group according to the first aid order, with 45 cases each. The study met the World Medical Association Declaration of Helsinki (2013) [10].

2.2. Inclusion and Exclusion Criteria. Inclusion criteria were defined as follows: (1) the patients who were diagnosed with AMI by coronary angiography, with clinical manifestations including severe angina, dizziness, dyspnea, and vomiting, and received first aid treatment within 12 h upon onset; (2) the patients who presented classic changes of myocardial enzymes of AMI (abnormal troponin, creatine kinase isoenzyme, and myoglobin levels); and (3) the patients who had good mental status and could cooperate with the treatment.

Exclusion criteria were defined as follows: (1) the patients who had chronic obstructive pulmonary disease (COPD) and severe mental diseases or were complicated with severe dysfunction in the liver, kidney, and other organs; (2) the patients who had a history of chronic heart disease or heart surgery; and (3) the patients who were complicated with cardiac insufficiency or language expressing difficulty.

2.3. First Aid Measures. The patients in the routine group accepted the traditional first aid mode. After admission, the blood test was performed on patients in time, two or three effective vein passages were opened as early as possible, patients were guided to rest in bed, and continuous electrocardiographic monitoring was conducted to closely monitor changes in various vital signs and carefully observe patients' condition. After the patients were diagnosed, the nurses prepared the patients for surgery and sent them to the catheterization room [11, 12].

The graded emergency nursing group mode under the assistance of multidisciplinary first aid knowledge Internet-based approach was conducted on patients in the observation group with the following specific steps. (1) An emergency nursing group consisting of 1 head nurse, 2 senior nurses, 5 nurses, and 2 specialist physicians was set up with the head nurse as the group leader. The emergency nurses were graded, to be specific, those with at least 5 years of working experience and obtained the professional title of above senior nurse were primary nurses; those with at least 3 years of working experience and obtained the professional title of nurse or senior nurse were secondary nurses; and the nurses, practice nurses, or senior nurses engaged in advanced studies with less than 3 years of working experience were tertiary nurses. (2) A regional Internet collaborative treatment mode for AMI was established. With the help of the "BianQueFeiJiu" remote emergency system and the AMI WeChat group, physicians of the community clinic, emergency clinic, and our hospital could quickly send patients' ECGs to our AMI emergency center and perform online communication, realizing disease recognition and consultation in a timely manner. The "BianQueFeiJiu" information-based system was equipped in ambulance that enabled the use of wireless 12-lead ECG monitor, oximetry, glucometer, etc., to monitor patients' various vital signs and transmit these data and site rescue video to our AMI emergency center via 4G satellite channel in real time so that the experts of the emergency center could carry out consultation on patients' sudden condition in advance based on the data and video and timely provide relatively reasonable guidance on first aid, and patients admitted to the primary-level medical unit of remote area or on the way to the hospital could receive treatment from our hospital in advance. (3) Weekly multidepartment assistance training was carried out to members of the group with the following contents. First, the group leader clarified the training key points and objectives; second, the director of the department of cardiology explained the clinical manifestations, diagnosis, and first aid key points of AMI with specific cases in detail, focusing on helping the emergency nurses to master relevant AMI knowledge; third, based on the selected cases, the director of emergency department explained the diagnosis, first aid, relevant examinations, escort, preoperative preparation, etc., in the first aid of AMI, nursing key points, and relevant precautions of various links and handing over to the catheterization room in detail; and finally, the head nurse of cardiac care unit explained the relevant nursing operation of patients in the unit by referring to classic cases and demonstrating on-site operation. Members of the group raised questions about the problems that occurred during first aid based on the explanation of each department. According to the training and possible problems, the group leader did in-depth organization and analysis, discussed with experts of other departments, optimized and improved various links of first aid in combination with the opinions of other group members, and established a new standardized first aid process.

2.4. Observation Indexes. Fast response indicators: the time from onset to admission, admission to the completion of first myocardial enzyme examination, first medical contact to vascular opening, and onset to calling 120 patients in the two groups was recorded.

After the patients' condition was stable, the satisfaction of the clinical care of AMI patients in our emergency center was investigated with the questionnaire made by our hospital, which contained 4 items, namely, reception operation, basic nursing, service attitude, and service quality. On a scale of 0–100 points, higher scores indicated higher patient satisfaction on clinical emergency care.

The quality of life of patients in the two groups was assessed by the myocardial infarction dimensional assessment scale (MIDAS) [13], which included 7 dimensions (emotional reaction, security, diet, physical activity, dependency, worry about medication, and adverse drug reactions) and 35 items. Each item was rated by the 5-grade scoring method (0–4 points), and higher scores indicated the worse quality of life.

Prognosis: the successful rescue rate, AMI recurrence rate, and PCI reuse rate of the two groups were observed and recorded.

The occurrence of complications of the two groups was recorded, which included arrhythmia, cardiogenic shock, chest pain, and hypotension.

2.5. Statistical Methods. In this study, the data were processed by the professional statistical software SPSS23.0, the picture drawing software was GraphPad Prism 7 (GraphPad Software, San Diego, USA), the enumeration data were examined by the X^2 test and expressed by (n(%)), the measurement data were examined by the t test and expressed by mean ± SD, and differences were considered statistically significant at $P < 0.05$.

3. Results

3.1. Comparison of Clinical Data. No statistical differences in general data including the mean age, blood pressure value, infarction site, and place of residence between the two groups were observed ($P > 0.05$) (see Table 1).

3.2. Comparison of Rapid Response Indicators. Various fast response indicators were significantly lower in the observation group than in the routine group ($P < 0.001$) (see Table 2).

3.3. Comparison of Nursing Satisfaction Scores. The nursing satisfaction score was significantly higher in the observation group than in the routine group ($P < 0.001$) (see Figure 1).

3.4. Comparison of Quality of Life Scores. The quality of life score was significantly lower in the observation group than in the routine group ($P < 0.001$) (see Figure 2).

3.5. Comparison of Prognosis. Compared with the routine group, the observation group obtained significantly higher successful rescue rate ($P < 0.05$) and significantly lower AMI recurrence rate and PCI reuse rate ($P < 0.05$) (see Table 3).

3.6. Comparison of Complication Rates. The total complication rate was significantly lower in the observation group than in the routine group ($P < 0.05$) (see Table 4).

4. Discussion

AMI is a symptom of myocardial necrosis due to acute, sustained ischemia and hypoxia in coronary arteries, which is often complicated by arrhythmias, heart failure, and other complications, seriously threatening the life health of patients [14]. Several studies have confirmed that, for AMI patients, the implementation of timely and effective care is a key to reducing mortality and improving the quality of survival [15–17]. Conventional first aid models are often less normative and methodical and tend to make mistakes in the actual on-site rescue process with low efficiency, resulting in poor patient outcomes. With the rapid development of Internet technology in recent years, the “Internet + smart first aid” mode has been established in hospitals, which integrates modern Internet communication technology into clinical first aid, breaks through the spatiotemporal limitations of traditional prehospital rescue medical activity, better achieves prehospital and in-hospital seamless docking, and greatly eliminates the rescue blind area [18]. AMI patients have an urgent and complex condition, which requires multiple departments to carry out a common rescue treatment by the way of consultation, which has achieved the expected effect in the first aid of AMI [19, 20]. The reasons are as follows: (1) In the rescue and treatment modes, the diagnosis and treatment of various departments are conducted independently, so the departments cannot timely communicate on the information of clinical diagnosis and understand the patients’ condition, often leading to missing the optimal treatment timing and extending the time of rescue treatment. (2) The multidepartment model of first aid has multiple roles from multiple departments and is able to ensure that, during the process of rescuing patients, the operation of the organization is not affected by external factors, thereby greatly enhancing the rescue effect [21]. Graded first aid triages patients separately from different grades of critical care such that nurses with different grades exert the greatest first aid efficiency, which has been proved in the first aid of patients with critical cardiovascular disease in the emergency department [22]. By reviewing relevant information and combining it with clinical first aid emergency, the study achieved better rescue outcomes by implementing graded acute care group rescue measures assisted by a multidisciplinary emergency knowledge Internet-based approach for AMI patients.

The comparison of various indices of rapid response between the two groups revealed that, compared with the routine group, the indices such as time from onset to admission and from first medical contact to vascular opening were significantly lower in the observation group, and the reason was that such care model well solved the problems such as delays in hospital care. This care model can connect emergency centers, clinics, medical service stations, ambulance, etc., into a single emergency network, which maximally extends advanced rescue technology to the front line and better achieves synergistic first aid of AMI, thus effectively avoiding under- or overtreatment, which has been confirmed in the rescue of patients with acute cerebral hemorrhage [23]. The study results showed that the nursing

Observation	45	0 (0.00)	1 (2.22)	0 (0.00)	1 (2.22)	4.44% (2/45)
Routine	45	1 (2.22)	2 (4.44)	2 (4.44)	3 (6.67)	17.78% (8/45)
t						4.050
P						<0.05

satisfaction score was significantly higher in the observation group than in the routine group, indicating that the graded emergency nursing group with the assistance of multidisciplinary emergency knowledge Internet-based approach could greatly improve patients' nursing satisfaction, and the reason was that group members performed their own tasks during the process of rescue, implemented comprehensive care to patients based on the first aid knowledge of AMI they had mastered, and obtained the recognition from patients and their family members because of their solid expertise and operational skills and high-efficient group care, thus enhancing the satisfaction [24, 25]. Shortcomings of the study are as follows: due to the limited study conditions, the study had a smaller sample size and single case source, and the effect of factors such as disease classification on study results was not considered, so the specific rescue plan should be constantly summarized and improved in future clinical practice.

The study aims to explore the effect of subclinical diabetic peripheral vascular disease and an epidemiological investigation of colour Doppler ultrasound images based on a logistic regression mathematical model and a medical image registration algorithm. Subclinical diabetes patients were selected as subjects, and after ultrasound colour Doppler ultrasonography of peripheral blood vessels, ultrasound images were taken. The experimental results show that the area under the curve (AUC) predicted by the model was 0.748, the sensitivity was 94.12%, and the specificity was 67.93%. All Δ were smaller than a single pixel. The detection rate of colour Doppler ultrasonography was 82.6%, which was significantly better than that of clinical examination ($P < 0.01$). The age, course of disease, SBP, low-density lipoprotein cholesterol (LDL-C), total cholesterol (TC), and triglyceride (TG) of the peripheral vascular disease group were significantly different from those of the no peripheral vascular disease group ($P < 0.05$). The incidence of peripheral vascular diseases and nonperipheral vascular diseases in male patients was remarkably higher than that in female patients ($P < 0.05$). Moreover, with the increase of age, the incidence of peripheral vascular disease and nonperipheral vascular disease in diabetic patients showed a trend of gradual increase ($P < 0.05$). In summary, the mathematical model and registration method have high accuracy for medical image registration of patients with the diabetes epidemic. In addition, the age, course of disease, SBP, LDL-C, TG, and TC of diabetic patients were significantly different from those of normal people, which can provide a reference for the development of later diabetes epidemiology.

1. Introduction

When doctors diagnose and treat patients' diseases, they often need to image patients with X-ray, CT, MRI, PET, SPECT, and other imaging modes to provide complementary information on patient anatomy and functional metabolism. Multimode medical image registration is to transform the spatial position of pixels in an image so that it is aligned with the pixels of other pattern images in spatial position, thereby merging image data of various imaging modes and utilizing respective image information [1]. The characteristic is to express information from many aspects of the human body on an image. The voxel similarity-based registration method is a method of high precision and robustness because it directly uses the statistical property of image pixel grayscale information, i.e., mutual information, as the basis for registration, without extracting the anatomical features of the image. Compared with the traditional method, this method has the advantages of high registration accuracy (reaching subturbulence level), good reliability, and no need for image presegmentation and feature extraction. The image after registration and fusion is more conducive to further clinical comprehensive diagnosis [2]. It has received widespread attention and has found wide application in the field of medical image registration.

The most used optimization algorithms in mutual information-based medical image registration are the simplex method and the Powell method, in addition to the simulated annealing algorithm and the genetic algorithm [3]. These optimization algorithms have their own advantages, but they all have shortcomings. The Powell method and the simplex method do not need to calculate the derivative, but the Powell method can easily fall into the local optimum in the registration process, while the simplex method converges too slowly; the simulated annealing algorithm can jump out of the local optimal trap. The time is long and sometimes enters the wrong search direction, so the optimal solution cannot be obtained, and the genetic algorithm is prone to the problem of "premature convergence" [4].

As China continues to age, the incidence of diabetes epidemiology is on the rise, and peripheral vascular disease is the main cause of disability in subclinical diabetes. Clinically, when there are obvious symptoms, it indicates that peripheral vascular lesions have occurred for macrovascular disease. 190 cases of subclinical diabetes epidemic patients in our hospital were examined by colour Doppler ultrasound. A binary logistic regression mathematical model was established to analyze the fitting effect, and a mutual information medical image registration algorithm was used for image analysis. The objective is to know the pathological changes and epidemiological characteristics of peripheral blood vessels more accurately in patients with diabetes mellitus and to explore the risk factors of pathological changes for early diagnosis and prevention.

2. Data and Methods

2.1. General Information. In this study, 190 cases of subclinical diabetes epidemic patients were selected from October 2017 to October 2020. The selected patients met the WHO criteria for diabetes diagnosis, including renal dysfunction, myocardial infarction, cerebral haemorrhage, and cerebral infarction. There were 130 males and 60 females, aged 38–79 years old, with an average of (58.9 ± 6.9) years. The course of disease was 1–28 years, with an average of (7.1 ± 3.4) years. Another 33 healthy subjects were selected as the group without peripheral vascular disease. The patients included had signed informed consent, and the study had been approved by the ethics committee of the hospital.

2.2. Research Methods

2.2.1. Laboratory Inspection. All patients were fasting venous blood on the 2nd day after admission and were checked for fasting blood glucose (FBG), glycosylated hemoglobin (HbAlc), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), total cholesterol (TC), and triglyceride (TG).

2.2.2. Colour Doppler Ultrasonography. Using the colour Doppler diagnostic instrument, the probe frequency was 7.5~10.0 MHz, the wall filter was 50~100 Hz, and the angle between the sound beam and the blood flow was <60°. The patient was placed in the supine or prone position, and the feet were straightened. The bilateral peripheral arterial vessels (femoral common femoral artery, superficial femoral artery, deep femoral artery, radial artery, dorsal artery, and anterior tibialis anterior artery) were examined to detect the diameter of the vessel. Intravascular wall plaque, observing vascular stenosis and colour flow filling, measuring intravascular-medial thickness (IMT). The diagnostic criteria for peripheral vascular disease are as follows: stenosis; plaque (single, multiple, and diffuse); intima is not thick, but echo is enhanced; femoral artery IMT ≥1 mm.

3. The Registration Method Based on Mutual Information and the Hybrid Optimization Algorithm

3.1. Image Registration Principle Based on Mutual Information. Mutual information is a basic concept in information theory. It is used to describe the statistical correlation between two random variables. It can be described by entropy as follows:

$$I(A, B) = H(A) + H(B) - H(A, B). \tag{1}$$

3.2. Registration Transformation Model. For the two images to be registered, a unified stereo coordinate system is first established. The coordinate origin is defined in the gravy centre of gravity of the image, and the two images are coarsely registered. Selecting one image as the reference image R and the other image as the floating image F, the rigid body transformation from the spatial coordinate PF of the floating image to the spatial coordinate PR of the reference image can be described by the following equation:

$$V_R \circ (P_R - C_R) = R_x(\Phi_x) \circ R_y(\Phi_y) \circ R_z(\Phi_z) \circ V_F \circ (P_F - C_F) + t(t_x, t_y, t_z). \tag{2}$$

3.3. Hybrid Optimization Algorithm. The genetic algorithm (GA) is an efficient parallel global search algorithm that simulates the principle of natural selection and genetic mechanism. The GA algorithm flow is shown in Figure 1. Unlike many traditional search algorithms, the search results are closely related to the initial point selection and are easy to fall into the local maximum excellent solution [5].

The SA starts from a higher initial temperature T, and with the continuous decrease of the temperature parameter, the probability of the jump feature is combined with the global optimal solution of the objective function in the solution space; that is, the local optimal solution jumps probabilistically and finally tends to be globally optimal [6]. The SA algorithm flow is shown in Figure 2.

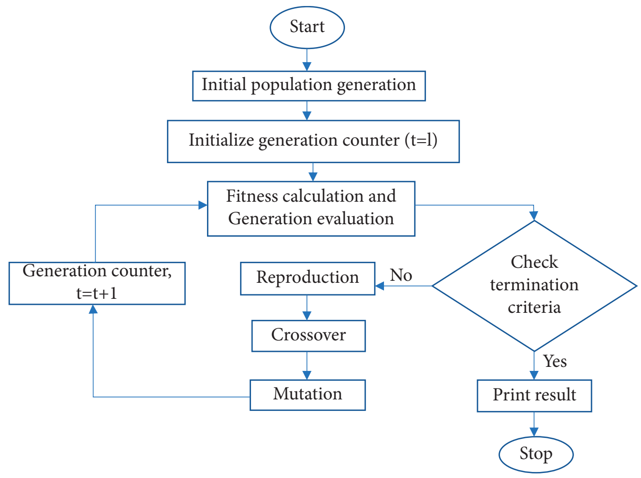

Figure 1: Genetic algorithm flow.

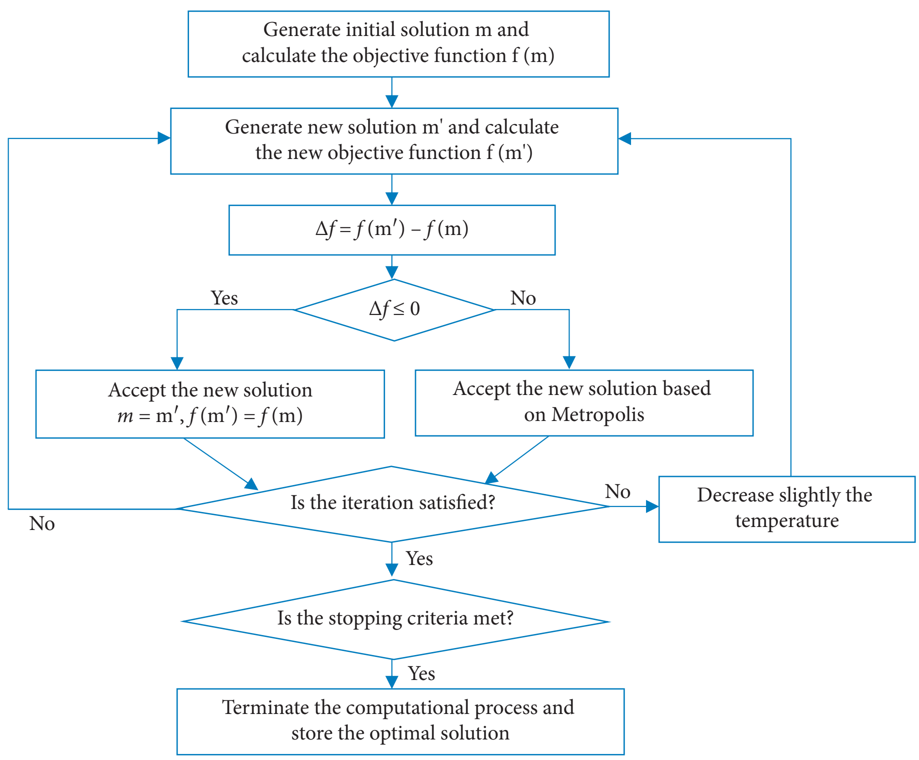

Figure 2: Simulated annealing algorithm (SA) process.

The scope of the search will be narrowed rapidly, but the rapidly converged group does not necessarily achieve the global optimal, which leads to the problem of "premature convergence" [7]. For this "premature convergence," a hybrid optimization algorithm combining the genetic algorithm and the simulated annealing algorithm is an effective solution to introduce Metropolis acceptance criteria in GA.

3.4. Hybrid Optimization Algorithm Parameter Determ ination

(1) In the implementation of the hybrid optimization algorithm, the gene population with the number of chromosomes $n = 50$ is selected, the gene string length is 57, the coding order is $(t_x, t_y, t_z, \Phi_x, \Phi_y, \Phi_z)$, the single-point crossover is adopted, the crossover probability is 0.6, and the mutation probability is 0.02.

Each parameter in the stiffness transformation parameter $(t_x, t_y, t_z, \Phi_x, \Phi_y, \Phi_z)$ is encoded. Since, the coordinate centre of the image is defined in the gravy centre of gravity of the image, which is equivalent to coarse registration of the two images, the amount of translation in the direction of the coordinate axis is generally not large, between −15 and 15 mm, each translation parameter uses 9-bit binary code, the rotation angle is between −10° and 10°, each translation parameter uses 10-bit binary code, so the resolution of the translation amount is about 0.06 mm/bit, and the resolution of the angle is about 0.02°/bit.

(2) In order for the algorithm to reach a quasiequilibrium state at the beginning, the initial acceptance rate should be made.

$$\chi_0 = \frac{M}{N} \approx 1. \tag{3}$$

In this study, it uses the method proposed in [8] to determine T_0 by calculating the average increment of the objective function of several random transformations:

$$T_0 = \frac{\overline{\overline{\Delta f^+}}}{\ln\left(\chi_0^{-1}\right)}. \tag{4}$$

The overall structure of mutual information hybrid algorithms is shown in Figure 3.

3.5. Applying a Hybrid Optimization Algorithm to Solve Spatial Transformation Parameters. The main steps of applying mutual information and hybrid optimization algorithms for image registration are as follows:

(1) Initialize the parameters of the algorithm, $T \longrightarrow T0$, randomly generate a group of initial individuals to form the initial population, and calculate the corresponding objective function value f of everyone in the population, called the fitness value. The individual fitness value of everyone in this study is individual. Mutual information minus the minimum mutual information in this generation of individuals;

(2) Determine whether the algorithm stops the criterion. If it is met, the algorithm ends and returns the optimal solution; otherwise, the following steps are performed;

(3) Using the roulette method to select n/2 pairs of individuals with large adaptation values from the population, as the parent, perform the following operations for each pair of parents:

 (a) Calculate the fitness value f_{C1}, f_{C2} of C1, C2 by the parent P1, P2 by crossing and mutating to generate the children C1, C2

 (b) If $f_{Ci}\,(f_{Pi}, (i = 1, 2))$, replace Pi with Ci; otherwise, accept Ci with probability $\exp[-(f_{Ci} - f_{Pi})/T]$

(4) $T = T \circ \alpha$, return 2.

4. CT-MR Registration

The Vanderbilt University "Review Image Registration Algorithm Evaluation" project has a set of subclinical diabetes patient data practice groups for researchers to conduct initial evaluation of the algorithm. The data set for CT-MR and PET-MR registration is also given. As a result, we applied this set of data and its standard results to evaluate the accuracy of the algorithm results.

The practice group includes a set of CT data and 6 sets of MR data for a subclinical diabetic patient. The 6 sets of MR data are PD, T1, T2, and PD-rectified, T1-rectified, and T2-rectified images, respectively. CT image resolution is $512 \times 512 \times 29$ and voxel size is $0.653595\,\text{mm} \times 0.653595\,\text{mm} \times 4\,\text{mm}$. MR image resolution is $256 \times 256 \times 26$, and voxel size is $(1.25\text{~}1.28\,\text{mm}) \times (1.25\text{~}1.28\,\text{mm}) \times (4\text{~}4.12\,\text{mm})$.

We use the registration method proposed in this study to register CT and MRI images, using MRI images as registration reference images, CT images as registration floating images, and the PV interpolation method for registration experiments. In the experiment, the image data is subsampled to speed up the calculation, and the sampling range on the XY plane is limited to the centre of gravity of the human brain, which reduces the influence of image background pixels on mutual information calculation. We evaluate the accuracy of the registration results by the following methods: 8 vertices qi, MI of the registered floating image, and 8 vertices $q_{i,\text{ref}}$ of the standard result:

$$\Delta = \frac{1}{8}\sum_{i=1}^{8}\left|q_{i,\text{ref}} - q_{i,\text{MI}}\right|, \tag{5}$$

$$\Delta k = \frac{1}{8}\sum_{i=1}^{8}\left|\sum_{i=1}^{8}\left|q_{i,\text{ref},k} - q_{i,\text{MI},k}\right|\right| k = x, y, z, \tag{6}$$

where Δ represents the average geometric distance of the eight corresponding vertices, representing the average absolute error along the coordinate axis, and the registration results are compared with the gold standard according to equations (5) and (6). The results are shown in Table 1.

The registration results of the first 4 behaviours in the table and the registration result of the 5th behaviour document are shown. The pixel diagonal distance in the M R image is taken as a pixel size, namely:

$$\sqrt{1.25^2 + 1.25^2 + 4.0^2} \approx 4.373\,\text{mm}. \tag{7}$$

It can be concluded from Table 1 that all Δ are smaller than a single pixel size, and our registration result meets the subpixel precision requirement. The characteristics of the data are used to set the transformation parameter search order in the Powell optimization process. However, the algorithm does not make any assumptions about the image data of the test. It is not necessary to modify the optimization process for the characteristics of the image. Overall, our algorithm's registration result is better, and the versatility is stronger.

Figure 4 shows the CT image and MR image of the patient in the practice group and the registration results. Comparing Figures 1(a) and 1(b), the original spatial

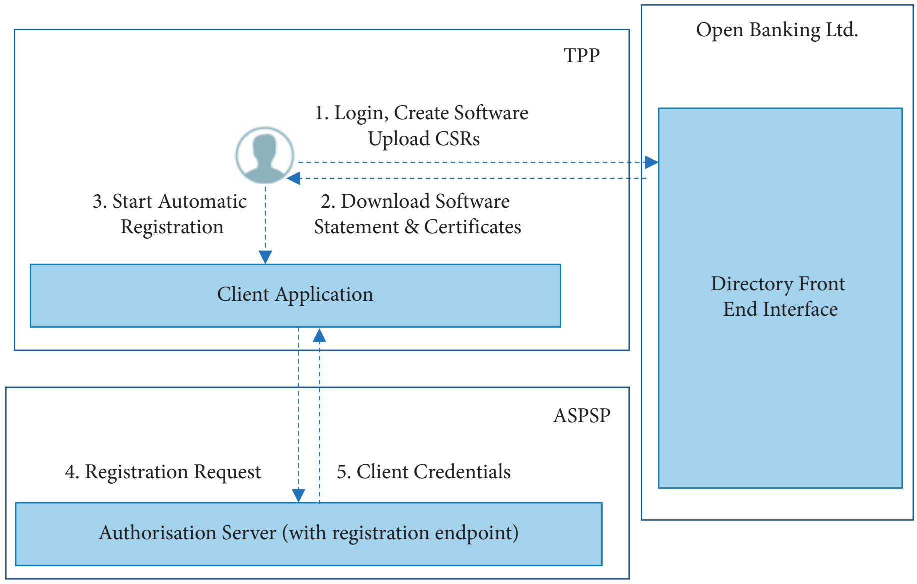

Figure 3: Mutual information hybrid algorithms.

Table 1: CT-MR registration results.

	CT-PD	CT-T1	CT-T2	CT-PDr	CT-T1r	CT-T2r
Δx	0.723	1.212	2.083	1.561	0.407	1.169
Δy	0.772	1.261	2.061	1.442	0.781	1.203
Δz	1.712	1.190	2.330	2.600	1.129	1.251
Δ	2.210	2.262	3.891	3.818	1.535	2.350
Δ [9]	2.561	1.698	2.899	3.144	1.873	3.712

positions of the two images differ greatly. From (d), after the transformation, the two images achieved a good registration result.

5. Statistical Analysis

The results were expressed as mean ± standard deviation ($x \pm s$), and SPSS25.0 statistical software was used for statistical analysis. The incidence rate of peripheral vascular disease and nonperipheral vascular disease was observed by the rank sum test. The results of two groups were compared by the t test and the x^2 test. $P < 0.05$ showed that there was statistical difference, and $P < 0.01$ indicated significant statistical difference. The binary logistic regression model was established according to the single factor. The Hosmer–Lemeshow goodness-of-fit test was used to evaluate the fitting degree of the model. The accuracy of the prediction model was evaluated by AUC (area under the curve).

6. Results

6.1. Colour Doppler Ultrasonography for Peripheral Vascular Disease. Among 190 patients, 157 cases of peripheral vasculopathy were detected by colour Doppler ultrasound, including 132 cases of plaque, accounting for 84.1%; 64 cases of intimal thickening, accounting for 40.8%; and 38 cases of arteriosclerosis, accounting for 24.2%. There were 32 cases of vascular stenosis, accounting for 20.4%, and 16 cases of vascular occlusion, accounting for 10.2%. 105 cases of the posterior tibial artery were involved, accounting for 66.9%; 90 cases of the dorsal artery, accounting for 57.3%; 65 cases of the femoral artery, accounting for 41.4%; 54 cases of the anterior tibial artery, accounting for 34.4%; and 40 cases of radial artery 6, accounting for 25.5% (Figures 5 and 6).

6.2. Comparison of Clinical Examination and Colour Doppler Ultrasonography. Among the 190 patients, 56 patients had symptoms (peripheral limb pain, numbness, peripheral cold sensation, foot ulcer, and dorsal artery pulsation disappeared). The detection rate was 29.5%; colour Doppler ultrasonography showed there were 157 cases of peripheral vascular disease, and the detection rate was 82.6%; the detection rate of the latter was significantly better than the former, and the difference was statistically significant ($P < 0.01$).

6.3. Analysis of Peripheral Vascular Disease Factors. The age, duration of disease, SBP, LDL-C, TG, and TC in the group with peripheral vascular disease were significantly different from those without peripheral vascular disease ($P < 0.05$ or < 0.01). There were no significant differences in gender, BMI, DBP, FBG, HbAlc, and HDL-C between the patients with peripheral vascular disease and those without peripheral vascular disease ($P > 0.05$) (Table 2).

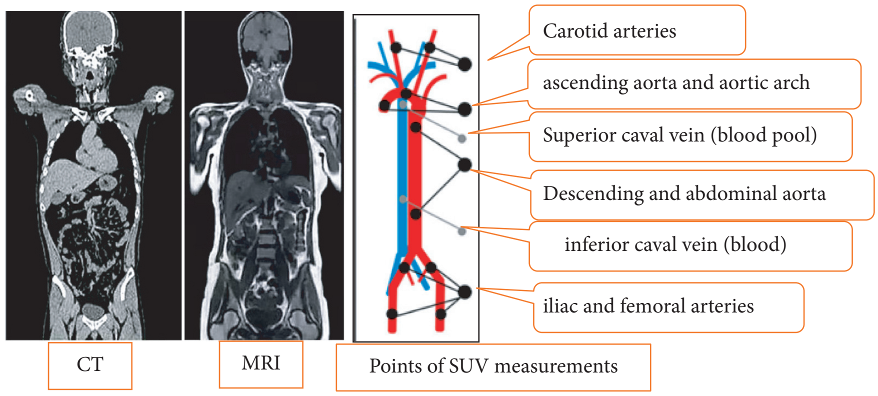

Figure 4: CT-MR image registration result.

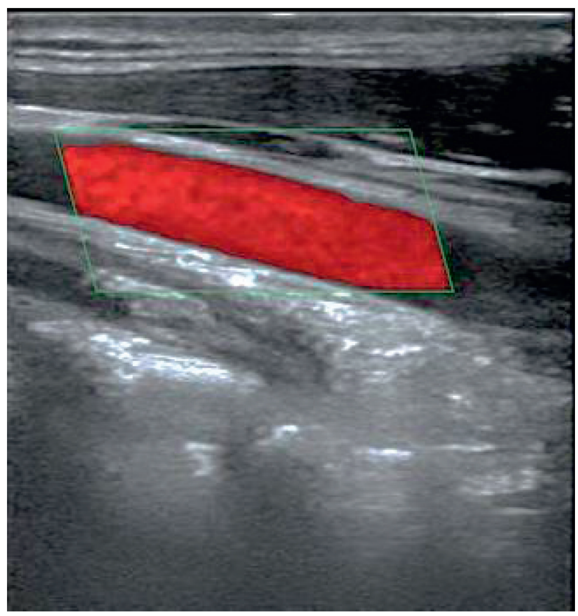

Figure 5: Colour Doppler image of the anterior tibial artery.

6.4. Epidemiological Analysis of Peripheral Vascular Diseases of Different Ages and Genders. The incidence of peripheral vascular disease and nonperipheral vascular disease was compared in diabetic patients of different ages and genders (Table 3). It was found that the incidence rate of peripheral vascular disease and nonperipheral vascular disease in male patients were higher than that in females, and the difference was statistically significant ($P < 0.05$). With the increase of age, the incidence rate of peripheral vascular disease and nonperipheral vascular disease in diabetes showed a gradual increase trend ($P < 0.05$).

6.5. Analysis of Prediction and Fitting Effects of the Mathematical Model. The meaningful independent variables were selected, and the ROC curve of the mathematical model constructed is shown in Figure 7. Through repeated calculation, the AUC value predicted by the model was 0.748, the sensitivity was 94.12%, and the specificity was 67.93%, which indicated that the logistic regression model had a good fitting effect.

7. Discussion

Subclinical diabetic peripheral vascular disease is a common complication of diabetes, and severe cases can cause gangrene in patients. According to statistics, the amputation rate of diabetic peripheral vascular disease is 5 to 10 times that of normal people, and the incidence of peripheral vascular disease with a diabetes duration of more than 5 years is more than 90%, while that of nondiabetics is 10%. The early clinical manifestations of peripheral vascular disease lack specificity. Once there is resting pain, intermittent claudication, ischemic gangrene, etc., trauma treatment or amputation is needed, which brings psychological and physiological relief to the patient. The pain also increases the pressure on the patient's life [10]. Diabetes epidemiology was investigated, and the results showed that the incidence rates of peripheral vascular disease and nonperipheral vascular disease in male diabetic patients were higher than those in females ($P < 0.05$), and the incidence rates of prediabetes and diabetes increased gradually

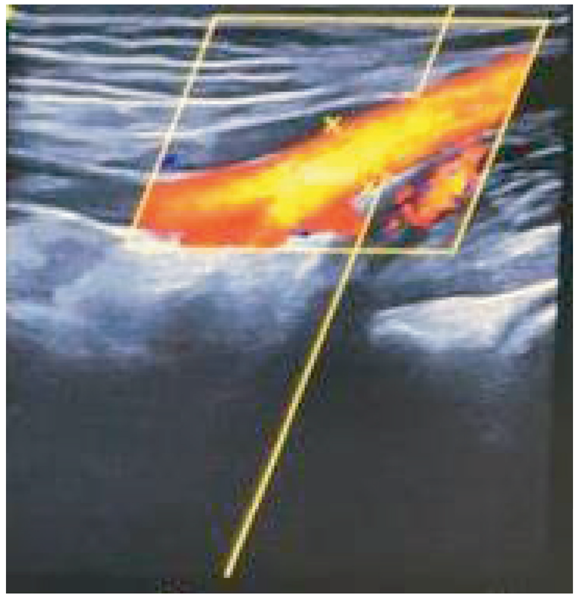

Figure 6: Brachial artery colour Doppler images.

Table 2: Analysis of related factors in the groups with peripheral vascular disease and without peripheral vascular disease.

Index	Peripheral vascular disease group ($n = 157$)	Without peripheral vascular disease group ($n = 33$)	χ^2/t	P
Gender (male or female)	108/49	20/13	0.363	0.125
Age (years)	66.2 ± 6.6	51.8 ± 5.4	7.791	0.000
Disease course (years)	9.1 ± 2.5	5.5 ± 1.6	6.772	0.000
BMI (kg/m^2)	24.1 ± 2.7	23.8 ± 2.2	0.547	0.120
SBP (mmHg)	160.4 ± 16.1	129.0 ± 14.9	7.039	0.000
DBP (mmHg)	78.2 ± 7.8	74.1 ± 6.2	0.993	0.088
FBG (mmol/L)	9.7 ± 2.5	9.6 ± 3.3	0.105	0.323
HbAlc (%)	8.2 ± 0.9	8.6 ± 1.0	1.326	0.072
HDL-C (mmol/L)	1.3 ± 0.5	1.4 ± 0.8	0.573	0.116
LDL-C (mmol/L)	2.9 ± 0.9	2.1 ± 1.0	2.674	0.063
TG (mmol/L)	2.6 ± 1.2	2.0 ± 1.8	2.558	0.069
TC (mmol/L)	5.6 ± 1.3	4.9 ± 0.7	2.373	0.072

Table 3: Comparison of the incidence of peripheral vascular disease and nonperipheral vascular disease in diabetic patients of different ages and genders (case (%)).

Age	Peripheral vascular disease ($n = 157$)			Nonperipheral vascular disease ($n = 33$)		
	Male	Female	Total	Male	Female	Total
30–40	8 (5.10)	7 (4.46)	15 (9.55)	3 (9.09)	1 (3.03)	4 (12.12)
40–50	12 (7.64)	10 (6.37)	22 (14.01)	3 (9.09)	2 (6.06)	5 (15.15)
50–60	18 (11.46)	13 (8.28)	31 (19.75)	4 (12.12)	2 (6.06)	6 (18.18)
60–70	24 (15.29)	16 (10.19)	40 (25.48)	5 (15.15)	3 (9.09)	8 (24.24)
70–80	29 (18.47)	20 (12.74)	49 (31.21)	7 (21.21)	3 (9.09)	10 (30.30)

with age, which was consistent with the results of [11]. Therefore, the early diagnosis and prevention of subclinical diabetes and peripheral vascular disease is particularly important.

Colour Doppler ultrasonography is characterized by simple operations and no trauma. It can detect arterial lesions early and make effective judgments on the severity of lesions and the location of lesions [12]. Research shows that colour Doppler ultrasound is the preferred method for peripheral vascular lesion examination in subclinical diabetes patients and has important clinical guiding significance for early diagnosis, prevention, and treatment. In this group of 190 patients with subclinical diabetes, the detection rate of peripheral vascular lesions was 29.5%, and colour Doppler ultrasonography was 82.6%. The detection rate of the latter was significantly better than the former. The difference was statistically significant ($P < 0.01$). Studies have shown that colour Doppler ultrasound examinations can be used as a

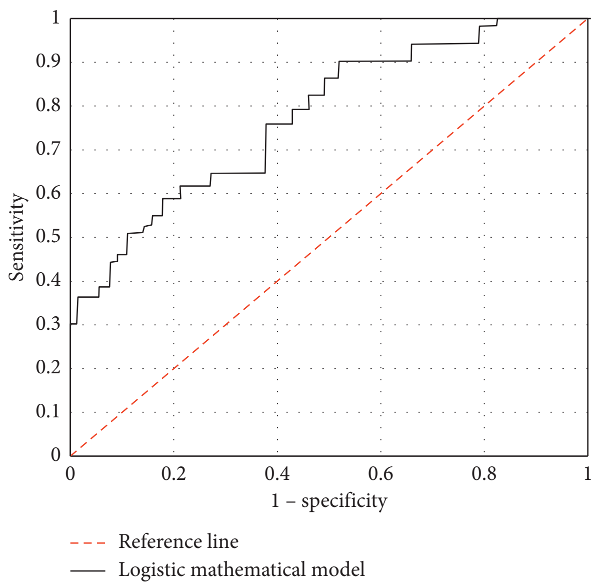

Figure 7: The ROC curve of the logistic regression mathematical model constructed.

routine examination of T2DM, which is conducive to the early detection of peripheral vascular lesions. Among the 157 patients with peripheral vascular disease, plaque accounted for 84.1%, followed by intima thickening in 64 cases. The cumulative posterior tibial artery was 66.9%, followed by the dorsal artery. Studies have shown that peripheral vascular lesions are mainly plaques, followed by intimal thickening, and cumulative after the posterior tibial artery. After the logistic regression mathematical model was constructed, the prediction fitting effect was good, which was consistent with the research of [13].

8. Conclusion

In this study, the hybrid optimization algorithm was used to register the multi-mode medical images. The genetic algorithm is a popular global optimization strategy with a wide application space. In addition, the algorithm also has good advancements, which can easily overcome the problem that the genetic algorithm is prone to early convergence, and it is not easy to fall into a local optimal state. The accuracy of the algorithm can reach subpixel levels, and the algorithm can be automatically implemented. This method is suitable for clinical application because it does not require manual intervention or more preprocessing of images. However, the theoretical derivation and model establishment need to be further discussed, and the registration accuracy also needs to be improved.

Retracted: MicroRNA-517c Functions as a Tumor Suppressor in Hepatocellular Carcinoma via Downregulation of KPNA2 and Inhibition of PI3K/AKT Pathway

Journal of Healthcare Engineering

Received 12 November 2022; Accepted 12 November 2022; Published 29 January 2023

Journal of Healthcare Engineering has retracted the article titled "MicroRNA-517c Functions as a Tumor Suppressor in Hepatocellular Carcinoma via Downregulation of KPNA2 and Inhibition of PI3K/AKT Pathway" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

Objective. Hepatocellular carcinoma (HCC) is a kind of solid and highly aggressive malignant tumor with poor prognosis. MicroRNA (miRNA/miR) has been confirmed to be involved in HCC development. The current study focused on the functions and mechanisms of miR-517c in HCC. *Methods*. Expressions of miR-517c and Karyopherin $\alpha 2$ (KPNA2) mRNA in HCC cell lines and tissue samples were examined using quantitative real-time polymerase chain reaction (qRT-PCR). Western blot was conducted for detections of epithelial-to-mesenchymal transition (EMT) and PI3K/AKT markers. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) and Transwell assays were utilized to investigate the influence of miR-517c on HCC cell proliferation, invasion, and migration. TargetScan and luciferase reporter assay were performed to search for the potential target gene of miR-517c. *Results*. We demonstrated that miR-517c expressions were decreased in HCC tissues and cells. Moreover, the clinical analysis showed that decreased miR-517c expressions in HCC tissues correlated with shorter overall survival and malignant clinicopathologic features of HCC patients. MTT assay showed that miR-517c upregulation prominently repressed HCC cell proliferation. In addition, miR-517c restoration could significantly suppress HCC cell invasion and migration as demonstrated by Transwell assays. We also found that miR-517c directly targeted KPNA2 and regulated the PI3K/AKT pathway and EMT, exerting prohibitory functions in HCC. *Conclusion*. Taken together, this study stated that miR-517c inhibited HCC progression via regulating the PI3K/AKT pathway and EMT and targeting KPNA2 in HCC, providing a novel insight into HCC treatment.

1. Introduction

Hepatocellular carcinoma (HCC) is one of the leading causes for tumor-related mortalities worldwide [1]. Deterioration of the original tumor, metastasis, and relapse have been identified as common factors for the high mortality rates of patients with HCC [2]. The current treatment strategies for HCC patients are mainly liver transplantation and tumor resection. However, advanced diagnoses of HCC patients are very common, and lacking specific biomarkers as well as high metastasis rates in advanced stages made tumor resection impracticable; as a result, only a few HCC patients are suitable for surgery [3, 4]. In addition, even in patients who had received the surgical treatment, the high metastatic and recurrent risks would limit the survival rates [5]. Therefore, it is emergent to unravel the mechanism of HCC metastasis and recurrence, to explore promising therapeutic approaches for HCC treatments.

MicroRNA (miRNA/miR) is a kind of small, noncoding single-stranded RNA, which regulates expressions of genes via interaction with mRNA 3′-UTRs, reducing the translation efficiencies and/or stabilities of target genes in sequence-specific manners [6]. Emerging evidence has indicated that miR is implicated in varieties of biological processes, including cell invasion, viability, and apoptosis [7, 8]. A number of known miRs have been confirmed to exert critical functions in tumorigenesis through regulating specific target genes. Recent studies have indicated that dysregulated miRs in HCC could be used as promising therapeutic and diagnostic targets [9]. Therefore, it is imperative to characterize novel miRs which participated in HCC metastasis and tumorigenesis, providing novel insights into HCC diagnosis, therapies, and prognosis.

miR-517c, a pivotal functional miR, has been recently identified as a tumor-related miR. Despite a previous study which indicated that downregulation of miR-517c promoted HCC proliferation [10], the clinical significance and potential mechanism of miR-517c in HCC need further elucidation. Therefore, we measured the expressions of miR-517c in HCC and searched for the effect of miR-517c on HCC. As demonstrated by the results of our study, we found that overexpression of miR-517c inhibited HCC cell proliferation, migration, and invasion. Moreover, we identified KPNA2 as a direct target of miR-517c in HCC. Consistent with our findings, studies by Lu et al. showed that miR-517c inhibited glioblastoma autophagy and EMT through disruptions of TP53 nuclear translocation via regulating KPNA2 [11]. Findings of our study indicated that miR-517c may act as a novel target in HCC therapies.

2. Materials and Methods

2.1. Tissue Specimens and Cell Cultures. Tissue samples were surgically resected from HCC patients with informed consent at Liaocheng People's Hospital. No patients had received any chemotherapy or radiotherapy treatment prior to the tissue collection. The tissues were frozen in liquid nitrogen immediately, followed by preservation at −80°C. The patients were divided into high and low miR-517c expression groups according to the median level of miR-517c. The present study was conducted in accordance with the Declaration of Helsinki.

The HCC cell lines (Huh7 and Hep3B) and normal liver cells LO2 were purchased from the Shanghai Cell Bank of Chinese Academy of Sciences (Shanghai, China). All cells were cultured in DMEM (Invitrogen, Carlsbad, CA, USA) including 10% FBS (Invitrogen) with 5% CO_2 at 37°C.

2.2. qRT-PCR. Total RNAs were isolated using TRIzol (Invitrogen) and reverse transcribed into cDNA using PrimeScript RT-PCR kit (Takara Biotechnology Co., Ltd., Dalian, China). The miR-517c and KPNA2 expressions were examined by RT-PCR analysis using the TaqMan miRNA assay (Applied Biosystems, Carlsbad, CA, USA) and One Step SYBR PrimeScript™ RT-PCR Kit (Takara) with U6 and GAPDH as internal controls on an ABI 7900 system (Applied Biosystems), respectively. The thermocycling conditions were as follows: pre-denaturation at 94°C for 5 min, followed by 40 cycles of denaturation at 94°C for 30 sec, annealing at 55°C for 30 sec, and extension at 72°C for 90 sec. The $2^{-\Delta\Delta Ct}$ method was utilized for the relative expression quantification. The primers were as follows: miR-517c forward, 5′-GCC ACA TCG TGC ATC CTT TT-3′, reverse, 5′-GTC GTA CCA GTG CAG GGT CC-3'; KPNA2 forward, 5′-ATT GCA GGT GAT GGC TCA GT-3′, reverse, 5′-CTG CTC AAC AGC ATC TAT CG-3′; GAPDH forward, 5′-GCA CCG TCA AGG CTG AGA AC-3′, reverse, 5′-TGG TGA AGA CGC CAG TGG A-3′; U6 forward, 5′- CTC GCT TCG GCA GCA CA-3′, reverse, 5′- AAC GCT TCA CGA ATT TGC GT-3′.

2.3. Cell Transfection. The HCC cells were transfected with miR-517c mimics, inhibitors, or the negative controls by Lipofectamine® 2000 (Invitrogen, Carlsbad, CA). 48 h after the transfections, cells were harvested for the subsequent experiments.

2.4. MTT Assay. The cell proliferation ability was detected by MTT assays. In brief, HCC cells with different transfections (miR-517c mimics/inhibitors) were plated into 96-well plates and incubated for 0, 24, 48, and 72 h. Then, MTT (5 mg/ml) solution was appended into each well and incubated for another 4 h. After that, 150 μl DMSO was added. The OD_{490} values were determined with a microplate (BioTek, Winooski, VT, USA).

2.5. Transwell Assays. Cell invasion and migration abilities were assessed by performing Transwell assays. 8 μm-pore-sized Transwell chambers (BD Biosciences, San Jose, CA, USA) coated with or without Matrigel were used for invasion and migration assays, respectively. The transfected cells maintained in the medium without serum were plated into the upper chambers. The medium containing 10% FBS was added into the lower chambers as a chemoattractant. After being incubated for 48 h at 37°C, the invasive or migratory cells in the bottom chamber were fixed with 95% ethyl alcohol for 15 min at room temperature and stained with 0.1% crystal violet for 10 min at room temperature. In the meantime, the noninvading or nonmigrating cells remaining on the top chambers were removed with cotton swabs. Finally, the results were photographed and quantified in five randomly selected fields under a microscope (Olympus, Japan).

2.6. Western Blotting. Total protein extractions were performed with lysis buffer (Thermo Fisher Scientific, Inc.). The BCA Protein Assay Kit (Thermo Scientific) was utilized to measure the protein concentrations. An equal amount of protein samples were subjected to 10% SDS-PAGE, followed by transfer onto PVDF membranes (Invitrogen). After being blocked with 5% skimmed milk, the membrane was then incubated at 4°C overnight with primary antibodies against E-cadherin (1 : 2000, Abcam), N-cadherin (1 : 2000, Abcam), vimentin (1 : 1000, Abcam), PI3K (1 : 1000, Abcam, Cambridge, MA, USA), p-PI3K (1 : 2000, Abcam), AKT (1 : 1000, Abcam), p-AKT (1 : 1000, Abcam), and GAPDH (1 : 1000, Abcam). After that, the membranes were probed with appropriate HRP-labeled secondary antibody (1 : 3,000, Abcam) for 2 h at room temperature. Finally, the protein band was visualized with ECL reagents (Millipore, USA). GAPDH was an internal control.

2.7. Bioinformatic Analysis. The putative human target genes of miR-517c were analyzed using TargetScan (version 6.0; targetscan.org/)

2.8. Luciferase Reporter Assay. Luciferase reporter plasmids containing wild-type (WT) or mutant (MUT) sequences of miR-517c in KPNA2 3′-UTR were chemically synthesized by GenePharma. For luciferase report assays, HCC cells were cotransfected with miR-517c mimics and KPNA2 3′-UTR-WT/MUT by Lipofectamine 2000 (Invitrogen) following the manufacturer's protocols. 48 h after the transfection, a Dual Luciferase Reporter Assay system (Promega, Fitchburg, WI, USA) was applied for the detection of the luciferase activity.

2.9. Statistical Analysis. All data in the current study were from at least three independent experiments. The statistical analysis was conducted using SPSS software version 17.0 (SPSS Inc., Chicago, IL). Comparisons between two groups were performed by Student's t test, while comparisons among multiple groups were conducted by ANOVA and Scheffe's post-hoc analysis. The Kaplan–Meier method with the log-rank test was utilized to estimate the survival rates. $P < 0.05$ indicated statistically significant differences.

3. Results

3.1. Lowered miR-517c Expressions in HCC Correlated with the Malignant Phenotypes of HCC Patients. miR-517c expressions in HCC tissues and cells were measured by qRT-PCR. The results indicated that that miR-517c was significantly downregulated in HCC tissues (Figure 1(a)). Similarly, the decreased miR-517c expression was also identified in HCC cells (Figure 1(b)). Furthermore, we sought for the clinical values of miR-517c in HCC progression. The HCC patients involved in the current study were divided into high and low miR-517c expression groups according to the median level of miR-517c. As shown in Table 1, patients with low miR-517c expressions exhibited more malignant clinicopathologic phenotypes than those with high miR-517c expressions. In addition, we also found that low miR-517c expression in HCC patients frequently led to shorter overall survival rates than high miR-517c levels (Figure 1(c)).

3.2. miR-517c Restoration Suppressed HCC Cell Proliferation. As we had confirmed the downregulation of miR-517c in HCC tissues and cells, the MTT assays were further conducted to assess the potential functions of miR-517c in HCC cell proliferation by performing gain or loss functions of miR-517c. In brief, Huh7 and Hep3B cells were transfected with miR-517c mimics or inhibitors to overexpress or inhibit miR-517c expressions. The transfection efficiencies were confirmed by qRT-PCR, and results revealed the successful overexpression or silence of miR-517c (Figures 2(a) and 2(b)). Then, results of MTT assays indicated that miR-517c overexpression in Huh7 cells significantly suppressed cell viability (Figure 2(c)). Moreover, miR-517c silence dramatically elevated the viability of Hep3B cells (Figure 2(d)).

3.3. miR-517c Inhibited Invasion and Migration of HCC Cells. To further confirm the biological effects of miR-517c on HCC progression, Transwell assays were performed. Results demonstrated that Huh7 cell invasion and migration were evidently inhibited by miR-517c overexpression (Figures 3(a) and 3(b)). Moreover, the promotion of cell invasion and migration was identified in Hep3B cells transfected with miR-517c inhibitor (Figures 3(c) and 3(d)). Therefore, we concluded that miR-517c exhibited prohibitory roles in HCC progression.

3.4. Overexpression of miR-517c Inhibited HCC EMT and Inactivated the PI3K/AKT Pathway in HCC Cells. To search for the mechanisms by which miR-517c inhibited HCC metastasis and tumorigenesis, we analyzed the influence of miR-517c on expression levels of proteins involved in the EMT and PI3K/AKT signaling pathway, which were related to tumorigenesis. Western blot results demonstrated obvious increase in E-cadherin and significant decrease in N-cadherin and vimentin in Huh7 cells transfected with miR-517c mimics (Figure 4(a)). In Hep3B cells, miR-517c silence dramatically downregulated the E-cadherin expressions and upregulated the N-cadherin and vimentin expressions (Figure 4(b)). Moreover, the phosphorylation of PI3K and AKT was evidently decreased by miR-517c overexpression and remarkably increased by miR-517c inhibition (Figures 4(c) and 4(d)). Collectively, all these findings showed that miR-517c exerted prohibitory functions in HCC cells via regulation of the EMT and PI3K/AKT signaling pathway.

3.5. KPNA2 Was Directly Targeted by miR-517c in HCC Cells. Finally, TargetScan was used to explore the potential targets of miR-517c for further discovery of the mechanisms by which miR-517c inhibited HCC progression. Results indicated that KPNA2 was a candidate target of miR-517c (Figure 5(a)). Thereafter, luciferase reporter assay was carried out to confirm the association between them. miR-517c mimics dramatically decreased the luciferase activity of HCC cells which were transfected with KPNA2-3′UTR-WT, while they did not prominently influence the luciferase activities of cells with transfection of KPNA2-3′UTR-MUT (Figure 5(b)). In addition, we also analyzed the effects of miR-517c on expressions of KPNA2. As demonstrated by the qRT-PCR analysis, we found that KPNA2 expressions presented significant decrease in Huh7 cells transfected with miR-517c mimics (Figure 5(c)). On the contrary, miR-517c inhibition increased the KPNA2 expressions in Hep3B cells (Figure 5(d)). Taken together, results suggested that KPNA2 was a target of miR-517c.

3.6. Increased KPNA2 in HCC Was Related to Shorter Survival Rate of HCC Patients. Subsequently, the expressions and clinical significance of KPNA2 in HCC patients were further investigated. qRT-PCR results indicated that KPNA2 was markedly upregulated in HCC tissues

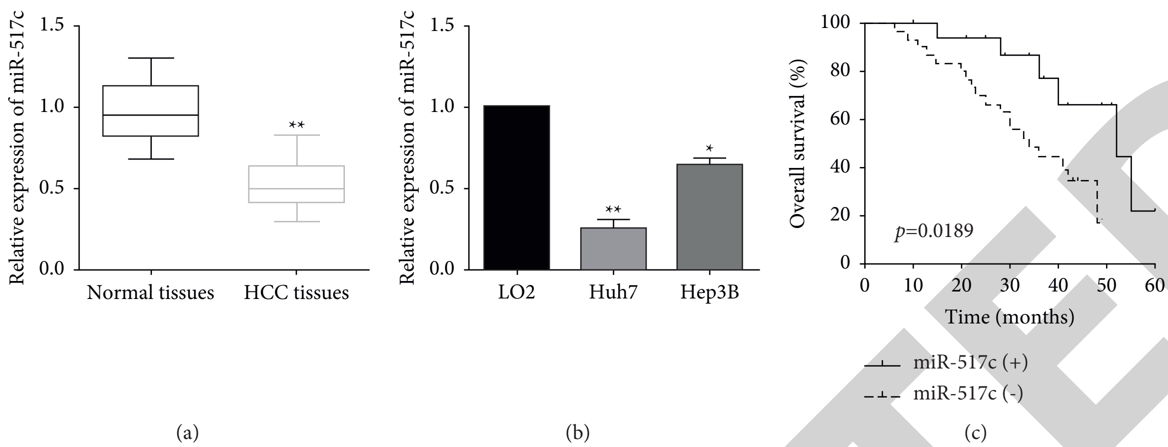

Figure 1: miR-517c was downregulated in HCC and correlated with the adverse clinicopathological features of HCC patients ($n = 47$). (a, b) miR-517c levels in HCC tissues or cells were detected by qRT-PCR. (c) Kaplan–Meier analysis of HCC patients with different miR-517c expressions. $^{*}p < 0.05$; $^{**}p < 0.01$.

(Figure 6(a)). Similarly, the increased KPNA2 expression was also found in HCC cells (Figure 6(b)). Thereafter, the Kaplan–Meier method was utilized to determine the influence of KPNA2 on the survival rate of HCC patients. As expected, we found that the overall survival of HCC patients with high KPNA2 expressions were significantly shorter than patients with low KPNA2 expressions (Figure 6(c)).

4. Discussion

Despite the improvements of the therapeutic methods in HCC treatments over the years, metastasis and relapse of HCC have recently compromised the efficiency of the novel therapies and the survival rates of patients with HCC remain dismal [12]. Hence, thorough understandings of the

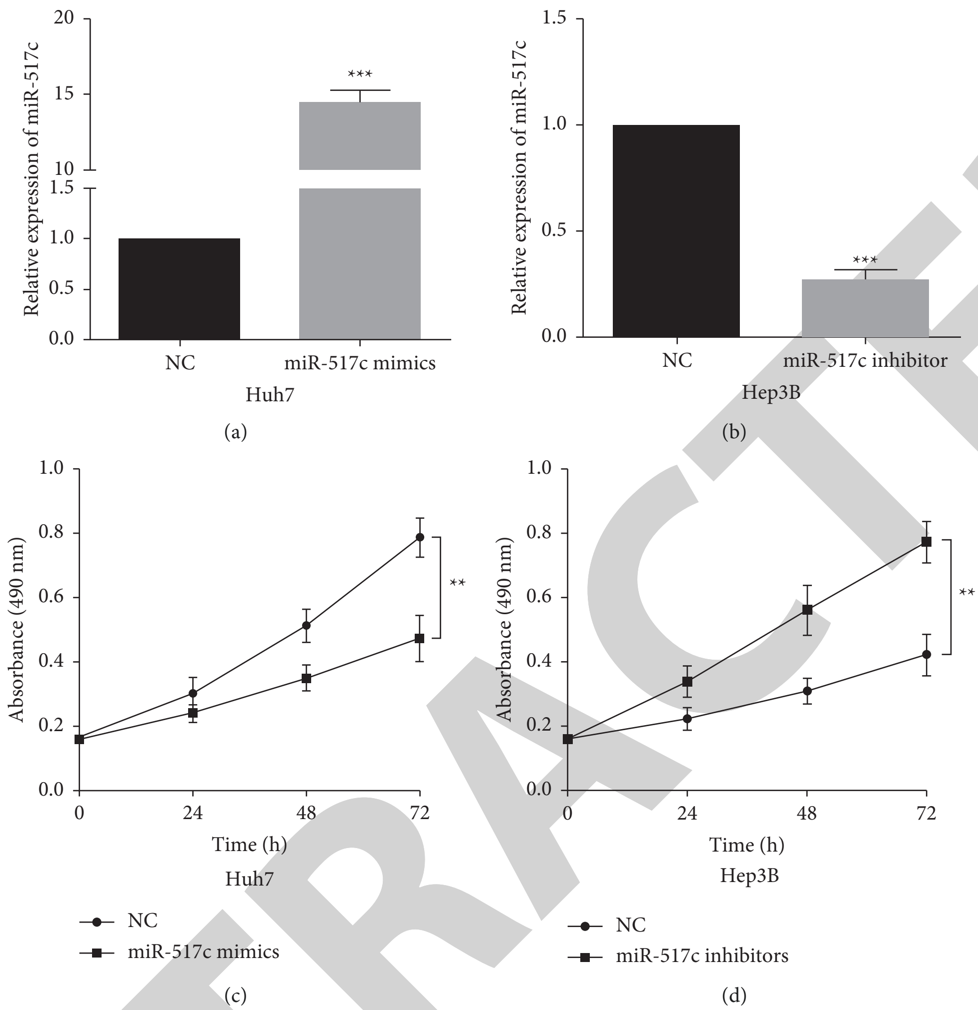

Figure 2: miR-517c overexpression inhibited HCC cell viability. (a, b) The transfection efficiencies of miR-517c mimics or inhibitors in Huh7 and Hep3B cells were examined by qRT-PCR. (c, d) MTT assays were performed to detect the influence of miR-517c on HCC cell viability. $^{**}p < 0.01$; $^{***}p < 0.001$.

mechanisms underlying HCC metastasis are imperative. Accumulating studies have shown that miRs are implicated in tumor development, serving as promising diagnosis biomarkers, effective prognosis factors, and novel therapy targets in numerous tumors, including HCC [13, 14]. Therefore, further study about the functional roles and responsible mechanisms of specific miRs in HCC may help to identify novel biomarkers. In our study, we identified the downregulated miR-517c in HCC and confirmed that decreased miR-517c indicated shorter survival rate and malignant clinical outcomes. Moreover, we also demonstrated that miR-517c upregulation inhibited HCC proliferation, invasion, and migration.

Epithelial-to-mesenchymal transition (EMT) plays a vital role in metastasis and invasion, which are the main causes of most tumor-related deaths, including deaths caused by HCC [15]. Therefore, metastasis and recurrence are mainly responsible for the lethal outcome of HCC patients [16]. It is of great importance to better understand the underlying mechanisms of HCC metastasis. During the typical EMT process, polarized and adherent epithelial cells would be transformed into invasive mesenchymal phenotypes [17]. In brief, the epithelial cell-cell adhesion molecules, such as E-cadherin, would be downregulated, whereas the mesenchymal markers, including vimentin and N-cadherin, are upregulated [18]. A growing number of studies have revealed that EMT served as a main cause for HCC metastasis. However, the association between miR-517c and EMT in HCC was poorly investigated. We found that miR-517c restoration significantly inhibited HCC cell EMT.

It is well known that the PI3K/Akt pathway plays important roles in cell differentiation, apoptosis, and proliferation and has been shown to be implicated in HCC development [19, 20]. Therefore, inhibition of the PI3K/Akt pathway is considered as a promising strategy in tumor therapies. We found that miR-517c upregulation deactivated this pathway in HCC cells. Karyopherin alpha 2 (KPNA2) belongs to the importin α family and participates in the regulation of nucleocytoplasmic transport [21]. It has been shown that KPNA2 is implicated in the pathogenesis of various cancers [22, 23]. Upregulated KPNA2 levels are

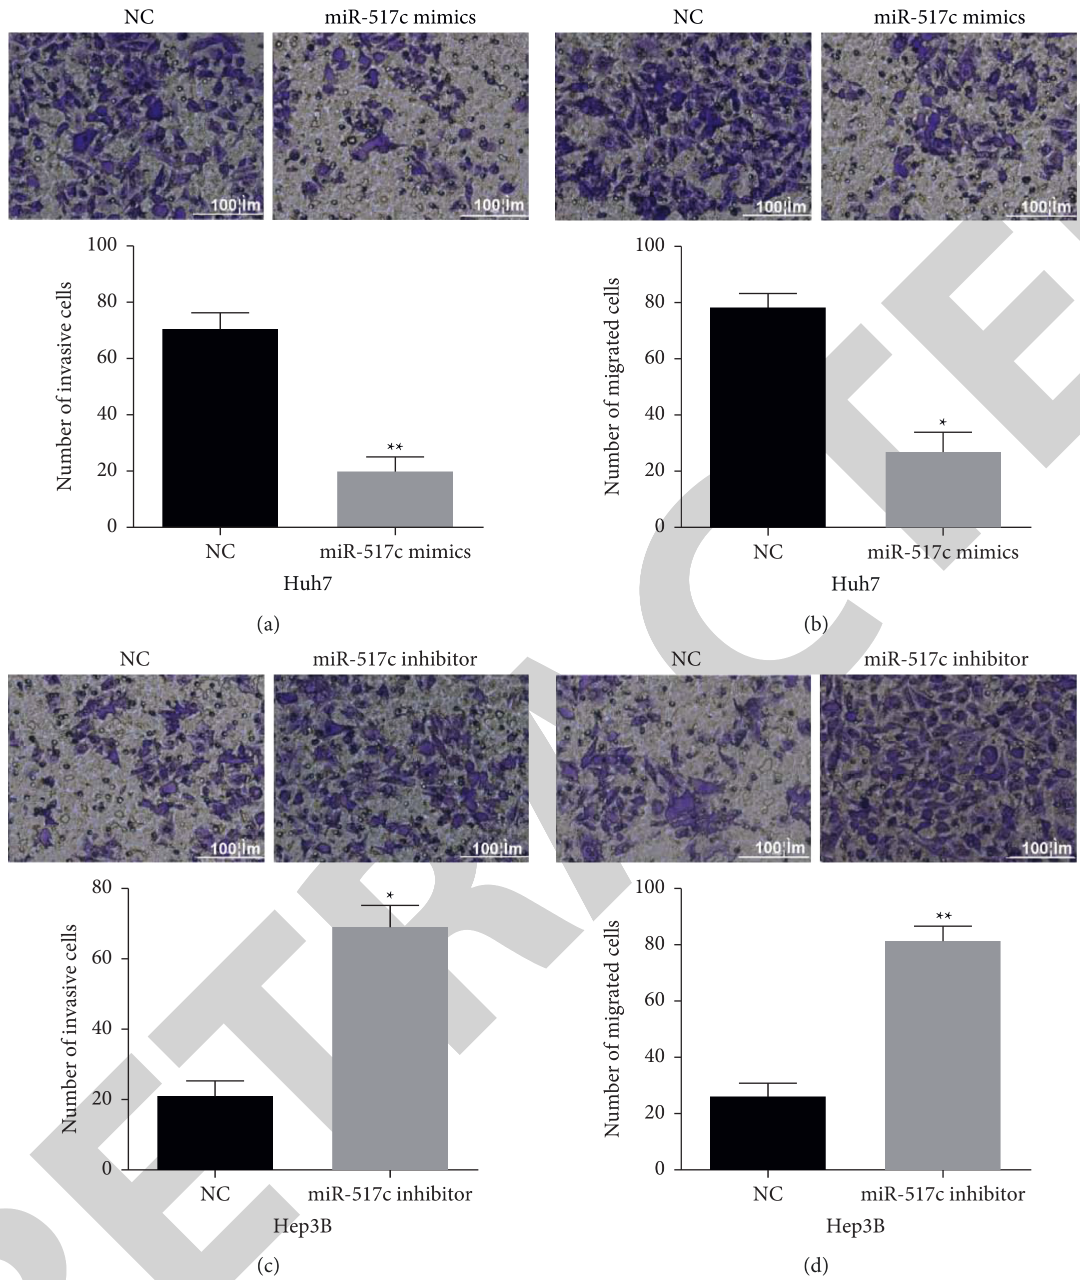

Figure 3: miR-517c upregulation suppressed HCC cell invasion and migration. (a, b) miR-517c upregulation inhibited Huh7 cell invasion and migration. (c, d) miR-517c inhibition facilitated Hep3B cell invasion and migration. $^{*}p < 0.05$; $^{**}p < 0.01$.

found to be correlated with adverse outcomes of patients with clear-cell and papillary renal-cell cancer [24], bladder cancer [25], epithelial ovarian cancer [26], and so forth. Regarding HCC, KPNA2 was confirmed to accelerate HCC progression, suggesting its oncogenic roles in HCC [27]. In the current study, we further explored the biological functions and clinical significance of KPNA2 in HCC. Results demonstrated that increased KPNA2 in HCC tissues correlated with the shorter survival rate of the HCC patients. Moreover, according to bioinformatic analysis, KPNA2 was a direct target of miR-517c. Furthermore, KPNA2 was also confirmed to partially participate in the functional roles of miR-517c in HCC progression.

In conclusion, results of our study demonstrated that miR-517c was downregulated in HCC. The decreased miR-517c expressions indicated adverse clinical outcomes of HCC patients. Moreover, we found that miR-517c inhibited HCC progression, such as viability, invasion, and migration, through regulating the EMT and PI3K/Akt pathway. In addition, the direct regulation of miR-517c on KPNA2 in HCC was also considered to be one of the mechanisms by which miR-517c exerted its inhibitory effects. Therefore, we draw the conclusion that the miR-517c/KPNA2 axis may be a novel treatment pathway of HCC. However, the functions of miR-517c in HCC should be further confirmed *in vivo* in future.

Retracted: Robotic-Assisted Laparoscopic Sacrocolpopexy for Pelvic Organ Prolapse: A Single Center Experience in China

Journal of Healthcare Engineering

Received 19 November 2022; Accepted 19 November 2022; Published 8 December 2022

Journal of Healthcare Engineering has retracted the article titled "Robotic-Assisted Laparoscopic Sacrocolpopexy for Pelvic Organ Prolapse: A Single Center Experience in China" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

The authors do not agree to the retraction.

Objective. The aim is to investigate the efficiency and outcome of robotic-assisted sacrocolpopexy (RASC) in a cohort of patients with pelvic organ prolapse (POP) in our Gynecology Department. *Methods*. We performed a retrospective study of female patients who underwent RASC in Chinese PLA General Hospital from January 2013 to December 2020. Their clinical features included age, degree of prolapse, menopause time, body mass index, pregnancy, delivery, operation time, and bleeding volume. All patients were followed up for more than 6 months. POP-Q was recorded to evaluate the position of prolapsed organs. PFDI-20, PFIQ-7, and PGI-I were used to evaluate the life quality after surgery. *Results*. Twenty-four patients with POP received RASC in our center. The intraoperative bleeding was 86.9 ± 98.3 ml (20–300 ml). The operation time was 143.5 ± 47.3 min (60–240 minutes). The hospitalization time was 10.4 ± 2.1 days (8–16 days). And the follow-up time was 40.8 ± 22.0 months (6–72 months). In the POP-Q follow-up, postoperative Aa, Ba, Ap, Bp, and C were significantly improved than those before surgery ($P < 0.05$). The objective and subjective cure rate was 100%. PGI-I score was very good in 9 (9/24), very good in 10 (10/24), and good in 3 (3/24). Postoperative PFDI-20 and PFIQ-7 were 2.78 ± 3.82 and 1.57 ± 3.86, which decreased dramatically after surgery ($P < 0.05$). Mesh exposure occurred in 4 cases (16.7%) at 2–12 months. The exposed diameters were less than 1 cm in 3 cases (2 A/T3/S1) and 1-2 cm in 1 case (3 B/T3/S1). These mesh exposures healed after conservative observation or mesh excision. *Conclusion*. RASC for POP has the advantage of less bleeding and hospitalization time. It is a minimally invasive option for pelvic organ prolapse.

1. Introduction

Pelvic organ prolapse (POP) is a common disease which occurs in about 40–60% of parous women [1, 2]. It causes a variety of symptoms and decreased the life quality of old women [3]. Because the aging population in China increased gradually, the rates of POP surgery are predicted to grow [4]. Traditional vaginal surgery for POP has been plagued with high failure rates and complications after mesh-transplantation. Sacrocolpopexy has been the gold standard for the treatment of vaginal vault prolapse for decades [5]. It offers better postoperative results than vaginal surgical techniques [6].

With the application of robotic-assisted surgery in gynecologic surgery from 2005, researchers began to introduce this technology into POP surgery. Robotic technology can provide enhanced visualization and wristed instrumentation, enabling surgeons to perform minimally invasive operations [7]. Robotic-assisted sacrocolpopexy (RASC) has been developed as minimally invasive adaptations of sacrocolpopexy [7]. Chinese PLA General Hospital is the first hospital to use robotic-assisted technology in gynecologic surgery in China. RASC has been performed since June 2013. The primary objective of the present study was to report the surgical and patient-centered outcomes as well as adverse events in RASC surgery.

2. Material and Method

We performed a retrospective analysis of patients undergoing RASC for symptomatic apical POP from January 2013 to December 2020 at Chinese PLA General Hospital. Inclusion criteria for RASC were symptomatic apical and anterior prolapse stage ≥ III, negative cervical cytology, and no abnormal uterine bleeding. The concomitant presence of urinary incontinence was not considered an exclusion criterion. RASC was performed using the Da Vinci Robot (Intuitive, Sunnyvale, CA, USA). The clinical data of the patients were collected, including age, body mass index, menopause, pregnancy and delivery times, previous pelvic floor surgery history, internal medicine complications, operation time, bleeding, postoperative complication, and quality of life.

POP was defined according to the pelvic organ prolapse quantification (POP-Q) system. A POP-Q with nine points (points Aa, Ba, Ap, Bp, C, *D*, Gh, Pb, and TVL) was used. The patients were followed up for more than 6 months by the chief physician by gynecological physical examination and postoperative prolapse evaluation in outpatient. Scores from the Pelvic Floor Distress Inventory (PFDI-20) and Pelvic Floor Impact Questionnaire (PFIQ-7) surveys were used to evaluate preoperative and postoperative life quality outcomes.

The basic data of patients were collected by Microsoft Excel (Microsoft Corporation, Redmond, WA, USA) and statistically analyzed by using SPSS 26.0 software.

3. Results

Twenty-four patients were involved in our study, with a mean age of 63.3. They were all menopausal. Preoperative demographic characteristics are listed in Table 1.

3.1. Intraoperation Information. The mesh materials used for robot-assisted vaginal vault fixation are all Johnson and Johnson mesh. There were no conversions to laparotomy or intraoperative complications.

3.2. Postoperative Follow-Up. 24 patients received robotic-assisted operation, including 15 patients who received laparoscopic-assisted hysterectomy (LAH) and bilateral salpingo-oophorectomy (BSO). Mean operation time was 149 min and bleeding was 62.9 ml. Urinary catheter was placed before operation and was removed at 2–4 days after operation. Mean follow-up time was 58.9 months (as shown in Table 2).

All the patients were followed up for more than 6 months (40.8 ± 22.0 months (6–72 months)). Anatomic outcomes are listed in Table 3. The standard of postoperative objective cure was POP-Q stage I. In outpatient follow-up, stage I was found in all cases. The objective cure rate was 100%. No prolapse recurrence occurred. PGI-I score was very good in 9 (9/24), very good in 10 (10/24), and good in 3 (3/24). Postoperative PFDI-12 and PFIQ-7 decreased dramatically. The subjective cure rate was 100% (as shown in Table 4).

However, mesh exposure occurred in 4 cases (16.7%) at 2–12 month after surgery. The exposure diameter was less than 1 cm in 3 cases (2 A/T3/S1) and 1-2 cm in 1 case (3 B/T3/S1) (IUGA/ICS Prosthesis/Graft Complication Classification System). The adverse symptoms were increased vaginal secretions and bloody vaginal secretions. According to the guidelines proposed by the American Society of Obstetricians and Gynecologists (ACOG) and the Gynecological Urology Association (AUGS) in 2017, estrogen ointment and metronidazole suppository were used locally in 3 cases (2 A/T3/S1), and the exposed mesh was partially excised in 1 case (3 B/T3/S1). All patients healed in 3 months.

4. Discussion

Our prospective review shows that RASC is safe and highly effective in treating advanced apical and anterior prolapse at a midterm follow-up. It has obvious advantages in intraoperative bleeding (86.9 ml in average), operation time (149.0 min), and hospitalization time (8.5 days). Also, the urinary catheter can be removed in 3 days after operation. In our follow-up, a significant improvement in POP-Q score and QOL was found in all patients with an overall objective cure rate of 100%. These results indicated that it is a minimal invasive technique for POP.

In 2005, U.S. Food and Drug Administration (FDA) approved Da Vinci surgical system for gynecological surgery. In 2006, the Chinese PLA General Hospital introduced China's first Da Vinci robot operation system. Elliott reported the first series of robot-assisted laparoscopic sacrocolpopexy for high-grade vaginal vault prolapse [8]. The first robot-assisted gynecological operation in China was completed in our hospital in 2009. In 2013, we began to perform RASC for patients with POP. In our series, mean intraoperative bleeding was 86.9 ml and operation time was 149.0 min. Postoperative PFDI-20, PFIQ-7, and PGI-I were significantly improved than before surgery ($P < 0.05$). The objective and subjective success rate was 100% at more than 6-month follow-up. In previous research studies, Di Marco et al. reported that the average operation time was 210 minutes, and there was no recurrence after 4 months of follow-up [9]. Salamon et al. reported a series of 120 patients who underwent RASC [10]. The average operation time was 161 minutes, and the bleeding volume was the lowest (<100 ml). The cure rate was 89%. Serati et al. systematically reported that the objective cure rate was 84–100% in patients of all prolapses after RASC with an overall recurrence rate of 6.4% [7]. Culligan reported that 97% of the patients were satisfied, 95% of the patients were cured, and there was no prolapse symptom in the PDFI-20 questionnaire [11]. These data show that the RASC is a reliable and mature technique for POP.

The robot-assisted surgery is a dedicated technique, so the learning curve is also important for surgeons, especially for the beginners. In 2018, Carter-Brooks CM et al. found that the dedicated robotic team decreased operative time significantly by 26 minutes during robotic-assisted sacrocolpopexy with a 17.7% reduction [12]. Geller et al. believed that after 20 surgeries, the total time required for RASC surgery was significantly reduced [13]. Mourik et al. described a reduction in operative time after 12 sacral vaginal surgeries and 12 consecutive surgeries [14]. Germain et al.

reported an 18% reduction in surgical time after 10 surgeries in 52 patients treated with the RSC over a seven-year period [15]. Similarly, Akl et al. also reported that the operation time was reduced by 25.4% based on the experience of the first 10 cases [16]. We divided 24 patients into two groups by the admission time (Group 1 : 2013.06–2016.06, $n = 12$; Group 2 : 2016.06–2020.12, $n = 12$). The mean bleeding and operation time were 92.5 ml and 164.0 min in Group 1 and 29.2 ml and 133.3 min in Group 2, suggesting a 68.0% and 18.7% reduction. The hospitalization decreased from 9.4 days to 7.7 days. These results confirmed that RASC is a feasible procedure with short learning curve. Yet, when we started adopting RASC in 2013, we had performed more than 1000 robot-assisted gynecological operations. For surgeons without any robot-assisted gynecological operation experience, more than 20 cases may be needed to gain enough experience for RASC.

The cost of robotic surgery is an important issue in choosing individual strategies. It includes the purchase and the maintenance of robot platform [17]. In addition, the robotic surgical instruments and the need for professional and special engineering assistance are key factors to be considered [17]. In 2011 Judd reported that the cost of robotic surgery was $8,508, 47% more than commitment

ASC ($5,792) and 15.7% more than laparoscopic surgery ($7,353) [18]. In China, the average cost of robotic surgery is $8,400, about 8 times of ASC ($1,000) and about 7 times of laparoscopic surgery ($1,200). Meanwhile the robot-assisted surgery has not been covered by social insurance. The high cost hindered the wide application in China. Therefore, the cost-efficiency analysis is needed to confirm which patients benefit more from robotic surgery.

Our study has some limitations. First, it was a single-center prospective study that did not allow comparing the possible efficacy of RASC with ASC or LASC. Furthermore, the sample size is small due to the high costs. Lastly, we lack the assessment of storage and voiding urinary symptoms before and after surgery.

5. Conclusions

The introduction of robotic technology has significantly improved the efficacy and safety of ASC by converting open surgical procedures to a minimally invasive approach. We think RASC can be recommended to patients with old age or with financial support. Due to the complex manipulation, the operators should have enough practice of laparoscopic surgery. Long-term follow-up is also necessary to help inform surgeons to build a shared decision-making model. The cost-efficiency evaluation is also needed due to the expensive cost of the surgery.

Background. Keloid is a benign dermal tumor characterized by abnormal proliferation and invasion of fibroblasts. The establishment of biomarkers is essential for the diagnosis and treatment of keloids. *Methods*. We systematically identified coexpression modules using the weighted gene coexpression network analysis method (WGCNA). Differential expressed genes (DEGs) in GSE145725 and genes in significant modules were integrated to identify overlapping key genes. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analyses were then performed, as well as protein-protein interaction (PPI) network construction for hub gene screening. *Results*. Using the *R* package of WGCNA, 22 coexpression modules consisting of different genes were identified from the top 5,000 genes with maximum mean absolute deviation in 19 human fibroblast samples. Blue-green and yellow modules were identified as the most important modules, where genes overlapping with DEGs were identified as key genes. We identified the most critical functions and pathways as extracellular structure organization, vascular smooth muscle contraction, and the cGMP-PKG signaling pathway. Hub genes from key genes as BMP4, MSX1, HAND2, TBX2, SIX1, IRX1, EDN1, DLX5, MEF2C, and DLX2 were identified. *Conclusion*. The blue-green and yellow modules may play an important role in the pathogenesis of keloid. 10 hub genes were identified as potential biomarkers and therapeutic targets for keloid.

1. Introduction

Keloids are mainly associated with excessive proliferation of fibroblasts and massive deposition of the extracellular matrix following skin injury [1]. The clinical presentation of keloids is primarily a growth of scar tissue above the skin, usually accompanied by pruritus and pain [2]. Some studies have shown that keloid formation is closely related to genetic regulation, inflammatory factors, cytokines, and immune factors [3, 4]. The treatment of keloid is not ideal because of unclear pathogenesis and regulatory mechanisms underlying keloids [5]. For these reasons, the identification of hub genes involved in keloid is urgent and highly demanded for improving the clinical outcome.

Keloids have some similarities to tumors; in particular, the fibroblasts in keloids have unlimited proliferation and invasive growth [6]. Fibroblasts are the most abundant cells in the dermis and maintain dermal structure by producing an extracellular matrix (ECM) [7]. The ECM is in a constant state of synthesis, degradation, and remodeling, both under normal conditions and in the presence of disease or injury [8]. After a 2-3 d period of haemostasis and inflammation, the dermis undergoes a proliferative phase in which fibroblasts move from a homeostatic state to an activated state, where their ability to proliferate and migrate is significantly enhanced and they differentiate into a unique phenotype, myofibroblasts, which have stronger contractile properties and synthesized the ECM more rapidly, thereby accelerating wound closure [9]. Once the tissue is fully repaired, these myofibroblasts undergo apoptosis and senescence or revert to deactivated fibroblasts [10]. However, the persistence of active fibroblasts (including myofibroblasts) at the site of injury may lead to excessive deposition of the ECM and the formation of abnormal scarring. So, the thickness of the scar is usually positively correlated with the number of fibroblasts in the dermis and the density of collagen (the main component of the ECM). Therefore, inhibition of fibroblast proliferation has long been a hot topic in scar research.

Weighted gene coexpression network (WGCNA) analysis [11] first clusters genes with similar expression patterns into a module by calculating expression correlations between genes and then analyses the correlation between the module and the sample characteristics, such as clinicopathological parameters and treatments. WGCNA rapidly extracts modules and genes that correlate with sample characteristics from transcriptomic data and obtains biomarkers with better biological significance than differential expression analysis based on comparative intramodule connectivity and gene significance [12]. In this study, we constructed a WGCNA-based gene coexpression network, identifying 22 modules. We also performed GO and KEGG enrichment analysis of genes overlapping in 2 modules closely related to keloid fibroblast and DEGs. A PPI network was also constructed, and 10 hub genes were screened out, including BMP4, MSX1, HAND2, TBX2, SIX1, IRX1, EDN1, DLX5, MEF2C, and DLX2. These hub genes may be biomarkers for diagnosis and therapy of keloid.

2. Methods

2.1. Data Collection. The gene expression dataset GSE145725 (https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE145725) provided by Yuanyuan Kang et al. [13] was downloaded from the Gene Expression Omnibus (GEO) database [14]. 10 cell lines (5 normal fibroblast and 5 keloid fibroblast) were grown in replicate cultures and subjected to RNA extraction. One of the keloid samples was removed after QC. RNA samples with RNA integrity number (RIN) above 9.8 were hybridized to GeneChip PrimeView Human Gene Expression Arrays (Affymetrix).

2.2. Weighted Gene Correlation Network Analysis (WGCNA). WGCNA aims to identify coexpressed gene modules to explore the relationship between gene networks and phenotypes and to examine the core genes in the network [11]. Only top 5000 genes with maximum mean absolute deviation were selected, and abnormal samples were detected using the Z-score method, with Z-score value −2.5 as a cutoff for identifying outliers. According to the scale-free topology criterion, 22 was determined as the optimal soft threshold, with minimum module size 30 and the module detection sensitivity deep split 2. Based on the soft threshold, scale-free network and topology matrices were constructed. The gene modules were dynamically cut and eigengenes were calculated, with 30 as the minimum number of genes in the module. According to the module eigengenes, intermodule correlations were constructed and hierarchical clustering was performed. Finally, 22 modules were obtained and Pearson correlations between modules and clinical features were analyzed.

2.3. Differential Expression Analysis. The GSE145725 dataset was downloaded from the GEO database via the *R* (version 3.6.3) package of GEO query 2.54.1 [15]. The probes corresponding to more than one molecule were removed, and only the probe with the largest signal value was retained when probes correspond to the same molecule. Then, the samples were normalized by box plots, and the clustering between sample groups was demonstrated by PCA plots and UMAP plots. The limma 3.42.2 package was then used for the differential expression analysis between the keloid fibroblast group and normal fibroblast. The top 20 differentially expressed genes (DEGs) were visualized as heatmap using the ComplexHeatmap 2.2.0 package [16] with the clustering method of Euclidean distances.

2.4. Key Gene Identification and Enrichment Analysis. The green-yellow and blue modules are the modules most associated with the keloid fibroblast phenotype. The overlapped genes in the two modules and DEGs were identified as the key genes. Using the org.Hs.eg.db 3.10.0 package, the key gene symbols were converted into Entrez IDs and then subjected to Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis through the cluster Profiler 3.14.3 package [17].

2.5. Protein-Protein Interaction (PPI) Network Construction. Key genes were uploaded to the STRING database (version 11.0) to construct the PPI network [18]. Interactions with a score above 0.4 were considered significant. The PPI network was visualized using Cytoscape software (version 3.8.3) [19]. Top 10 key genes with highest degree were detected as hub genes by CytoHubba plugin.

2.6. Correlation Analysis and Expression of Hub Genes. Correlations between hub genes were analyzed, and Spearman's correlation coefficients were calculated for variables that did not satisfy the normal distribution ($P < 0.05$). The correlation matrix and scatter plot were also plotted using the ggplot2 3.3.3 package.

The expression profiles of the hub genes were first subjected to the Shapiro–Wilk normality test. The Wilcoxon rank sum test was chosen when the gene expression values did not satisfy the normality test ($P < 0.05$).

3. Results

3.1. WGCNA. To identify significant modules, firstly, expression profile distribution of all samples was checked and abnormal samples were detected. The results showed that the median across the samples was essentially at one level, indicating good normalization between samples (Figure 1(a)). Besides, no outlier sample was found (Figure 1(b)). Then, all given soft powers were traversed to get the smallest one which can make the correlation network conform to non-scale network attributes, and a soft threshold of 22 was chosen (Figure 1(c)). Based on the soft threshold power and dynamic tree cut, 22 modules were identified (Figure 2(a)).

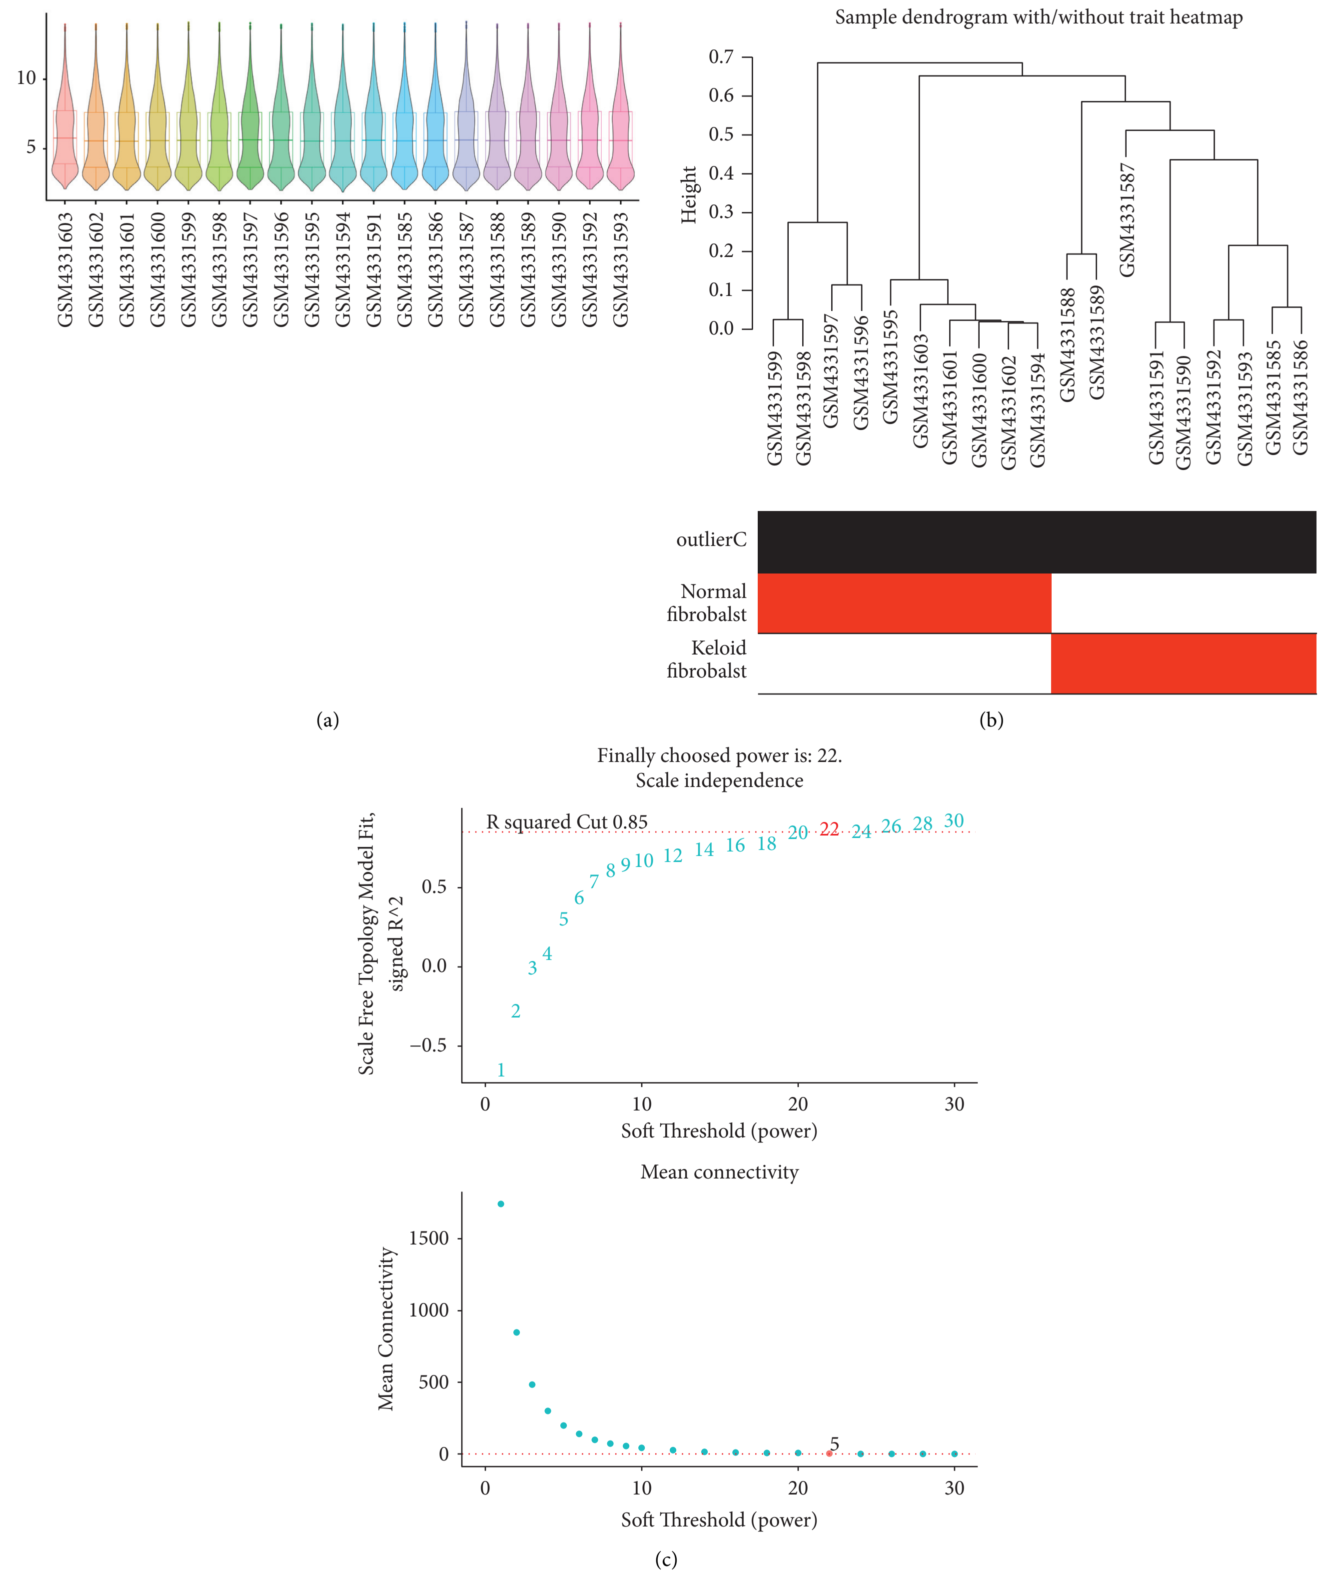

Figure 1: Expression data preprocess and soft power detection. (a) Boxplot plus violin plot showing the expression profile distribution of all keloid fibroblasts samples. (b) Hierarchical clustering showing sample correlations and outlier samples. Samples labeled with red bars in the outlier C row are detected potential outlier samples. (c) Network topology for different soft powers. The soft threshold power in the WGCNA was determined based on a scale-free R^2 ($R^2 = 0.85$).

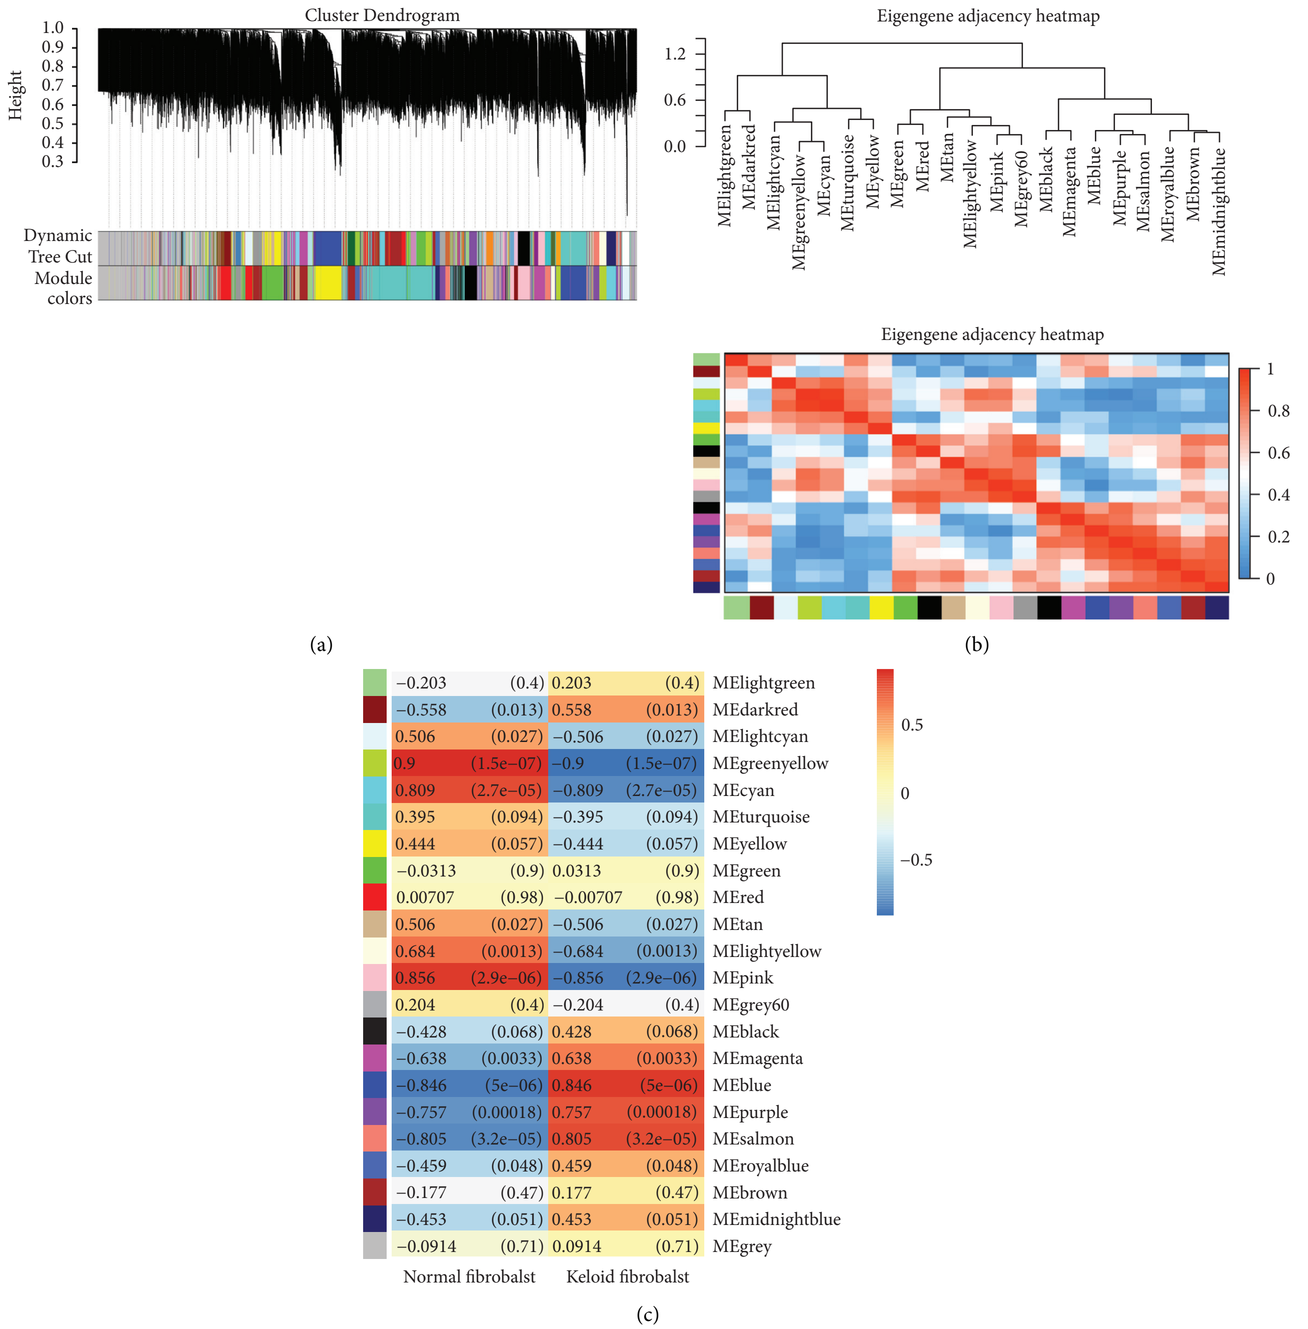

Figure 2: Construction of coexpression modules. (a), WGCNA module plot. Dynamic Tree Cut represents initial modules. Module colors represent final modules. Each branch in the hierarchical tree or each vertical line in color bars represents one gene. Genes not attributed to any module would be colored by grey. (b) Correlation of all identified modules. Each color represents one module. (c) WGCNA module trait correlation plot. Each row represents one module. Each column represents one trait attribute. Blue color represents negative correlation, and red color represents positive correlation.

To clarify the interrelationship between the 22 coexpression modules, we performed a cluster analysis (Figure 2(b)). 22 modules differed significantly from each other (Figure 2(c)). Several modules were associated with keloid fibroblasts. In particular, the blue module was most positively correlated with keloid fibroblasts, and the green-yellow module was the most negatively correlated with keloid fibroblasts.

3.2. Differential Expression Analysis. Meanwhile, we performed differential expression analysis on the GSE145725 dataset to identify aberrantly expressed genes in keloid fibroblasts. Principal component analysis (PCA) plots showed significant differences between the keloid fibroblast and normal fibroblast groups (Figure 3(a)). Subsequently, 19043 genes were filtered. Of these, 458 IDs met

the threshold of |log2(FC)| > 1 and p.adj<0.05, under which the number of upregulated gene in keloid fibroblasts was 215 and in normal fibroblasts was 243 (Figure 3(b)). In addition, we show the expression profile of top 20 genes with high and low expression in a heat map (Figure 3(c)).

3.3. Key Gene Screening and Enrichment Analysis. From WGCNA modules, we selected the blue module and green-yellow module as the important modules (Figure 4(a)). The genes in these modules were then intersected with DEGs, and the 186 overlapped genes were regarded as key genes (Figure 4(b)). To understanding the functions and pathways in

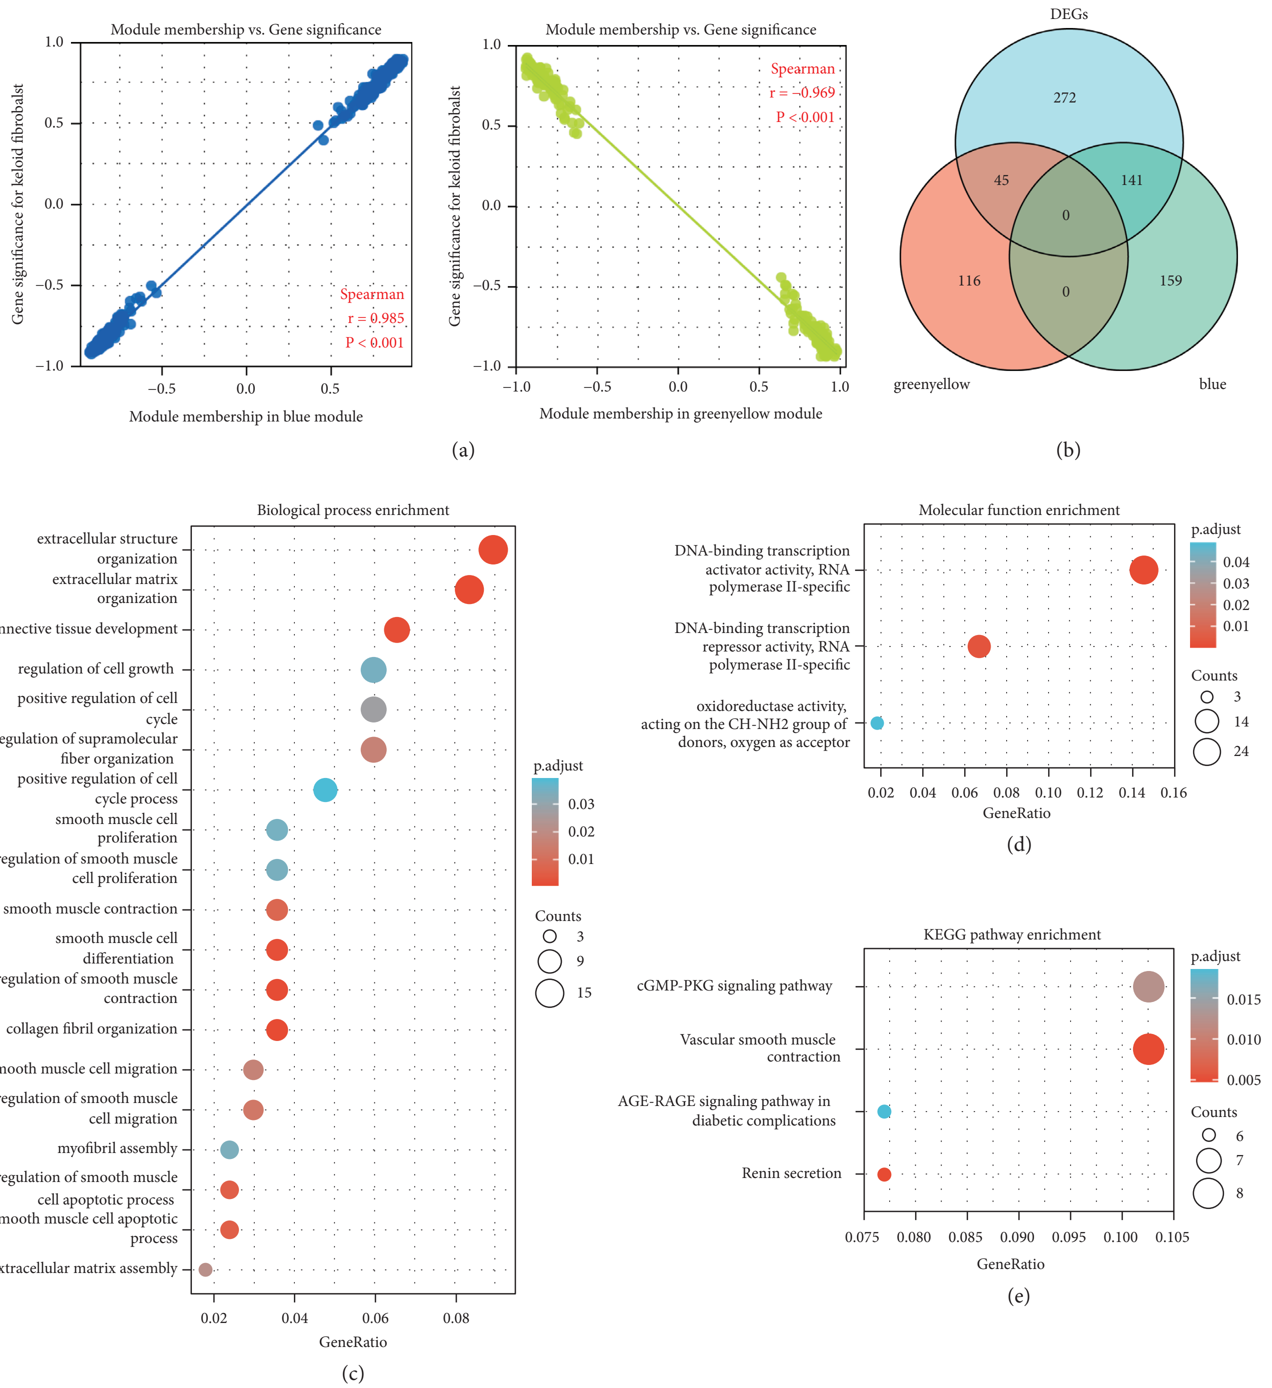

FIGURE 4: Key genes' screening and function prediction. (a) The scatterplot reveals a strong correlation between module membership (MM) and gene significance (GS) in the blue and green-yellow modules. The dot indicates all genes within the modules. (b) The Venn diagram showing key genes. (c) GO-BP enrichment analysis of key genes. (d) GO-MF enrichment analysis of key genes. (e) KEGG enrichment analysis of key genes.

which these genes are involved, GO and KEGG enrichment analysis were performed. Through ID conversion, 176 Entrez ID was filtered. Under the criterion of p.adj<0.05 and q value<0.2, there were 537 entries for biological process (BP), 3 entries for molecular function (MF), and 4 entries for KEGG. In GO-BP analysis, a bubble plot showed that key genes were significantly enriched in the regulation of supramolecular fiber organization, extracellular structure organization, extracellular matrix organization, regulation of cell growth, positive regulation of cell cycle, connective tissue development, and extracellular structure organization (Figure 4(c)). Oxidoreductase activity, acting on the CH-NH2 group of donors, oxygen as the acceptor, DNA-binding transcription activator activity, RNA polymerase II-specific, DNA-binding transcription repressor activity, and RNA polymerase II-specific were the significant MF entries (Figure 4(d)). Besides,

(b)

FIGURE 5: PPI network construction. (a) PPI network was constructed based on 186 key genes in the String website, with interaction score 0.4. (b) Top 10 hub genes were identified by degree algorithm in Cytoscape software.

key genes were involved in the vascular smooth muscle contraction, cGMP-PKG signaling pathway, renin secretion, and AGE-RAGE signaling pathway in diabetic complications (Figure 4(e)). There were no GO-CC enrichment terms.

3.4. Hub Gene Identification. To find the hub genes in keloid fibroblasts, we uploaded the 186 key genes to the String database. Under the threshold of 0.4 interaction score, a PPI network was constructed (Figure 5(a)). Then, the interaction

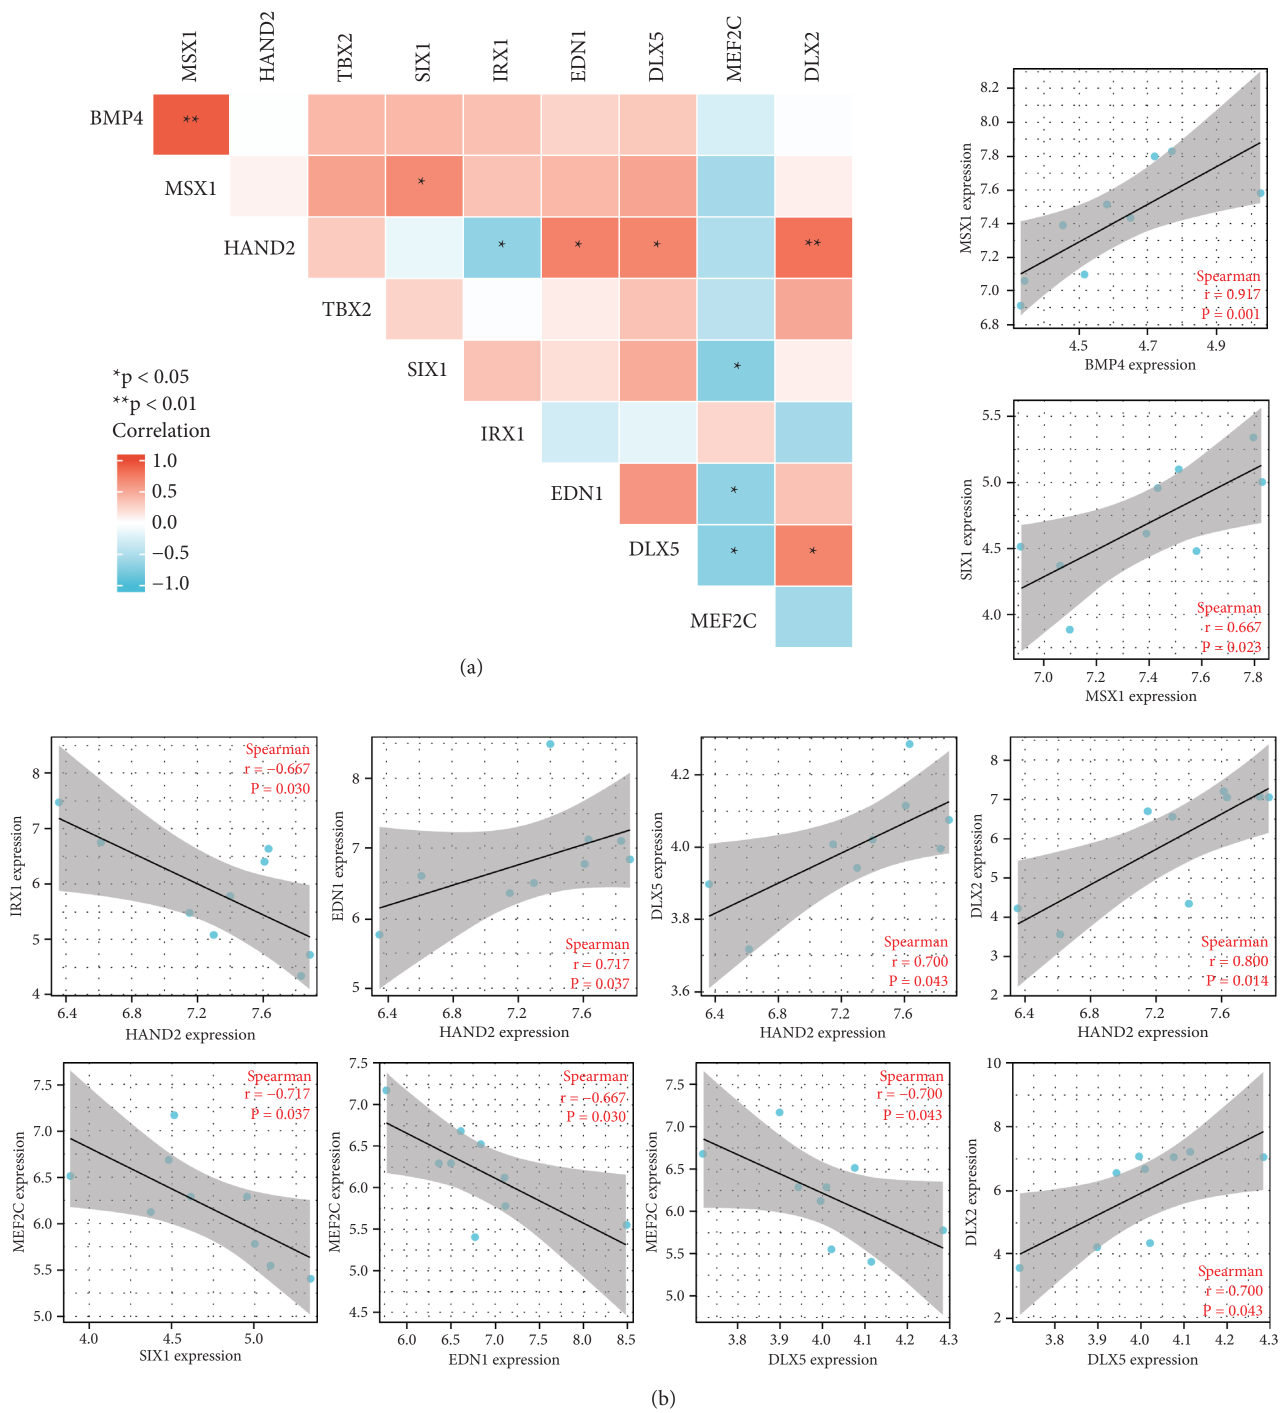

Figure 6: Hub gene correlation. Correlation among hub genes was calculated by Spearman's method and visualized as a matrix heat map (a) and scatter plot (b).

data were downloaded and imported into Cytoscape software. Filtered by CytoHubba calculation, the top 10 hub genes with highest degree were BMP4, MSX1, HAND2, TBX2, SIX1, IRX1, EDN1, DLX5, MEF2C, and DLX2 (Figure 5(b)). Then, we calculated the correlation of hub gene expression with Spearman's rank (rs) test. There was a positive correlation between BMP4 and MSX1, between MSX1 and SIX1, between HAND2 and EDN1, between HAND2 and DLX5, between HAND2 and DLX2, and between DLX5 and DLX2. Additionally, IRX1 was negatively correlated with HAND2. MEF2C was negatively correlated with SIX1, EDN1, and DLX5 (Figures 6(a) and 6(b)). In terms of expression level, BMP4, MSX1, TBX2, SIX1, DLX5, and DLX2 were lowly expressed, while HAND2, IRX1, EDN1, and MEF2C were highly expressed in keloid fibroblasts (Figure 7).

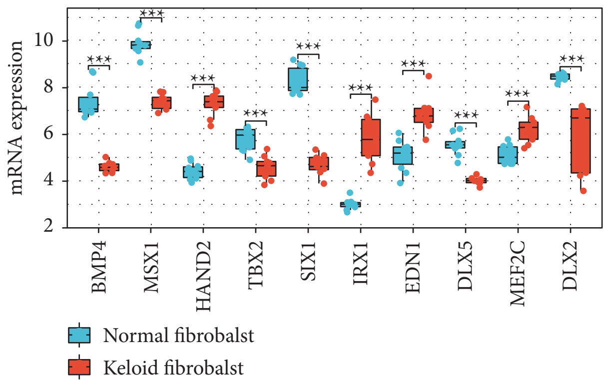

Figure 7: Hub gene expression. The difference of hub gene expression between the normal fibroblast group and keloid fibroblast group was calculated by the Wilcoxon rank sum test. $^{***}P < 0.001$.

4. Discussion

Despite different treatments such as compression therapy, corticosteroid injection, and surgical methods, the recurrence rate of keloids remains high [20]. To identify better treatment targets of keloid, this study used WGCNA analysis, differential expression analysis, and degree algorithm and screened out 10 hub genes associated with keloid fibroblast from the GSE145725 dataset, including BMP4, MSX1, HAND2, TBX2, SIX1, IRX1, EDN1, DLX5, MEF2C, and DLX2.

Among these hub genes, only BMP4 was reported in keloid. As we know, this gene encodes a secreted ligand of the transforming growth factor (TGF)-β superfamily of proteins. Ligands of this family bind various TGF-β receptors leading to recruitment and activation of SMAD family transcription factors that regulate gene expression [21]. According to the work of Xing Dai et al., activation of the BMP4/Smad signaling pathway may promote transdifferentiation of primary keloid myofibroblasts to adipocyte-like cells [22].

The emergence of myofibroblasts is an inevitable process of tissue repair, and this transdifferentiation process is dependent on signaling through the TGF-β1/Smads pathway, whose activation leads to the binding of Smad3 to Smad4 and the initiation of fibrotic genes expression such as ACTA2 [23, 24]. The TGF-β1/Smads signaling pathway runs through the entire process of wound healing from the inflammatory phase to the remodeling phase and is one of the major pathways regulating scar formation [25]. BMP4 could facilitate this pathway, thus suggesting the reliability of the results of this study.

In GO-BP-enriched terms shown in the bubble plot, BMP4 was enriched in terms including smooth muscle cell differentiation, regulation of smooth muscle cell proliferation, smooth muscle cell proliferation, and connective tissue development. These BPs were all related to keloid fibroblasts or keloid [26]. In addition to BMP4, other hub genes were also involved in many GO-BP. EDN1, in particular has a regulatory effect on many keloid-related BPs, including regulation of supramolecular fiber organization, myofibril assembly, regulation of smooth muscle contraction, smooth muscle cell differentiation, smooth muscle contraction, regulation of smooth muscle cell proliferation, smooth muscle cell proliferation, regulation of smooth muscle cell migration, smooth muscle cell migration, smooth muscle cell apoptotic process, regulation of smooth muscle cell apoptotic process, regulation of cell growth, positive regulation of cell cycle process, positive regulation of cell cycle, connective tissue development.

Besides, KEGG enrichment analysis showed that the cGMP-PKG signaling pathway was significantly enriched. As we know, this pathway mediates platelet activation, cardioprotection, smooth muscle relaxation, decrease in intracellular free calcium, and reduced cardiac hypertrophy [27]. Importantly, PKG is a protein kinase that when activated by the second messenger cGMP, phosphorylates VASP, thereby promoting cell growth and differentiation [28], and phosphorylates Bad [29] and CREB [30], thereby decreasing the activity of caspase-3 and inhibiting apoptosis.

Although the sample size of this study is not rich enough and there is no external dataset to validate the screening results, this study is still the first to identify key aberrant genes in keloid fibroblast based on the WGCNA algorithm, which provides therapeutic targets for keloid and reference for future research. The limit is that there are not enough solid foundation to support the opinion. Further experiments are still needed to confirm the study.

5. Conclusions

The blue-green and yellow modules may play an important role in the pathogenesis of keloid. 10 hub genes were identified as potential biomarkers and therapeutic targets for keloid.

In 6G edge communication networks, the machine learning models play a major role in enabling intelligent decision-making in case of optimal resource allocation in case of the healthcare system. However, it causes a bottleneck, in the form of sophisticated memory calculations, between the hidden layers and the cost of communication between the edge devices/edge nodes and the cloud centres, while transmitting the data from the healthcare management system to the cloud centre via edge nodes. In order to reduce these hurdles, it is important to share workloads to further eliminate the problems related to complicated memory calculations and transmission costs. The effort aims mainly to reduce storage costs and cloud computing associated with neural networks as the complexity of the computations increases with increasing numbers of hidden layers. This study modifies federated teaching to function with distributed assignment resource settings as a distributed deep learning model. It improves the capacity to learn from the data and assigns an ideal workload depending on the limited available resources, slow network connection, and more edge devices. Current network status can be sent to the cloud centre by the edge devices and edge nodes autonomously using cybertwin, meaning that local data are often updated to calculate global data. The simulation shows how effective resource management and allocation is better than standard approaches. It is seen from the results that the proposed method achieves higher resource utilization and success rate than existing methods. Index Terms are fuzzy, healthcare, bioinformatics, 6G wireless communication, cybertwin, machine learning, neural network, and edge.

1. Introduction

Since the development of edge computing [1], it has emerged as a key strategic approach in a variety of application areas, especially in the fields of data aggregation, network connectivity, and other industrial tasks. The edge is regarded as an open platform for storage and computing applications because it is situated near a data source or an object on the network side. Edge computing is placed between the cloud and end devices and uses a high-speed data communication channel with a local data processing capability between them to transfer data with processing power equivalent to that of the cloud [2].

There are some basic facilities in the current healthcare system, but time and space are the main obstacles. Because of the existing circumstances, this is unavoidable; nevertheless, in the near future, it will not be a hindrance to progress. It is also worth noting that an ambulance service is nothing more than a vehicle for transporting patients with oxygen and road traffic priority. In addition, the current state of aged care is woefully inadequate. There is a great deal of emphasis on medical staff in the care of the older population. However, it has not been made available yet. In ambulances, most patients die on the way to or from the hospital or even before the ambulance gets there. Current healthcare systems also lack an accident detection system [3].

Real-time accident detection is needed to ensure that medical services are available immediately and on the scene. Furthermore, outbreaks like COVID-19 cannot be handled due to a lack of technological infrastructure. This includes epidemics and pandemics. In the future, a virus identical to this one is likely to surface. As a result, creating an intelligent healthcare system is critical. The high data throughput and low delay needs of 6G technology for future healthcare necessitate the use of this technology. Telesurgery, in particular, necessitates instantaneous communication. Intelligent healthcare systems will also benefit from holographic communication and augmented or virtual reality. As a result, intelligent healthcare cannot make use of 5G and 5G B5G. In the 5G era, intelligent healthcare will be largely adopted, which will propel a significant amount of progress [4].

The virtual cyberspace in the edge cloud is where the virtual representation of the end (humans and things) resides, making it a critical part of the cybertwin communication model. Cybertwin can meet three distinct needs by supplying 3 different features: network communications assistant feature, network behaviour logger feature, and digital asset feature [5, 6]. It is crucial that an end device connect to the server offering the services. The cybertwin will access the network in order to provide the required service to the end, and once that service is completed, will return the service to the end. This is the most fundamental function of the cybertwin's communications assistant. Cybertwin can be thought of as the digital representation of the goals, which allows the system to collect and log all the data about the network behaviour of the user's system. After removing sensitive information, cybertwin converts the behaviour data of the users into a digital asset for sale [7].

Cybertwin on the boundary has been configured to meet the needs of various industries, such as rapid connection and strong security. Data are being gathered at the cloud centre, while, on the other hand, edge computing features device-based processing. As end-user resources get closer to users, latency between the cloud data centre and devices decreases. This, in turn, allows for slightly improved quality of service (QoS). Also, as the number of devices that will be able to connect to the internet increases, the network bandwidth or capacity will be a major constraint on cloud computing. Likewise, the complexity of end-user requirements raises the difficulty of service allocation. Above all, excellent resource selection is critical to meeting end-user needs [8–14].

During the onset of large-scale distributed neural network use, the limited computing resources found at the edge devices present several challenges. A shortage of resources limits storage. These limitations are the shortage of energy and defects in architecture. Despite their complementary relationship and the reduced latency that they enjoy, the edge did not have the necessary resources to make use of cloud computing. A significant influence on application performance, task scheduling, and end-user QoS is the allocation or prediction of available resources. Providing an estimate of the required resources for each end-user will produce an appropriate resource plan, which should use certain parameters to estimate the amount of resources consumed. Therefore, in order to meet the user's QoS, the resource estimation needs to incorporate a task allocation strategy that is optimised for edge computing.

Historical research has identified cloud, edge nodes, and end-user devices as the requirements for neural network deployment. Neural networks are less latency-sensitive when there is increased resource allocation, but they have the potential to pass on the original source in the event of latency-critical applications. Edge users are offered distributed services via multiple hidden layers of neural networks. The neural network model predicts and then allocates energy resources in a near real-time manner, with minimal delay [7]. The distributed neural network architecture can identify when tasks get allocated to different partitions at the edge and will always use a partition with fewer resources if distributed edge nodes are utilised.

The aim is to design and implement distributed neural networks (DNNs) on edge networks with better performance, so that devices at the edge are capable of intelligent workload prediction. A long-standing constraint on computation and resourcing, represented by the trade-off between the computational load and resourcing task, has to be maintained using distributed neural networks.

Here, we developed federated learning (FL) [15, 16] as a subset of cybertwin as a preliminary model to assist with decisions related to reresource allocation. Such constraints as memory and communication complexity are incorporated into the preliminary model.

The major contribution of the proposed work is stated as follows:

(i) To improve the effectiveness of resource allocation decisions, the author built a FL model. With the DNN serving as a secondary model, it is now possible to use the following rules: edge resources allow zero or multiple edge devices, resources available, memory requirements, and user quality of service requirements.

(ii) Decentralized training data distribution is a solution that optimises the reuse of valuable network resources, even in the event of an unreliable network. To distribute environments such as this, FL (each iteration) enables the edge node to compute updates to the cloud centre independent of system requirements, user cases, data size, and implementation effort.

(iii) Conceptually, it can be said that the model compares the total number of servers connected to the data centre, the number of servers on the edge that connect to the cloud, and the response time

This study is structured as follows: Section 2 provides the network model. Section 3 discusses the problem formulation, and Section 4 provides a detailed discussion on resource allocation using the FNN wireless healthcare model. Section 5 evaluates the entire work with existing resource allocation models. Section 6 concludes the entire work with possible directions for future scope.

2. Network Model

Edge computing fundamentals are discussed in this section, which finds it situated between the cloud and the edge devices. Storage, computation, and network services can benefit from edge computing. Edge computing has a distributed FNN wireless healthcare model that is utilised to make distributed computation possible with severely limited memory and processing power in the edge nodes and edge devices. Because edge devices are near the resources, real-time communication is possible.

The cyber twin aims to process data while providing the ability to communicate and perform computations freely. The present study uses a 3-tier architecture with an edge computing model, as shown in Figure 1.

The control BSs is responsible for data providing to the control plane that decides the required resources for the edge IoT devices. This resource allocation with uplink and downlink BSs enables user plane to allocate the resources for data communication from edge devices via edge IoT devices.

This edge device is made to generate data and make the client consume more of it. In particular, it urges clients to use more resources from the edge nodes rather than the cloud. Devices may range from smartphones to IoT sensor nodes, intelligent vehicles, and even smart cities. The edge devices collect data and communicate with each other using a sensor network. The cloud servers located in the cloud centre have significantly more energy and computing power than numerous edge devices [10].

Switches, routers, and local servers, which are typically deployed for special services, sit on the edge nodes. The compute, storage, processing, and data forwarding are all in place with these nodes. A single or multihop connection can be used to connect edge devices with edge nodes or edge servers. Computing, network, storage, and software resources are all available in the microdata centre (MDC). Cluster servers and data centres that act as storage and processing points for data received from edge devices are positioned at the top of the cloud layer.

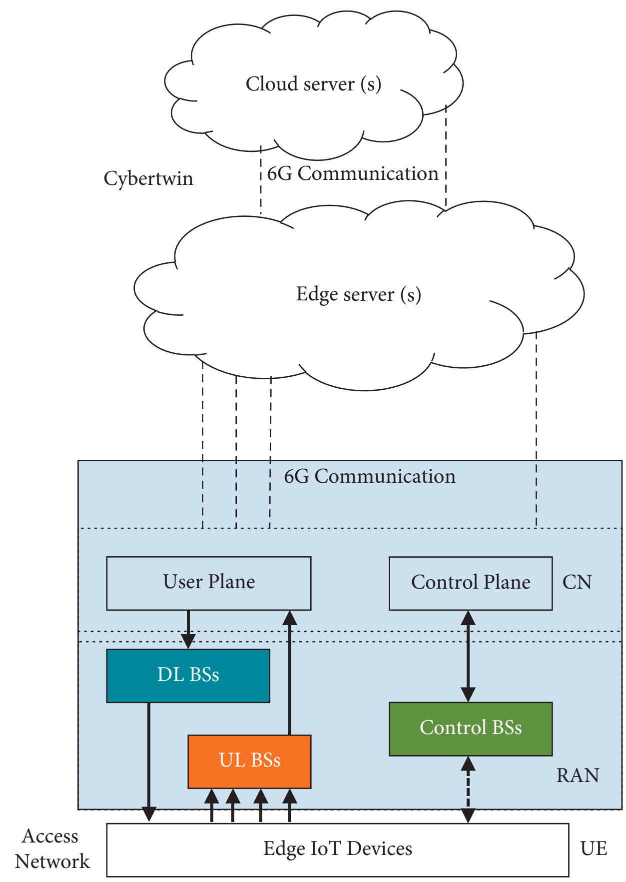

Figure 1: 6G edge computing framework.

Figure 2 shows the process of a service request when using edge computing. Users can submit requests to the administrator by using edge devices at the beginning. In order to meet the QoS user requirements, the query is stored in the edge nodes and is then passed on to the cloud centres through the edge nodes. Resources, sensor availability, service, and applications influence the statistics generated by the monitoring equipment. This equipment processes data that are sent to the edge nodes and QoS service levels for each user requirement, and these data are analysed to provide appropriate levels of service for each user. To allocate resources in an optimal manner, a FNN wireless healthcare model processes each service on an edge device locally to provide the optimal distribution of energy and bandwidth. A distributed FNN wireless healthcare model selects an existing resource and allocates it according to user QoS requirements.

3. Problem Formulation

The study aims to improve the allocation of energy considering all constraints for optimal consumption of energy at the IoT edge network. Furthermore, it considers various constraints including resource allocation constraints, computational resource constraints, radio resource constraints, radio resource allocation over IoT edge constraints, latency constraints, and task execution constraints. It is hence formulated as follows:

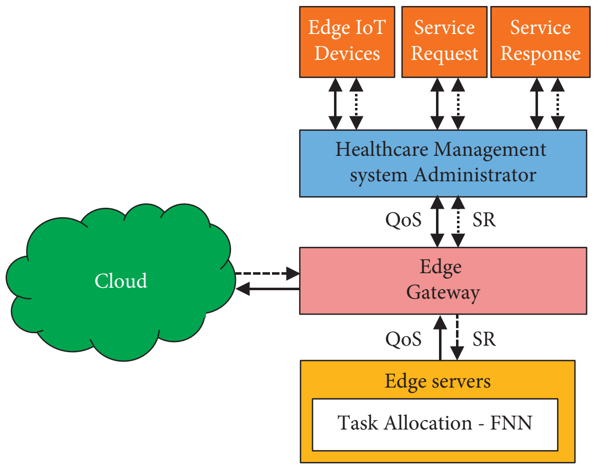

FIGURE 2: The service request in cybertwin for resource allocation.

$$
\begin{aligned}
&\min_{a,\theta,f} \sum_{i=1}^{N} a(i)\left(e_c(i)\right) + C(i)\Big(1 - k\big(f^2(i)\big)a(i)\Big),\\
&C_1\colon \sum_{i=1}^{N} f(i) \leq F,\\
&C_2\colon 0 \leq f_i \leq a_i * F,\\
&C_3\colon \sum_{i=1}^{N} \theta_i \leq L,\\
&C_4\colon 0 \leq \theta_i \leq a_i L,\\
&C_5\colon a_i \in \{0,1\},\\
&C_6\colon \frac{C(i)}{f(i)}(1 - a(i)) + a(i)\left(\frac{C(i)}{f(i)} + \frac{D(i)}{R(i)}\right) \leq T(i),
\end{aligned}
\tag{1}
$$

where α is the execution vector, θ is the allocation of radio resource by 6G network, and f is the resource allocated in servers.

Furthermore, the tasks are executed locally while considering all the constrains $\alpha(i) = 0$ [6], and the parameters are set as follows: $\alpha(i)t_c(i) = 0$ and $\alpha(i)e_c(i) = 0$ for local task execution.

(i) $C1$—resource allocation constraints
(ii) $C2$—computational resource constraints
(iii) $C3$—radio resource constraints
(iv) $C4$—radio resource allocation over IoT edge constraints
(v) $C5$—latency constraint
(vi) $C6$—task execution constraints

4. FNN Resource Allocation

A multinode FNN wireless healthcare model is often referred as the FNN wireless healthcare model that aims to improve the precision and performance and scales according to larger data size. The increasing size of input data learning for learning reduces significantly the training errors and enables error-free complex operations [8]. This allows the distributed FNN wireless healthcare model computing to draw significant decisions and conclusions over larger data sizes or in case of complex computing. The purpose-built distributed FNN wireless healthcare model operates in distributed edge computing environment that gains advantage in terms of its performance requirement, user cases, data size, and implementation effort.

The FNN wireless healthcare model learns the entire model with suitable parameters in the form of a matrix $W \in Rx \times y$ from the data stored across edge devices, where x and y represent the input and output dimensions. Consider a FL model at round $t \geq 0$, where the server is allowed to distribute the current FL $W(t)$ over the edge IoT devices. The edge devices update independently the FL model $W(t)$ in terms of its local data. The data model after update is considered as $W_1(t), W_2(t), \ldots, W_n(t)$, and hence, the update on the edge device say i is defined as $H_i(t) = W_i(t) - W(t)$, where the edge devices $i \in S(t)$. The edge device sends update to the edge node and then to the cloud centre, where it computes the global update based on the aggregation of edge device update.

$$
\begin{aligned}
W(t+1) &= W(t) + H(t)\,\eta(t),\\
H(t) &= n^{-1}(t)^{\sum_{i\in S(t)} H_i(t)}.
\end{aligned}
\tag{2}
$$

The edge node is allowed to select $\eta(t)$, the learning rate, and for faster computation, we have considered $\eta(t) = 1$. The FL is described for the DNN in next section, where it uses an individual matrix (W) in order of representing the parameters over each hidden layer. The parameters representing the full connected layers of the DNN in FL is hence described in the form of 2D matrix. On the other hand, the study aims to increase the efficiency of communication using the FNN wireless healthcare model that tends to reduce the communication and transmission cost of sending the updates $H_i(t)$ to the cloud centre. Whereas, the edge model considers learning the data from edge devices with constrained internet connectivity and its computational availability. To attain gradient computations, the loss function L with a parameter vector w is minimised using the learning problem to attain a closed form solution.

The study considers a simplest circulant matrix approach considering a vector r with viable error rates. Hence, the circulant matrix $R \in R^{x \times y}$ over a vector r is expressed as follows:

$$
\mathrm{Cir}(r) = R \coloneqq \begin{bmatrix} r_0 & r_{d-1} & \cdots & r_2 & r_1\\ r_1 & r_0 & r_{d-1} & \cdots & r_2\\ \vdots & r_1 & r_0 & \cdots & \vdots\\ r_{d-2} & \vdots & \vdots & \ddots & r_{d-1}\\ r_{d-1} & r_{d-2} & \cdots & r_1 & r_0 \end{bmatrix}. \tag{3}
$$

It has reduced the cost of storage to $O(d)$ instead of $O(d^2)$. The computations using the circulant matrix uses fast Fourier transform to increase the speed of computations.

Therefore, the computational complexity for a single-layered DNN (Figure 3) with a vector r having a dimension d is defined as $O(d\log d)$.

The modified circulant matrix $R \in R^{d\times n}$ is expressed as

$$R = SHG\Pi HB, \tag{4}$$

where G, S, and B are the diagonal matrices, H is the Walsh–Hadamard matrix, and $\Pi \in \{0, 1\}^{d\times d}$ is the permutation matrix.

At the edge IoT device, the resource allocation should meet the user needs, and it should satisfy the QoS needs. Therefore, the set of resources in the edge node with the same service is stated as follows:

$$R = \{r_1, r_2, \ldots, r_n\}. \tag{5}$$

Considering all the attributes for resource allocation, the resource allocation is carried out based on user requirement, and the resource set $q(i)$ is defined in terms of QoS attributes available for resource allocation.

$$q(i) = \{q_1, q_2, \ldots, q_n\}, \tag{6}$$

where n is the index resource with QoS attributes including response time, availability, cost, and reliability.

Here, the cost is estimated as follows:

$$p = UbD_{ed}\frac{\mu}{\varphi}, \tag{7}$$

where U is the basic service cost, μ is the total requests, φ is the total service requests, b is the cost regulation, and D_{ed} is the edge IoT device.

If the resource is similar to the QoS attributes as demanded by edge device, the attributes set is thus expressed as follows:

$$u = \{u_1, u_2, \ldots, u_m\}. \tag{8}$$

The attribute matrix for QoS with respect to the resources is defined in the form of a decision matrix.

$$\begin{aligned} R &= (r(ij))_{n\times m},\\ &= \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1m}\\ r_{21} & r_{22} & \cdots & r_{2m}\\ \vdots & \vdots & \ddots & \vdots\\ r_{n1} & r_{n2} & \cdots & r_{nm} \end{pmatrix}, \end{aligned} \tag{9}$$

where $r(ij)$ is the QoS attribute of j^{th} value over a resource (i).

The processing of the attribute matrix is considered meaningless if the units of measurement units are different for the QoS attributes. Hence, the relationship existing between user satisfaction and the QoS attributes is formulated as follows:

$$z(ij) = \begin{cases} \dfrac{r(ij) - \min r(j)}{\max r(j) - \min r(j)}, & q > 0,\\[2ex] \dfrac{\min r(j) - r(ij)}{\max r(j) - \min r(j)}, & q \le 0. \end{cases} \tag{10}$$

Here, an objective weight is set for each attribute, since the edge devices at the end-user have selected preference for a specific attribute that tends to affect the measurement directly, and it utilizes a weighted technique to estimate the preference.

$$\begin{aligned} d(u,i) &= \sum_{j=1}^{m} \sqrt{w(j) * (q(j) - u(j))^2},\\ \operatorname{sim} d(u,i) &= \frac{1}{1 + d(u,i)}, \end{aligned} \tag{11}$$

where $w(j)$ is the resource attribute weight, $d(u, i)$ is the distance from ideal to edge node (i), and sim$d$ (u, i) is the proximity degree [0, 1].

5. Performance Evaluation

In this section, the entire simulation is conducted in Matlab environment to study the effectiveness of the proposed model. This section focuses on the experimentation that has been conducted to verify the effectiveness of the FNN wireless healthcare model in helping resource allocation decisions regarding metrics like average success rate, job response time, and resource utilisation levels. Latency is calculated by finding the Euclidean distance between edge devices according to the distance model in [9]. Response time is a factor in resource allocation, and an edge device with a high-valued response time would be considered a failure-allocated task. The study uses three data centres with 100 servers, where each server consists of 6 cores with 5 hostings per server. The location of data centre is considered random with 30 ms response time and with 100 bytes low latency level.

FNN wireless healthcare model effectiveness is studied through 3 different performance metrics in this study. For the first time, the average response time of each allocated resource to the edge device is measured when computing the impact of cloud servers on the network node. Also, the average task utilisation is estimated at the node where the task is created, and third, the likelihood of tasks allocated per failure is calculated. Each of these 3 responses is analysed under consideration of response time constraints, and eventually, network throughput is estimated.

5.1. Influence of Data Centre with Core Server. According to estimations, the performance of three techniques on three different servers connected to a data centre is expected. This study will lead to the increase of between 200 and 2000 cloud servers. Careful consideration has been given to the servers, such that the total servers that are connected to the cloud data centre have the same number of servers as those connected to a microdata centre. Figure 4(a) shows the total servers connected to edge servers for each allocated task. The FNN wireless healthcare model improves the performance relative to the current FL and DNN when more resources are shared among the edge nodes. There is an optimum level of performance even if only a small number of servers are connected to the edge servers.

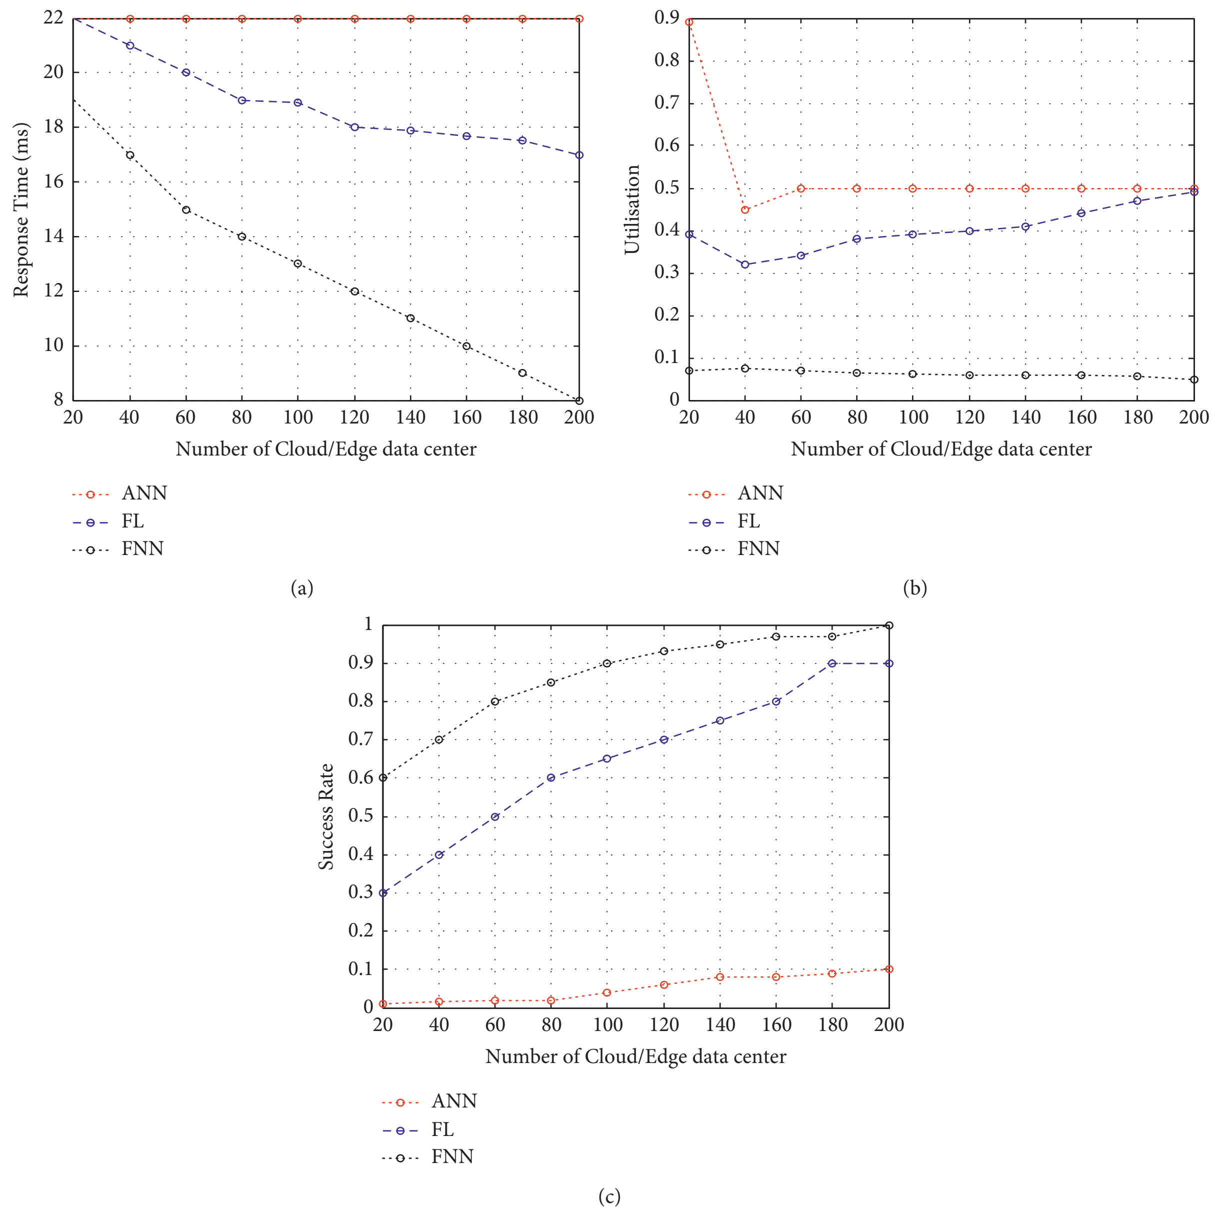

FIGURE 3: (a) Response time w.r.t the influence of data centre. (b) Resource utilisation w.r.t the influence of data centre. (c) Success rate w.r.t the influence of data centre.

In Figure 4(b), higher-order use of resources is illustrated. One microdata centre of edge handles over 150 cloud servers, allowing for greater overall resource utilisation than just the amount of time spent on scare resources. Additionally, as more servers are added, the resource utilisation success rate increases and never reaches 99.99%. The higher the burden, the less successful the existing FL and DNN methods are. As these methods have a harder time handling the increased burden, they have a negative impact on the success rate. However, missing the response time constraint (Figure 4(c)) is a significant barrier to making neighbourhood edge data centres a reality. Constrained response time, limited resource utilisation, and improved success rate were found to improve overall performance with the experimental results.

5.2. Influence of Data Centre on the Entire Network. This proposed study confirms that the FNN wireless healthcare model achieves the desired performance even when run on several edge nodes or in microdata centres. Here, we go from a state with around 200 edge nodes to around 20 edge nodes, and then, groups of 20 edge nodes are grouped together with each group assigned to a service provider. Figure 3(a) shows that as edge nodes increase, response time decreases from 20 to 10 ms. It is because the edge nodes and edge devices are farther apart today. Another feature that already exists functions with a similar range; response time grows from 18 ms to 21 ms. Since the cloud centre appears unaffected by available edge nodes, it can be concluded that the cloud centre does not rely on the availability of nodes on the edge. Figures 3(b) and 3(c) illustrate an increase in the amount of

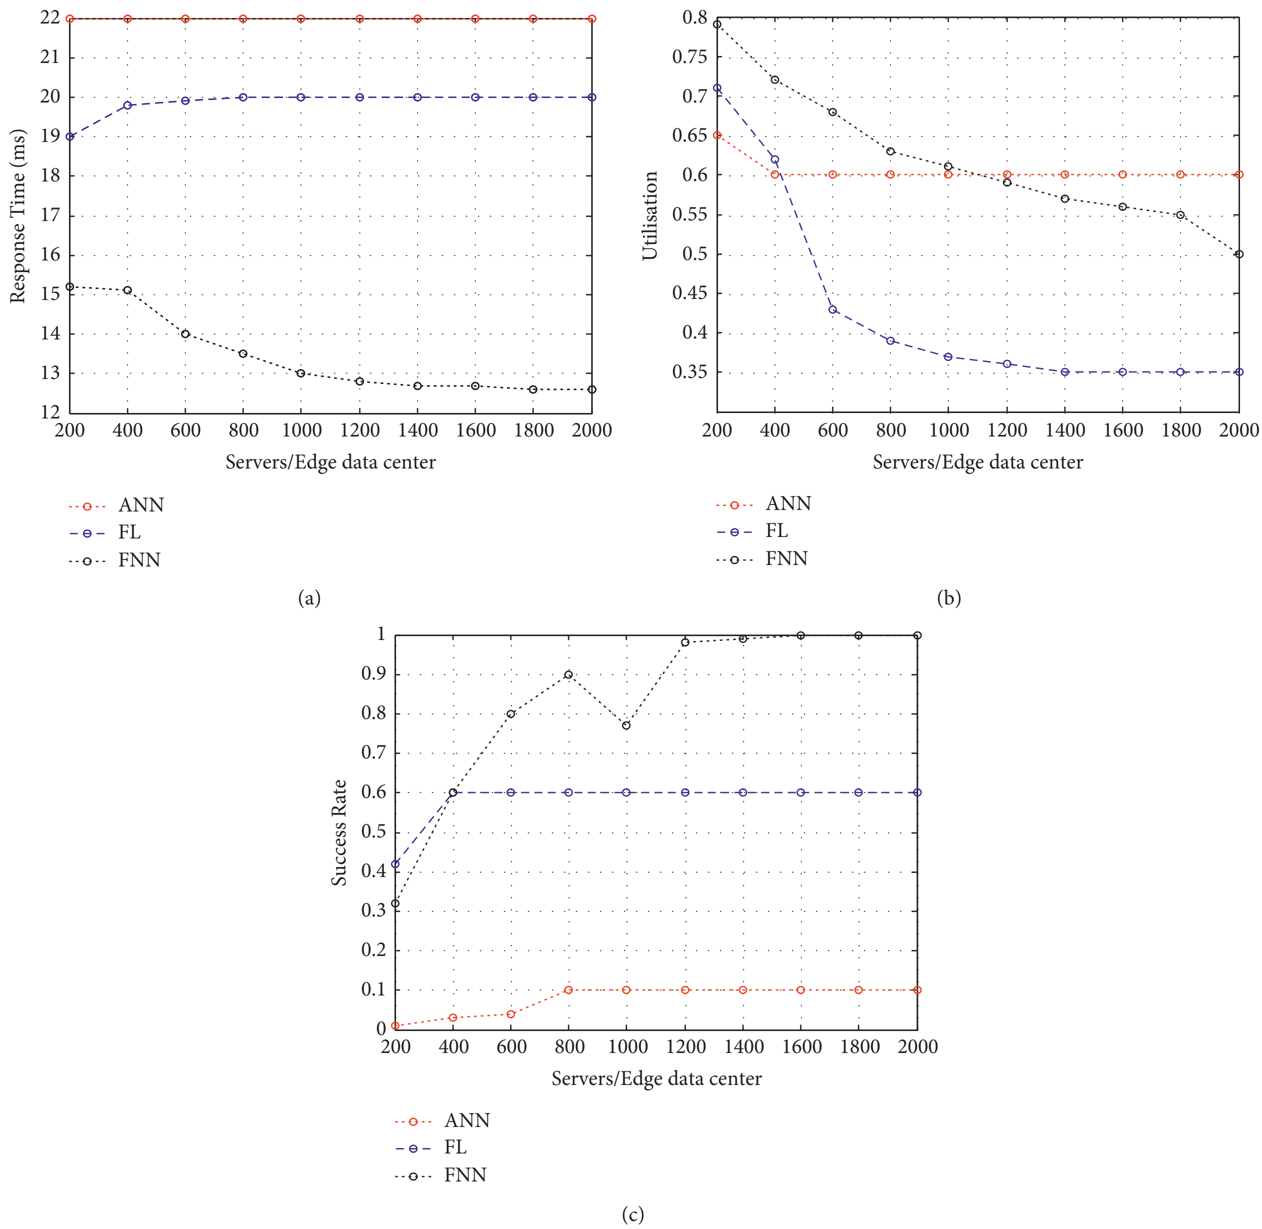

FIGURE 4: (a) Response time w.r.t the influence of connected data centre. (b) Resource utilisation w.r.t the influence of connected data centre. (c) Success rate w.r.t the influence of connected data centre.

resources used by the FNN wireless healthcare model compared to the existing FL and DNN. Additionally, the proposed mechanism has a higher success rate than in Figure 3(c). The findings demonstrate that the FL and DNN are better than other systems at significantly increasing performance.

5.3. Impact of Response Time Constraint. The average response time tends to increase as the response time constraint increases (Figure 5(a)). This increases scalability, as the workloads can be distributed fairly between edge devices and edge nodes. Because of their distance, their response time tends to be impacted. For example, in Figure 5(b), the resource utilisation is compared, and it is found that the increased response time constraint causes the utilisation to increase. Performance similar to the FNN wireless healthcare model can be achieved if the response time constraint at the edge nodes is increased. The edge node can provide a higher percentage of completed tasks in cloud locations because it has a lower response time constraint. Furthermore, as shown in Figure 5(c), the average success rate increases when reresponse time constraints are extended. When compared to other existing resource allocation methods, the proposed solution obtained an average success rate of 99.9%. According to the results, the FNN wireless healthcare model has an edge over other methods, even when response time limits are present.

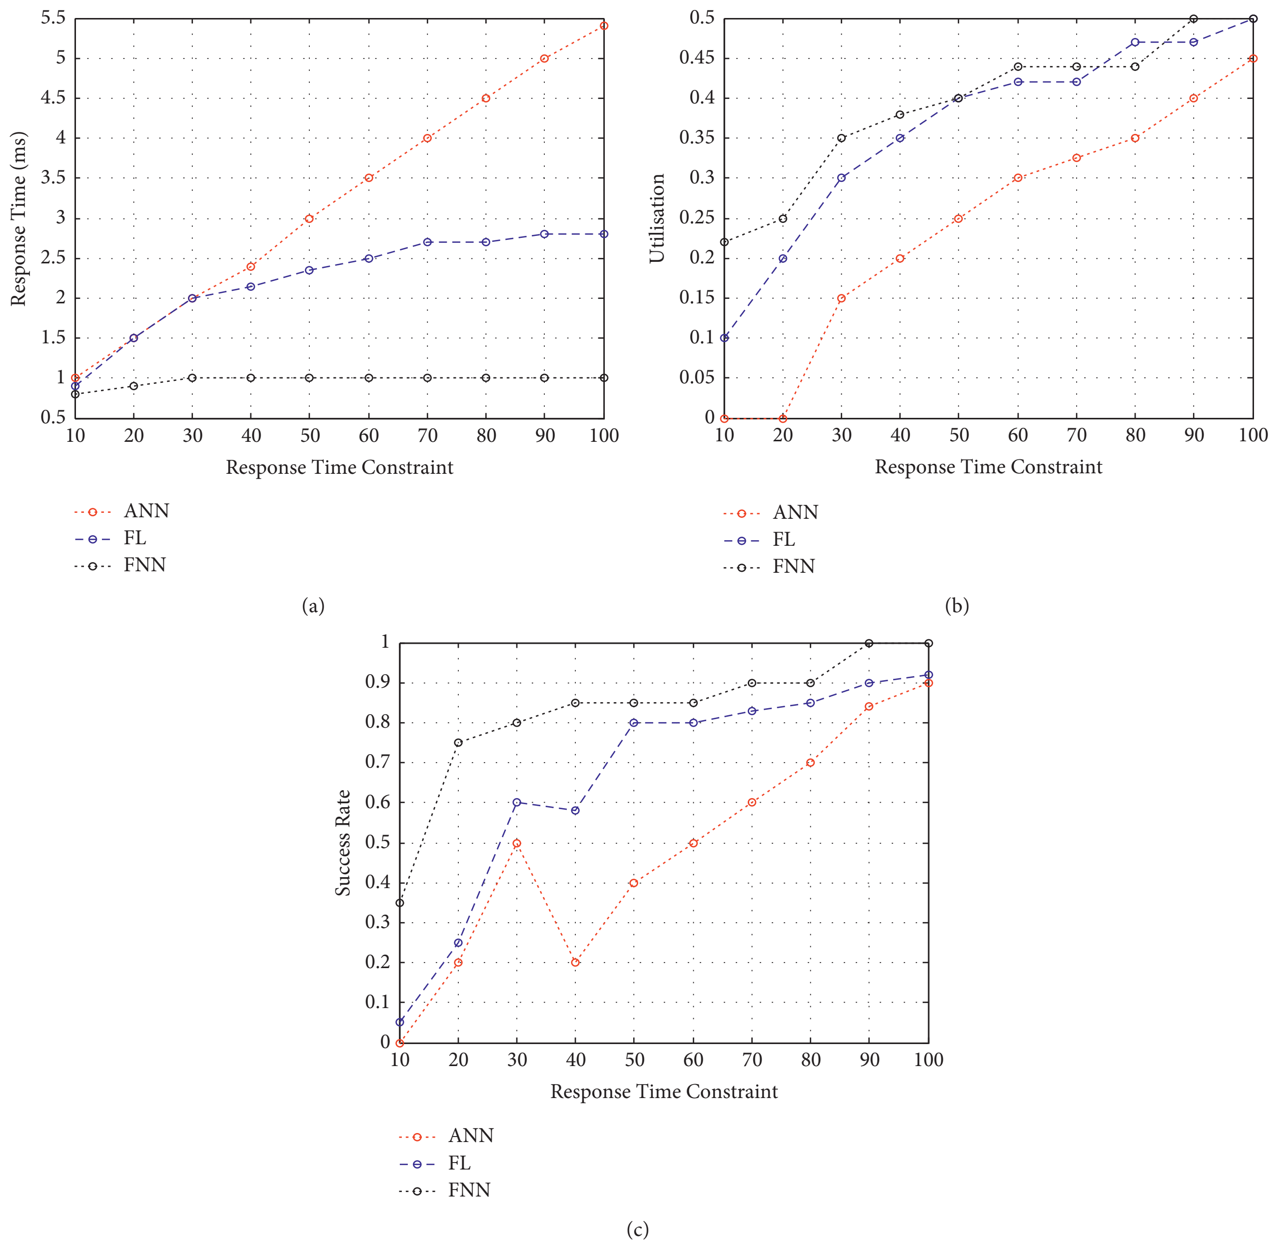

Figure 5: (a) Response time w.r.t response time constraints. (b) Resource utilisation w.r.t response time constraints. (c) Success rate w.r.t response time constraints.

6. Conclusion

In this study, the FNN wireless healthcare model applies its distributed resource allocation settings to allocate optimal resources to the edge devices. To support the distributed settings of edge intelligence, FL adjustments are implemented. In terms of improved average success rate, higher resource utilisation, and increased network throughput, the design of computational and storage cost reduction in the edge network and in hidden layers has been a big success. Conventional methods demonstrate higher scalability in distributed deep learning models compared to the FNN wireless healthcare model. In future, metaheuristic models can be deployed to create shear intelligence on detecting optimal resource allocation to edge devices.

Data Availability

The datasets used and/or analysed during the current study are available from the corresponding author upon request.

Authentication is a suitable form of restricting the network from different types of attacks, especially in case of fifth-generation telecommunication networks, especially in healthcare applications. The handover and authentication mechanism are one such type that enables mitigation of attacks in health-related services. In this paper, we model an evolutionary model that uses a fuzzy evolutionary model in maintaining the handover and key management to improve the performance of authentication in nanocore technology-based 5G networks. The model is designed in such a way that it minimizes the delays and complexity while authenticating the networks in 5G networks. The attacks are mitigated using an evolutionary model when it is trained with the relevant attack datasets, and the model is validated to mitigate the attacks. The simulation is conducted to test the efficacy of the model, and the results of simulation show that the proposed method is effective in improving the handling and authentication and mitigation against various types of attacks in mobile health applications.

1. Introduction

In recent times, the mobile and telecommunication devices get faster and more functional with each wireless network applicable on mobile health programs in healthcare. The speeds we have today were made possible by 4G [1]. Nevertheless, 4G networks are nearing their capacity limit as more people get online and demand even more data from their gadgets and smartphones. The researchers are now on the verge of transitioning to 5G, the wireless technology.

The increased traffic can be handled on this network than on Long-Term Evolution (LTE) networks. The 5G mobile network concept is being discussed by both business and academia. Next-generation mobile networks should be in place by 2020, according to current estimates. With increasing data traffic, devices are being studied to see if it is possible to attain 1 ms latency [2]. There will also be new features in 5G, such as the heterogeneous network integration with the network security over reliability and provisioning [3, 4].

As a result of these performance requirements, various 5G network technology solutions have been implemented, including HetNets, software-defined networking (SDN), and more. SDN has gotten a lot of interest recently as a promising new technology for the next generation of wireless mobile networks [5–8]. Control plane and data forwarding are separated or decoupled in an SDN, allowing a centralised controller to take control of the network. The control plane of an SDN network is independent of data forwarding and programmable. This SDN functionality makes network configuration and reconfiguration much simpler [9].

Additionally, it offers excellent security management over network opportunities in terms of adaptability and programmability. In contrast, developing SDN and NFV technologies may run and instantiate networks and their services in order to minimise costs and improve performance [10]. The 5G heterogeneous networks are critical to achieving goals such as low energy consumption, low cost, and full coverage. HetNet heterogeneity allows for more coverage, higher capacity, and improved performance.

Different 5G cells, including relays, microcells, and femtocells are being proposed to support imminent coverage [11]. As a result, the next-generation network is expected to be significantly more heterogeneous, and because of the densified deployment of a small cell, users should expect to see more frequent handoffs [12–21].

Vertical handover is critical in such a heterogeneous environment because it allows different networks to be integrated with one another. As a result, the researchers will be able to take advantage of the best features of existing networks. For a registered and valid user to gain access to network resources, authentication is necessary. Furthermore, mutual authentication can maintain secrecy by protecting communication entities from diverse threats and ensuring the integrity of their data. Due to frequent user movement across multiple networks, a smooth and secure solution for handover authentication is required to protect against various attacks.

In order to provide secured access to users on a foreign network, a rapid and effective authentication mechanism must be designed. However, there are not many studies looking specifically at 5G mobile network architecture and security in mobile healthcare applications.

Due to certificate-based authentication high security and ability to provide authentication, a system based on shared key distribution for certificate authentication is proposed. Thus, users in the 5G network environment can be certified by other networks. It is intended that the effectiveness of security management techniques, as well as the overall network view, will be improved using an evolutionary model. Transport Layer Security (TLS) is used in the proposed approach, but it is enhanced with preinitial authentication, which gives a shared certificate to registered user equipment only. As a result, the suggested system incorporates mutual authentication, key exchange, and agreement components. Data integrity and privacy are also provided as well as resistance against many forms of attacks.

The main contributions are given as follows:

(i) Using the SDN for network management and security, as well as the HAU for seamless and effective handover, helps to create a global perspective of the network.

(ii) To provide great security and mutual authentication, the TLS protocol should be used.

(iii) This ensures that vertical handover processes are consistent and secure because the certificate authentication relies on key distribution that has a fuzzy evolutionary model. The evolutionary model maintains the handover and key management to improve the performance of authentication with nanocore elements in 5G networks.

2. Related Works

By extending the 3GPP LTE hierarchical architecture and integrating the SDN technology, they presented a 5G mobile network architecture that can leverage intelligence and programmable networking capabilities. An authentication handover [22] based on SDN functions is presented in the design, and this allows subscribers to track their movements and their next location to be monitored. As a result, AHM is able to recognise prospective target cells and begin the handover operation to minimise the associated signalling delay.

Symmetric key cryptography and Elliptic Curve Diffie–Hellman are used in [23] to propose an authentication mechanism for LTE networks. With the addition of a local authenticator, they fixed the flaws in the EAP-AKA protocol. As a result, this approach can safeguard user identification against a variety of attacks while also enabling data integrity and mutual authentication across users. In the context of 5G networks, the approach may not be efficient or scalable due to the high number of small cells and users.

He et al. [24] presented a technique based on binary pairing functions to secure the operation of handover and reduce the communication and computation costs as an alternative authentication scheme. The delay can be as high because the authentication server is normally placed remotely, which makes it unsuitable for 5G requirements due to frequent handovers between the authentication server and tiny cell access points.

An evolved packet system in LTE networks was proposed by in [25] to overcome numerous flaws of EAP by lowering computational overhead and authentication latency and satisfying security requirements. EPS uses simple password key exchange. With a secret key, the major goal is to keep the user UE private while also minimising the size of sent messages and speeding up the protocol. The authentication process gets more simplified, but there is a risk of increased delays in 5G small cell networks due to a higher frequency of enquiries.

3. System Model

In order to have robust security against multiple attacks, the heterogeneous 5G mobile network environment should match the criteria of secured data transmission from mobile health applications [26, 27].

The researchers also need to meet the following requirements: mutual authentication, data privacy and integrity, and protection from passive and active attacks such as DoS and Man in the Middle (MitM) attacks. Because millimetre waves have poor signal transmission characteristics and operate at very high frequencies, the 5G mobile network is more heterogeneous, with many tiny cells.

Network accessing over UE differs from that of access points (APs) and evolved network nodes (eNBs). Using 5G multilayer coverage, this heterogeneous paradigm not only keeps up with the progress of existing technologies but also meets the data traffic demand with small cells that provide extremely high throughput and underlying macrocells that provide ubiquitous coverage even with small cell deployment. Minimal power tiny cells are, therefore, expected to be a significant part of the 5G network, enabling users to communicate at low cost while also providing great capacity.

Figure 1 shows the handover authentication unit (HAU) installed in the 5G mobile network SDN controller, which underpins SDN technology.

All 5G access points, base station (BS), and switches are equipped with relevant SDN protocols to support SDN-enabled 5G networks. To ensure flawless handover authentication, the implemented HAU must keep tabs on and forecast the locations of registered mobile users and then prepare the necessary BS and APs before the users arrive. The HAU stores and analyses user data by employing a traffic flow filter to collect physical layer attributes from registered users. Once user equipment has been preauthenticated for the first time, data collection will begin.

The study uses a downlink LTE system, where the eNB is placed within the UE (u) set. It is then distributed inside the network coverage range. The eNBand UE is of a single SISO antenna type.

We consider the user set $S = \{1, 2, \ldots, S\}$ with the service set u_s, where $\cup_{s\in S} u_s = u$ and $s \in S$. Each individual user is allowed to authenticate the network for one time $\cap_{s\in S} u_s = \varnothing$.

While TDMA is employed in LTE, the OFDMA technology is used in the multiple access strategy. Due to signalling limits and the assignment of radio resource blocks, this is taken into account. The LTE system places the K RBs in k sets, which are then distributed. The TTI is the period of time during which the UE is given access to the RRA algorithm-allocated resources. The TTI here is the same as the RB timing duration, and each RB is assigned to a single UE for the period of a single TTI.

Each TTI complex channel coefficient $h_{u,k}$ contains the propagation effects over the LTE channel, such as shadowing, path loss, and small-scale fading UE ($u \in U$) and eNB over RB ($k \in K$). Channel response is referred to as a complex channel coefficient because coherence is greater than RB; hence, the channel fades flatly. Subcarrier and the 1st OFDM

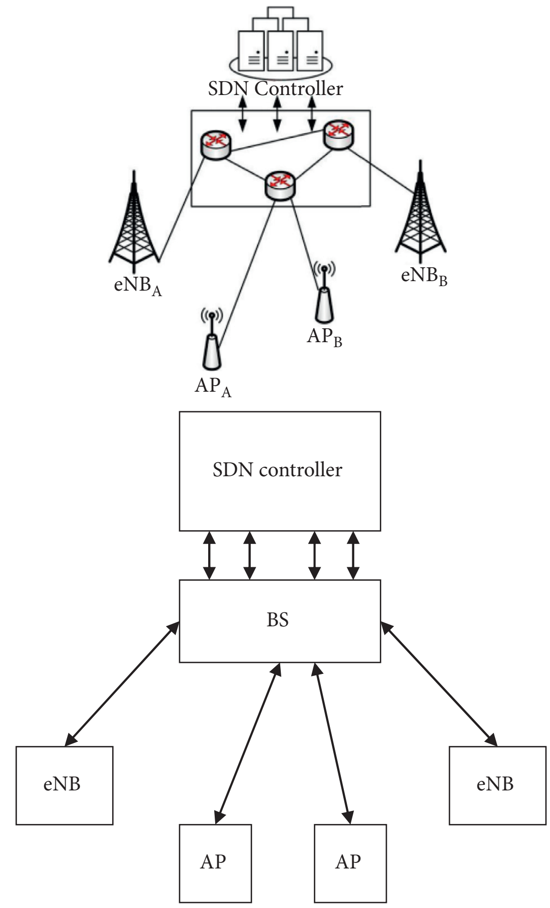

Figure 1: Simplified 5G network architecture with SDN for medical datasets.

symbol are the most common uses for this. In order to estimate the $h_{u,k}$, UE uses pilot symbols, and the data are transmitted via eNB for transmission. This estimates the channel $\widehat{h}_{u,k}$ to be as, and it is modelled as follows:

$$\widehat{h}_{u,k} = \sqrt{(1-\xi)h_{u,k}} + \sqrt{\xi_\eta}, \tag{1}$$

where $\xi \in (0, 1)$- channel estimation degradation and $\eta \in C$- channel estimation error.

The channel estimation error is modelled as a random variable as follows:

$$E\left\{|\eta|^2\right\} = E\left\{\left|h_{u,k}\right|^2\right\}. \tag{2}$$

The current research finds the authentication error linked to channel estimate errors, and the parameter ξ is assessed depending on the impact of those flaws. Finally, reports are taken into account at each TTI, and the eNB obtains measurements immediately.

Additionally, the estimated instantaneous SNR $\widehat{\gamma}_{u,k}$ for each TTI is determined as follows:

$$\widehat{\gamma}_{u,k} = \frac{p_{u,k}\left|\widehat{h}_{u,k}\right|^2}{\sigma^2}, \tag{3}$$

where $p_{u,k}$- eNB power and σ^2- AWGN power.

The link adaptation mechanism, which is employed in LTE as well, selects the MCS (m) from a list of MCSs using eNB (M).

When applied to the set, the MCS selection employs $\hat{\gamma}_{u,k}$ and considers $M = |M|$ with varying MCS, where $|\cdot|$ specifies the cardinality. The UE u in k-related MCS $m_{u,k}$ is determined as follows:

$$m_{u,k} = f\left(\hat{\gamma}_{u,k}\right), \tag{4}$$

where $f\,(\hat{\gamma}_{u,k})$- link adaptation function.

The eNB used in this study selects the superior MCS from among the available UE, resulting in a higher data rate per unit of network power consumed.

UE uses MCS to transmit information to the eNB, which assures the block error rate value. The needed block error rate value is utilised to acquire the link adaption curve with minimal SNR $\hat{\gamma}_{u,k,m}$, and it is evaluated as follows:

$$\hat{\gamma}_{u,k,m} = f^{-1}\left(m_{u,k}\right), \tag{5}$$

where $f^{-1}(\cdot)$- inverse link adaptation function.

The throughput rate $r_{u,k,m}$ over a user k of UE u through a multichannel system m is illustrated as follows:

$$R_u = \sum_{k=1}^{K=|K|} \sum_{m=1}^{M=|M|} r_{u,k,m} x_{u,k,m}, \tag{6}$$

where $x_{u,k,m}$- assignment allocation index.

The authentication τ_u for the UE u is obtained via R_u rate using $\varphi(\cdot)$ function as follows:

$$\tau_u = \phi\left(R_u\right). \tag{7}$$

4. Proposed Method

Because the 5G mobile network will be highly heterogeneous, mutual authentication between the users and server is one network criterion. The suggested system makes use of mutual authentication and FEA-TLS security capabilities. Apart from these characteristics, FEA-TLS comes with even more noteworthy ones, including fragmentation, key exchange and agreement, reauthentication, and resilience to MitM and replay attacks.

When it comes to the FEA-TLS protocol specification, the following shows the process of the proposed protocol:

(i) Public key infrastructure is used by FEA-TLS; therefore, certificates are required
(ii) The UE and the authentication server are the first points of contact
(iii) The certification authority issues certificates to authentication servers and user equipment
(iv) The user equipment certificate must be validated with a network server during the UE lifetime
(v) To verify a user certificate, the authentication server needs a certificate from a certification authority

4.1. Proposed FEA-TLS Protocol. According to the estimations, the suggested protocol is more efficient than other evolutionary TLS-based systems when it comes to handover authentication with the signed certificate. It also fits the 5G mobile network requirement for a heterogeneous environment. Key exchanges are made possible with the deployment of this FEA-TLS-based system for authenticating user equipment.

An initial authentication strategy using shared key cryptography is proposed for use in the new protocol, and this key will be utilised by the UE to obtain a certificate and gain access to resources on the foreign network during vertical handover. UE requests for the foreign network certificate rather than transferring it straight from that authority to UE, which is one of the key aspects of the proposed system.

Figure 2 shows the beginning of the handover authentication procedure. Figure 3 shows the process as it continues. As a result, the proposed technique protects the UE identity from being attacked.

4.1.1. Preinitial Authentication. The user equipment will transmit the handover request and physical layer attributes to the home network eNB. The HAU then verifies these data before distributing the symmetric keys. eNB on the home network then responds with symmetric keys from the home networks, as depicted in Figure 2.

4.1.2. FEA-TLS Authentication. Before the UE begins the authentication process, the eNB shares the identity of UE with the AP of a foreign network for the identification verification process that is provided by the UE during the handover request, as illustrated in Figure 3. The UE will now send the AP a start packet. It is common for this AP to send the UE a FEA-TLS request packet. The UE responds to the AP with a packet including identification information.

As soon as the AP receives the UE identification information, it compares it with the UE id received from the eNB in the home network and confirms the information. Additionally, the AP will need to send an empty FEA-TLS/start packet, which is an FEA-TLS-packet type with the start bit set, to the UE during this verification process. The UE will send a welcome message with a cipher message, packet type, a session Id, and a random number to begin the FEA-TLS interaction.

This will be followed by a response from the AP with an EAP request packet with the FEA-TLS packet type along with the hello message and version number along with an acknowledgement to begin key exchange with the AP settings. To verify the certificate, the UE will send an already shared symmetric key along with a signed response from it. This packet is subsequently forwarded to the AP, which verifies and responds with the completed message containing the signed certificate and key of the response of UE authentication to the AP. After receiving the completion handshake message, the UE responds using a null message if

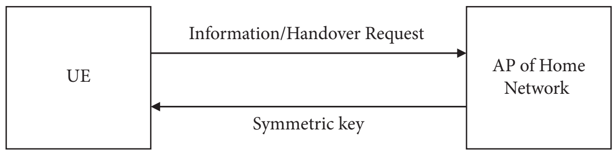

Figure 2: Healthcare security (initial authentication).

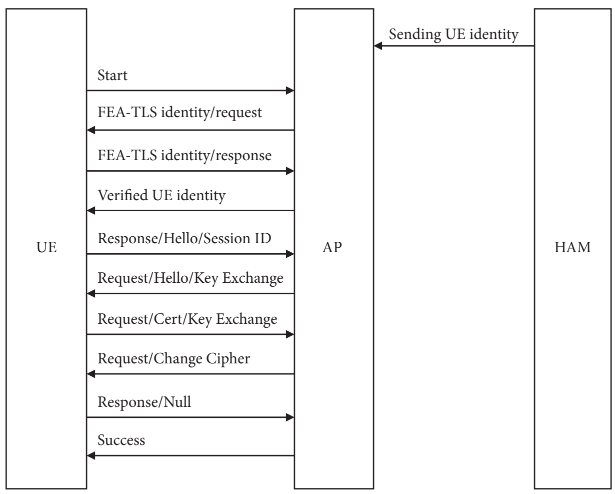

Figure 3: Flow of authentication for medical data.

the verification was successful. This session will come to an end when the AP responds with a success message.

Assume that the home network registers the UE with a SIM and a key is shared between the two networks. Therefore, when the UE leaves its home network and enters a foreign network, it must gain access to the foreign network. Both parties to the roaming agreement have signed it, as shown in Figure 3.

Public keys that are known by the UE, home network, and the foreign network tend to get shared between the networks via the proposed FEA-TLS authentication. A certificate issued by the certification body is also present on both networks. SDN controller HAU shares user identity with the foreign network AP prior authentication based on UE location.

By eliminating the need to communicate identity verification to the HAU, this AP can perform UE identity verification faster, allowing for seamless authentication handover for the UE. As soon as the UE returns to its home network, the HAU will see if the new UE it just added is in the list of previously registered ones. As long as the UE is on the list, HAU will have access to its own private network.

5. Security Verification

This section conducts both informal analyses as shown below.

5.1. Mutual Authentication. FEA-TLS provides mutual authentication between the HAU and UE. With a handover request, the UE challenges the HAU preinitial authentication. Only the HAU has access to UE secret key, which grants UE network access.

5.2. User Identity Protection. The UE will have access to foreign Aps, if it requests a certificate. By distributing certificates in a fresh order, random variable, time, and the UE location are obscured. Each time a new user registers, the generation of temporary Id is carried out using a randomly generated variable. Aside from that, this temporary identifier will be altered at random, making it impossible to track down the original registrant. HAU in SDN has access to the user current location. By doing this, the user equipment identity is protected.

5.3. Signaling Overhead. In the FEA-TLS approach, authentication takes place between an AP of a foreign network and a user. Due to the SDN-enabled 5G network, there are no additional user ID verification and round-trip delays, and it takes much less time.

5.4. Passive Attack. A valid request packet may be obtained with this technique, but the message cannot be decrypted without private key. The fact that SHA-1 features a mechanism for generating keys makes it difficult to decrypt without the private key. As a result, the study designed the evolutionary system to be resistant to a passive attack.

5.5. MitM Attack. MitM attacks will not be able to succeed against this model. When an identity of the user is secured by a temporary public key pair issued by the UE, attackers cannot get their hands on or change the key, and thus, it is useless to them. As a result, the HAU only shares the UE identification with the AP when the UE makes a handover request and finds the UE position. As a result, passive attacks are not a problem.

6. Results and Discussion

In this section, the performance evaluation is conducted on fuzzy evolutionary algorithm to control the HAU. The model is compared with existing methods in terms of various metrics including space complexity, communication overheads, executed handovers, and latency in handover.

6.1. Communication Overheads. Figure 4 shows the communication overhead between FEA-TLS on HAU with existing fuzzy and TLS methods. The results of communication overhead show that the proposed FEA-TLS achieves reduced communication overhead than the other methods.

6.2. Space Complexities. Figure 5 shows the space complexity between FEA-TLS on HAU with existing fuzzy and TLS methods. The results of space complexity show that the proposed FEA-TLS achieves reduced space complexity than the other methods.

6.3. Handover Latencies. Figure 6 shows the handover latencies between FEA-TLS on HAU with existing fuzzy and TLS methods. The results of handover latency show that the proposed FEA-TLS achieves reduced handover latency than the other methods.

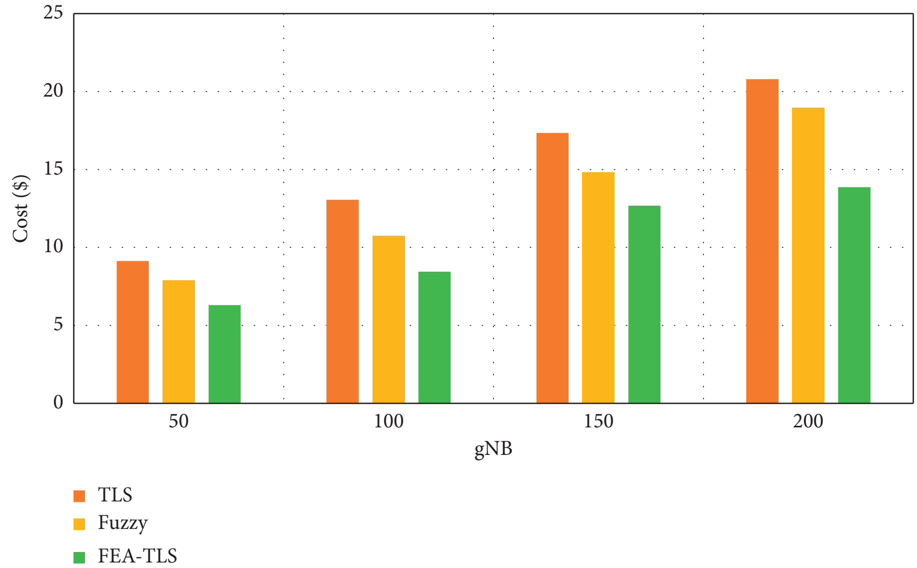

Figure 4: Communication overhead in the medical database.

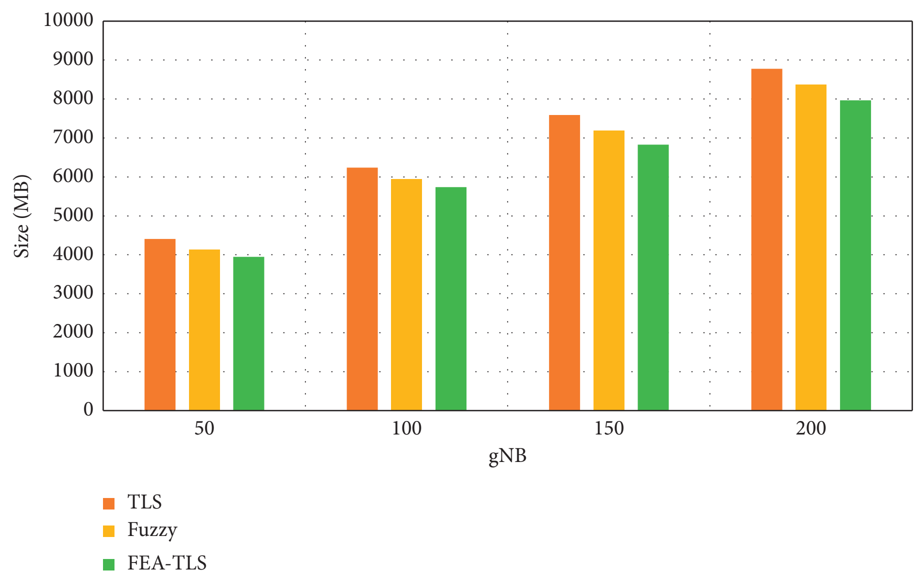

Figure 5: Space complexity for medical databases.

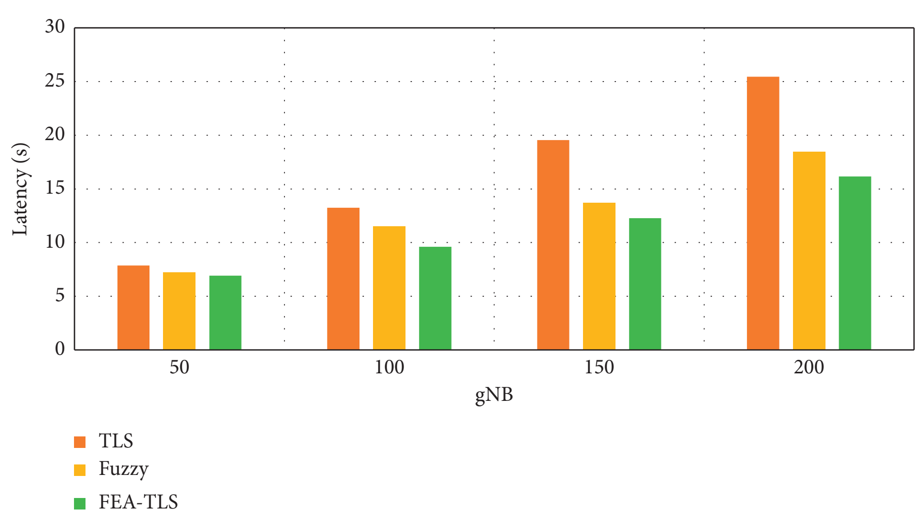

Figure 6: Handover latency in patients' history.

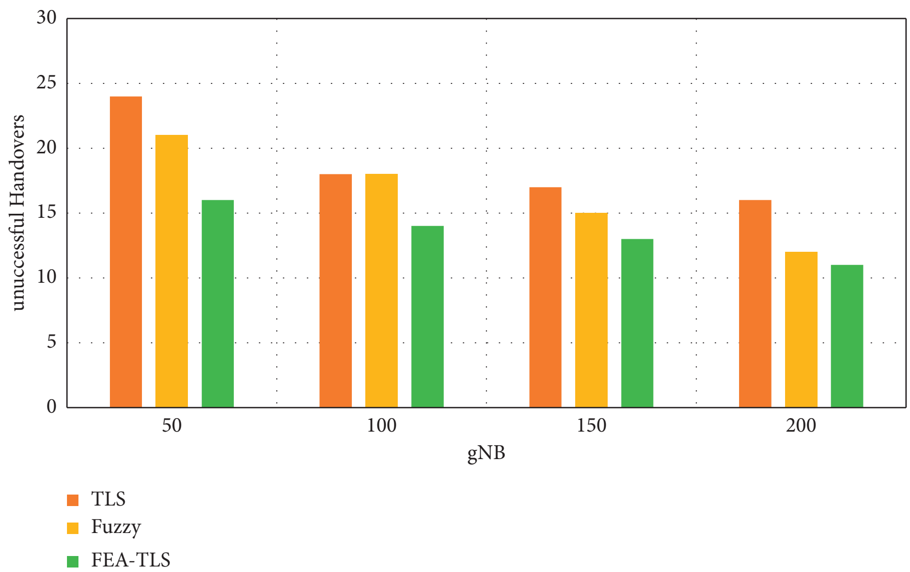

Figure 7: Executed handover security in the medical Mongo database.

6.4. Executed Handovers. Figure 7 shows the executed handover between FEA-TLS on HAU with existing fuzzy and TLS methods. The results of executed handover show that the proposed FEA-TLS achieves highly successful handover than the other methods.

From the results, it cloud be inferred that the proposed method achieves higher rate of accuracy in detecting the attacks while the data are transmitted from mobile health programs in healthcare. This shows higher efficacy in improving the mitigation of attacks in the healthcare field.

7. Conclusions

In this paper, we proposed the fuzzy evolutionary model for handover and key management in 5G networks for improving the network performance in terms of authentication in mobile health programs. The use of nanocore elements in 5G hardware with the fuzzy evolutionary model reduces the computational complexity and delays while authenticating the messages and users. The evolutionary model mitigates the attacks during the training process with relevant datasets, and the validation shows improved detection accuracy for the mitigation of the attacks. The simulation shows an improved efficacy of the fuzzy evolutionary model in terms of improved accuracy, and furthermore, it shows secured authentication of input messages and users into the network against various type of attacks in mobile health programs. The space complexity, handover latency, and executed handovers are minimal in the fuzzy evolutionary model than in other methods.

The objectives of this study were to improve the efficiency and accuracy of early clinical diagnosis of cervical cancer and to explore the application of tissue classification algorithm combined with multispectral imaging in screening of cervical cancer. 50 patients with suspected cervical cancer were selected. Firstly, the multispectral imaging technology was used to collect the multispectral images of the cervical tissues of 50 patients under the conventional white light waveband, the narrowband green light waveband, and the narrowband blue light waveband. Secondly, the collected multispectral images were fused, and then the tissue classification algorithm was used to segment the diseased area according to the difference between the cervical tissues without lesions and the cervical tissues with lesions. The difference in the contrast and other characteristics of the multiband spectrum fusion image would segment the diseased area, which was compared with the results of the disease examination. The average gradient, standard deviation (SD), and image entropy were adopted to evaluate the image quality, and the sensitivity and specificity were selected to evaluate the clinical application value of discussed method. The fused spectral image was compared with the image without lesions, it was found that there was a clear difference, and the fused multispectral image showed a contrast of 0.7549, which was also higher than that before fusion (0.4716), showing statistical difference ($P < 0.05$). The average gradient, SD, and image entropy of the multispectral image assisted by the tissue classification algorithm were 2.0765, 65.2579, and 4.974, respectively, showing statistical difference ($P < 0.05$). Compared with the three reported indicators, the values of the algorithm in this study were higher. The sensitivity and specificity of the multispectral image with the tissue classification algorithm were 85.3% and 70.8%, respectively, which were both greater than those of the image without the algorithm. It showed that the multispectral image assisted by tissue classification algorithm can effectively screen the cervical cancer and can quickly, efficiently, and safely segment the cervical tissue from the lesion area and the nonlesion area. The segmentation result was the same as that of the doctor's disease examination, indicating that it showed high clinical application value. This provided an effective reference for the clinical application of multispectral imaging technology assisted by tissue classification algorithm in the early screening and diagnosis of cervical cancer.

1. Introduction

Cervical cancer is a common malignant tumor in women. Its incidence ranks third in the world and ranks among the top three fatal gynecological tumors in most developing countries. According to a report from the World Health Organization (WHO), approximately 550,000 women worldwide become patients with new cases of cervical cancer each year, and more than half of these patients die of cervical cancer. As a developing country, China has more than 150,000 new patients with cervical cancer each year, of which more than 60,000 fatal cases accounting for more than 30% of new female patients with cervical cancer in the world. In recent years, the number of young female patients has gradually increased [1]. The site of cervical cancer is in the female cervix, and the cause is the growth and proliferation of abnormal cells in the female body. Early cervical cancer generally has no special differential symptoms, and late cervical cancer can develop into cervical cancer in situ and cervical invasive cancer [2]. Some countries under development and with scarce medical resources lack advanced medical resources and inspection equipment, so that women cannot get timely early screening and diagnosis, leading to cervical cancer gradually becoming the death killer of women.

The early diagnosis and identification methods of cervical cancer mainly include cell smear, colposcopy, and biopsy [3]. These examination methods have different shortcomings. For example, the cell smear method can easily lead to missed diagnosis of cancer cells because of the limited available cell smears; and the colposcopy method is mainly the result of the subjective judgment of the colposcopy doctor, so it is highly subjective and cannot make individualized diagnosis of patients. For female patients, the biopsy method needs to bear a physical and psychological burden, the test results are usually not available in a short time, and it is easy to delay the patient's treatment opportunity [4,5]. Cervical cancerous tissue will undergo physiological and pathological changes, which will cause optical changes in the tissue. Optical pathological diagnosis can avoid the above defects and has the characteristics of noninvasive and rapid. Especially, multispectral imaging technology has been widely used in recent years. Multispectral imaging technology is a new photoelectric detection technology. As an analysis tool, it has been widely used in many fields including biomedicine due to its unique technical advantages of both spectral detection and imaging. The biggest difference between multispectral imaging technology and ordinary imaging technology is that it converts black and white imaging or red, blue, and green imaging with low color accuracy into spectral imaging with higher color dimensions. A set of image sequences collected at different band positions are used to accurately record the "color" information of the marker sample and to obtain a high-resolution spectrum of each pixel in the image, instead of the three primary color images seen by the naked eye. With the assistance of multispectral fluorescence microscopes, quantum dots can achieve high accuracy and sensitive quantitative detection of molecular information, in situ and real-time co-imaging, and multimolecule co-imaging and interaction. Multispectral fluorescence imaging based on quantum dots can help improve tumor classification and predict tumor prognosis. Hu and Ma [6] used the snapshot multispectral narrowband imaging technology to accelerate the spectral image acquisition process, improve the grayscale contrast between tissues of different disease levels, and realize the automatic classification of cervical tissue lesions with high frame rate.

In order to better screen for cervical cancer, it is necessary to identify and segment the image of the lesion. At present, the extraction of cervical cancer image lesions is generally performed by doctors for manual segmentation, which depends on the doctor's theoretical knowledge and experience, and is highly subjective. In addition, it is time-consuming and labor-intensive, more and more images need to be processed, and manual segmentation obviously cannot meet the demand. With the application of computer algorithms in medical imaging, the use of intelligent algorithms for automatic or semiautomatic segmentation of lesions can greatly reduce the workload of doctors. The tissue classification algorithm is through the aid of computer algorithms; all elements in the original image will be summarized into several clusters with different differences [7]. The elements in the cluster have similar elements, but there are big differences between clusters [8]. That is, after inputting the original feature map, it is a computer technology that divides the feature regions of different images. It includes several modules such as computer signal processing, image analysis, image fusion, segmentation, and recombination. The type, size, range, shape, and other information of the target are displayed in the figure in the form of division, and the final inspector will get the most intuitive image morphology [9]. At present, there have been research projects on applying tissue classification algorithm to the research of lung cancer, and there are very few research projects corresponding to cervical cancer. Therefore, the characteristic wavelength of whether the lesion occurs were adopted in this study, and the tissue classification algorithm-assisted multispectral imaging technology was applied to the screening and diagnosis of cervical cancer patients, so as to realize the early screening and discrimination of cervical cancer, providing theoretical reference for clinically rapid and efficient screening of cervical cancer.

2. Methods

2.1. Research Objects. In this study, 50 patients with suspected cervical cancer from October 2019 to October 2020 in the hospital were selected as the research objects. They were between 25 and 55 years old, with an average age of 40.2 ± 5.3 years.

The inclusion criteria were defined as follows: patients who were between 25 and 55 years old; patients with no pregnancy and no sexual history during the experimental study; patients with no symptoms of reproductive tract infections or bleeding; and patients without vagina operations such as lavage.

The exclusion criteria were defined as follows: patients with reproductive tract co-infected diseases or vaginal bleeding; women during pregnancy and menstrual period; patients who underwent cervical resection or took drugs to wash and treat the cervix within 48 hours; patients with mental or consciousness disorder and poor compliance; and patients who were allergic to alcohol.

All patients in this study and their authorized persons had signed the informed consent forms, and the study had been approved by the Medical Ethics Committee of the hospital.

2.2. Principle of Multispectral Imaging for Cervical Tissue Examination. The micro-snapshot narrowband multispectral imaging system was adopted in this study. Three narrowband multispectral images of 50 patients' cervical tissues were collected under conventional white light waveband, narrowband green light waveband, and narrowband blue light waveband, with the number of acquisition frames of about 25 fps. The specific details are shown in Figure 1.

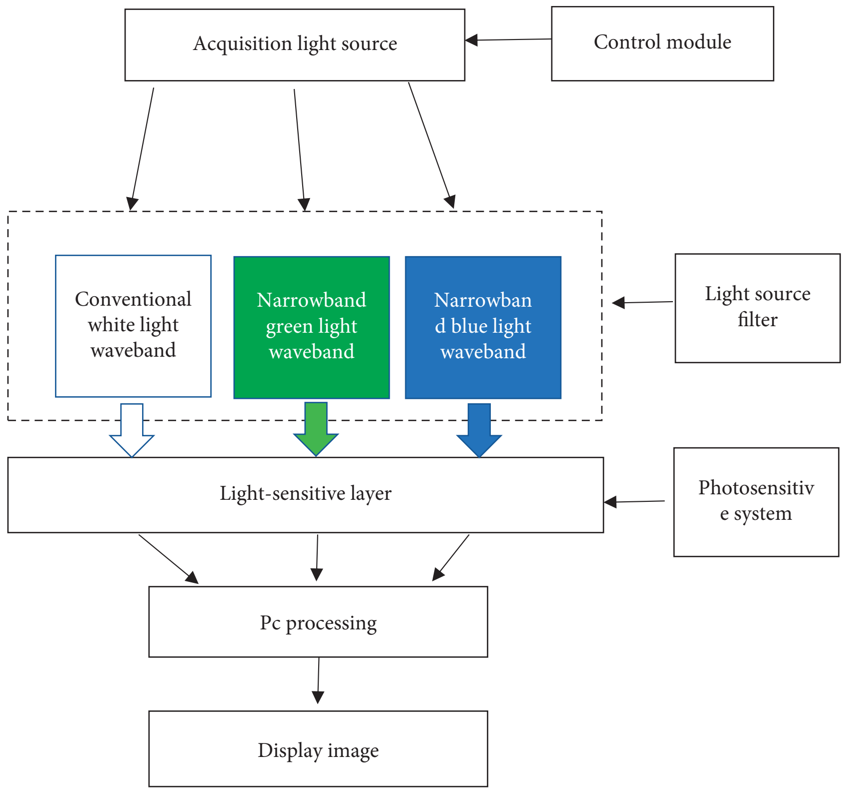

Figure 1: Schematic diagram of multispectral imaging system.

2.3. Multiband Image Fusion. Before the organization algorithm, the multispectral image was firstly fused to eliminate the influence of factors such as different wavebands, degree of filtering, and conversion rate with different wavebands [9]. In this study, contrast was used to measure image clarity, and the below equation is taken as the calculation standard:

$$\text{Contrast} = \sum_{\delta} \delta(i, j)^2 p_{\delta}(i, j). \tag{1}$$

In (1), $\delta(i,j) = |i - j|$ represents the difference in gray value between two adjacent image elements and $p_{\delta}(i,j)$ refers to the distribution probability of two image elements when the gray value between the two adjacent image elements was δ.

2.4. Multispectral Fusion Image Combined with Tissue Classification Algorithm. Due to the difference in the contrast of the multiband spectrum fusion image between the uninfected cervical tissue and the diseased cervical tissue, the gray value of the lesion area is generally slightly smaller than that of the normal tissue [10]. Therefore, the tissue classification algorithm was used to classify the spectra of different tissues in this study. The tissue classification algorithm is to use the band characteristics or spatial characteristics of the multispectral image as the boundary between normal and diseased, so that the elements on the spectrum are divided into different levels or categories, thereby realizing alternative subjective analysis [11]. The tissue classification algorithm used in this study was mainly to adopt the K-value clustering algorithm to summarize and analyze the physiological and pathological regional features of the cervical cancer site and then apply the corresponding regional features to analyze the cervical tissues of 50 patients with no lesions. The second step was to convert a monochrome black and white image into a distribution image of a given color. The algorithm principle is shown in Figure 2. The K-means clustering (KMC) algorithm was adopted to divide the lesion area and the nonlesion area, and then a single gray-scale image was stored into a multicolor image that can be intuitively distinguished. On the one hand, it improved the precise identification of the target area on multispectral imaging and increased the feature discrimination of the image and the features that can be easily distinguished; on the other hand, it can also make the clinical imaging physicians more acceptable when judging the multispectral imaging map intuitively [12]. Therefore, after the KMC algorithm obtained the gray image, the most classic Bayer image color array format interpolation algorithm was used. In this study, the diseased cervical tissue was marked in red, and the normal cervical tissue was marked in green.

2.5. Evaluation Indicators for Tissue Classification Algorithm-Assisted Multispectral Image. In order not to be affected by subjective evaluation, a quantitative evaluation equation was adopted to evaluate the image quality, so as to evaluate the restored color images through quantitative indicators to improve the accuracy of image discrimination. The average gradient, SD, and image entropy were selected as the evaluation indicators to restore the image results. The results

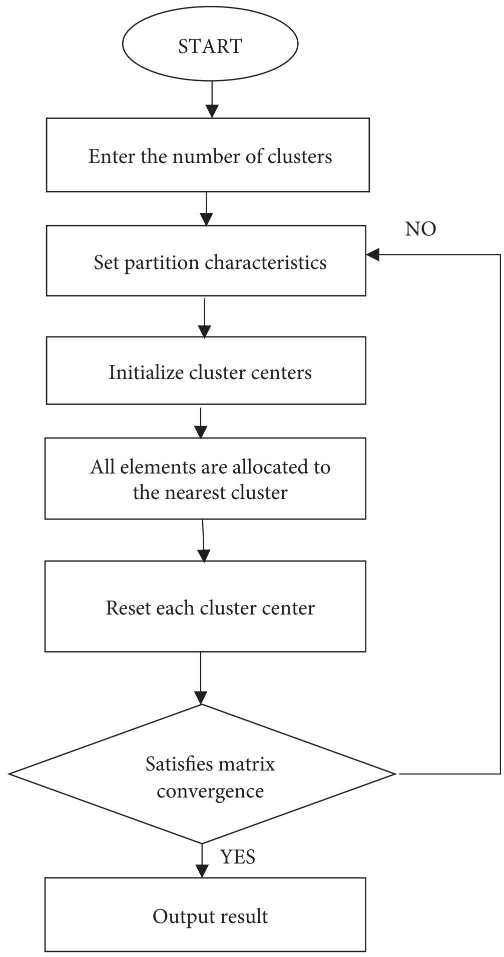

Figure 2: The algorithm principle.

of this study were compared with the reported International Commission on Illumination (CIE) color reduction method [13]. In the below equations, G represents the average gradient, which was the average of the image gray value change rate and used to reflect the sharpness of the image; and the larger the G, the better the image; SD represents the dispersion of the pixels and the average value in the image. Generally, the larger the SD value, the higher the image pixels and the better the quality; H is the image entropy, which represents the characteristics of all gray values of each image. The larger the value of G, the more average information the image contains and the better the image quality.

$$G = \frac{1}{M \times N} \sum_{i=1}^{M} \sum_{j=1}^{N} \sqrt{\frac{\Delta f/\Delta x^2 + \Delta f/\Delta y^2}{2}}, \quad (2)$$

$$SD = \sqrt{\frac{1}{M \times N} \sum_{i=1}^{M} \sum_{j=1}^{N} \left(p_{i,j} - \overline{x}\right)^2}, \quad (3)$$

$$H = -\sum_{i=0}^{n-1} p_i \log_2 p_i. \quad (4)$$

In (2) above, $M \times N$ represents the size of the image; i and j represent the pixel value of an element in the i-th row and j-th column, respectively; $\Delta f/\Delta x$ is the image on the X axis (horizontal direction); and $\Delta f/\Delta y$ is the gradient of the image on the Y axis (vertical direction). In (3), $P_{i,j}$ represents the pixel value of the i-th row and j column; and $\overline{x}$ represents the average value of the image. In the above equation (4), $n-1$ represents the $n-1$ gray levels of the image, and p_i refers to the probability of occurrence of the i-th gray value.

2.6. Indicators for Combination of Algorithm and Clinical Examination. The aforementioned tissue classification algorithm combined with multispectral imaging was used to systematically examine the cervical cancers of 50 patients. In order to prevent infection, in all patients were used disposable operating tools during the examination, and experienced imaging physicians and gynecologists perform biopsy sampling, detection, image collection, and analysis of results. At least 3 test points were collected for each patient. Sensitivity and specificity were selected as the indicators of the algorithm in clinical multispectral imaging.

$$Se = \frac{A}{A + C} \times 100\%. \quad (5)$$

$$Sp = \frac{B}{C + B} \times 100\%. \quad (6)$$

In equations (5) and (6) above, *Se* and *Sp* refer to the sensitivity and specificity, respectively; *A* means that the results of the disease examination and the algorithm check of this research were both positive (with disease); *B* means that the results of the disease examination and the algorithm check of this study were both negative (no disease); *C* means that the result of the disease examination was positive and the result of algorithm adopted in this study was negative; and *D* means that the side-by-side result was negative and the result of this algorithm was positive.

3. Results

3.1. Multiband Image Fusion Results. After all the cervical tissues were preprocessed, the images were fused and processed according to whether different cervical tissues had different characteristic bands and response to light. It was found that there was a great difference between the fused spectral image 3(b) and the image 3(a) without lesions. At the same time, it was found that the contrast of the fused spectral image was 0.7549, which was also higher than the contrast of 0.4716 after the fusion, showing statistical difference ($P < 0.05$). It indicated that the separation of the fused image was improved and the image was clearer, as shown in Figures 3 and 4.

3.2. Algorithm-Assisted Spectral Image Results. The histological algorithm and multispectral image were combined to perform K-means unsupervised classification processing and color restoration technology on the collected cervical tissue. Figure 5(a) shows the 3 detection points of the cervical tissue and whether there were lesions. Figure 5(b) shows the multispectral image after fusion processing and the location of the detection points on the image. Figure 5(c) shows the tissue classification algorithm-assisted fusion processing spectral cervical tissue and the results of segmentation in this image. The green mark in the figure is the area without lesions, while the red mark is the area with lesions. In the results of tissue classification diagnosis, Figure 5(c) is more intuitive than Figures 5(a) and 5(b) for whether the cervical tissue was cancerous or not and its scope, making it easier for clinicians to diagnose quickly.

3.3. Evaluation Indicators for Tissue Algorithm Image. The restored image was evaluated using three indicators. As given in Figure 6, the multispectral image average gradient, SD, and image entropy in this study based on the tissue classification algorithm were 2.0765, 65.2579, and 4.974, respectively, which were higher in contrast to the reported values (1.1777, 50.4657, and 3.9025, respectively), showing statistical difference ($P < 0.05$). It disclosed that the multispectral cervical tissue image based on the tissue classification algorithm was clearer, the segmentation of the lesion was clearer, and the overall quality of the image was better. Therefore, it could be applied in clinics to assist doctors in effectively completing the diagnosis of cervical cancer.

3.4. Results on Clinical Examination Indicators. To test the clinical performance of the tissue classification algorithm for cervical cancer tissue screening, the overall performance was evaluated by using two indicators (sensitivity and specificity). The multispectral image was compared with the tissue classification algorithm and the multispectral image without the algorithm. It was found (as illustrated in Figure 7) that the sensitivity and the specificity of the multispectral image with the tissue classification algorithm were 85.3% and 70.8%, respectively, both of which were larger than those of the images without the algorithm. Such results suggested that the use of tissue classification algorithm to assist multispectral imaging in screening cervical cancer showed higher accuracy and clinical application value.

4. Discussion

There are nearly 150,000 new cases of cervical cancer in China each year, and deaths due to cervical cancer account for nearly 20% of the female tumor deaths all over the world. The main cause of cervical cancer is that women are infected by human papillomavirus (HPV) [14]. Infection with high-risk HPV can cause abnormal cancer of the cervix and cause epithelial damage of the cervix. Women who are infected with high-risk HPV, without effective and timely treatment, will have a 10% chance of developing persistent HPV. Persistent HPV will continue to infect epithelial cells in the cervical tissue, causing heterogeneous proliferation of cervical epithelial cells, triggering cervical epithelial cancer, and greatly increasing the risk of eventually becoming cervical cancer [15]. Some researchers use HPV virus testing to screen cervical cancer to improve the screening and early diagnosis of cervical cancer. The detection method proposed by Digene has little specificity for HPV detection, the specificity for detecting all types of HPV viruses is not more than 10%, and the specificity for detecting high-risk HPV viruses that have been typed is only 30% [16]. Testing for HPV not only is low in specificity and produces unsatisfactory results but also causes physical and psychological distress to women. In recent years, some physicians have used multispectral imaging technology to assist in the screening of cervical cancer. Generally speaking, most new HPV infections do not cause symptoms or the disease can resolve spontaneously, but persistent infection with high-risk HPV (mainly types 16 and 18) may cause precancerous lesions. The high incidence of HPV infection is usually between 16 and 20 years old. It usually heals on its own but may also continue to be infected. If it is not treated in time, it may develop into cervical cancer after 10 to 20 years. Therefore, if cervical cancer can be detected early and treated early, most patients can be cured. Therefore, early screening and diagnosis of cervical cancer is of great significance for

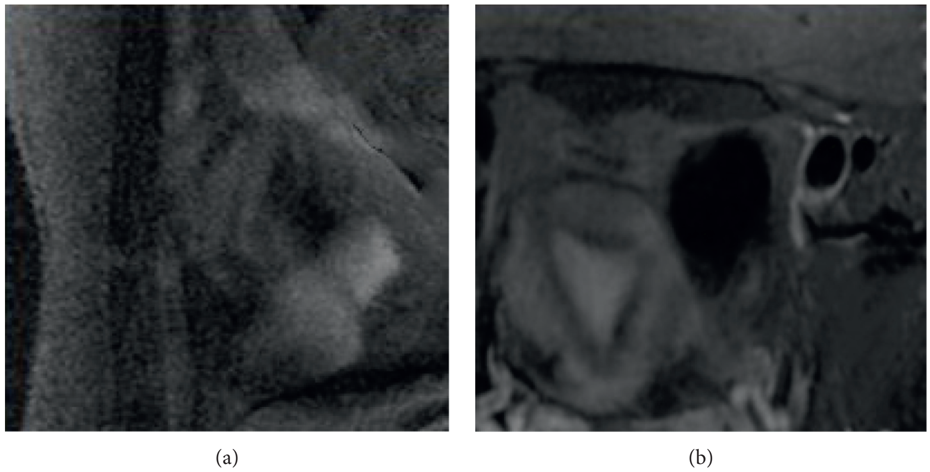

FIGURE 3: Processed images of normal tissue and fusion image: (a) image of the extracted cervical tissue (b) image for lesion area after multispectral fusion processing.

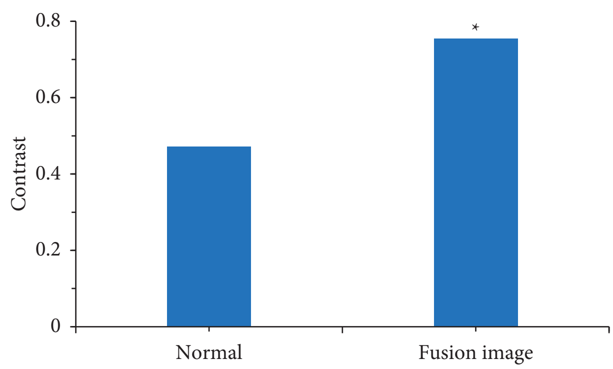

FIGURE 4: Contrast of two extracted images. *Note.* * means the difference was statistically great in contrast to the fusion image ($P < 0.05$).

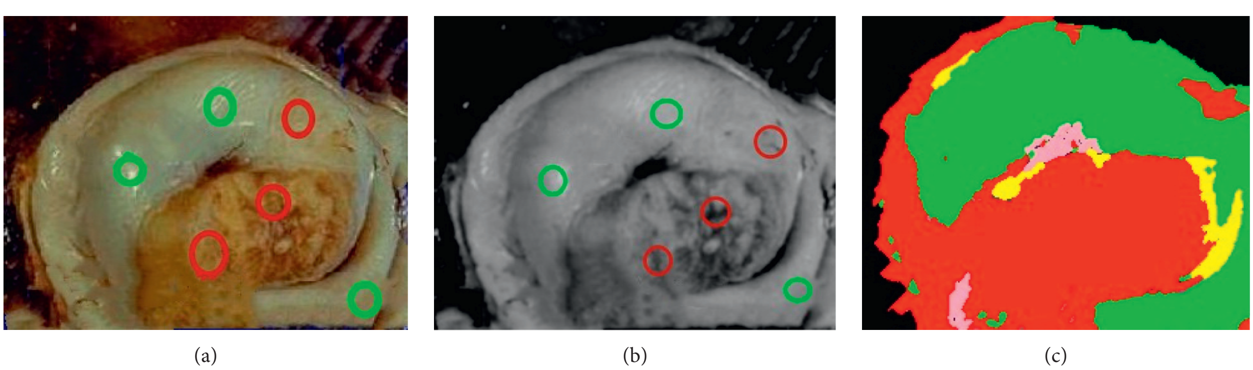

FIGURE 5: Classification and diagnosis results of tissues: (a) the 3 detection points of cervical tissue and whether there were lesions; (b) the multispectral image after fusion processing and the position of the detection points on the image; and (c) the tissue classification algorithm-assisted fusion processing spectral cervical tissue and the result of the segmentation.

reducing the morbidity and mortality of patients. Cervical cancer screening begins with the introduction of Hirsch cytology test into the clinic as a routine screening item. At present, the early diagnosis and identification methods for cervical cancer have different shortcomings. Multispectral imaging examination, as a way of using the optical changes of cervical cancerous tissue, is noninvasive and effective in the screening of cervical cancer.

Multispectral imaging generally refers to a type of spectrum with a narrowband and high resolution and does not specifically refer to a certain spectrum. Its imaging principle is a spatial three-dimensional cube image formed

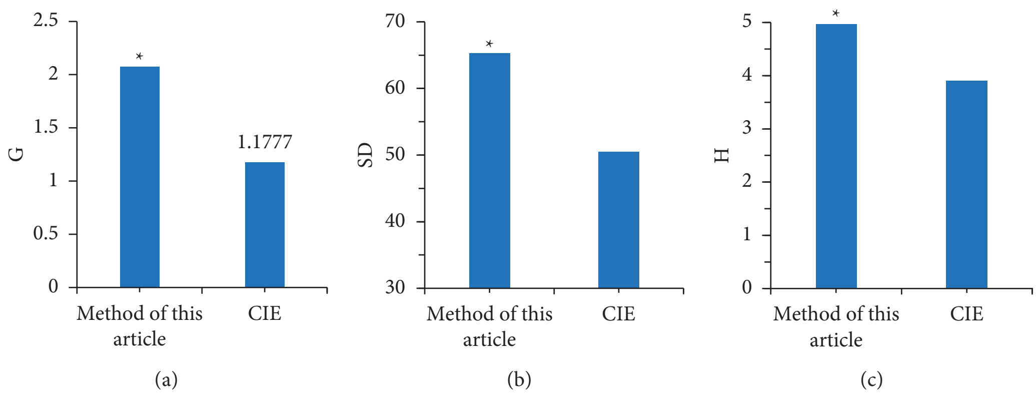

Figure 6: Comparison on evaluation indicators of restored color images: (a) the average gradient of the image; (b) the standard deviation of the image; and (c) the image entropy of the image. *Compared with the CIE algorithm, the difference was statistically significant ($P < 0.05$).

by an optical image at a certain wavelength. Through the multispectral image, not only the image data of the research target at a certain wavelength can be obtained, which is used to obtain the two-dimensional morphological data of the research object, but also the spectral data of a certain wavelength in the three-dimensional space can be used to obtain the research object information contained within the space. Therefore, multispectral imaging technology has been applied to various aspects [17]. Image fusion is also an important point in multispectral imaging technology. The definition of multispectral image fusion is to combine all the characteristic information of the multispectral image at the same wavelength through a specific combination. Relying on their spatial correlation and complementarity, it finally gets a clearer and higher resolution image than the original image [18]. In this study, it was found that after the cervical tissues of all patients were processed, the spectral image after image fusion processing and the image 3(a) without lesions were combined according to the characteristic wavelength band of different cervical tissues and the response to light. In addition, the contrast of the fused multispectral image was 0.7549, which was also higher than the fused contrast of 0.4716, indicating that the separation of the fused image was improved and the image was clearer.

At present, artificial intelligence algorithms have been widely used in the medical field. For example, Dorta-Estremera uses deep learning algorithms to identify unbalanced error reports in medical data [19]. The tissue classification algorithm uses the band characteristics or spatial characteristics of the multispectral image to classify it as the boundary between unoccurring lesions and suspected lesions, so that the elements on the spectrum are divided into different levels or categories, thereby realizing alternative subjective analysis [20]. In this study, the tissue classification algorithm was applied to analyze the multispectral image of cervical tissue. Comparison of unfused and fused multispectral images showed that after the tissue classification algorithm was used to process the fused cervical tissue image, the area and the range of the cervical tissue in the image were more intuitive so that it was easier for doctors to quickly screen out cancerous lesions by color classification. In addition, the restored image was evaluated using three indicators. The result revealed that the multispectral image average gradient, SD, and image entropy in this study based on the tissue classification algorithm were 2.0765, 65.2579, and 4.974, respectively, which were higher in contrast to the reported values (1.1777, 50.4657, and 3.9025, respectively). It suggests that the multispectral cervical tissue image based on the tissue classification algorithm is clearer, the segmentation of the lesion is clearer, and the overall quality of the image is better.

With the application of optical imaging and computer algorithm technology in medical treatment in recent years, multispectral imaging technology can present high-definition and high-resolution imaging and lesion screening of cervical tissue. Studies have found that the sensitivity of multispectral imaging technology can reach nearly 96% and the specificity can reach nearly 56% [21]. In this study, the multispectral image of the tissue classification algorithm was compared with the multispectral image of the nonapplied algorithm. It was found that the sensitivity and specificity of the multispectral image with the tissue classification algorithm were 85.3% and 70.8%, respectively, which were higher than those of the image without the algorithm. It indicates that the use of tissue classification algorithm to assist multispectral imaging shows higher accuracy and higher clinical application value in screening of the cervical cancer.

5. Conclusion

Multispectral imaging assisted by tissue classification algorithm can effectively screen for cervical cancer and can quickly, efficiently, and safely segment the cervical tissue from the lesion area and the no-lesion area. The segmentation result was the same as the result of the physician's medical examination, showing that its clinical application value was high. This study could provide a new idea for the clinical application of tissue classification algorithm-assisted multispectral imaging technology in the early screening and diagnosis of cervical cancer. However, there were still some shortcomings in this study. The included sample size was small. To obtain more detailed results, more sample studies are needed in the future.

Retracted: Study on Toll-Like Receptor 2-Mediated Inflammation-Induced Familial Hypertension Combined with Hyperlipemia and Its Mechanism

Journal of Healthcare Engineering

Received 11 February 2023; Accepted 11 February 2023; Published 18 February 2023

Journal of Healthcare Engineering has retracted the article titled "Study on Toll-Like Receptor 2-Mediated Inflammation-Induced Familial Hypertension Combined with Hyperlipemia and Its Mechanism" [1] due to concerns that the peer review process has been compromised.

Following an investigation conducted by the Hindawi Research Integrity team [2], significant concerns were identified with the peer reviewers assigned to this article; the investigation has concluded that the peer review process was compromised. We therefore can no longer trust the peer review process, and the article is being retracted with the agreement of the Chief Editor.

The authors disagree with the retraction.

According to the latest clinical data, cardiovascular diseases have ranked first in prone diseases, causing 40% of the premature deaths of China's population. This study aimed to investigate the influence of Toll-like receptor 2- (TLR2-) mediated inflammation on the occurrence and development of familial hypertension combined with hyperlipemia and its related mechanism. Blood specimens from 66 patients undergoing coronary atherosclerosis were collected and grouped, including 22 patients into the control group, 25 into the familial hypertension group, and 19 into familial hypertension combined with hyperlipemia group. In this study, ELISA was conducted for determining the levels of four inflammatory factors of TLR2 and IL-1β, IL-6, TNF-ɑ, and CCL2 in serum and the levels of relevant indicators in mice. C57Bl/6j and genetically engineered *C.129(B6)-Tlr2tm1Kir/J* mice were given subcutaneous injection of normal saline (wild-saline group), 8-week 40% high-fat diet (wild-high-fat group), and subcutaneous Alzet-implanted angiotensin II micropump supplemented with the research diet (wild-high fat-Ang II group, *Tlr2*$^{-/-}$-high fat-Ang II group). Blood pressure in mice was recorded consecutively with a noninvasive hemopiezometer for eight weeks. TLR2 and IL-1β, IL-6, TNF-ɑ, and CCL2 in serum of patients with familial hypertension combined with hyperlipemia and the hypertension combined with hyperlipemia mouse model were higher than those in the normal group. Under combined intervention of Ang II and the research diet, mRNA expression related to blood pressure, blood lipid, and fat metabolism in *Tlr2*$^{-/-}$ genetically engineering mice was significantly lower than that in the wild-high fat-Ang II group. The phosphorylation levels of AKT, IKK, and p65 in mice with hypertension combined with hyperlipidemia were significantly higher than those in normal group. The levels of blood pressure and blood lipid in mice after blocking the AKT or NF-κB pathway were significantly downregulated compared with those in the wild-high fat-Ang II group, with statistically significant differences (both $P < 0.05$). In conclusion, TLR2 regulates inflammation through Akt-NF-κB pathway, thus inducing the occurrence and development of familial hypertension combined with hyperlipemia.

1. Introduction

According to the latest clinical data, cardiovascular diseases have ranked first in prone diseases, causing 40% of the premature deaths of China's population [1–3]. Among these, hypertension and hyperlipemia are the most common diseases. Patients with hypertension account for about 43% of the total patients with cardiovascular diseases [4, 5], and patients with dyslipidemia accounting for 40.4% [6]. With the improvement of quality of life, hypertension combined with hyperlipemia has become the normal state for patients with cardiovascular diseases. Long-term hypertension and hyperlipemia can result in malignant diseases, such as stroke, myocardial infarction, renal failure, congestive heart failure, progressive atherosclerosis, and dementia [7]. Gender, age, smoking, regulation of intestinal flora, lifestyle, and genetic determinism can all be taken as individual difference factors for the occurrence of hypertension combined with hyperlipemia. The complexity of influencing factors is one of the important reasons for its long-time treatment courses [8–11]. At present, the main means for regulating blood pressure and blood lipid is a drug intervention, with hypotensors (calcium-ion-channel antagonists, ACEI, ARB, etc.) combined with lipid-lowering drugs (HMG-CoA inhibitors) as a common strategy for early and long-term blood pressure and blood lipid control [12, 13].

Primary familial hypertension is a relatively special disease, which is mainly induced by the family inheritance as the disease factor, and acquired factors as the induction factor. A series of recent studies have shown that immune system disorders are closely linked to the occurrence of primary hypertension combined with hyperlipemia. T cells act with angiotensin II receptors to release TNF-α, IL-6, IL-17A, and other proinflammatory factors to regulate blood pressure [14]. HMBG1/TLRs and HMBG1/RAGE signaling pathways cause arterial spasm, inflammatory cell adhesion infiltration, and vascular injury, thereby leading to hypertension by acting vascular endothelium [15]. Infiltration and adhesion were also found in proinflammatory factors, such as IL-1β and CCL2 in lipid disorders [16, 17]. Therefore, we speculated that inflammation plays an important role in the occurrence and development of primary hypertension combined with hyperlipidemia.

TLR systems have been proven to play a key role in regulating the release, migration, and infiltration of inflammatory factors [18]; TLR2/TLR4 pathway interacts with NF-B, MAPK, PI3 K-Akt, mTOR, and other related pathways, regulating IL-1β, IL-6, TNF-α, CCL2, and other proinflammatory factors involved in a variety of physiological activities [19]. Recent research has shown that intestinal floras regulate inflammation on the occurrence and development of cardiovascular diseases through TLR2 [20], which can also promote the occurrence of thrombotic diseases combined with hyperlipemia [21]. Therefore, we speculated that TLR2-regulated inflammatory response also plays a role in primary hypertension combined with hyperlipemia.

On the basis of conventional medication treatment, the study on new pathological intervention targets for hypertension and hyperlipemia is still vacant. It is urgent to explore the pathogenesis of hypertension and hyperlipemia from the molecules and signaling pathways, providing a new treatment direction for clinical practice. For that, in this study, we explored the correlation between hypertension and hyperlipidemia and TLR2 level starting from the clinical blood specimen, and the specific role and molecular mechanism of TLR2 inducing the occurrence and development of hypertension and hyperlipidemia in the animal model. And we found that TLR2 can regulate inflammatory factor levels through Akt/NF-κB pathway, inducing the occurrence of hypertension combined with hyperlipemia, which may be a new clinical intervention target.

2. Methods

2.1. Collection and Grouping of Clinical Blood Specimen. Blood specimen was collected from 80 patients with atherosclerosis who underwent percutaneous coronary intervention (PCI) in the Cardiology Department during the time from August 2019 to December 2020. Among these, 14 were excluded due to blood test failure and incomplete patient information, and 66 were included in statistical analysis. According to blood pressure and blood lipid, the 66 samples were divided into three groups: (1) 22 into the control group (with normal levels of blood pressure and blood lipid); (2) 25 into the primary hypertension group (with higher systolic or diastolic pressure than normal, and normal blood lipid level); and (3) 19 into primary hypertension combined with hyperlipemia (with higher systolic or diastolic pressure than normal, as well as higher TC, triglyceride, and LDL). This study has been approved by the Ethics Committee of our hospital, and all patients have signed informed consent.

2.2. Animals and Construction of Animal Model. 4-week C57Bl/6j male mice (weight: 17.36 ± 0.82 g) and 4-week genetically engineered *C.129(B6)-Tlr2tm1Kir/J* male mice (i.e., *Tlr2*$^{-/-}$ mice, weight:18.55 ± 0.91 g) were all raised in Class SPF Animal Experimental Center, with the temperature of 21~25°C, the humidity of 40%~60%, breeding illumination degree of 20lx, and light and shade alternating of (12 h : 12 h), and were free of food and water. C57Bl/6j mice were purchased from Charles River Laboratories (Animal License No. SCXK (Shanghai) 2017–0011). *C.129(B6)-Tlr2tm1Kir/J* mice (Product No. 022507) were purchased from Jackson Laboratory, and all tests have been approved by the Animal Ethics.

Anesthesia in mice was abdominal injection of pentobarbital sodium (50 mg/kg), while euthanasia in mice was hypoxia to death with carbon dioxide.

2.2.1. Construction of Animal Model

(1) *Construction of Mice Model with Hypertension (22–23).* Angiotensin II (Ang II, MCE, 4474-91-3) was dissolved into dimethyl sulfoxide (DMSO, 10%) and corn oil (10%) successively into 5.23 mg/ml (5 mM) mother solution, which was poured into Alzet-implanted administration pump (US Alzet, 2006 micropump) capsule. After anaesthesia, 1 cm off the right of the back centerline of mice was cut into the skin parallel along the spine, isolated 2~3 cm length to the head bluntly; a micropump was implanted, with the release outlet toward the head, and finally, the cut was stitched. The drug pump released Ang II to the surrounding skin at 1000 ng/kg/min for 8 weeks, acting on AT1 receptor to induce the occurrence of hypertension.
(2) *Construction of Mice Model with Hyperlipemia.* From 4 weeks old, the mice were fed with research diets (D12492) for 8 weeks to induce the occurrence of hyperlipidemia.
(3) *Construction of Mice Model with Hypertension Combined with Hyperlipemia.* Ang II administration pump capsule was implanted combined with hyperlipemia feed as intervention to construct model

mice with hypertension combined with hyperlipemia.

(4) *Construction of Mice Model with Blocking Akt Pathway.* Akt pathway inhibitor CCT128930 (MCE, 885499-61-6) was dissolved into 2.75 mg/mL (8.04 mM) mother solution with dimethyl sulfoxide (DMSO, 10%), polyethylene glycol 300 (PEG300, 40%), and Tween-80 (Tween-80, 5%) successively. Mice were injected with CCT128930 5 mg/kg caudal vein 3 times a week from 4 weeks old for 8 weeks to block the Akt pathway.

(5) *Construction of Mice Model with Blocking NF-κB Pathway.* NF-κB pathway inhibitor BAY 11–7082 (MCE, 19542-67-7) was dissolved into 2.5 mg/mL (12.06 mM) mother solution with dimethyl sulfoxide (DMSO, 10%) and corn oil (10%) successively. Mice were intraperitoneally injected with 2.5 mg/kg BAY 11–7082 twice a week from 4 weeks old for 8 weeks to block the NF-κB pathway.

2.2.2. Mouse Grouping and Quantity

(1) Levels of TLR2, related proinflammatory factors, and lipid metabolism-related mRNAs in mice with hypertension combined with hyperlipidemia induced by Ang II combined with the research diet: in this section, the mice were divided into three groups ($n = 5$): (a) wild saline; (b) wild-high fat; and (c) wild-high fat Ang II.

(2) Levels of blood pressure and blood lipid and related inflammatory factors in mice knockout *Tlr2* genes: in this section, the mice were divided into three groups ($n = 5$): (a) wild saline; (b) wild-high fat-Ang II; and (c) $Tlr2^{-/-}$-high fat-Ang II.

(3) Akt, IKK, and p65 protein expressions and their phosphorylation levels in model mice with hypertension combined with hyperlipemia: in this section, the mice were divided into three groups ($n = 5$): (a) wild saline; (b) wild-high fat-Ang II; and (c) $Tlr2^{-/-}$-high fat-Ang II.

(4) Verification of Akt pathway in TLR2-induced hypertension combined with hyperlipemia: in this section, the mice were divided into four groups ($n = 5$): (a) wild saline; (b) wild-high fat-Ang II; and (c) $Tlr2^{-/-}$-high fat-Ang II; and (d) wild-high-fat-Ang II-CCT128930.

(5) Verification of NF-κB pathway in TLR2-induced hypertension combined with hyperlipemia: in this section, the mice were divided into four groups ($n = 5$): (a) wild saline; (b) wild-high fat-Ang II; (c) $Tlr2^{-/-}$-high fat-Ang II; and (d) wild-high fat-Ang II-BAY11-7082.

2.3. Blood Pressure Monitoring. A noninvasive hemopiezometer (Kent) was adopted to record diastolic and systolic pressure every Wednesday and calculate MAP (MAP = (systolic pressure + 2 × diastolic pressure/3).

2.4. Blood Lipid Test

2.4.1. Clinical Blood Specimen. Clinical blood specimen was collected into the procoagulant tube and centrifuged at 3500 rpm for 7 min after resting for 5 min. The upper serum was absorbed into the EP tube for measurement. TC detection kit (Nanjing Jiancheng Bio, A111-1-1), triglyceride detection kit (Nanjing Jiancheng Bio, A110-1-1), LDL cholesterol LDL-C detection kit (Nanjing Jiancheng Bio, A113-1-1), and HDL cholesterol HDL-C determination kit (Nanjing Jiancheng Bio, A112-1-1) were adopted for coloring. The absorbance value was measured with the enzyme plate analyzer to calculate the concentration of the four components.

2.4.2. Blood Specimen from Mice. After fasting overnight, 1 ml blood was collected from mouse eyeballs and placed into a coagulation procoagulant tube (BD) after fully anesthetized by intraperitoneal injection of pentobarbital sodium (80 mg/kg). After resting for 5 min, the mice were centrifuged at 3500 rpm for 7 min, and the upper serum was absorbed into the EP tube for measurement. The determination method was the same as above.

2.5. ELISA

2.5.1. Clinical Blood Specimen. The collection method for serum was the same as "4. Blood lipid detection of clinical blood specimen." Human TLR2 ELISA Kit (ABCAM, AB227897), human IL-1β ELISA Kit (ABCAM, AB100562), human IL-6 ELISA Kit (ABCAM, AB178013), human TNF-ɑ ELISA Kit (ABCAM, AB181412), and human CCl2 ELISA Kit (ABCAM, AB179886) were used to detect the levels of TLR2, IL-1β, IL-6, TNF-ɑ, and CCL2 in serum.

2.5.2. Blood Specimen of Mice. The collection method for serum was the same as "4. Blood lipid detection of clinical blood specimen." Mouse TLR2 ELISA Kit (ABCAM, AB224880), mouse IL-1β ELISA Kit (ABCAM, AB197742), mouse IL-6 ELISA Kit (ABCAM, AB100712), mouse-derived TNF-ɑ ELISA Kit (ABCAM, AB208348), and mouse-derived CCl2 ELISA Kit (ABCAM, AB208985) were used to detect the levels of TLR2, IL-1β, IL-6, TNF-ɑ, and CCL2 in serum.

2.6. Quantitative Real-Time PCR (qRT-PCR). After sacrificing mice with carbon dioxide, the liver was collected and washed for residual blood with 0.9% saline and stored at −80°C. 30 mg tissues was taken, fully broken on the ice in homogenate, with 1 ml TRIzol RNA separation reagent (Thermo Fisher, 10296010). After resting 5 min, the tissues were centrifuged at 12000 rpm for 15 min, and the upper clarification aqueous phase was taken. RNA was precipitated with isopropanol and washed with 75% ethanol solution. After the precipitation was air-dried, RNA concentration was determined with a microplate analyzer. After recording the RNA reversal to a cDNA template with the Reversal

Reagent (Takara, RR037Q), qRT-PCR (Applied Biosystems ABI 7500) was performed with TB Green qPCR reagent (Takara, RR82LR). Amplification conditions: (1) Phase I, 95°C for 30 s; (2) Phase II, 95°C for 5 s, 60°C for 30 s, for 40 cycles; (3) Phase III, 95°C for 15 s, 60°C for 60 s, and 95°C for 15 s. The amplification multiple of genes relative to the internal reference was calculated by $2^{-\Delta\Delta\ Ct}$ formula according to Ct value. The upstream and downstream primer sequences are shown in Table 1.

2.7. Western Blot. After intraperitoneal injection of pentobarbital sodium (80 mg/kg) anaesthesia in mice, the hearts were collected and the residual blood was washed with 0.9% saline and stored at −80°C. The total protein was extracted from 30 mg tissues, with a 600 ml protein cracking solution (Keyki, KGP702). The protein concentration was determined with a protein concentration determination kit (Beyotime, P0006), and SDS-PAGE protein upper-like buffer (Beyotime, P0015) was added to obtain the protein sample 5 min after 100°C degeneration. 50 μg proteins was sampled from each lane. After SDS-PAGE cataphoresis, the proteins were transferred to PVDF membrane and incubated overnight at 4°C, with primary antibodies at 1 : 1000 of p-Akt (Thermo Fisher, PA5-95669, 1 : 5000), t-Akt (Thermo Fisher, PA5-29169, 1 : 4000), p-IKK (Thermo Fisher, PA5-104696, 1 : 4000), t-IKK (Thermo Fisher, PA5-86059, 1 : 1000), p-p65 (Thermo Fisher, PA5-104961, 1 : 5000), t-p65 (Thermo Fisher, PA5-16545, 1 : 4000), and Gapdh (Thermo Fisher, AM4300, 1 : 8000). Secondary antibodies of HRP-labeled sheep anti-rabbit (ABCAM, AB205718, 1 : 10,000) and rabbit anti-mouse (ABCAM, AB6728, 1 : 10,000) were added after washing 3 times with TBST and incubated at room temperature for 2 h. After washing with TBST, a chemiluminescence system (Millipore Corporation, Billerica, MA, USA) was adopted for developing, and ImageJ (NIH, Bethesda, MD, USA) for Grayscale analysis of the strips.

2.8. Statistical Methods. SPSS 19.0 software and GraphPad Prism 8.0 software was employed as well. The count data were statistically analyzed with *t*-test (two sets of data) or one-factor ANOVA (three sets and above data). Data were represented by $x \pm s$. $P < 0.05$ was defined as the statistically significant difference.

3. Results

3.1. Levels of TLR2 and Related Proinflammatory Factors in Clinical Blood Specimen. The general conditions of three clinical patients' specimen were statistically analyzed, and the baseline was adjusted to the same level. Except for related indicators of hypertension, hyperlipemia and medication, there were no statistical differences in age, gender distribution, smoking, previous history, and medication in the subjects of control, familial hypertension, and familial hypertension combined with hyperlipidemia groups (all $P > 0.05$, Table 2). Both systolic and diastolic pressure were significantly higher in the primary hypertension group and primary hypertension combined with hyperlipidemia group than those in the control group (both $P < 0.001$, Table 2). TC, triglyceride, and LDL were significantly higher and lower HDL in the primary hypertension combined with hyperlipidemia group than those in the other two groups (both $P < 0.001$, Table 2). According to the results of ELISA for relevant indicators of blood specimen in serums, the levels of TLR2, IL1-β, IL-6, and TNF-ɑ were significantly higher in primary hypertension group and primary hypertension combined with hyperlipidemia group than those in the control group (all $P < 0.001$, Table 3), with no significant difference in CCL2 levels among three groups ($P = 0.805$, Table 3). ELISA for a clinical sample of serum showed that in primary hypertension and primary hypertension combined with hyperlipemia groups, TLR2 and the concentration of related inflammatory factors were above normal levels, suggesting that TLR2 may be related to the development of inflammation.

3.2. TLR2, Related Proinflammatory Factors, and Fat Metabolism-Related mRNA Levels in Mice with Hypertension Combined with Hyperlipidemia Induced Jointly by Ang II and Research Diet. In order to further explore the correlation between hypertension combined with hyperlipidemia and TLR2 in the animal model, the combined method of Ang II and research diet was adopted in this study. Significant changes in blood lipid and blood pressure levels were found in the wild-high fat group and wild-high fat-Ang II group in which TC and LDL levels were significantly elevated compared with those in the wild-saline group, with statistically significant difference ($n = 5$, all $P < 0.001$, Figure 1(a)). No significant differences were observed between HDL and triglyceride ($n = 5$, both $P > 0.05$, Figure 1(a)). MAP also increased significantly compared with that in the control group ($n = 5$, all of $P < 0.001$, Figure 1(b)), and the model of mice with hypertension combined with hyperlipidemia was successfully constructed. TLR2, IL1-β, IL-6, and TNF-ɑ levels in serum of mice with hypertension combined with hyperlipidemia also significantly increased ($n = 5$, all $P < 0.001$, Figure 1(c)), but there was no obvious difference in CCL2 ($n = 5$, $P > 0.05$, Figure 1(c)). In addition, in the qPCR detected lipid metabolism-related mRNAs, genes responsible for fatty acid oxidation, fat hydrolysis, and cholesterol hydrolysis were downregulated to varying degrees ($n = 5$, all $P < 0.001$, Figure 1(d)). In the model of mice with hypertension combined with hyperlipidemia constructed by hyperlipemia and Ang II, blood lipid and blood pressure levels and lipid metabolism functions have changed pathologically to different degrees. At the same time, TLR2 and related inflammatory factors also increased to varying degrees in serum, suggesting the occurrence and development of hypertension combined with hyperlipidemia.

3.3. Blood Pressure, Blood Lipid, and Related Inflammatory Factor Levels in Mice with Knockout Tlr2 Gene. To intuitively verify the influence of TLR2 on pathology processes, the study group purchased $Tlr2^{-/-}$ mice bred by the Jackson Laboratory. In mice, after knocking out of Tlr2 gene, MAP

CCL2	153.60 ± 18.63	149.80 ± 19.99	151.40 ± 19.87	0.22	0.805

***Familial hypertension group versus control group, $P < 0.001$; †††familial hypertension compared with hyperlipemia versus control group, $P < 0.001$.

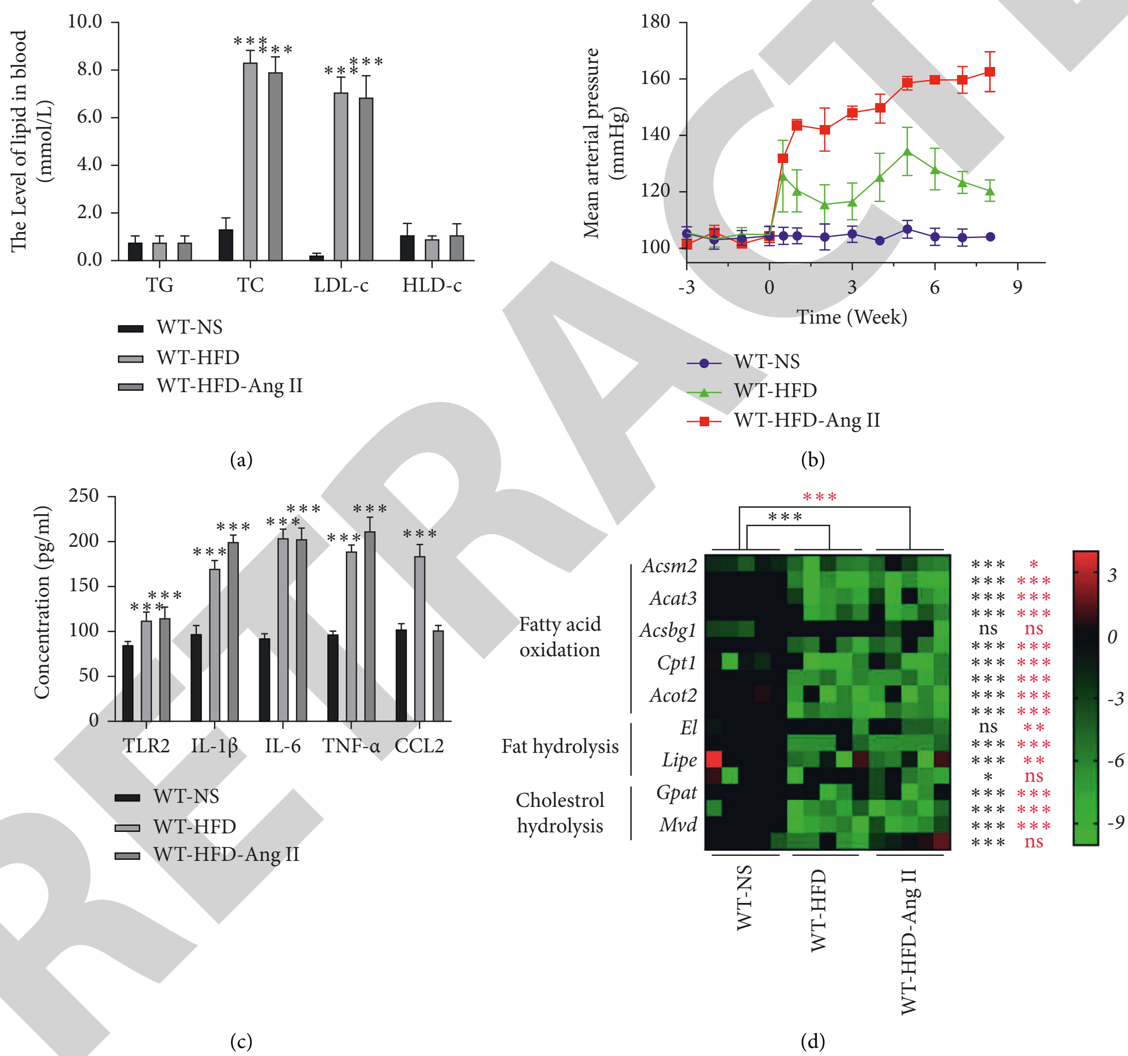

Figure 1: Comparison of blood lipid levels, MAP, TLR2 and expressions of inflammatory factors, and changes of gene expression in each group. (a) Comparison of blood lipid levels: the concentration of TC and LDL in serum was lower in high fat-Ang II group and high-fat group than that in the control group, and the difference in the concentration of triglyceride and HDL was not statistically significant compared to the control group. (b) Comparison of MAP levels in each group: high fat-Ang II group had significantly higher MAP than high-fat group after the construction of the model, and in the meantime, MAP in the two groups was significantly higher than that in the control group. (c) Comparison of TLR2 and proinflammatory factor levels in serum of each group: TLR2 and proinflammatory factor levels were significantly higher in high-fat group than those in the control group, and TLR2 and IL-1β, IL-6, TNF-α, and CCL2 levels did not significantly increase compared to the control group, while CCL2 levels were not statistically significant compared to the control groups. (d) Heat map of gene expression abundance detected by qPCR showed significantly lower genes related to fatty acid oxidation, fatty hydrolysis, and cholesterolosis in high fat-Ang II group and high-fat group compared with the control groups ($n = 5$; $^{***}P < 0.001$).

significantly decreased compared with those in the wild-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 2(c)). The levels of IL-6 and CCL2 did not differ significantly among the groups ($n = 5$, all $P > 0.05$, Figure 2(c)). Lipid metabolism-related mRNAs increased in varying degrees in *Tlr2*$^{-/-}$-high fat-Ang II group compared with those in the wild-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 2(d)), while there were no significant differences in the expressions of these genes in *Tlr2*$^{-/-}$-high fat-Ang II group and wild-saline group ($n = 5$, both $P > 0.05$, Figure 2(d)). After directly knocking out TLR2 gene to eliminate TLR2 function in model mice, the symptoms of hypertension and hyperlipemia were relieved in the knockout group compared with those in hypertension combined with hyperlipidemia group. It showed that TLR2 plays a role in the occurrence and development of hypertension combined with hyperlipidemia.

3.4. Akt, IKK, and p65 Protein Expressions and Phosphorylation Levels in Mice with Hypertension Combined with Hyperlipidemia. To explore the molecular mechanisms of occurrence and development of TLR2-induced hypertension combined with hyperlipidemia, the study group conducted a Western blot assay for proteins to explore the expressions of key proteins in TLR2-related inflammatory pathways in this case model. The phosphorylation levels of Akt, IKK, and p65 proteins in the wild-high fat-Ang II group were significantly increased ($n = 5$, all $P < 0.001$, Figure 3), which were significantly lower than in the wild-high fat-Ang II group after knocking out *Tlr2* gene ($n = 5$, all $P < 0.001$, Figure 3), with no significant difference from the wild-saline group ($n = 5$, mean $P > 0.05$, Figure 3). The protein results suggested that Akt and NF-κB pathways may participate in the occurrence and development of TLR2 regulatory disease.

3.5. Verification of Akt Pathway in TLR2-Induced Hypertension Combined with Hyperlipemia. To verify the apparent involvement of Akt in the process, the study group adopted the inhibitor to block the Akt pathway, and the phosphorylation level of Akt protein was significantly downregulated compared with that in the wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 4(a)). The mice model with inhibited Akt pathway was successfully constructed. After knocking out of Tlr2 gene, MAP in mice significantly decreased compared with that in the wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 4(b)). Similarly, after blocking the Akt pathway, MAP in the wild-high fat-Ang II group-CCT128930 group significantly decreased compared with that in the wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 4(b)), with no significant difference from the *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, $P > 0.05$, Figure 4(b)). The TC and LDL of wild-high fat-ANG II-CCT128930 group were significantly lower than those in the wild-high fat-ANG II group ($n = 5$, both $P > 0.05$, Figure 4(c)), with no significant difference from *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, all $P > 0.05$, Figure 4(c)). The levels of IL-1β and TNF-α in serum in the wild-high fat-Ang II-CCT128930 group were lower than those in the wild-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 4(d)), with no significant difference from those in the *TLR2*$^{-/-}$-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 4(d)). The CCL2 level was also lower than that in the wild-high fat-Ang II group and *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 4(d)). IL-6 level did not differ significantly in wild-high fat-Ang II-CCT128930 group and wild-high fat-Ang II group ($n = 5$, both $P < 0.001$, Figure 4(d)). *Tlr2* gene knockout improved the hypertension and hyperlipidemia symptoms, suggesting that TLR2 promotes inflammation by activating Akt pathway, thus inducing the occurrence and development of hypertension combined with hyperlipemia.

3.6. Verification of NF-κB Pathway Involved in TLR2-Induced Hypertension Combined with Hyperlipemia. To verify the involvement of NF-κB in the process, the study group employed the inhibitor to block the NF-κB pathway. The phosphorylation levels of NF-κB protein were significantly downregulated compared with that in the wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 5(a)). The mice model with inhibited NF-κB pathway was successfully constructed. After knocking out of *Tlr2* gene, MAP in mice significantly decreased compared with that in wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 5(b)). It was also lower in the wild-high fat-Ang II-BAY11-7082 group than that in the wild-high fat-Ang II group after blocking the NF-κB pathway ($n = 5$, $P < 0.001$, Figure 5(b)), with no significant difference from *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, $P > 0.05$, Figure 5(b)). The TC and LDL in wild-high fat-Ang II-BAY11-7082 group decreased significantly compared with the wild-high fat-Ang II group ($n = 5$, $P < 0.001$, Figure 5(c)), with no significant difference from *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, $P > 0.05$, Figure 5(c)). The levels of IL-1β and TNF-α in serum of the wild-high fat-Ang II-BAY11-7082 were lower than those of the wild-high fat-Ang II-BAY11-7082 group ($n = 5$, $P < 0.001$, Figure 5(d)), with no significant difference from *Tlr2*$^{-/-}$-high fat-Ang II group ($n = 5$, both $P > 0.05$, Figure 5(d)). IL-6 and CCL2 levels showed no significant difference in the wild-high fat-Ang II-BAY11-7082 group and wild-high fat-Ang II group ($n = 5$, both $P > 0.05$, Figure 5(d)). Inhibiting NF-κB pathway also improved hypertension and hyperlipemia symptoms, suggesting that TLR2 promotes inflammation through the activation of NF-κB pathway, thus inducing the occurrence and development of hypertension combined with hyperlipemia.

4. Discussion

With the development of society and the improvement of material levels, hypertension has become the most common cardiovascular disease [1, 2]. Among them, primary familial hypertension is a relatively special type. Although genetic factors are dominant in such patients, nongenetic factors still cannot be ignored. Relevant studies have shown that the degree and speed of nongenetic factors inducing hypertension is greater in patients with familial hypertension [2]. In recent years, there have been many studies on

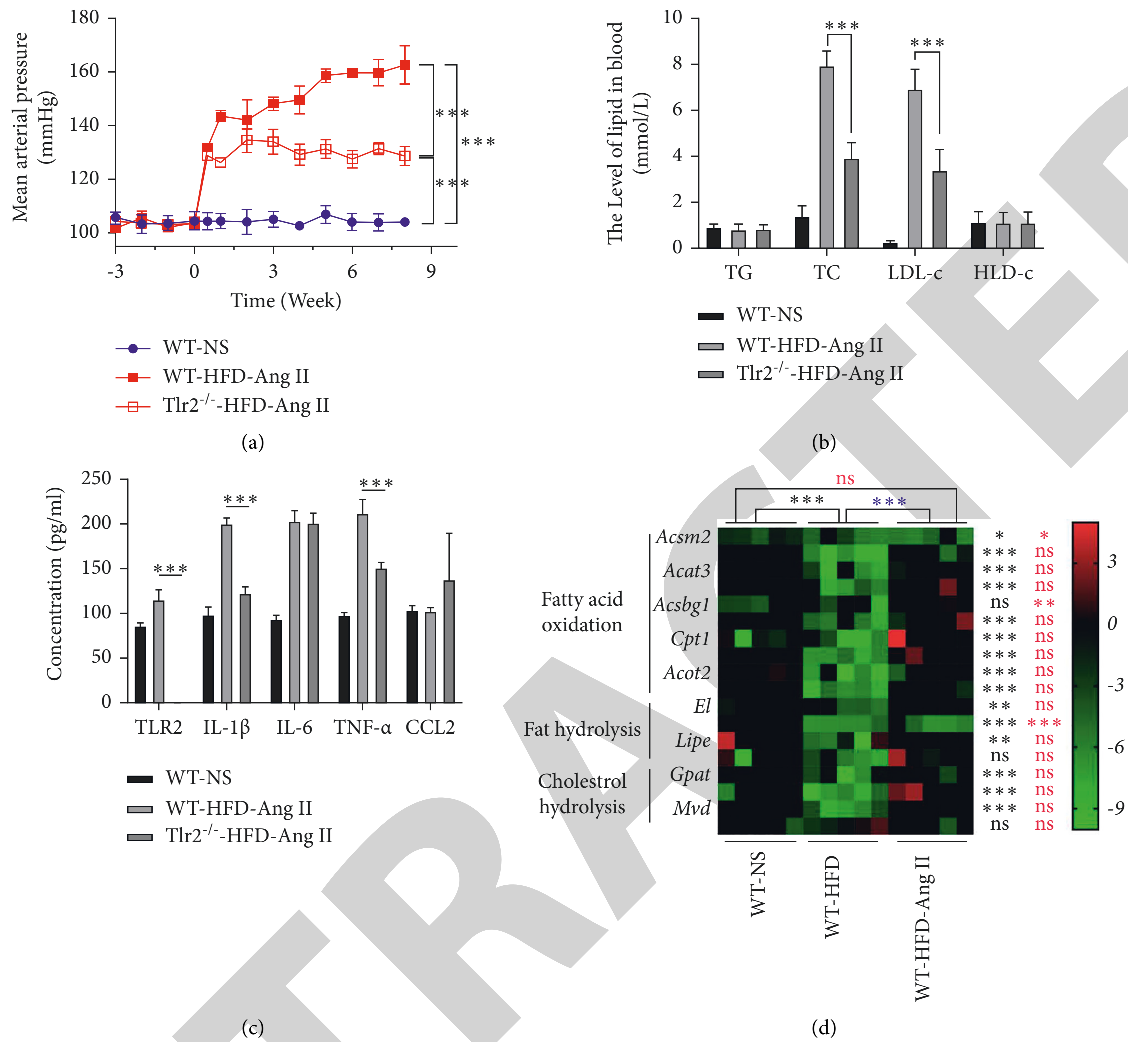

Figure 2: Changes of MAP, blood lipid levels, TLR2 in serum and inflammatory factor concentrations, and lipid metabolism-related gene expression between *Tlr2*$^{-/-}$-high fat-Ang II group and wild-high lipid-Ang II groups. (a) Comparison of MAP in *Tlr2*$^{-/-}$-high fat-Ang II group and wild-high fat-Ang II group, MAP after the construction of the model was significantly lower in the *Tlr2*$^{-/-}$-high fat-Ang II group than that in the wild-high fat-Ang II group. (b) Comparison of lipids and apolipoproteins in serum in *Tlr2*$^{-/-}$-high fat-Ang II group and wild-high fat-Ang II group, TC and LDL in serum significantly decreased in the *Tlr2*$^{-/-}$-high fat-Ang II group compared to the wild-high fat-Ang II group, while there was no significantly statistical difference between triglyceride and HDL between the two groups. (c) *Tlr2*$^{-/-}$-high fat-Ang II group was not detected TLR2 in serum; at the same time, the levels of IL-1β and TNF-α were significantly lower than those in wild-high fat-Ang II group, with no statistical difference in IL-6 and CCL2 concentrations in serum than those in the wild-high fat-Ang II group. (d) Heat map of gene expression abundance detected by qPCR showed significantly increased related gene expressions of fatty acid oxidation, fat hydrolysis, and cholesterol hydrolysis in the *Tlr2*$^{-/-}$-high fat-Ang II group compared to the wild-high fat-Ang II group ($n = 5$; $^{***}P < 0.001$).

hypertension combined with hyperlipemia from the perspective of immune function and related signaling pathways, with the increasing connection between cardiovascular diseases and inflammatory response. But the study of hypertension and hyperlipemia has no good target and inflammatory regulation methods [22–24]. The exploration of hypertension combined with hyperlipemia intervention target and its association with inflammatory response are the hot spots in recent years. Therefore, we expect to screen a protein target related to inflammation with a positive regulatory effect on primary hypertension combined with hyperlipemia.

First, we collected three clinical blood specimens: control, primary hypertension, and primary hypertension combined with hyperlipemia, and measured the levels of IL-1β, IL-6, TNF-ɑ, and CCL2 inflammatory factors in serum by ELISA. It was found that the four inflammatory factor levels in serum of primary hypertension group and primary hypertension combined with hyperlipidemia group were significantly higher than those in the control group, and the research conclusions of the correlation between inflammation and primary hypertension complicated with hyperlipidemia are consistent with the existing conclusions [25–27]. Inflammation is closely related to cardiovascular

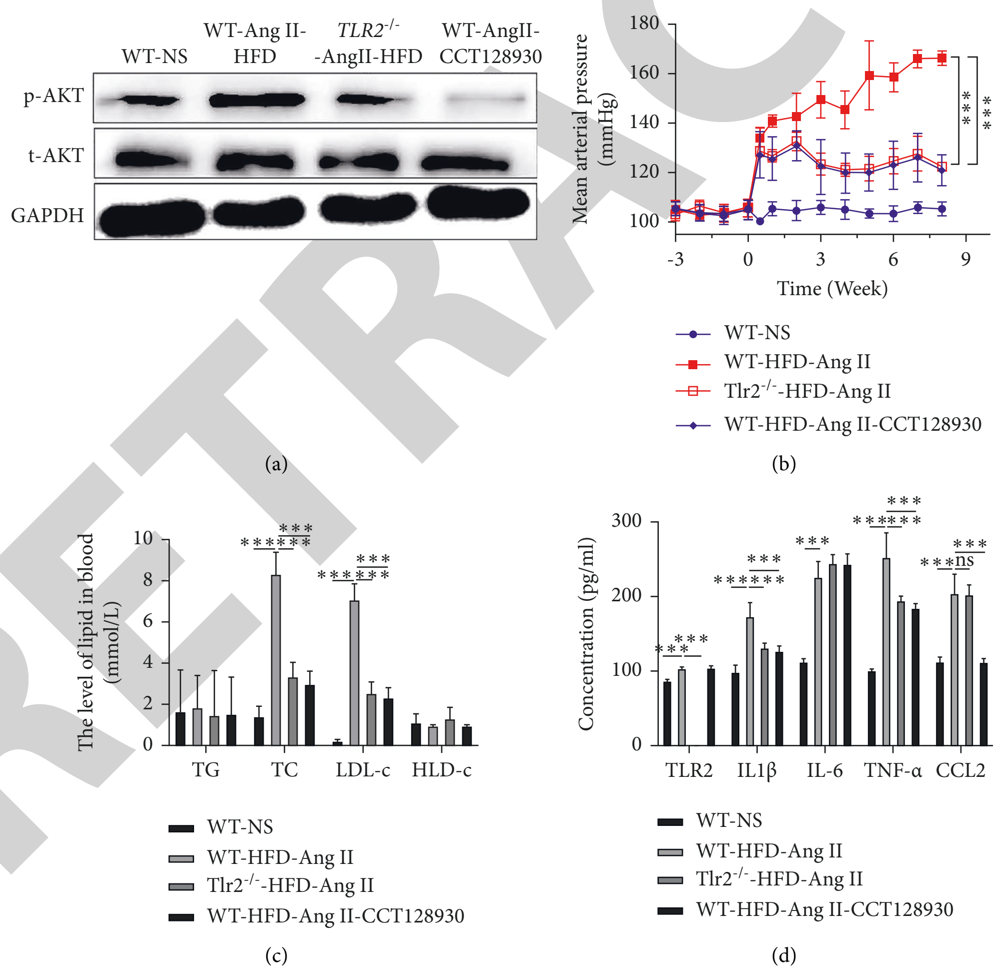

FIGURE 4: Changes of Akt pathway protein, MAP, lipid level, and apolipoprotein level, TLR2 and inflammatory factors compared those after blocking the Akt pathway. (a) The expression of p-Akt, t-Akt proteins in the wild-high fat-Ang II-CCT128930 group was significantly lower than that in wild-high fat-Ang II group. (b) After the construction of the model, MAP in the wild-high fat-Ang II-CCT128930 group significantly decreased compared with that in the wild-high fat-Ang II group. (c) The TC and LDL in serum decreased significantly in wild-high fat-Ang II-CCT128930 group and wild-high fat-Ang II group compared with those in the wild-high fat-Ang II group, but there was no significantly statistical difference in triglyceride and HDL between the two groups. (d) Comparison of serum levels of TLR2 and proinflammatory factor in each group. The concentration of IL-1β, TNF-α, and CCL2 in serum significantly decreased in the wild-high fat-Ang II-CCT128930 group compared with that in the wild-high fat-Ang II group, with no statistical difference in the concentration of TLR2 and IL-6 ($n = 5$; $^{***}P < 0.001$).

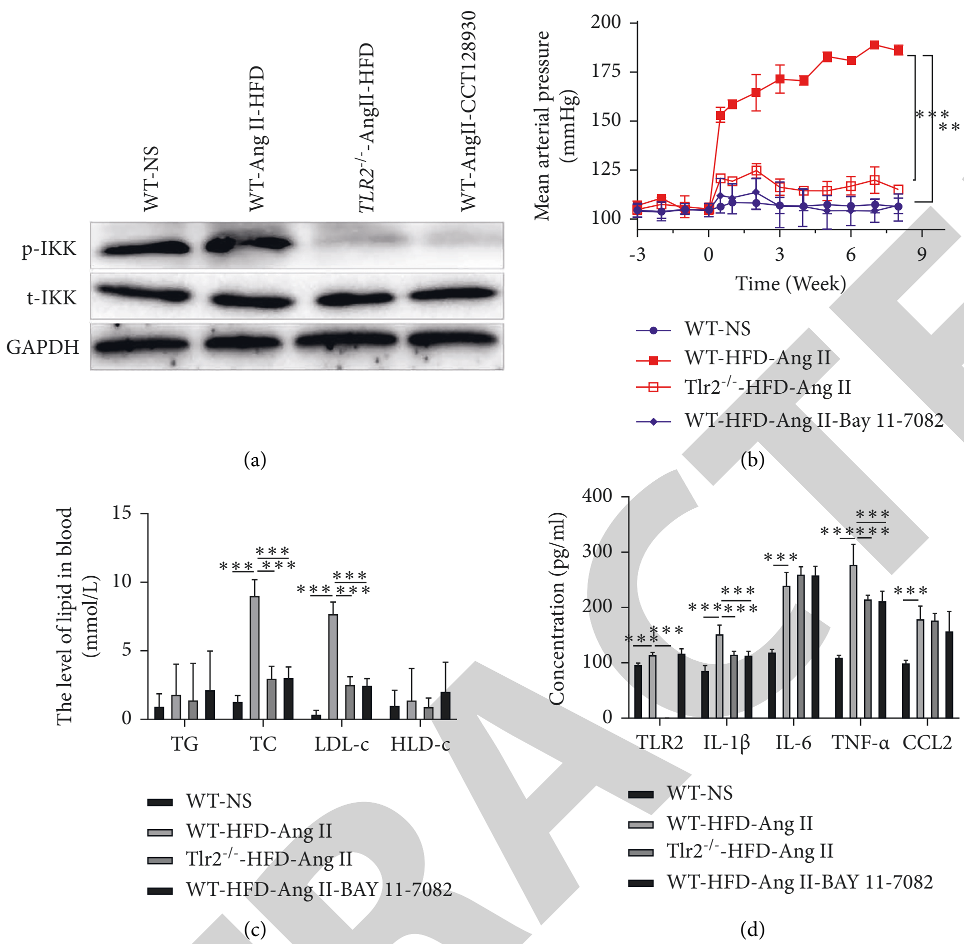

FIGURE 5: Changes in NF-κB pathway protein, MAP, lipid level, and apolipoprotein levels, TLR2, and inflammatory factors after blocking the NF-κB pathway. (a) IKK and protein expression levels of the wild-high fat-Ang II-BAY11-7082 group were significantly lower than those of the wild-high fat-Ang II group. (b) MAP in the wild-high fat-Ang II-BAY11-7082 group significantly decreased compared with the wild-high fat-Ang II group. (c) The TC and LDL in serum significantly decreased in the wild-high fat-Ang II group and wild-high fat-Ang II group, with no significant statistical difference between triglyceride and high-density lipoprotein in the two groups. (d) The concentrations of IL-1β and TNF-α in serum significantly decreased in the wild-high fat-Ang II-BAY11-7082 group compared with the wild-high fat-Ang II group, with no statistical difference in the concentrations of TLR2, IL-6, and CCL2 ($n = 5$; $^{***}P < 0.001$).

disease, and early inflammation infiltration is of important significance in cardiovascular pathogenesis. Regulation of inflammation is extremely extensive and involves complex signaling pathways [28]. Among these, NF-κB signaling pathway was studied deeply and thoroughly. We expected to investigate the effects of NF-κB signaling and hypertension with hyperlipemia, so we first assumed the inflammatory effects of TLR-related protein molecules upstream of NF-κB signaling pathway, measured TLR2 levels in the three clinical specimens by ELISA, and found a significant increase in TLR2 levels in familial hypertension group and familial hypertension combined with hyperlipidemia group compared with those in the control group. In conclusion, we assumed that TLR2-mediated inflammatory responses can play a role in primary hypertension combined with hyperlipemia.

This study is clinical problem-oriented, and after finding that TLR2 has a role in primary hypertension combined with hyperlipemia, we focused on the animal model. The specific effect of TLR2 on the occurrence and development of the diseases is highly controllable in the animal model, so we constructed the models of hypertension, hyperlipidemia, and hypertension combined with hyperlipidemia according to the relevant and reliable model-making methods [29–32]. Real-time monitoring of blood pressure of different models was given to the mice in different models to ensure the reliability of blood lipid levels in different mice for the occurrence of a lipid disorder. With high similarity to clinical blood specimens, some levels of inflammatory factors in pure hypertension were elevated. Despite irregular changes in IL-6 and CCL2, the overall inflammation remains elevated; also, TLR2 levels increased in serum. The conclusions as above obtained in the mouse model made us more convinced that TLR2 has great significance in the occurrence and development of hypertension combined with hyperlipemia. To provide a more direct verification of the role of the TLR2, we compared the degree of pathological changes of hypertension and hyperlipidemia in wild mice and gene knockout mice under the same modeling method with a *TLR*$^{2\ -/-}$ knockout mouse model. Compared with wild mice, the occurrence of hypertension and hyperlipidemia in mice after losing TLR2 gene function was more delayed, and the degree of pathological changes was less. Meanwhile, the related inflammatory factors were reduced to comparable levels in the control group after knocking out *Tlr2* gene. In conclusion, we can determine that TLR2-induced inflammation plays an important role in the disease process of hypertension combined with hyperlipemia.

In order to deeply reveal the molecular effect of TLR2-induced diseases, as well as add new cognition to the pathogenesis of hypertension and hyperlipidemia, we have conducted further studies on the signaling pathway. Recent literature reported that TLR2/4 has clear molecular interaction mechanisms with the downstream PI3K/Akt pathway and NF-κB pathway [33–35]. Therefore, we assumed that the presence of TLR2 activates these two signaling pathways, which are then activated for the transcription of downstream inflammatory factor encoding genes, resulting in increased release of inflammatory factors, creating a microenvironment of inflammatory infiltration, and ultimately inducing the occurrence of hypertension and hyperlipidemia. First, we tested the degree of activation of Akt and NF-κB signaling pathways in control, hypertensive combined with hyperlipemia and *Tlr2*$^{-/-}$ groups. Western blot essay found a significant increase in phosphorylation levels of Akt, IKK, and p68 proteins, meaning that Akt and NF-κB signaling pathways were activated in the model of hypertension combined with hyperlipemia. To elucidate the role of TLR2, we simultaneously detected the degree of activation of Akt and NF-κB signaling pathways in the *Tlr2*$^{-/-}$ model and found that the phosphorylation levels of Akt, IKK, and p68 proteins were recovered to comparable to controls in the gene knockout model. As in the above conclusion, it can be proved that Akt and NF-κB signaling pathways have a certain role in hypertension combined with hyperlipemia. To further confirm the role of the two signaling pathways in the occurrence and development of this disease, we blocked Akt and NF-κB signaling pathways with different inhibitors corresponding to the two pathways. As expected, we found that blood pressure and lipid levels were still higher than those in the wild-saline group (controls) regardless of which path was being knocked out. However, it significantly decreased in the wild hypertension combined with hyperlipemia model, even the pathological changes were comparable after knocking out *Tlr2* gene, with lower inflammatory factor levels. Therefore, we can confirm the positive effect of blocking Akt and NF-κB pathways on the improvement of hypertension combined with hyperlipemia.

5. Conclusion

According to our study, TLR2, inflammatory response, Akt pathway, and NF-κB pathway all contributed to the occurrence and development of hypertension combined with hyperlipemia, and previous literature have more or less reported the relationship between the four factors and hypertension combined with hyperlipidemia [36, 37]. However, there was almost no systematic research of the four on the occurrence and development of the disease. Our study systematically explained the induction of inflammation through Akt/NF-κB pathway and thus promoted the occurrence and development of hypertension combined with hyperlipemia. In addition, we removed the effects of TLR2, Akt, and NF-κB pathways, respectively, and found that the three were more or less effective in the occurrence and development of the disease. These findings added new cognition to gene-level research of cardiovascular disease. Although our research reveals the role of TLR2 on hypertension combined with hyperlipemia, it still lacks systematic verification for whether TLR2 is a good intervention target to control hypertension. We expect to continuously expand the subsequent protein interaction network with TLR2 as the center and finally screen the new target to intervene in primary familial hypertension combined with hyperlipemia to effectively control the occurrence and development of such cardiovascular diseases.

Data Availability

The datasets used and/or analyzed during the present study are available from the corresponding author upon reasonable request.

Ethical Approval

The study was approved by the Ethics Committee of The First Affiliated Hospital of Qiqihar Medical University.

Consent

Signed written informed consent was obtained from the patients and/or guardians.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

JL, CJL, and JQ conceived and designed the study. JL, QW, HH, CHL, and JQ were responsible for the collection, analysis and interpretation of the data. CJL drafted the manuscript. JQ revised the manuscript critically for important intellectual content. All authors read and approved the final manuscript.

Objective. Hepatocellular carcinoma (HCC) remains a devastating tumor globally. Serum exosomes are reliable biomarkers for tumors, including HCC. Hence, this study explored the efficacy and mechanism of serum exosomes in HCC. *Methods*. microRNA (miR)-122 and miR-148a expressions in serum exosomes from HCC patients and healthy subjects and their predictive efficacy for HCC were detected. Correlation between serum exosomal miR-122/148a expressions with survival rate, clinical stage, lymph node metastasis, and tumor differentiation level and levels of HCC-related serum markers (CA199, FucAFP, ALD-A, and AFu) were detected. PAX2 staining intensity and expression in HCC were measured. PAX2 predictive efficacy for HCC and its correlation with clinical stage, lymph node metastasis, tumor differentiation level, and HCC-related serum marker levels were analyzed. The targeted binding relationship between miR-122 and miR-148a and PAX2 was predicted and verified. *Results*. Serum exosomal miR-122 and miR-148a expressions were downregulated in HCC, showing potent predictive efficacy for HCC, which was negatively related to clinical stage and lymph node metastasis and positively related to tumor differentiation level, patient survival rate, and HCC-related serum marker levels. PAX2 showed increased staining intensity and expression in HCC, together with high predictive efficacy for HCC. PAX2 expression showed a positive correlation with clinical stage and lymph node metastasis and a negative correlation with tumor differentiation level and HCC-related serum marker levels. miR-122 and miR-148a conjointly targeted PAX2 in HCC. *Conclusion*. We demonstrated that serum exosomal miR-122 and miR-148a played a predictive role and were linked to prognosis in HCC via interactions with PAX2.

1. Introduction

Hepatocellular carcinoma (HCC), as a frequent malignancy that usually occurs in the presence of chronic liver disease, accounts for 75–85% of primary liver cancers and contributes to the vast majority of cancer-related deaths [1, 2]. HCC develops mostly as a consequence of hepatitis B infection; in addition, other risk factors including genetic causes, excessive drinking, hepatitis C infection, and fatty liver disease also contribute to HCC initiation and progression [3, 4]. Due to insidious symptoms in the early stage and subsequent rapid tumor development, a majority of HCC patients are not diagnosed until the late stage, during which HCC is largely incurable due to the low therapeutic response rate and apparent drug resistance [5, 6]. Surgical resection and liver transplantation are still two standard methods for treating HCC; however, the recurrence rate after radical resection and transplantation remains high, notably reducing the long-term survival of HCC patients [7–9]. Therefore, novel predicative biomarkers are in urgent need for promoting HCC diagnosis as well as improving the prognosis.

Exosomes are characterized by small bilipid protein structures with a diameter of 30–150 nm and show the presence of almost all biological fluids including serum, which makes them recognized as reliable biomarkers for cancer prognosis and diagnosis [10]. Exosomes harbor abundant biological cargoes, such as DNA, microRNAs (miRs), and proteins, which underlie their potential to be biomarkers for diagnostic applications [11]. miRs, defined as a group of small endogenous noncoding RNAs, are potent regulators of posttranscriptional gene expression, promising to be candidates for developing biomarkers [12, 13]. Serum exosomal microRNAs (miRs) are very stable and can act as effective biomarkers for early cancer diagnosis [14]. Accumulating studies have demonstrated that serum exosomal miRs have great value in HCC diagnosis and therapy and can also be used as novel hallmarks for HCC recurrence prediction [6, 15].

Therefore, it was reasonable to hypothesize that serum exosomes may possess an underlying value in HCC prediction and prognosis via carrying miRs through possible mechanisms. Consequently, a series of predictions and experiments were performed to determine the role of HCC-related serum exosomal miRs and their related mechanisms in HCC prediction and prognostic evaluation with the purpose to provide some novel insights for HCC treatment.

2. Materials and Methods

2.1. Clinical Sample Collection. HCC serum samples were collected from Chongqing General Hospital. HCC patients had no history of acute, chronic, or malignant diseases or surgery in the previous 12 months based on the screening results of the physical examination center of Chongqing General Hospital. Histologically, HCC patients were confirmed with no radiotherapy and chemotherapy history and no acute/chronic inflammation signs. Normal subjects ($n = 31$) were matched with HCC patients ($n = 59$) by age and gender. This study got approval from the Ethics Committee of Chongqing General Hospital. All subjects signed informed consent. All experiments were performed following the guidelines and principles of the Declaration of Helsinki.

Peripheral blood samples were collected in the serum separation tube and treated within 2 h. After centrifugation (1200g, 4°C, and 10 min) of the blood samples, the supernatant was absorbed and centrifuged (3,000g, 4°C, and 15 min). Next, the supernatant was crushed into several equal parts and stored at −80°C.

2.2. Extraction of Serum Exosomes. The exosomes were separated using gradient centrifugation as previously described [16]. Specifically, serum samples were unfrozen on ice. Next, serum (1 mL) was diluted in phosphate-buffered saline (PBS, 11 mL) and then ultracentrifuged (150,000g, 4°C overnight). After discarding the supernatant, the precipitate was rinsed with PBS (11 mL), followed by centrifugation (150,000g, 4°C, and 2 h). Afterwards, after the supernatant was removed, the precipitate underwent a resuspension in PBS.

2.3. Transmission Electron Microscope (TEM) Analysis. Exosome samples were diluted using PBS at an appropriate volume. Next, the diluted exosomes (10 μL) were added to the copper mesh for 1 min with excess liquid absorbed using filter paper, followed by a 1min staining with 2% uranyl acetate (10 μL) with excess staining solution absorbed using filter paper. Next, the copper mesh underwent a 15-minute air-drying and was imaged on an FEI Tecnai G2 Spirit TEM (Thermo Fisher Scientific Inc., Waltham, MA, USA) at a voltage of 120 kV.

2.4. Nanoparticle Tracking Analysis (NTA). NTA was conducted for the determination of exosome size and distribution utilizing the NanoSight NS300 system and NTA 2.3 (Malvern Instruments Ltd., Malvern, UK) in compliance with the instructions of the manufacturer.

2.5. Flow Cytometry. Anti-CD63, anti-CD81, and anti-CD47 antibodies or PI were used to label the extracted exosomes. A flow cytometer was used to excitate 525/620 nm band-pass filters at 488 nm wavelength for detecting FITC/PI fluorescence to evaluate the positive rates of CD63, CD81, CD47, and PI in the extracted exosomes.

2.6. Detection of HCC-Related Serum Markers. Concentrations of cancer antigen 199 (CA199), fucosylated alpha-fetoprotein (FucAFP), aldolase A (ALD-A), and Alpha-L-fucosidase (AFU) were detected using enzyme-linked immunosorbent assay kits (Nanjing JianCheng Bioengineering Institute, Nanjing, Jiangsu, China). All operations were carried out as per the kit instructions.

2.7. Dual-Luciferase Reporter Gene Assay. The binding relationship of miR-122/148a and PAX2 was first predicted through StarBase (https://starbase.sysu.edu.cn/). The wild-type (WT) PAX2 3′UTR fragment containing miR-122/148a binding sites or mutant (MT) (in the absence of predicted miR target sequence) was inserted into pmirGLO (Shanghai Generay Biotech Co., Ltd., Shanghai, China) plasmid. The reporter plasmid (pmirGLO-PAX2-WT/MT) was cotransfected with miR-122/148a mimic or mimic NC into HEK293T cells. After 48 h of transfection, cell lysate was collected and luciferase activity was measured using Tecan Infinite M200 PRO instrument and Dual-Luciferase Reporter System (Promega Corp., Madison, Wisconsin, USA). The firefly luciferase fluorescence intensity was standardized using Renilla luciferase fluorescence intensity.

2.8. Bioinformatics Analysis. HCCGSE104251 and GSE138178 microarrays were obtained from the Gene Expression Omnibus (GEO) database (https://www.ncbi.nlm.nih.gov/geo/), which were then normalized using the R language limma package (https://cran.r-project.org/web/packages/pheatmap/) with $|\log FC| > 2$ and adj. $p < 0.05$ as the screening thresholds. The heatmaps were drawn. The targeted binding relationship between miR-122/148a and PAX2 was predicted through StarBase (https://starbase.sysu.edu.cn/). The relationship between miR-122 and miR-148a expressions and the survival rate of HCC patients was measured using the KM-Plotter website (https://kmplot.com/analysis/). The staining intensity of paired box (PAX) 2, cyclinD1 (CCND1), myelocytomatosis viral oncogene homolog (MYC), neural precursor cell expressed, developmentally downregulated 4 (NEDD4), and C-X-C motif chemokine ligand 5 (CXCL5) in normal liver tissues and HCC tissues was determined through the Human Protein Atlas website (https://www.proteinatlas.org/).

2.9. Reverse Transcription-Quantitative Polymerase Chain Reaction (RT-qPCR). cDNA synthesis was performed using the All-in-One™ miRNAFirst-Strand cDNA Synthesis Kit (GeneCopoeia, Rockville, MD, USA) as per the manufacturer's protocols. Reverse transcription was accomplished via a 60-minute incubation of the mixture at 37°C and then a 5-minute incubation at 85°C, followed by storage at 4°C. RT-qPCR was carried out utilizing ChamQ SYBR qPCR Master Mix (NanJing Vazyme Biotech Co., Ltd, Nanjing, Jiangsu, China) as per the instructions of the manufacturer. All reactions were checked three times. miRprimer2 software 32 was used for miRNA forward primer design, and its synthesis was finished by Nanjing Genscript Technology Co., Ltd. (Nanjing, Jiangsu, China). RT-qPCR was carried out on the StepOnePlus real-time PCR system (Applied Biosystems, Waltham, MA, USA) under the conditions of 3 min at 95°C, and then 40 cycles of 10 s at 95°C and 30 s at 60°C. The geometric mean of the internal reference was used for RT-qPCR value normalization, and the relative expression was determined using the $2^{-\Delta\Delta Ct}$ method.

2.10. Statistical Analysis. SPSS 21.0 (IBM Corp., Armonk, NY, USA) was utilized to analyze data. The Kolmogorov–Smirnov test confirmed that data were normally distributed. The results were represented as mean ± standard deviation. The comparison between the two groups was analyzed using a *t*-test. A comparison among multiple groups was analyzed using one-way and two-way analysis of variance (ANOVA) followed by Tukey's multiple comparison test. Fisher's exact test was utilized for measurement data. Correlation was analyzed utilizing Pearson's correlation coefficient test, and a receiver operating characteristic (ROC) curve was drawn to evaluate the predictive efficacy of miR-122/148a and PAX2 for HCC. The p value was gained from a two-sided test. $p < 0.05$ meant statistically significant.

3. Results

3.1. Serum Exosomes in HCC Patients Were Successfully Extracted. First, exosomes were extracted from the serum of 31 healthy subjects and 59 HCC patients using gradient centrifugation. The size of the extracted particles was analyzed using the NanoSight NS300 system and NTA 2.3 software, which was observed to be about 92.46 ± 2.41 nm (Figure 1(a)). In addition, the extracted particles were found to be barrel-shaped, ellipsoidal, or round, with a diameter of about 100 nm under a TEM (Figure 1(b)). To further exclude the influence of apoptotic bodies on the subsequent experimental results, we used PI staining and observed that the extracted exosomes were negative for PI staining, as shown by flow cytometry results (Figure 1(c)). Exosome specific surface markers (CD63, CD81, and CD47) were further determined using flow cytometry, and it was found that CD63, CD81, and CD47 showed positive expression in the extracted exosomes (Figure 1(d)). From all the above-mentioned, we confirmed that the extracted particles were in line with the characteristics of exosomes.

3.2. miR-122/148a Was Poorly Expressed in HCC Patient Serum Exosomes and Correlated with Prognosis. Firstly, differentially expressed miRs in serum exosomes of 5 HCC patients and 5 healthy subjects in the GSE104251 dataset from the GEO database (https://www.ncbi.nlm.nih.gov/geo/) were analyzed, and 179 differentially expressed miRs were screened (Figure 2(a)) based on the threshold of $|\log FC| > 2$ and $p < 0.05$. The first 50 miRs with differential expression were displayed on the heatmap (Figure 2(b)). Next, expressions of the first 6 differentially expressed miRs (miR-122, miR-239, miR-148a, miR-447, miR-681, and miR-581) in serum exosomes of 31 healthy subjects and 59 HCC patients were detected using RT-qPCR. miR-122 and miR-148a were found to be dramatically downregulated in serum exosomes of HCC patients (Figure 2(c)). Meanwhile, the predictive efficacy of the first 6 differentially expressed miRs (miR-122, miR-239, miR-148a, miR-447, miR-681, and miR-581) for HCC patients was measured using an ROC curve. miR-122 and miR-148a showed the largest area under the curve (Figure 2(d)). Subsequently, miR-122 and miR-148 effects on HCC patient survival rate were predicted through the KM-Plotter website (https://kmplot.com/analysis/), and it was found that HCC patients with low expression of miR-122/148a had a lower survival rate (Figure 2(e)). In addition, according to our findings, miR-122/148a expression was negatively correlated with the clinical stage and lymph node metastasis of HCC patients, while positively correlated with the tumor differentiation level (Figures 2(f)–2(h)).

3.3. miR-122/148a Expression Was Negatively Correlated with HCC-Related Serum Marker Levels. To further determine the role of miR-122/148a in HCC patients, we further analyzed the relationship between miR-122/148a expression in serum exosomes and the concentration of HCC-related serum markers (CA199, FucAFP, ALD-A, and AFu) in HCC patients. First, levels of CA199, FucAFP, ALD-A, and AFu in 59 HCC patients were found to show an obvious elevation relative to those in 31 healthy subjects (Figures 3(a)–3(d)). Next, as shown by our results, miR-122/148a expression was negatively related to HCC-associated serum marker concentrations (Figures 3(e)–3(h)).

3.4. PAX2 Was Highly Expressed in Serum of HCC Patients. Subsequently, we downloaded the HCC GSE138178 microarray (including HCC tissues and normal adjacent liver tissues of 49 HCC patients) from the GEO database (https://www.ncbi.nlm.nih.gov/geo/). By setting the threshold $|\log FC| > 2$ and $p < 0.05$, 539 differentially expressed genes were identified (Figure 4(a)). The first 50 differentially expressed mRNAs were displayed in the heatmap (Figure 4(b)). The staining intensity of PAX2, CCND1, MYC, NEDD4, and CXCL5 in normal liver tissues

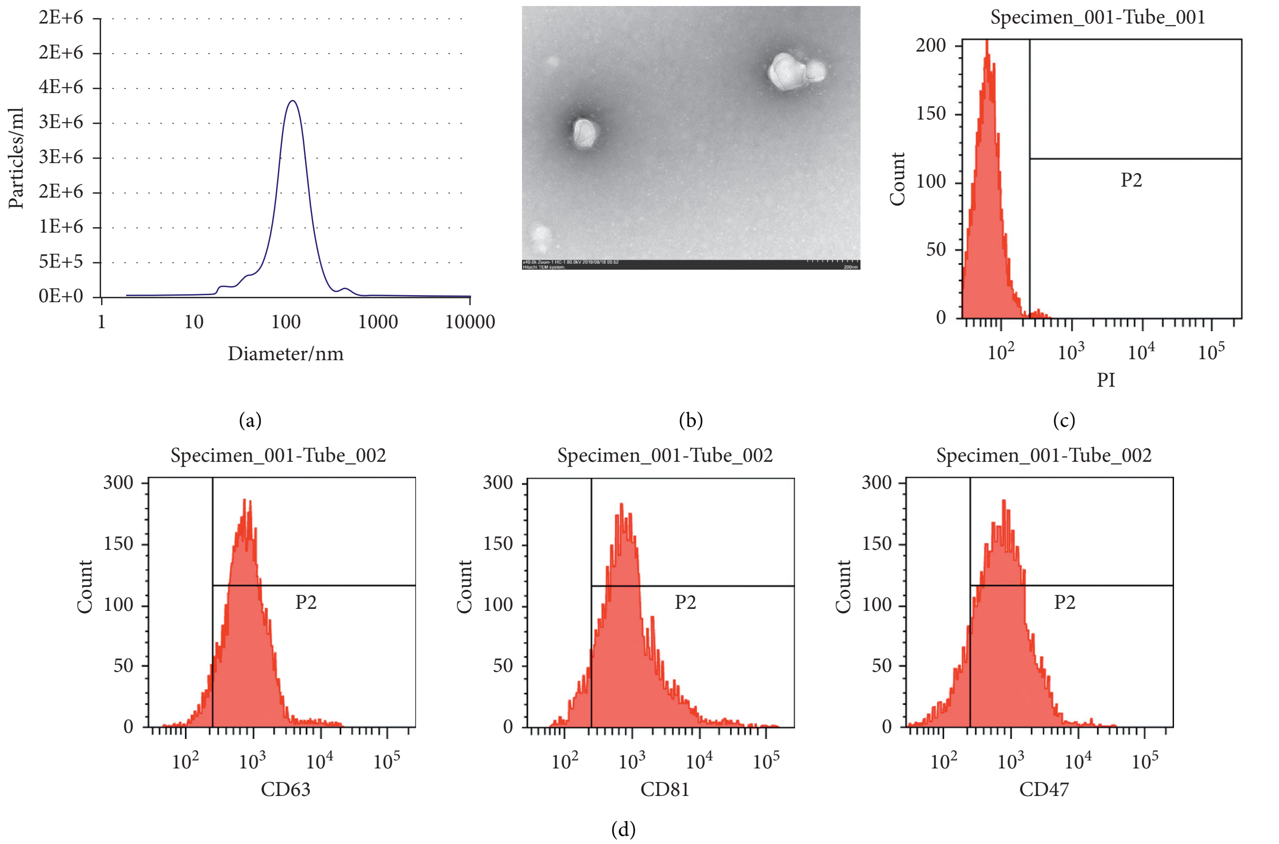

Figure 1: Serum exosomes in HCC patients are successfully extracted. (a) The size and distribution of exosomes was analyzed using NanoSight NS300 system and NTA 2.3 software; (b) the shape and size of exosomes were detected using a TEM; (c) the positive rate of exosomes was detected by PI staining; (d) the surface marker proteins CD63, CD81, and CD47 of exosomes were determined utilizing flow cytometry. All tests were repeated three times.

and HCC tissues was further determined through the Human Protein Atlas website (https://www.proteinatlas.org/), which was found to show a notable elevation in HCC tissues compared to that in normal liver tissues (Figures 4(c)–4(g)). Furthermore, PAX2, CCND1, MYC, NEDD4, and CXCL5 expressions in the serum of 31 healthy subjects and 59 HCC patients were detected using RT-qPCR, and they were found to be noticeably increased in the serum of HCC patients relative to those in normal subjects, among which PAX2 exhibited the most significant expression difference (Figure 4(h)).

3.5. PAX2 Expression Was Related to HCC Patient Prognosis. To further explore PAX2's role in HCC and its clinical-predictive efficacy, we first used a ROC curve to predict the predictive efficacy of PAX2, CCND1, MYC, NEDD4, and CXCL5 expressions for HCC. PAX2 showed the highest predictive efficacy for HCC (Figure 5(a)). The relationship between PAX2 expression and the clinical stage, lymph node metastasis, and tumor differentiation level of HCC patients was further analyzed. As shown by our results, PAX2 expression showed a positive correlation with clinical stage and lymph node metastasis, while a negative correlation with tumor differentiation level (Figures 5(b)–5(d)). Furthermore, levels of CA199, FucAFP, ALD-A, and AFu were found to be positively correlated with PAX2expression in the 59 HCC patients (Figures 5(e)–5(h)). From all of the abovementioned, PAX2 was crucial in the HCC occurrence and prediction.

3.6. miR-122 and miR-148a Conjointly Targeted PAX2. To further determine the regulatory mechanism of miR-122 and miR-148a in PAX2, we first predicted the targeted binding relationship between miR-122/148a and PAX2 via the StarBase website (https://starbase.sysu.edu.cn/), and it was observed that miR-122 and miR-148a could target PAX2 3′UTR sequence (Figures 6(a) and 6(b)). The dual-luciferase reporter gene assay was designed to further verify the above binding relationship. 293 T cells cotransfected with miR-122/148a mimic and PAX2-WT showed remarkably decreased luciferase activity, while those cotransfected with mimic NC and PAX2-MT exhibited no obvious change (Figures 6(c) and 6(d)). Subsequently, we verified that miR-122/148a expression showed a negative correlation with PAX2expression in HCC (Figures 6(e) and 6(f)).

4. Discussion

Globally, HCC still accounts largely for tumor-related death [17]. Exosomes, widely distributed in biological fluids including serum, are found to be implicated in

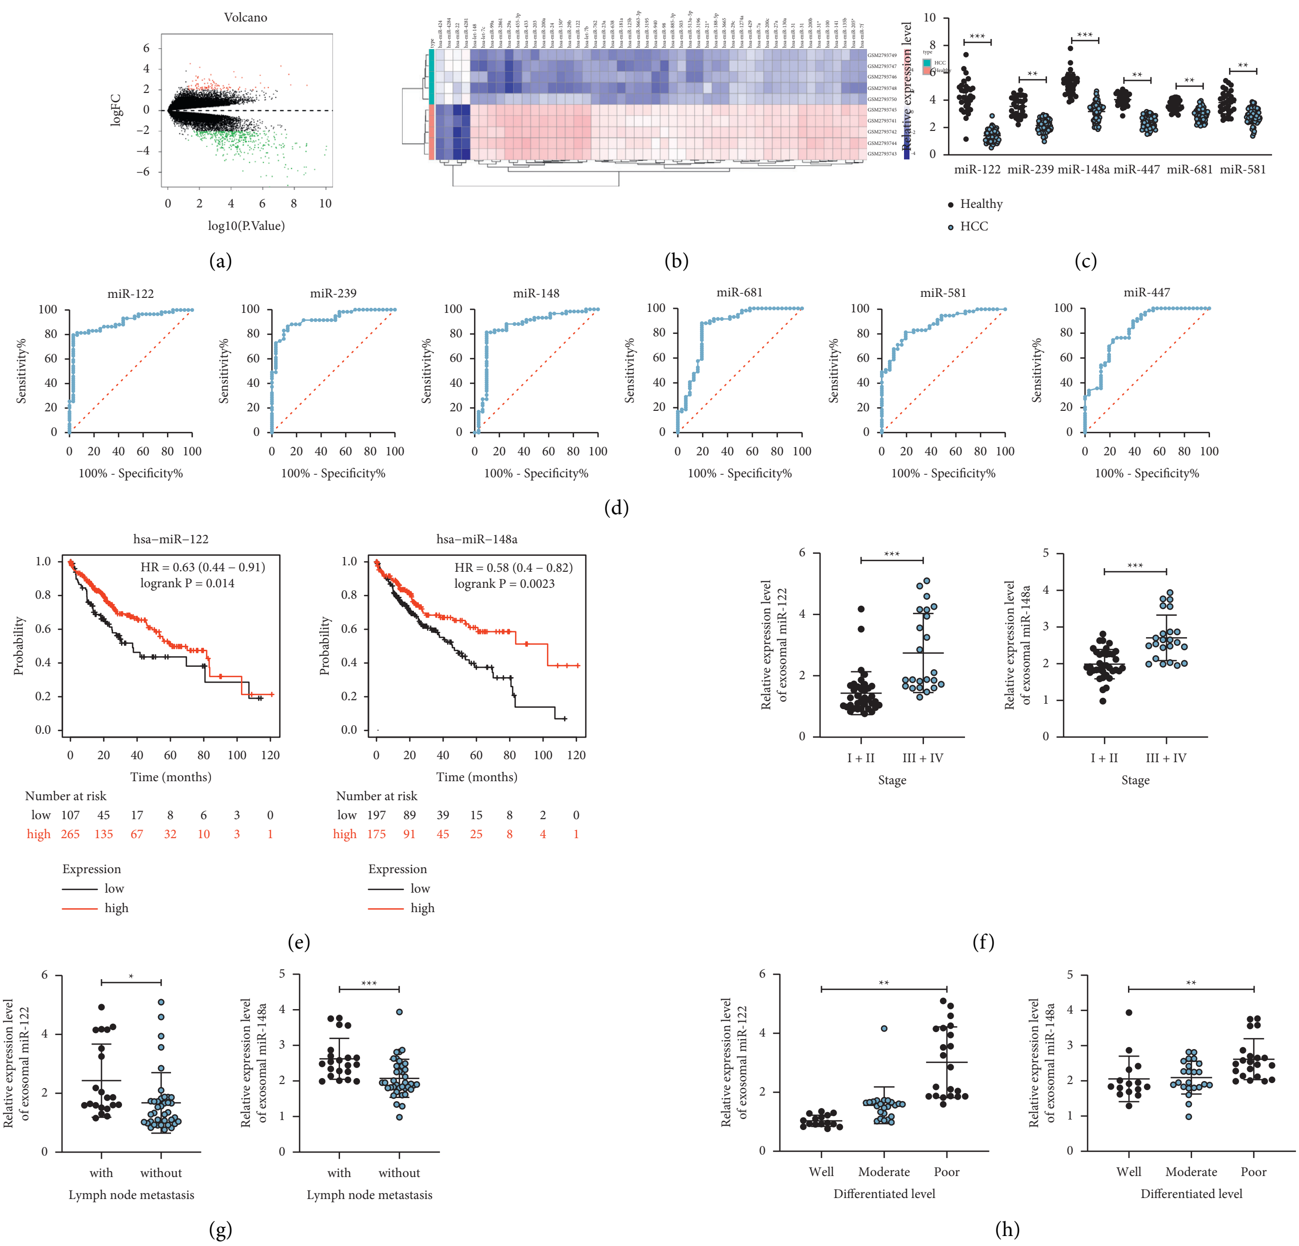

Figure 2: Serum exosomal miR-122 and miR-148a are poorly expressed in HCC and are correlated with prognosis. (a) Volcano plots for the differentially expressed miRs in serum exosome GSE104251 dataset; (b) a heatmap of the top 50 miRs with the highest degree of differential expression in GSE104251 microarray; (c) RT-qPCR was utilized to measure expressions of miR-122, miR-239, miR-148a, miR-447, miR-681, and miR-581 in serum exosomes of 31 healthy subjects and 59 HCC patients; (d) the predictive efficacy of miR-122, miR-239, miR-148a, miR-447, miR-681, and miR-581 for HCC patients was measured using ROC curves; (e) miR-122/148a effects on HCC patient survival rate were predicted using the KM-Plotter website (https://kmplot.com/analysis/); (f–h) the relationships between miR-122/148a expression and the clinical stage, lymph node metastasis, and tumor differentiation level of HCC patients. All experiments were repeated at least three times, and each point represented one subject. Data in panel C were analyzed utilizing the unpaired t-test. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$.

tumors via carrying their functional cargos, including miRs, thereby showing potential applications in the therapeutic interventions of tumors [18]. In the present study, we demonstrated that HCC patient serum exosomal miR-122 and miR-148a were predictive factors for HCC and related to HCC patient prognosis, which were mediated by their conjointly targeted PAX2 in HCC.

Serum exosomal miRs promise to be biomarkers for HCC prediction [6, 15]. In addition, as has been reported previously, miR-122 is abundant in the liver, and its reduction plays a pathogenic role in liver diseases [19]. Aberrantly decreased miR-148a expression has been described in multiple tumors, with its depletion frequently related to an advanced clinical stage and metastasis, as well as poor clinical

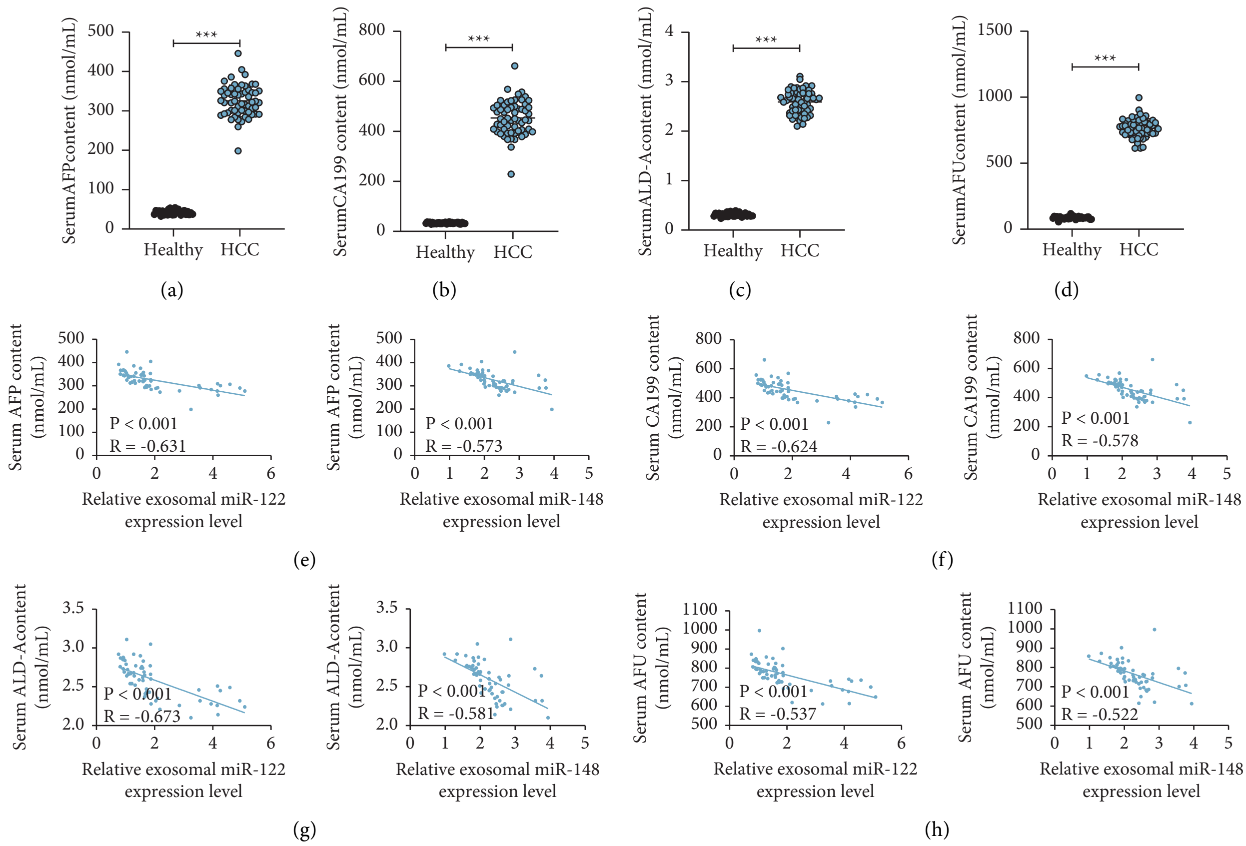

FIGURE 3: miR-122/148a expression is negatively related to levels of HCC-related serum markers. (a–d) Concentrations of CA199, FucAFP, ALD-A, and AFu in 59 HCC patients were detected; (e–h) the correlation of miR-122/148a expression with the serum levels of CA199, FucAFP, ALD-A, and AFu was analyzed. Data were analyzed using the unpaired t-test. $^{***}p < 0.001$.

outcome [20]. In the present study, differentially expressed miRs in serum exosomes of HCC patients and healthy subjects were first obtained using the GSE104251 microarray, and then we identified the first 6 differentially expressed miRs, among which miR-122 and miR-148a were the two most downregulated miRs in serum exosomes of HCC patients and showed potent predictive efficacy for HCC, and their expressions were negatively related to the clinical stage and lymph node metastasis, and positively correlated with the survival rate and the tumor differentiation level of HCC patients. Likewise, serum exosomal miR-122 shows an obvious downregulation in HCC patients, promising to be a reliable serological biomarker for HCC [21]. miR-122 expression is tightly linked to tumor size and tumor stage in HCC, and reduced miR-122 expression is associated with the short survival of HCC patients [22]. Numerous studies have demonstrated the abnormally reduced miR-148a expression in HCC [23, 24]. A previous work further pointed out that serum miR-148a expression strongly exhibits a negative correlation with tumor size and tumor-node-metastasis stage in HCC and a positive correlation with overall survival and prognosis of HCC patients [25].

As has been demonstrated previously, FucAFP, AFU, CA199, and ALD-A are effective HCC-specific indexes with their high levels correlated with a high risk of HCC [26–29]. According to our findings, levels of HCC-related serum markers (CA199, FucAFP, ALD-A, and AFu) were obviously elevated in HCC patients, and miR-122/148a expression showed a negative correlation with levels of these indexes. Consistently, downregulated miR-122 has been pointed out to be related to the deregulation of ALD-A in liver disease [30]. miR-122 is negatively linked to AFP, an independent risk factor, in HCC [31].

On the other hand, growing studies have shown that PAX2 acts as an oncogenic gene in diverse cancers, such as endometrial cancer and ovarian cancer [32, 33]. Differentially expressed genes in HCC were screened in this study, and we identified PAX2 as the most remarkably upregulated gene in HCC. In agreement with our observations, in prior work, PAX2 is found dramatically elevated in HCC [34]. PAX2 is proposed to possess a clinical-predictive role in endometrial endometrioid carcinoma [35]. As shown by our results, PAX2 showed strong predictive efficacy for HCC, with its expression positively correlated with clinical stage, lymph node metastasis, and HCC-related serum markers (CA199, FucAFP, ALD-A, and AFu), and negatively correlated with tumor differentiation level. Likewise, it has been shown that upregulated PAX2 is tightly related to HCC cell propagation [36].

To further determine the regulatory mechanism of miR-122/148a in PAX2, we first predicted and then verified that miR-122 and miR-148a conjointly targeted PAX2 in HCC.

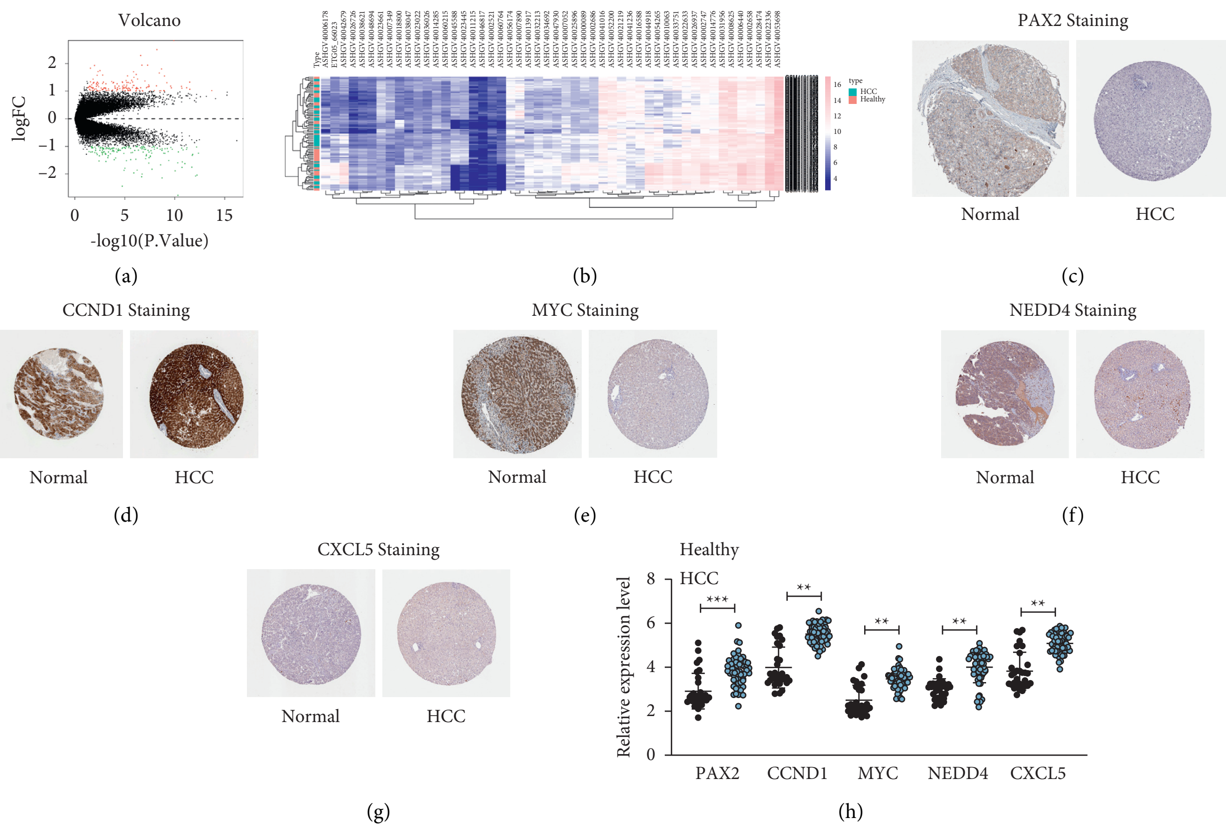

Figure 4: PAX2 is highly expressed in serum of HCC patients. (a) Volcano plots for the differentially expressed mRNAs in the GSE138178 dataset; (b) a heatmap of the top 50 differentially expressed mRNAs in the GSE138178 dataset; (c–g) the staining intensities of PAX2, CCND1, MYC, NEDD4, and CXCL5 in normal liver tissues and HCC tissues were determined through the Human Protein Atlas website (https://www.proteinatlas.org/); (h) PAX2, CCND1, MYC, NEDD4, and CXCL5 expressions in the serum of 31 healthy subjects and 59 HCC patients was detected using RT-qPCR. Data in panel H were analyzed utilizing the unpaired t-test. $^{**}p < 0.01$; $^{***}p < 0.001$.

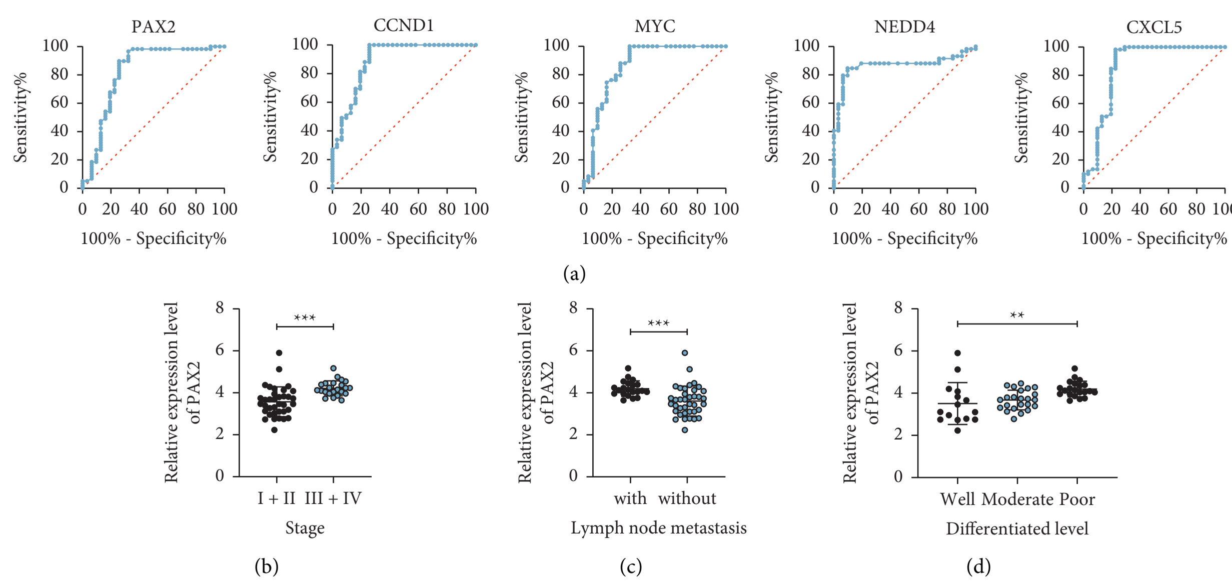

Figure 5: Continued.

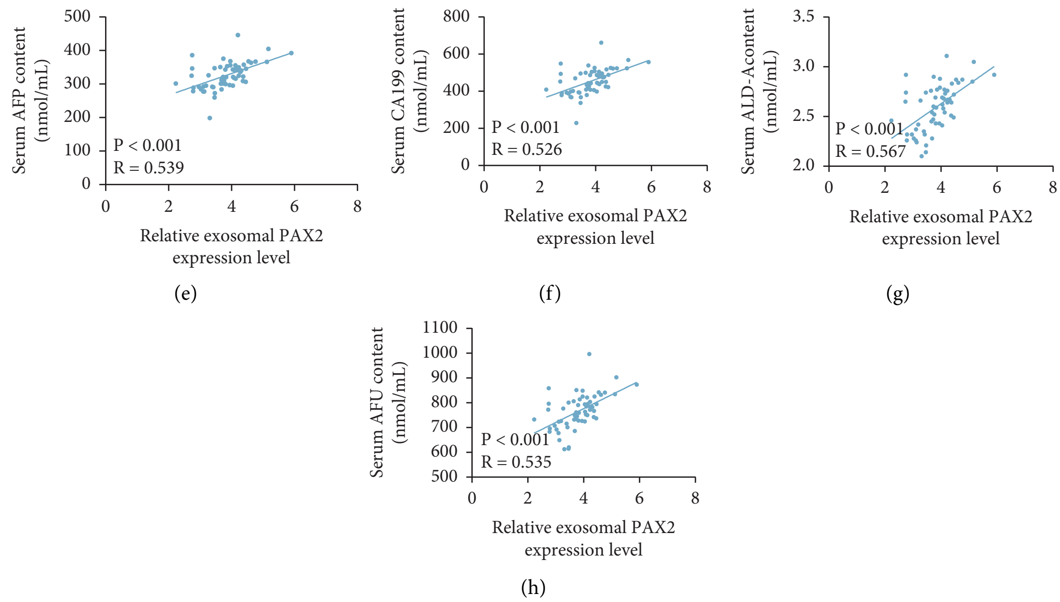

Figure 5: PAX2 expression is related to the prognosis of HCC patients. (a) The ROC curve was used to predict the predictive efficacy of PAX2, CCND1, MYC, NEDD4, and CXCL5 expressions in HCC patients; (b–d) the relationship between PAX2 expression and clinical stage, lymph node metastasis, and tumor differentiation level of HCC patients was analyzed; (e–h) the correlation between levels of CA199, FucAFP, ALD-A, and AFu and PAX2 expression in 59 HCC patients was analyzed. Each experiment was done three times repeatedly. $^{**}p < 0.01$; $^{***}p < 0.001$.

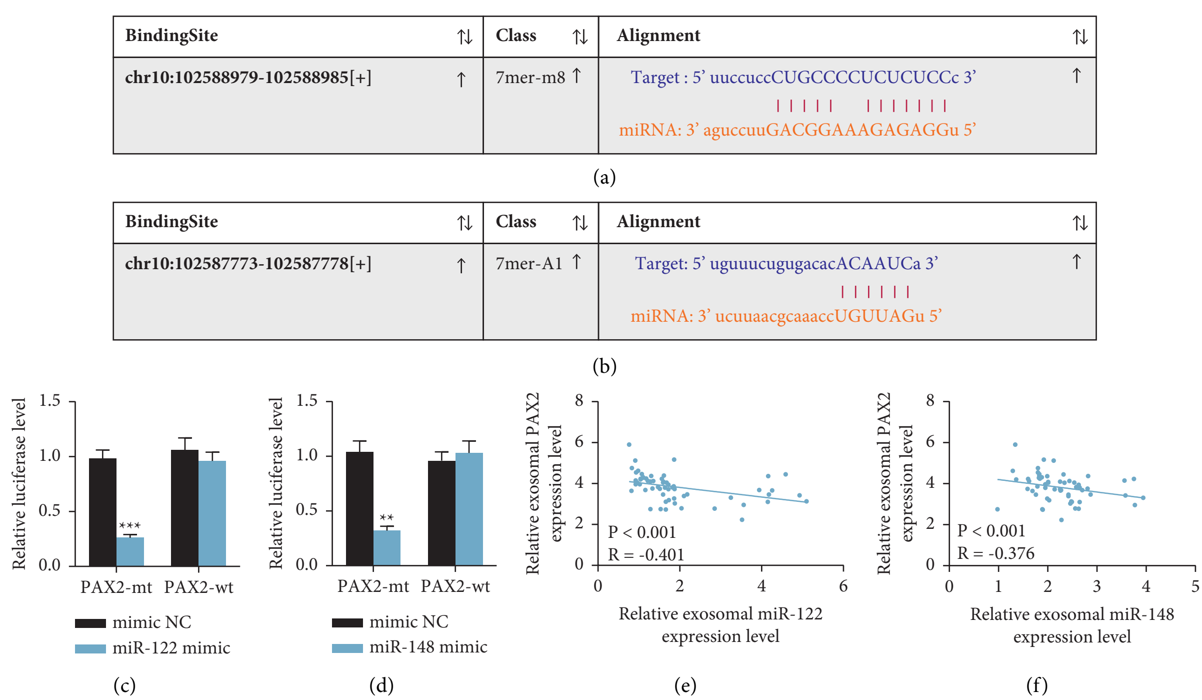

Figure 6: miR-122 and miR-148a jointly target PAX2. (a, b) The targeting binding sites between miR-122/148a and PAX2 were predicted through the StarBase website (https://starbase.sysu.edu.cn/); (c, d) The dual-luciferase reporter gene assay was designed to further verify the targeted binding relationships between miR-122/148a and PAX2; (e, f) Pearson's correlation coefficient test was used to analyze the correlation between miR-122/148a expression and PAX2 expression. Each experiment was done three times repeatedly. $^{**}p < 0.01$; $^{***}p < 0.001$.

Consistently, previous work has proposed that PAX2 functions as a serum exosomal miR-targeted gene in HCC [36]. miR-122 exhibits a negative correlation with PAX8 in H9C2 myocytes [37]. Nevertheless, little could be retrieved about PAX2's predictive efficacy in HCC and the interplay between miR-122/148a and PAX2 in HCC, which, on the other hand, demonstrated the novelty of this study.

5. Conclusion

All in all, this study supported that HCC patient serum exosomal miR-122 and miR-148a played predictive roles in HCC and were linked to patient prognosis via interactions with their conjointly targeted PAX2 in HCC. miR-122 seemed to have higher relevance to PAX2 expression than miR-148; however, more studies are required to draw a certain conclusion that miR-122 had a more important effect than miR-148. We would like to focus on this issue in our future studies, and we would like to investigate the involvement of other potential targets such as CCND1, MYC, NEDD4, and CXCL5 in the near future. Anyway, these results discovered a novel serum exosome-based therapy for HCC patients and provided therapeutic values for HCC treatment.

The objective of this study was to analyze the application of proportional hazard mathematical model (PHMM) in Hepatitis B Virus (HBV) infection analysis of interventional liver cancer patients treated with entecavir, so as to provide data support for clinical diagnosis and treatment. Based on the survival analysis, the treatment factor x was undertaken as an independent variable to perform linear regression. The regression model took the hazard rate function as the dependent variable to establish an exponential regression equation to construct a PHMM. 136 patients with primary liver cancer receiving interventional chemoembolization combined with the drug (entecavir) were selected as the experimental group, who were in the computer gene expression omnibus (GEO). 87 patients with primary liver cancer who underwent interventional chemoembolization therapy without antiviral treatment were taken as the control group. The PHMM was adopted for comprehensive analysis. In addition, the factors affecting the virological response to antiviral therapy were analyzed using the multiple logistic regression. The results revealed that HBV deoxyribonucleic acid (DNA) negative conversion rate, Hepatitis B e-Antigen (HBeAg) negative conversion rate, and HBeAg serological conversion rate in the experimental group were much higher than those in the control group ($P < 0.05$). HBV DNA level and proportion of HBsAg <100 IU/mL in the experimental group were much lower than those in the control group ($P < 0.05$). The virological breakthrough rate and incidence of adverse events at week 24 in the experimental group were greatly lower than those in the control group ($P < 0.05$). The adverse virological response of patient was positively correlated with HBV DNA load and HBeAg status and negatively correlated with alanine aminotransferase (ALT) level ($P < 0.05$). Therefore, entecavir can significantly inhibit HBV DNA replication in patients with liver cancer, showing high antiviral effect. High baseline HBV DNA load, positive HBeAg, and low baseline alanine aminotransferase levels were independent risk factors for adverse virology response to entecavir antiviral therapy, which provided a reference for the selection of antiviral drugs for HBV infection.

1. Introduction

Primary liver cancer is one of the most common malignant tumors in China [1, 2]. China is a major country in the incidence of hepatitis, and the main causes of morbidity and mortality include HBV, HCV, and aflatoxin [3, 4]. According to relevant research reports, the proportion of people carrying HBV virus in China is about 10%, and HBV usually acts together with other related factors to lead to the occurrence of cirrhosis, resulting in human hepatocellular carcinoma [5]. Considering that the early symptoms of liver cancer are relatively insidious and not typical enough, they often develop to middle to advanced stages when they are discovered. At this time, liver transplantation, liver resection, interventional therapy, radiotherapy, chemotherapy, and other methods should be selected [6]. Transcatheter arterial chemoembolization (TACE) is the most common surgical treatment for liver cancer, which has a strong inhibitory and killing effect on tumor. However, during the period, it will affect the transport of liver blood, cause damage to the normal liver tissues, and greatly reduce the antivirus effect, which will eventually lead to a large number of rapid replications of HBV, resulting in liver failure, hepatic encephalopathy, and other complications [7–9]. Therefore, antiviral therapy during surgery is crucial for the prognosis of patients.

There is also a lot of research on antiviral drugs. For example, Cho et al. [10] compared the efficacy of tenofovir and entecavir in antiviral therapy in 53 patients with chronic kidney disease and found that the safety of hepatic artery embolization in patients with chronic kidney disease was comparable between tenofovir and entecavir. Liao et al. [11] compared the roles of lamivudine and entecavir in the reactivation of HBV induced by chemotherapy and found that entecavir had better clinical observation effect than lamivudine. Entecavir is a guanine nucleoside analogue that can inhibit HBV activity through phosphorylation and competition with HBV polymerase deoxyguanosine triphosphate nucleoside [12]. In clinical follow-up studies for some malignant tumors, chronic diseases, and other diseases, it is not comprehensive enough to consider the outcome, and it is also necessary to consider the length of time the subject has experienced a certain outcome. At present, proportional hazard mathematical model (PHMM) is commonly used for multivariate analysis of survival data so that the survival outcome, survival time, and processing censored data can be handled synchronously. The advantage of PHMM analysis is that it can analyze categorical and numerical variables and expand the scope of survival analysis from single-factor to multifactor analysis. In addition, it can analyze the survival of several factors at the same time, and the statistical model provides the effect of each factor. PHMM takes the occurrence of end-point events and the time elapsed for the end-point events as dependent variables. It can analyze the impacts of multiple factors on survival time and analyze data with censored data and does not require estimation of the distribution type of data. During the observation, it is necessary to avoid the loss of follow-up of the observation object, the censorship ratio is too large, and the bias accelerates. However, the application of PHMM analysis has an important premise, which refers to the proportional hazard (the impact of a certain factor on survival is the same at any time and does not change with time). When the premise is met, the PHMM can be applied.

In summary, TACE has the side effects of destroying liver function, so it is particularly important to choose appropriate antiviral drugs for interventional therapy. Based on this, the clinical efficacy of entecavir was comprehensively evaluated by comparing the HBV deoxyribonucleic acid (DNA) conversion rate, HBV DNA infection level, HBeAg conversion rate, serum positive conversion rate, HBsAg <100 IU/mL ratio, and complications between the two groups of patients, to comprehensively evaluate the efficacy and safety of entecavir in the treatment of HBV infection in HCC patients.

2. Materials and Methods

2.1. Research Object and Basic Information. In this study, 136 patients with primary liver cancer who underwent interventional chemoembolization combined with antiviral therapy of entecavir in the computer gene expression omnibus (GEO) data library were selected as the experimental group, and 87 patients with primary hepatocellular carcinoma treated with interventional chemoembolization without antiviral drugs were taken as the control group. This study had been approved by the ethics committee of hospital, and patients and their families had been informed of the study and signed informed consent.

Inclusion criteria were as follows: patients aged 30–76 years, patients diagnosed with hepatocellular carcinoma by pathology, and patients without obvious diseases of heart, lung, kidney, and other organs. Exclusion criteria were as follows: patients with antiviral history before surgery, patients with cerebral renal syndrome before surgery, patients with other types of liver disease, and patients who have received liver surgery before.

2.2. PHMM Analysis. Kaplan-Meier curves and Logrank test tests were univariate analysis, which studied the relationship between a single variable and survival, and they were only applicable to categorical variables instead of numerical variables, such as gene expression in malignant tumors. In univariate analysis of survival, the survival function (or cumulative survival rate) was expressed as follows:

$$S(t, x), \tag{1}$$

where S represented the probability that the survival time T of the research object was greater than a certain time t and x represented the independent variable (a certain processing factor), whose assignment rules were given as follows:

$$x = \begin{cases} 0, \text{no treatment} \quad \text{factor} \\ 1, \text{ treatment} \quad \text{factor} \end{cases}. \tag{2}$$

Then, the risk of patients in a treatment group at time t was shown in (3); and the risk of patients in the control group at time t was shown in (4).

$$w(t) = w_0(t) \times \exp(\beta), \tag{3}$$

$$w(t) = w_0(t), \tag{4}$$

$$\begin{aligned} \text{relative risk degree} &= \frac{\text{handling group risks}}{\text{control group risk}} = \frac{w_0(t) \times \exp(\beta)}{w_0(t)} \\ &= \exp(\beta). \end{aligned} \tag{5}$$

The death function was written as

$$D(t,x) = 1 - S(t,x), \tag{6}$$

where D represented the cumulative mortality from the observation follow-up to time t. The death density function was $m(t,x) = D(t,x)$, where m referred to the death density function (the instantaneous death rate at time t). The risk function was shown as follows:

$$w(t,x) = \frac{m(t,x)}{S(t,x)}, \tag{7}$$

where w was the hazard rate function, which represented the ratio of the instantaneous death rate at time t to the number of survivors at time t (conditional instantaneous mortality rate).

The PHMM could be established as follows.

The data in survival analysis contained censored data, and the time variable t usually does not satisfy normal distribution and homogeneity of variance. Therefore, the PHMM could not take $S(t,x)$ as the dependent variable directly, and x was undertaken as the independent variable for linear regression. The regression model has taken $w(t,x)$ as the dependent variable, and an exponential regression equation was established as

$$w(t) = w_0(t)e^{(\beta_1 x_1+\beta_2 x_2+\beta_3 x_3+\cdots\beta_k x_k)}. \tag{8}$$

In equation (8), $w(0)$ was the hazard rate function of the baseline survival distribution, which referred to the hazard function when all accompanying variables were 0; $x = (x_1, x_2, x_3, \ldots x_k)$ was the prognostic variable (independent variable covariate, which could be continuous or discrete); $w_0(t)$ was the risk function when the covariate value was 0; and $\beta = (\beta_1, \beta_2, \beta_3, \ldots \beta_k)$ referred to the regression coefficient of the model, and the meaning of which was as follows:

$$\mathrm{In}\left(\frac{w(t)}{w_0(t)}\right) = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \cdots \beta_k x_k. \tag{9}$$

In the PHMM, survival time or recovery time was taken as the dependent variable, and a group of variables related to survival time were used as independent variables and prognostic variables or covariates. The assumption of the regression model was as follows:

$$\text{risk ratio} = \frac{w(t)}{w_0(t)}. \tag{10}$$

The hazard ratio was a fixed value, which meant that the impact of the covariate on the survival rate did not change with time.

2.3. PCR Detection of HBV DNA Levels and Drug Resistance Gene Mutations. HBV DNA level and drug-resistant gene mutation were detected by fluorescence quantitative polymerase chain reaction (PCR), which was carried out on the ABI7500 PCR instrument produced by Life Technology in the United States. The amplification degree was as follows: 2 minutes of incubation at 50°C, 4 minutes of predenaturation at 94°C, 50 seconds at 60°C, and 50 cycles. HBV DNA $<10^3$ copy/mL is considered negative. HBV serological marker HBsAg was detected by enzyme-linked immunosorbent assay with reagent from SYM-BIO LIFESCIENCE in Suzhou province. The patient's serum was dripped on the microporous plate, incubated at 37°C for 30 minutes, and OD value was determined by an enzyme marker after washing and color development. HBsAg <0.5 PEI U/mL was considered negative.

2.4. Observation Indicators. HBV DNA negative conversion rate, HBV DNA infection level, HBeAg negative conversion rate, serological conversion rate, and condition of HBsAg <100 IU/mL were compared between the two groups at weeks 10, 20, 30, 40, and 50. rtL180M variation, rtL180M + rtM204V/I + rtA181T variation, and rtL180M + rtM204V/I were recorded in the two groups. Virological breakthrough rate (virological breakthrough rate = number of patients with genetic mutations/total number of patients) and incidence of adverse events (HBV DNA $<10^3$ copy/mL indicates a good virological response) at week 24 were compared between the two groups. And postoperative complications were recorded in both groups.

2.5. Statistical Methods. In this study, SPSS19.0 statistical software was used for data processing, the measurement data was expressed as mean ± standard deviation ($\overline{x} \pm s$), and the counting data was expressed as percentage. Multivariate logistic regression was adopted to analyze the factors affecting the virological response to antiviral therapy. T test was conducted to compare the data of experimental group and control group. $P < 0.05$ indicated statistical significance, and Origin8.0 was used for plotting.

3. Results

3.1. Comparison of Basic Conditions before Surgery. As shown in Figure 1, there was no statistically significant difference in age, height, weight, tumor size, hemoglobin albumin, total bilirubin, ALT, positive rate of HBV infection, proportion of sclerosing hepatocellular carcinoma, and proportion of tumor thrombus between the two groups ($P > 0.05$). Figure 2 shows the preoperative CT diagnostic images of some patients. Figure 2(a) shows a 63-year-old male patient with low density shadow in the right lobe and the left lobe of the liver, pleural effusion on the right, and multiple metastases in both lungs, and space-occupying lesions are considered. Figure 2(b) shows a female patient aged 58 years old. Most of her liver is metastatic lesions, and the lesions on the medial segment of the left lobe of the liver and the upper part of the right anterior lobe of the liver are relatively large. Figure 2(c) shows a female patient aged 70 years with dotted high-density shadow in the right lobe of the liver and dilatation of the intrahepatic bile duct. The carcinoma of the bile duct cells in the right lobe of the liver with multiple intrahepatic metastases is considered.

(b) Tumor size, hemoglobin albumin, total bilirubin, and ALT in the two groups. (c) The positive rate of HBV infection, the proportion of sclerosing hepatocellular carcinoma, and the proportion of tumor embolism in the two groups.

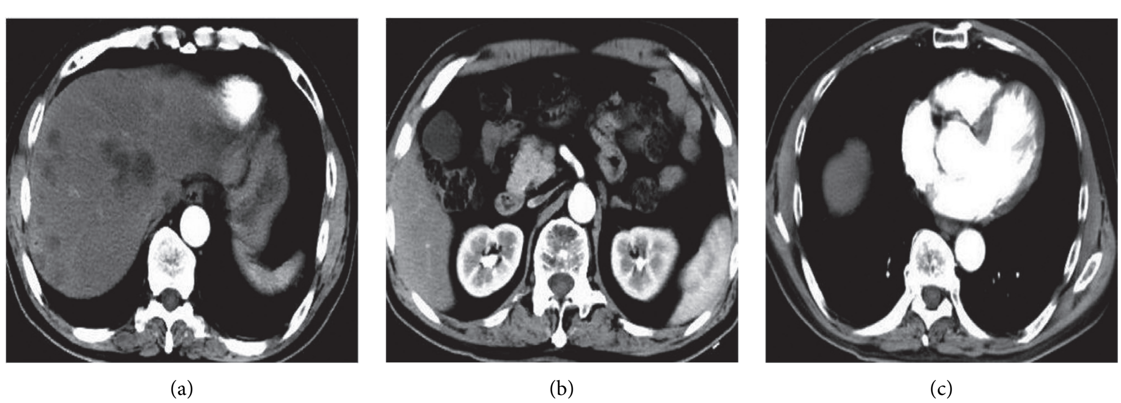

Figure 2: Preoperative CT diagnostic images of patients. (a) The image of a male patient aged 63 years. (b) The image of a female patient aged 58 years. (c) The image of a female patient aged 70 years.

3.2. Comparison of HBV DNA Level and Negative Conversion Rate between the Two Groups. As shown in Figure 3, in the experimental group, at weeks 10, 20, 30, 40, and 50, the HBV DNA negative conversion rates were 78.43%, 83.59%, 90.93%, 92.56%, and 94.83%, respectively, and the HBVDNA levels were 5.21 ± 1.75, 4.28 ± 1.16, 4.07 ± 0.86, 3.59 ± 1.42, and 3.51 ± 0.47, respectively. In the control group, at weeks 10, 20, 30, 40, and 50, HBV DNA negative

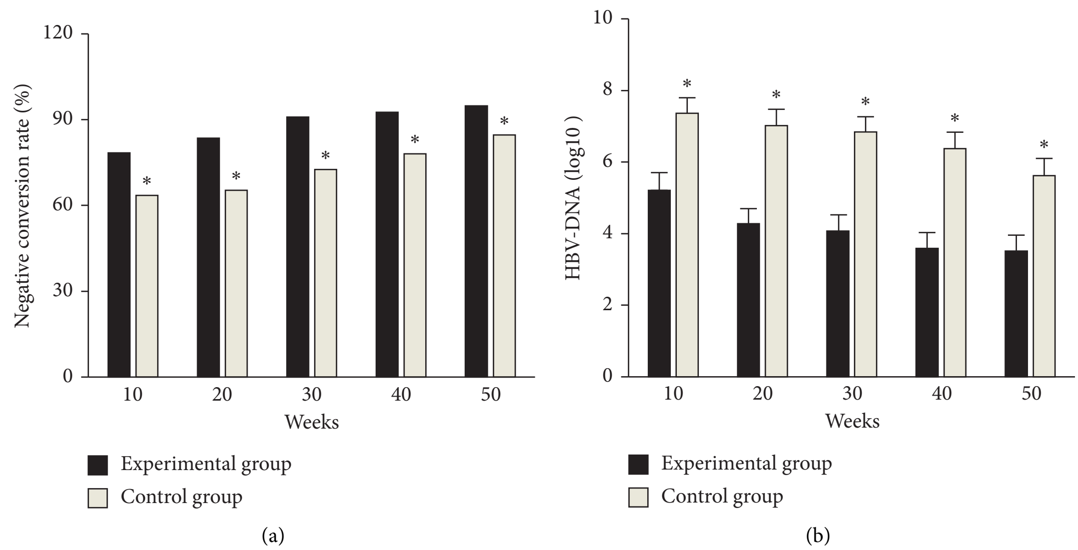

Figure 3: Comparison of HBV DNA level and negative conversion rate between the two groups in each period. (a) HBV DNA negative conversion rate of patients in the two groups. (b) HBV DNA level in both groups; ∗ indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

conversion rate was 63.51%, 65.27%, 72.54%, 78.05%, and 84.62%, and HBV DNA levels were 7.36 ± 2.86, 7.02 ± 3.03, 6.84 ± 2.55, 6.37 ± 2.84, and 5.62 ± 1.93, respectively. Among them, the HBV DNA negative conversion rate in the experimental group was significantly higher than that in the control group at each time period, and the difference was statistically significant ($P < 0.05$). HBV DNA level in the experimental group was significantly lower than that in the control group at each time period, and the difference was statistically significant ($P < 0.05$).

3.3. The Change of HBeAg in the Two Groups. As shown in Figures 4 and 5, in the experimental group, at weeks 10, 20, 30, 40, and 50, the negative conversion ratios of HBeAg were 20.43%, 31.54%, 46.77%, 59.41%, and 71.53%, respectively, and the serological conversion rates of HBeAg were 4.66%, 7.83%, 15.92%, 28.71%, and 39.08%, respectively. In the control group, at weeks 10, 20, 30, 40, and 50, the patients' negative conversion ratios of HBeAg were 9.38%, 22.58%, 30.19%, 39.56%, and 54.28%, and the serological conversion rates of HBeAg were 2.96%, 4.22%, 7.17%, 12.04%, and 18.37%, respectively. Among them, the negative conversion rate of HBeAg in the experimental group was significantly higher than that in the control group at each time period, and the difference was statistically significant ($P < 0.05$). The serological conversion rate of HBeAg in the experimental group at each time period was significantly higher than that in the control group, and the difference was statistically significant ($P < 0.05$).

3.4. Virological Breakthrough Rate and Incidence of Adverse Events in the Two Groups. As shown in Figure 6, 8 patients with adverse virological response finally appeared in the experimental group at week 24, with an incidence of adverse events of 5.81%. rtL180M mutation was found in 4 patients, and rtL180M + rtM204V/I + rtA181T mutation was found in

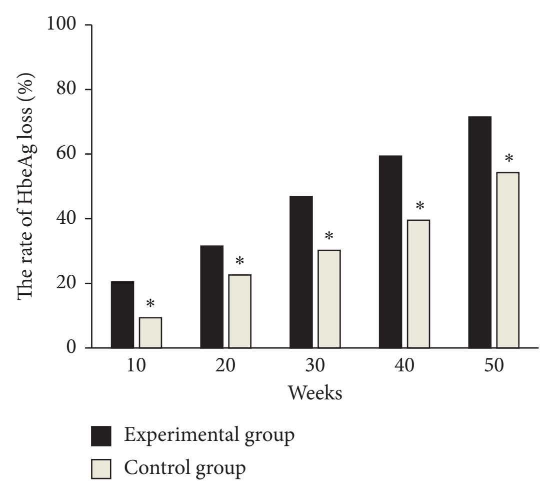

Figure 4: Comparison of negative conversion rate of HBeAg in each period between the two groups. * indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

5 patients, and the virological breakthrough rate was 6.62%. In the control group, 9 patients with adverse virological response finally appeared at week 24, with an incidence of adverse events of 10.34%. There were 3 patients with rtL180M mutation, 5 patients with rtL180M + rtM204V/I mutation, and the virological breakthrough rate was 9.20%. Among them, the virological breakthrough rate and incidence of adverse events in the experimental group were significantly lower than those in the control group, and the differences were statistically significant ($P < 0.05$).

3.5. Condition of HBsAg <100 IU/mL in the Two Groups. As shown in Figure 7, at weeks 10, 20, 30, 40, and 50, the proportion of HBsAg <100 IU/mL in the experimental

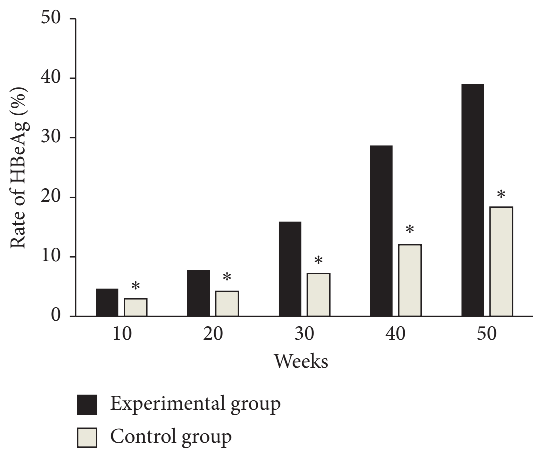

Figure 5: Serological conversion rate of HBeAg in two groups of patients in each period. * indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

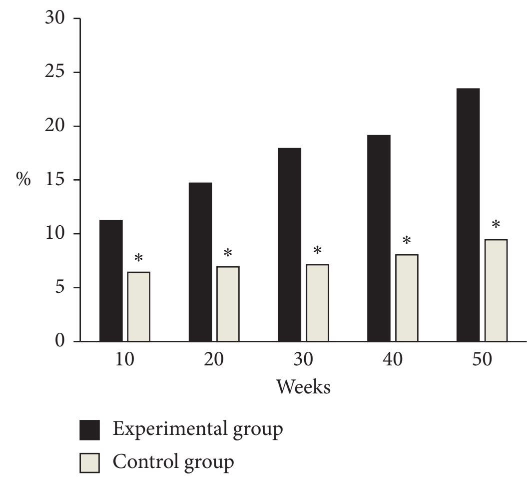

Figure 7: Condition of HBsAg <100 IU/ml in two groups of patients. * indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

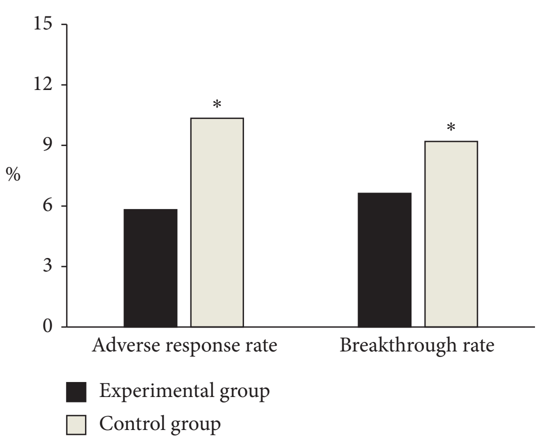

Figure 6: Virological breakthrough rate and incidence of adverse events of patients in the two groups. * indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

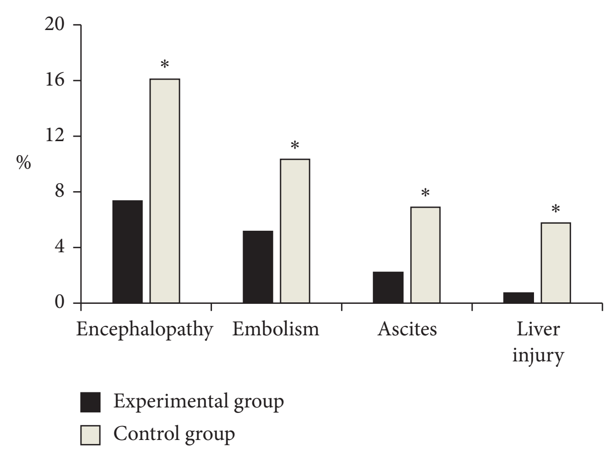

Figure 8: Postoperative complications of the two groups of patients. * indicates that the difference between the experimental group and the experimental group is statistically significant ($P < 0.05$).

group was 11.24%, 14.70%, 17.93%, 19.11%, and 23.46%, respectively. And the proportion of HBsAg <100 IU/mL at weeks 10, 20, 30, 40, and 50 in the control group was 6.42%, 6.93%, 7.14%, 8.05%, and 9.46%, respectively. Among them, the proportion of HBsAg <100 IU/mL in the experimental group was significantly lower than that in the control group at each time period, and the difference was statistically significant ($P < 0.05$).

3.6. Postoperative Complications of the Two Groups of Patients. As shown in Figure 8, in the experimental group, there were 10 cases of postoperative hepatic encephalopathy, with the complication rate of 7.35%; 7 cases with concurrent embolization, with the complication rate of 5.15%; 3 cases with concurrent ascites, with the complication rate of 2.21%; and 1 case with acute liver function injury, with the complication rate of 0.74%. In the control group, there were 14 cases of postoperative hepatic encephalopathy, with a complication rate of 16.09%; 9 cases of concurrent embolization, with a complication rate of 10.34%; 6 cases of concurrent ascites, with a complication rate of 6.90%; 5 cases of acute liver function injury, with a complication rate of 5.75%. Among them, the incidence of postoperative complications in the experimental group was significantly lower than that in the control group, and the difference was statistically significant ($P < 0.05$).

3.7. Regression Analysis of Human Papillomavirus (HPV) Infection and Clinical Pathological Characteristics of Patients. The PHMM analysis was performed to eliminate the impacts and effects of age, height, weight, baseline HBV DNA load, HBeAg status, ALT level, tumor size, proportion of sclerosing hepatocellular carcinoma, hemoglobin albumin level, and total bilirubin level. The variables with statistical significance for the virological adverse reactions of patients selected by the univariate analysis were analyzed by the proportional hazard function model, and the results were shown in Table 1. The analysis results suggested that the regression coefficients of the adverse virological response with age, HBV DNA load, and HBeAg state were 0.419, 0.593, and 0.473, respectively, showing significant positive correlation ($P < 0.05$); and the regression coefficient to the ALT level was −0.452, showing significant negative correlation ($P < 0.05$). There was no significant correlation between adverse virological response of patients and their height, weight, tumor size, proportion of sclerosing hepatocellular carcinoma, hemoglobin albumin level, and total bilirubin level ($P > 0.05$). Then, the age, HBV DNA load, HBeAg status, and ALT level of patients were undertaken as independent variables for multivariate logistic regression analysis, and the results were shown in Table 2. The results revealed that the regression coefficients of the adverse virological response of patient with HBV DNA load and HBeAg status were 0.631 and 0.569, respectively, showing significantly positive correlations ($P < 0.05$); the regression coefficient with ALT level was −0.583, showing an obviously negative correlation ($P < 0.05$); and there was no visible correlation between age and adverse virological response of patients ($P > 0.05$).

Table 1: Univariate regression analysis of virological responses to antiviral therapy.

Independent variables	Regression coefficients	t	P
Age	0.419	4.642	0.048
Height	0.246	2.115	0.087
Weight	0.218	2.074	0.070
HBV DNA load	0.593	5.116	0.005
HBeAg status	0.473	5.025	0.008
ALT level	−0.452	4.957	0.014
Tumor size	0.327	3.116	0.053
The proportion of sclerosing hepatocellular carcinoma	0.253	1.528	0.071
Hemoglobin albumin level	0.166	1.395	0.054
Total bilirubin level	0.280	1.507	0.062

Table 2: Multivariate regression analysis of virological responses to antiviral therapy.

Independent variables	Regression coefficients	t	P
Age	0.270	3.127	0.056
HBeAg status	0.569	5.731	0.014
ALT level	−0.583	5.114	0.017
HBV DNA load	0.631	6.427	0.006

4. Discussion

In the era of computer big data, how to effectively mine the value of data has become one of the key issues concerned by all walks of life. In particular, data information in the medical field is complex and has many categories. Only by filtering and integrating with computers can the value of data be maximized, and the database is the representative of this means [13]. Therefore, the treatment factor x was undertaken as an independent variable to perform linear regression based on the survival analysis. The regression model took the hazard rate function as the dependent variable to establish an exponential regression equation to construct a PHMM. The data of the first-line liver cancer patients in the GEO database were collected for multiple logistic regression to analyze the factors that affect the virological response to antiviral therapy. The results showed that the negative rates of HBV DNA of the experimental group at weeks 10, 20, 30, 40, and 50 were greatly higher than those of the control group ($P < 0.05$), and the HBV DNA level was observably lower in contrast to the control group ($P < 0.05$). Such results were consistent with the research results of Kim et al. [14], showing that entecavir could effectively reduce the HBV DNA level of patients undergoing surgical treatment and maintain the long-term inhibition. Hepatitis B surface antigen is an indicator of HBV infection. The seroconversion of hepatitis B surface antigen shows that the host immune system has an overwhelming advantage over the virus and is used as a sign of recovery from HBV infection. It was found in this study that the HBeAg negative conversion rate and serum conversion rate of the experimental group at weeks 10, 20, 30, 40, and 50 were remarkably higher in contrast to those of the control group ($P < 0.05$), which was consistent with the long-term follow-up results of Mücke et al. [15]. This may be because entecavir can directly act on transcription and replication of ccc DNA and subgenomic mRNA related to HBsAg expression, thus improving the negative conversion ratio and serological conversion rate of HBeAg [16]. In this study, it was found that the probability of postoperative hepatic encephalopathy, embolism, ascites, and acute liver function injury in the experimental group was significantly lower than that in the control group ($P < 0.05$), indicating that entecavir could reduce the risk of postoperative complications and was safe and feasible.

At present, it is generally believed that virological response evaluation should be carried out in the 24th week of antiviral therapy, and targeted treatment can be carried out according to the virological response. In this research, it was found that the virological breakthrough rate and incidence of adverse events of patients in the experimental group at week 24 were significantly lower than those in the control group ($P < 0.05$), which was similar to the study results of Zhu et al. [17], indicating that entecavir had higher antiviral intensity. In addition to that, the PHMM was also used to analyze the relevant factors that affect the virological response of antiviral therapy. It was found that there was an observably positive correlation between the adverse virological response, HBV DNA load, and HBeAg status of patients ($P < 0.05$). Such results indicated that the high baseline HBV DNA load is a risk factor for the adverse virological response to entecavir treatment. The higher the load, the greater the likelihood of adverse virological reactions. The positive HBeAg is more likely to cause adverse reactions. ALT is an evaluation index of liver inflammation, and its level also reflects the degree of immune clearance of patients. In this research, it was found that there was a significant negative correlation between adverse virological response and ALT level ($P < 0.05$), which was similar to the result of Mak et al. [18] who found a higher rate of adverse virological response when baseline ALT level < 5ULN. The lower the ALT level, the better the virological response, and the better the antiviral effect of entecavir.

5. Conclusion

Based on the computer GEO database under the PHMM, the clinical efficacy of entecavir antiviral therapy in patients undergoing interventional surgery for liver cancer was analyzed, which provided a reference for the future application of entecavir in malignant tumors. However, there were many shortcomings for this study. The sample size of the selected patients was small and the follow-up time was short, lasting only 50 weeks, which was not clear enough for the patients after half a year. The samples with longer follow-up time could be selected accordingly. In summary, entecavir could greatly reduce the HBV DNA levels and ALT levels, increase the HBeAg negative conversion rate, and exert a good antiviral effect compared with the seropositive conversion rate of interventional therapy for liver cancer patients. The PHMM analysis revealed that high baseline HBV DNA load, positive HBeAg, and low baseline ALT levels were independent risk factors for poor virological response to entecavir antiviral therapy.

The study focused on how to improve the diagnostic coincidence rate of patients with gallbladder stones and gallbladder cancer based on an optimized Segnet network algorithm and the relationship of gallbladder cancer with multiple tumor suppressor 1 (P16). 300 patients diagnosed with gallbladder cancer in the hospital were selected as the research subjects. The pyramid pooling operation was incorporated into the original Segnet network algorithm, and its performance was evaluated, factoring into the intersection of union (IoU), algorithm precision (Pre), and recall rate (Recall). After 8 hours of fasting, conventional ultrasound and contrast-enhanced ultrasound examinations were performed, and the images were evaluated by three experienced ultrasound diagnosticians. The positive signal of P16 immunohistochemical staining was brownish yellow, which was generally concentrated in the nucleus, and a small part was located in the cytoplasm. In each slice, ten visual fields were selected. Then, they were observed under a high-power mirror, and the number was counted. It was found that the optimized Segnet network algorithm increased the IoU by 7.3%, the precision by 8.2%, and the recall rate by 11.1%. The diagnostic coincidence rates of conventional ultrasound and contrast-enhanced ultrasound examinations for gallbladder cancer were 78.13% (25/32) and 87.5% (25/32), respectively. The positive expression rate of P16 in gallbladder adenocarcinoma (47.06%) was significantly lower than that of acute cholecystitis with gallbladder stones (84.38%) and gallbladder polyps (67.16%) ($P < 0.05$). The positive expression rate of P16 in patients with stage III and stage IV (33.33% and 40%) was significantly lower than that in patients with stages I and II (87.5% and 80%) ($P < 0.05$). The positive expression rate of P16 in high differentiation (86.67%) was significantly higher than that of moderate differentiation (40%) and poor differentiation (28.57%) ($P < 0.05$). In short, contrast-enhanced ultrasound can effectively improve the diagnostic coincidence rate of gallbladder cancer, and the expression of P16 in gallbladder cancer is closely related to tumor staging and differentiation.

1. Introduction

Gallbladder carcinoma, mainly adenocarcinoma, is a common malignant tumor in the extrahepatic biliary system [1]. In China, the average age of the onset of gallbladder cancer is approximately 56 years. Generally speaking, gallbladder cancer is more common in women. In addition, more than 85% of clinical gallbladder cancer patients have gallbladder stones [2]. The incidence of gallbladder cancer in patients with gallbladder stones is about 7 times higher than that of people without gallbladder stones. Among patients with gallbladder stones, the risk of gallbladder cancer in patients with a single gallbladder stone greater than 3 cm in diameter is 10 times that of patients with a gallbladder stone less than 1 cm in diameter. Therefore, the cause of gallbladder cancer may be related to gallbladder stones [3]. The P16 gene, also known as multiple tumor suppressor 1 (MTS-1) gene, is a new type of tumor suppressor gene located on human chromosome 92P1. When the P16 protein is expressed at a low level, it will cause cell disorders and abnormal cell growth, and ultimately, it will lead to the formation of tumors [4].

For a long time, the main methods to diagnose gallbladder cancer included conventional ultrasound, computerized tomography (CT), endoscopic ultrasound, and magnetic resonance imaging (MRI) [5]. Conventional ultrasound can make accurate judgments on the morphological changes of gallbladder cancer, such as whether the size, location, and shape are regular, whether the bile duct is dilated, the degree of dilation, and the invasion of the adjacent tissue and lymph node metastasis, and it is recognized as the first choice to diagnose malignant tumors of the biliary system. Its diagnostic coincidence rate is approximately 80% [6]. Contrast-enhanced ultrasound can specifically diagnose tumors with rich and poor blood supply, and especially in the parenchymal stage, it can comprehensively scan the surrounding tissue of gallbladder cancer and detect lesions that conventional ultrasound cannot find [7]. Contrast-enhanced ultrasound uses a contrast agent to perfuse the tissue. The peak time (TTP), peak intensity (PI), contrast agent perfusion rate, and other related parameters are recorded to determine the benign and malignant tumors. It significantly improves the diagnostic coincidence rate [8].

Deep learning can extract the essential features of the target by network training on a large amount to elevate the classification accuracy. During the training, it can not only automatically learn but also automatically modify the learning parameters [9]. In this research, a Segnet algorithm was proposed that can reduce the running time of the model while keeping the detection accuracy unchanged. The Segnet algorithm can store the pooled index, avoid saving the feature map of the decoded part, and save memory [10].

The innovation of this study was to propose a new Segnet algorithm to process the conventional two-dimensional ultrasound image of 300 patients with gallbladder stones and gallbladder cancer. The immunohistochemical method was used to detect the expression level of the P16 protein in the cancer tissue. The primary objective of the study was to explore the accuracy, specificity, and sensitivity of contrast-enhanced ultrasound in the diagnosis of gallbladder cancer, as well as the relationship between the P16 protein expression and the tumor to fully understand the mechanism of gallbladder cancer and provide an evidence-based basis for the clinical diagnosis and treatment of gallbladder cancer.

2. Materials and Methods

2.1. Research Subjects. In the study, 300 patients diagnosed with gallbladder cancer in the hospital from October 15, 2017, to April 25, 2021, were selected as the research subjects, including 135 males and 165 females, with an average age of (56.82 ± 12.74) years. Inclusion criteria include those (I) aged over 50, (II) suffering from gallbladder stones for more than five years, (III) with the diameter of stones greater than 2 cm, (IV) with the local gallbladder wall thickened, and (V) with gallbladder polyps greater than 1 cm. The clinical symptoms included dull pain, abdominal distension, indigestion, nausea, and vomiting. The experiment has been approved by the ethics committee of the hospital. The patients and their families understood the research and signed an informed consent form.

2.2. Segnet Network Algorithm. The Segnet network algorithm mainly includes an encoding network and a decoding network. It can completely retain the feature information of the image, reduce the number of training parameters, shorten the training time, and display high-precision semantic segmentation images. The Segnet network algorithm comprises the convolutional layer, the normalization layer, the activation function, and the pooling layer (Figure 1).

The Segnet network algorithm structure has a symmetrical structure, with the left side of the network representing the encoding network and the right side representing the decoding network [11]. In the Segnet network, the pooling layer and the upsampling layer are used for image segmentation. The feature extraction of the target is completed by the left convolution layer, i.e., the encoding network. The pooling layer is used mainly to shrink the picture and perform deconvolution and upsampling operations [12]. Deconvolution is to make the classification features of the image more obvious. Upsampling is to restore the image to the same size as the input image. The encoding network extracts the features of the segmented image, transmits it to the decoding network, and outputs the semantic segmentation image (Figure 2).

In the training process, the linear expression cannot fully meet the actual needs, and the Relu function is often used for fitting. The Relu function is easy to calculate and fast to converge, and it is expressed as follows:

$$\mathrm{f}(\mathrm{x}) = \begin{cases} x, & x > 0, \\ 0, & x \leq 0. \end{cases} \quad (1)$$

When the input signal ≤ 0, the output is 0. When the input signal $x > 0$, the output is equal to the input.

2.3. Pyramid Pooling Operation. In the original segnet network, the pooling operation will cause the loss of some high-frequency components in the image, produce a purification module, and lose the pixel position and spatial information (Figure 3). To avoid this problem, the pyramid pooling operation is introduced. The pyramid pooling module uses different coarse and fine scales to fuse features, and the output of different scales includes feature maps of various sizes. It avoids producing fuzzy blocks as much as possible and retains the original features extracted by the convolutional neural network (CNN) (Figure 4).

2.4. Evaluation Indicators of Experimental Results. There are three evaluation indicators to determine the accuracy of feature extraction. The first is the intersection of union (IoU). It represents the degree of overlap between the candidate area generated when detecting the target and the original marked area, and it is expressed as follows:

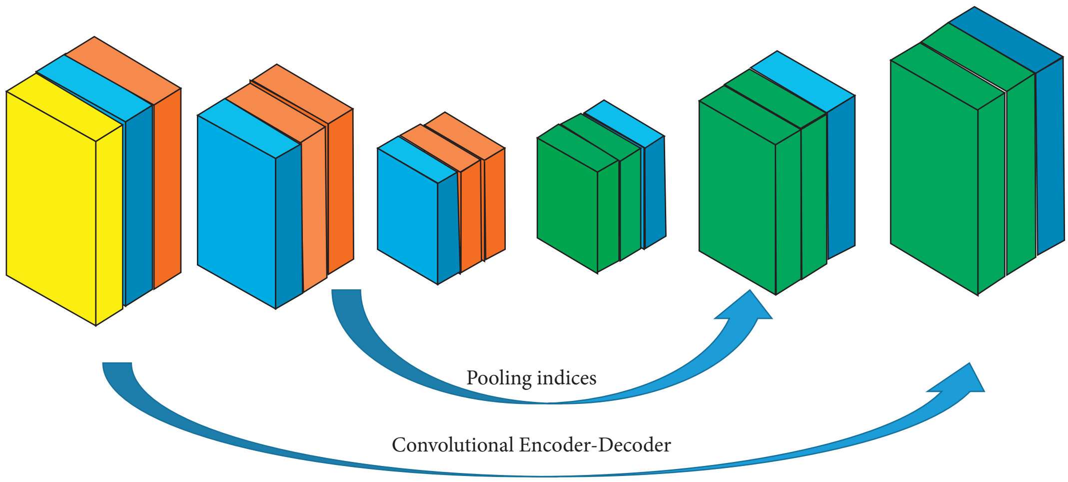

Figure 1: Structure of the Segnet network algorithm.

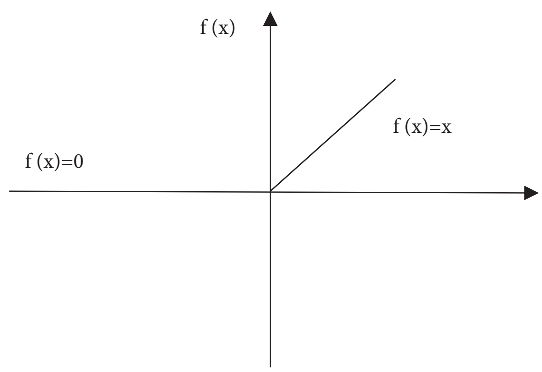

Figure 2: Relu function.

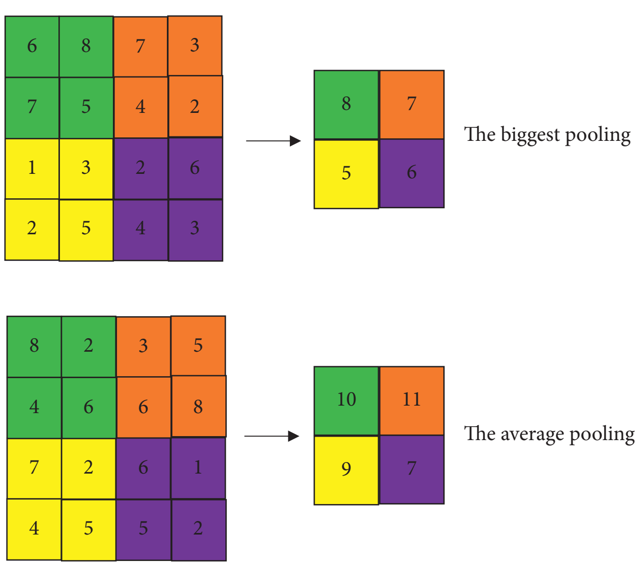

Figure 3: Original pooling operation.

$$\mathrm{IoU} = \frac{T1}{T1 + S1 + S2}, \tag{2}$$

where T1 represents a correctly detected nontarget feature, S1 represents a nontarget feature that is erroneously detected as a target feature, and S2 represents a target feature that is erroneously detected as a nontarget feature.

The second is the precision (Pre), which is the percentage of real target pixels in the detected target features, and it is expressed as follows:

$$\mathrm{Pre} = \frac{T1}{T1 + S2}, \tag{3}$$

where $T1$ represents a correctly detected nontarget feature, and S2 represents a target feature that is incorrectly detected as a nontarget feature.

The third is the recall rate (Recall). It is the ratio of the detected real target pixels to all the ultrasound samples of the test set and is expressed as follows:

$$\mathrm{Recall} = \frac{T1}{T1 + T2}, \tag{4}$$

where $T1$ represents the nontarget feature that is correctly detected, and $T2$ represents the target feature that is correctly detected.

2.5. Ultrasonic Diagnostic Equipment. After 8 hours of fasting, patients with gallbladder cancer underwent a routine ultrasound examination. The patient was in a supine position to have the multisection examination of the upper abdomen, and

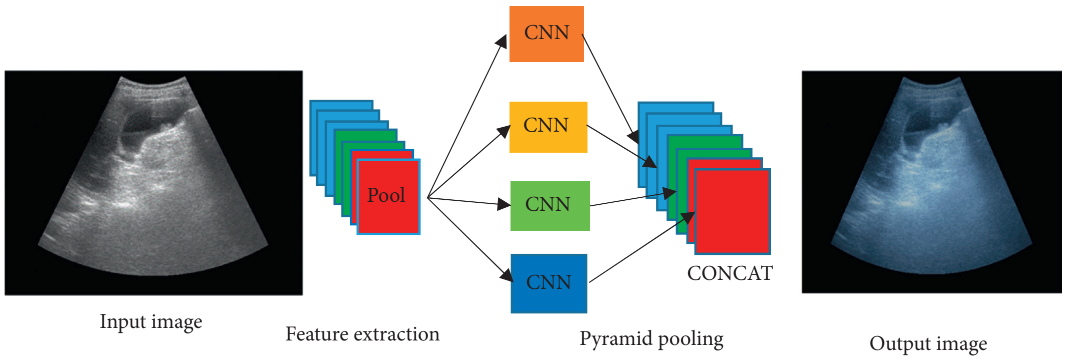

Figure 4: Pyramid pooling module.

the location, number, size, shape, boundary, and thickness of the gallbladder wall were recorded. Color ultrasound diagnostic apparatus was used for contrast-enhanced ultrasound, and an abdominal probe with a frequency of 3.5 MHz was used to detect the blood flow signal and shape of the lesion and determine the blood flow velocity. After angiography, three experienced ultrasound diagnosticians evaluated the images independently.

2.6. Immunohistochemical Staining Procedure and Result Judgment. The P16-positive gastric cancer tissue was used as a positive control, and the phosphate buffered saline (PBS) instead of P16 primary antibody was used as a negative control. The specific steps were as follows:

Firstly, after being dewaxed and hydrated, the paraffin sections were rinsed with PBS (PH = 7.4) three times for 3 minutes each time. Then, according to the requirements of each antibody, the tissue antigen was repaired accordingly. Each slice was immersed in 50uL peroxidase blocking solution to incubate for 10 minutes at room temperature to block the activity of endogenous peroxidase. Then, it was rinsed with PBS three times for 3 minutes each time. Next, each slice was immersed in 50uL normal nonimmune animal serum to incubate for 10 minutes at room temperature. Subsequently, the serum was removed, and each slice was immersed in 50uL of the primary antibody to incubate for 60 minutes at room temperature. Again, it was rinsed with PBS three times for 3 to 5 minutes each time. After the PBS solution was removed, each slice was immersed in 50uL biotin-labeled secondary antibody to incubate for 10 minutes at room temperature. Then, it was rinsed with PBS three times for 3 minutes each time. After the PBS solution was removed, each slice was immersed in 50uL streptavidin-peroxidase solution to incubate for 10 minutes at room temperature. Then, it was rinsed with PBS three times for 3 minutes each time. After the PBS solution was removed, each slice was immersed in 100uL of freshly prepared diaminobenzidine (DAB) solution and observed under a microscope for 3 to 10 minutes. Next, it was rinsed with tap water and stained with hematoxylin, followed by rinsing with PBS or tap water to return to blue. DAB was used for color development. The slices were dehydrated and dried with gradient alcohol, cleared with xylene, and mounted with neutral gum.

The positive signal of P16 immunohistochemical staining was brownish-yellow, generally concentrated in the nucleus, with a small part in the cytoplasm. In each slice, 10 fields of view were selected, which were then observed under a high-power mirror to count the number. More than 60% of the cells in the field of view with brown-yellow particles was defined as strong positive (+++), 30% to 60% of the cells with brown-yellow particles was defined as positive (++), 5% to 30% of cells with brown-yellow particles was defined as weakly positive (+), and no obvious brown particles in the cell were defined as negative (-). A weak positive expression or above was considered a positive expression.

2.7. Statistical Methods. In this study, SPSS21.0 statistical software was used for statistical analysis of the result data. The calculated data that conformed to the normal distribution were represented by the mean standard deviation ($\overline{x} \pm s$), and the calculated data that did not conform were represented by the percentage (%). The comparison of counting data adopts χ^2 test. $P < 0.05$ indicated that the difference was significant.

3. Results

3.1. Performance of the Segnet Network Algorithm. The Segnet and the optimized Segnet with the pyramid model were trained separately. Figure 5 shows the loss value/accuracy change curve of the training set and the validation set. Figure 6 shows the semantic segmentation network. According to the result data, the optimized Segnet network algorithm of the pyramid pooling operation increased the IoU by 7.3%, the precise (Pre) by 8.2%, and the recall rate (Recall) by 11.1%. It suggested that the semantic segmentation model with pyramid pooling elevated the accuracy and speed of target extraction.

3.2. General Information of the Subjects. There were 300 patients with gallbladder cancer, including 135 males and 165 females, ranging in age from 50 to 75 years. Pathological examination showed 32 cases of gallbladder malignant tumors, of which gallbladder adenocarcinoma accounted for 53.12% (17 cases), gallbladder squamous cell carcinoma accounted for 25% (8 cases), gallbladder adenosquamous

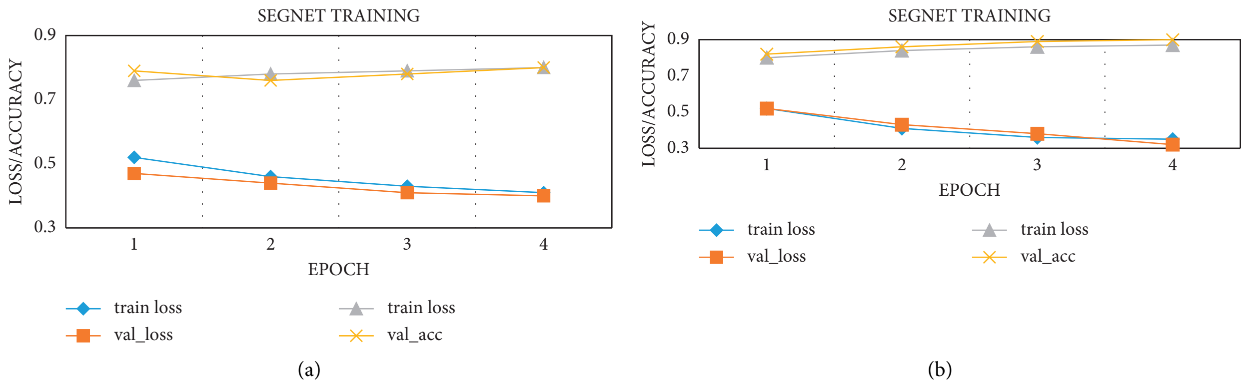

Figure 5: Loss value/accuracy curve of training set and validation set. (a) Segnet network algorithm. (b) Optimized Segnet network algorithm.

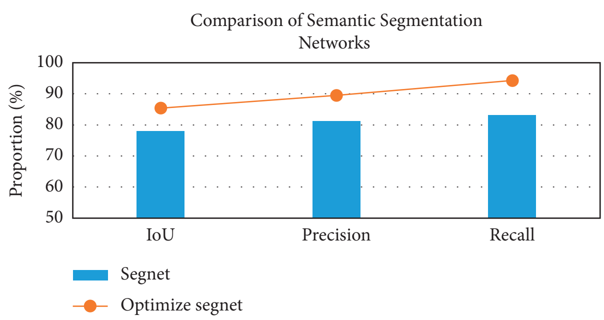

Figure 6: Comparison of semantic segmentation networks.

carcinoma accounted for 15.63% (5 cases), and gallbladder villous cystic glands tumor accounted for 6.25% (2 cases). There were 168 cases of benign gallbladder lesions, including 40% (67 cases) of gallbladder polyps, 11.31% (19 cases) of gallbladder adenoma, 8.33% (14 cases) of biliary sludge, 19.04% (32 cases) of acute cholecystitis with gallbladder stones, and 21.43% (36 cases) of chronic cholecystitis with gallbladder stones (Figure 7).

3.3. Results of Conventional Ultrasound Examination. 25 cases of gallbladder cancer were detected by conventional ultrasound examination. The diagnosis coincidence rate was 78.13% (25/32). 4 cases of nodular gallbladder carcinoma had nodular protrusions in the gallbladder cavity, wide basement, irregular edges, and heterogeneous internal echoes. The abnormal central echoes caused by stones, air, or necrosis were noted (Table 1). In 5 cases of thick-walled gallbladder carcinoma, the gallbladder wall was locally thickened or diffusely unevenly thickened, showing hyperechoic (more common) or hypoechoic signals, and the entire gallbladder was stiff, deformed, and the wall was rough or irregular. In 5 cases of solid gallbladder carcinoma, the entire gallbladder showed disordered low-echo or medium-echo solid masses, and the dark areas in the gallbladder cavity disappeared, often accompanied by gallbladder stones. There were 6 cases of mixed gallbladder carcinoma, and both thick-walled and nodular types were noted (Figure 8).

3.4. Results of Contrast-Enhanced Ultrasound Examination. 28 cases of gallbladder cancer were examined by contrast-enhanced ultrasound, and the diagnosis coincidence rate was 87.5% (25/32). For patients with gallbladder stones combined with gallbladder cancer, the mass was large, the boundary was not clear, and the surrounding halo was visible. There were irregular liquid dark areas inside, the mass was adjacent to the gallbladder, and the boundary with the gallbladder was not clear (Figure 9; Table 2).

3.5. Immunohistochemical Staining Results of P16. The positive expression of P16 was mainly concentrated in the nucleus and cytoplasm, with brownish-yellow particles, and some cell membranes were also stained (Figure 10).

3.6. Expression of P16 in Lesions of Gallbladder Carcinoma. In 17 cases of gallbladder adenocarcinoma, the positive expression rate of P16 was 47.06%. In 67 cases of gallbladder polyps, the positive expression rate of P16 was 67.16%. In 32 cases of acute cholecystitis with gallbladder stones, the positive expression rate of P16 was 84.38%. In 36 cases of chronic cholecystitis with gallbladder stones, the positive expression rate of P16 was 81.56%. The positive expression rate of P16 in gallbladder adenocarcinoma was significantly lower than that in patients with other gallbladder lesions, and the difference was significant ($P < 0.05$) (Figure 11).

3.7. The Relationship between the Positive Expression of P16 and Pathological Features. As per the clinical staging of gallbladder cancer, there are 8 cases in stage I, 5 cases in stage II, 9 cases in stage III, and 10 cases in stage IV. The positive expression rate of P16 in the patients of stages III and IV (33.33% and 40%) was significantly lower than that of the patients of stages I and II (87.5% and 80%), and the difference is significant ($P < 0.05$) (Figure 12).

According to the results of tumor differentiation, 7 cases were poorly differentiated, 10 cases were moderately differentiated, and 15 cases were highly differentiated. The positive expression rate of P16 in the high differentiation (86.67%) was significantly higher than that of moderate

differentiation (40%) and poor differentiation (28.57%), and the difference was significant ($P < 0.05$) (Figure 13).

4. Discussion

Gallbladder cancer is a common malignant tumor of the biliary system, and its incidence has been increasing in recent years. Gallbladder cancer combined with gallbladder stones continuously stimulates the gallbladder wall mucosa, causing the abnormal proliferation of mucosal epithelial cells and cholestasis. Gallbladder cancer lacks specific clinical manifestations in the early stage and has similar symptoms of gallbladder stones. Therefore, when it is discovered, it is already in the middle and late stages when the best treatment opportunity has been lost [13,14]. At present, the early diagnosis of gallbladder cancer combined with gallbladder stones is a clinical problem that needs to be solved urgently.

Conventional ultrasound examination is easy to operate, noninvasive, low in price, and easy to be accepted by patients. It is recognized as the first choice for the diagnosis of gallbladder cancer [15]. However, because of the limitations

(d)

Figure 9: Contrast-enhanced ultrasound examination. (a) The patient was a 62-year-old male with a history of gallbladder stones for 5 years and epigastric pain for 5 days. Contrast-enhanced ultrasound examination of the abdomen showed that the continuity of the gallbladder wall was locally interrupted, and a slightly strong echogenic nodule protruding into the cavity was seen near the bottom. (b) The patient was a 55-year-old female with dull pain in the upper abdomen for half a year. Contrast-enhanced ultrasound examination of the abdomen showed the thickening of the gallbladder wall, and a moderate echogenic mass filled the cyst cavity at the bottom of the gallbladder. (c) The patient was a 53-year-old female with abdominal pain for 3 days. Contrast-enhanced ultrasound examination of the abdomen showed that the gallbladder volume increased significantly, and a solid mass with irregular shape was seen in the cyst cavity. (d) The patient was a 64-year-old female with a history of gallbladder stones for 5 years and epigastric pain for 5 days. Contrast-enhanced ultrasound examination of the abdomen showed clear boundaries of gallbladder lesions and irregular thickening of the cyst wall.

of the technology itself, the microvessels of the lesion cannot be well-evaluated. In this study, 25 cases of gallbladder cancer were detected by conventional ultrasound, and the diagnosis coincidence rate was 78.13% (25/32), which was consistent with the research results of Rana et al. (2016) [16]. There were a total of 7 cases of missed and misdiagnosed cases. The main reasons were as follows: firstly, there is a certain amount of bile mud and viscous bile deposited in the gallbladder, and they do not move when the body position changes. Secondly, the thickness of the normal gallbladder wall is approximately 2 mm. When it is greater than 4 mm, the stone has an arc shape, and it is easy to misdiagnose the gallbladder with a thickened gallbladder wall and gallbladder cancer as chronic cholecystitis and gallstone disease. Thirdly, there are many organs around the gallbladder and abundant vessels. After gallbladder cancer has infiltrated, the outline of the gallbladder is unclear, and it is easy to be misdiagnosed as a tumor in the surrounding tissue.

Contrast-enhanced ultrasound technology is an imaging technology to understand the anatomy of tumor blood vessels. It can enhance the backscattered echo of the cells and improve the diagnostic coincidence rate. However, the low-resolution results in the unclear intima of large blood vessels, and it is unable to identify tiny blood vessels [17]. In this study, 28 cases of gallbladder cancer were detected by contrast-enhanced ultrasound, and the diagnosis coincidence rate was 87.5% (25/32). Contrast-enhanced ultrasound can observe the blood flow characteristics of the lesions of gallbladder cancer patients in real time, accurately display the spatial distribution of vascular perfusion, and significantly improve the signal ratio of detection. In this study, it can accurately detect the invasive growth of gallbladder tumors, providing a theoretical basis for the diagnosis of gallbladder cancer.

The P16 gene is a tumor suppressor gene directly involved in the negative feedback regulation of the cell cycle, and its level is closely related to the cell cycle [18,19]. When the P16 gene has mutations or deletions, it will lead to a low expression or the inactivation of the P16 protein, leading to cell cycle disorders [20]. In this study, the positive expression rate of P16 in gallbladder adenocarcinoma (47.06%) was significantly lower than that of acute cholecystitis with gallbladder stones (84.38%) and gallbladder polyps (67.16%) ($P < 0.05$). It showed that P16 was obviously missing in gallbladder cancer tissue, and the deletion and mutation of the P16 gene would lead to the occurrence of gallbladder cancer. The positive expression rate of P16 in the high differentiation (86.67%) was significantly higher than that in the middle differentiation (40%) and poor differentiation (28.57%) ($P < 0.05$), indicating that the positive expression of P16 protein in the gallbladder cancer tissue was related to the degree of tissue differentiation.

5. Conclusion

In this study, the ultrasound images based on the optimized Segnet network algorithm were used to diagnose 300 patients with gallbladder stones and gallbladder cancer. It was found that contrast-enhanced ultrasound can effectively improve the diagnostic coincidence rate of gallbladder cancer, and the expression of P16 in gallbladder cancer was closely related to tumor staging and differentiation. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study. In conclusion, ultrasound imaging as a new imaging technology has guiding significance in the early diagnosis and identification of gallbladder cancer.

This study aimed to investigate the application of positron emission tomography- (PET-) computed tomography (CT) image information data combined with serous cavity effusion based on clone selection artificial intelligence algorithm in the diagnosis of patients with malignant tumors. A total of 97 patients with PET-CT scanning and empirically confirmed as serous cavity effusion were retrospectively analyzed in this study. The clone selection artificial intelligence algorithm was applied to register the PET-CT images, and the patients were rolled into a benign effusion group and a malignant effusion group according to the benign and malignant conditions of the serous cavity effusion. Besides, the causes of patients from the two groups were analyzed, and there was a comparison of their physiological conditions. Subsequently, CT values of different KeV, lipid/water, water/iodine, and water/calcium concentrations were measured, and the differences of the above quantitative parameters between benign and malignant serous cavity effusion were compared, as well as the registration results of the clone algorithm. The results showed that the registration time and misalignment times of clonal selection algorithm (13.88, 0) were lower than those of genetic algorithm (18.72, 8). There were marked differences in CT values of 40–60 keV and 130–140 keV between the two groups. The concentrations of lipid/water, water/iodine, and water/calcium in basal substances of the malignant effusion group were obviously higher than the concentrations of the benign effusion group ($P < 0.05$). Benign and malignant effusions presented different manifestations in PET-CT, which was conducive to the further diagnosis of malignant tumors. Based on clone selection artificial intelligence algorithm, PET-CT could provide a new multiparameter method for the identification of benign and malignant serous cavity effusions and benign and malignant tumors.

1. Introduction

Serous cavity effusion (SCE) is a common symptom and sign in clinical work, which is divided into pleural effusion, ascites, and pericardial effusion [1, 2]. When the effusions occur in two or more parts of the patient's body simultaneously or successively during the course of the disease, they are called polyserositis. The causes of SCE are often complicated, and the common causes include malignant tumor, tuberculosis, hypoproteinemia, and hepatogenic, nephrogenic, cardiogenic, and autoimmune diseases [3–5]. At present, there are various methods for detection of SCE. The frequently used methods contain biochemical examination, tumor marker, exfoliated cell detection, flow cytometry, and telomerase activity assay. However, the detection rates of these methods are generally low, so it is often necessary to carry out repeated tests to get more accurate results [6]. Moreover, the traditional imaging detections such as X-ray, ultrasound, and computed tomography (CT) can only detect diseases by relying on morphological changes, and it is impossible to achieve more effective inspections for early disease [7, 8]. At this stage, medical diagnosis and treatment capabilities with the further advancement of E-health have been improved directly or indirectly from digital medical equipment to high-level information and knowledge sharing, and various digital imaging and postprocessing technologies make disease diagnosis more intuitive and accurate. Under this background, positron emission tomography-(PET-) CT has gradually been applied in the detection of SCE. The PET-CT imaging is a method combining molecular metabolism with anatomical structure images. It has obvious advantages in early identification and diagnosis of most diseases [9]. The detection method is easy to operate and noninvasive and lets patients suffer little pain. After long-term clinical application, it has been proved to have obvious advantages in the differential diagnosis of various diseases. Above all, it has been applied better in identifying the nature of effusion and finding the primary lesion of malignant effusion [10, 11]. In addition, the registration based on the shape feature points of the PET-CT image is difficult and requires the application of external reference point features for registration. However, due to the characteristics of mutual information function and multiple extreme values, there are usually multiple local extreme values, so that the optimization process may converge to the local extreme value and get wrong registration parameters, resulting in mismatching of image registration. In recent years, clonal selection algorithm is widely used in pattern recognition and combinatorial optimization. Its core is to multiply replication operator and mutation operator, retain the best individual, and improve the poor individual. It is an efficient and fast convergence algorithm. Therefore, the patients were detected by PET-CT using clone selection artificial intelligence algorithm in this study, and patients with benign and malignant effusions were evaluated, thereby providing new ideas for clinical treatment of peripheral facial paralysis and pointing out new directions.

2. Methods

2.1. Subjects Investigated and Grouping. 97 patients who underwent PET-CT scanning in hospital from June in 2017 to June 2019 and were empirically diagnosed as SCE were retrospectively analyzed. In the patients with malignant effusion, the primary lesions of some with malignant tumors have been confirmed by pathology, except for others with liver cirrhosis and primary liver cancer. According to the nature of effusion, 97 patients were divided into benign and malignant effusion, including 25 benign and 72 malignant. All the patients participating in the experiment had signed informed consent forms, and this study had been approved by ethics committee of hospital.

2.2. Inclusion and Exclusion Criteria. The inclusion criteria for the patients participating in the experiment were as follows: the patients met the diagnostic criteria of Western medicine, were above 20 years and below 65 years of age, had no other acute diseases or severe complications during the period of developing SCE, and were under no other treatment.

The exclusion criteria of patients participating in the experiment were as follows: patients in pregnancy or early pregnancy, having severe cardiovascular and cerebrovascular diseases, liver and kidney function disease, and hematopoietic failure, having cerebral infarction, cerebral hemorrhage, or other brain diseases, having participated in other clinical experiments, not developing SCE for the first time, and having the disease again after receiving treatments on the first onset.

2.3. Immunohistochemical Staining Reaction. The SCE was made into a smear and rinsed; after that, the smear was soaked in the permeable solution for 5 minutes, and then phosphate buffer solution (PBS) was applied to rinse the soaked smear. The rinsed section was added with PBS to be incubated in an incubator at 37°C for 30 minutes. After the incubation, the enzyme reaction solution was added to the incubated section for light avoidance reaction, and it was rinsed after 1 hour of the light avoidance reaction. Then, fluorescein isothiocyanate (FITC) working solution was added to continue the reaction for 30 minutes in the dark; and the section was rinsed after the reaction finished. Finally, 4′,6-diamidino-2-phenylindole (DAPI) working solution was dropped on the surface of the section, which was observed with a computer fluorescence microscope.

2.4. Positron Emission Tomography-Computed Tomography Scanning Detection Method. The Discovery ST 4 PET-CT instrument was for PET-CT scanning, and Advanced PET and Lightspeed 4-slice spiral computed tomography (CT) were combined on the same machine rack. Before the detection, the patient should fast for 4–6 hours in advance, and the fasting blood glucose of the patient had to be less than 7 mmol/L. If the patient's blood glucose was too high before the detection, the insulin should be injected appropriately to control the blood glucose within the normal range. After the patient stayed at rest for 15 minutes, the patient was given an intravenous injection of imaging agent with the amount of 3.71–4.82 MBq/kg. After the injection, the patient would continue to maintain a resting state for 45–60 minutes. Moreover, PET-CT scanning was applied immediately after the patient urinated. During the detection, the patient was placed in a supine position, held his head with his hands, kept breathing calm, and was scanned from the top of the skull to the upper femur on both sides. Gemstone spectral imaging (GSI) mode was used for CT scanning, with a spiral scanning speed of 0.6 s/ week, a detector width of 4 cm, a voltage of instantaneous switching between high and low energy (140 kVp and 80 kVp), and a tube current of about 600 mA. The first group of image reconstruction was the common 140 kVp image, which was used for real-time observation during the detection process, with a layer thickness/layer interval of 5 mm. The second group was a single energy (70 keV) image with a layer thickness/layer interval of 1.25 mm. In addition, standard algorithms were employed for image reconstruction.

2.5. PET-CT Image Registration Based on Clone Selection Algorithm. The clone selection process is a positive feedback process, and the clone selection algorithm is employed to find the maximum value of normalized mutual information and its corresponding registration parameters. The specific steps are as follows.

The first step is initialization. The PET-CT image is used as the initial research object, corresponding to the possible solutions of registration parameters. The floating-point number is encoded, and the base number is 19, in which the first 10 bits correspond to the rotation parameters of the image space transformation, and the last 9 bits correspond to the scale parameters of the image transformation. The probability of crossover is set as $Yi = 0.7$ and the probability of mutation as $Yt = 0.02$. The second step is evaluation and selection. The normalized mutual information value is calculated; the larger 30 of them are selected to enter the memory set Pn and the remaining Pm. The third step is clone. In the memory set Pn, K with higher normalized mutual information value are selected for cloning, and the number of clones is proportional to the fitness. It is ensured that the selection of registration parameters develops towards the optimization direction.

The fourth step is crossover and mutation. The supermutation process in biological clone selection is simulated, and the cross-mutation operation is carried out on the results after clone, so the mutation rate is inversely proportional to the fitness, thus enlarging the search range of registration parameters. The fifth step is the second evaluation and selection. The affinity of the mutated antibodies is recalculated. If the affinity of some clone results is higher than that of the highest Pn, the body with the lowest affinity in Pn is replaced with these antibodies to form a new memory set. The sixth step is extinction. The process of natural cell extinction in biological clonal selection is simulated. In Pm, d results with the lowest affinity are selected to reinitialize, which can ensure the speed of convergence. The seventh step is to check whether the termination conditions are met. If they are met, terminate; otherwise, go to the second step and enter the next generation avoidance.

The clone algorithm can realize the diversity of the search space and optimize the objective function of medical image registration, with good performance.

2.6. Image Processing, Analysis, and Measurement. The image analysis and measurement were on the professional workstation AW4.5. Three radiologists with ten years of work experience carried out the measurement independently, and they did not know the final results of the subjects investigated. On the mixed energy 140 kVp imaging image, the most obvious layer of the effusion in the image was selected to measure the CT value. Besides, circular reactive oxygen intermediate (ROI) with a diameter of 5–10 mm was selected, and three-point measurement was carried out, and the average value was selected. The single energy image (70 keV, and 5 mm) was loaded into spectrum imaging analysis software GSI viewer for analysis. The ROI of the same patient was measured against the corresponding region of the mixed energy, and the ROI data file was saved. The data file was an Excel spreadsheet file, containing the CT value (HU) of each single energy level 40–140 keV (the interval for 10 keV) and effective atomic number; the statistical software was employed to calculate the peak of effective atomic number distribution; and lipid (water), water (iodine), and water (calcium) were selected as the paired base substances, and their concentrations were generated by the data file.

2.7. Statistical Analysis. SPSS 17.0 statistical analysis software was used for the statistical methods. The results of counting were expressed as mean ± standard deviation ($\overline{x} \pm s$), and t-test was applied for comparison between the two groups. The receiver operating characteristic curve (ROC) was employed to evaluate the value of paired base substances in the diagnosis of malignant effusion, and AUC was applied to determine the accuracy of base substance concentration in the diagnosis of malignant effusion. What is more, the threshold value, sensitivity, and specificity for the diagnosis of malignant effusion were calculated, and $P < 0.05$ was considered to represent statistically significant difference.

3. Results

3.1. Comparison of the Basic Data of Patients. Based on the nature of the effusion, 97 patients were classified into benign and malignant effusion, respectively. There were 25 patients with benign effusion including 11 males and 14 females, the average age was 62.17 ± 6.33 years, and the course of disease was 2.57 ± 0.24 years. What is more, 72 patients were malignant effusion including 33 males and 39 females, with an average age of 63.74 ± 4.76 years and the disease course of 3.57 ± 1.24 years. The results in Figure 1 show that the difference in general data between the two groups of patients was not statistically remarkably significant ($P > 0.05$).

3.2. Analysis of the Causes of the Patients in the Two Groups. There were 25 patients in the benign effusion group, and their specific causes are shown in Figure 2. The benign effusion group included 8 patients of liver cirrhosis with ascites, 2 patients of heart failure with pleural effusion, 13 patients of pneumonia with pleural effusion, and 2 patients of tuberculous pneumonitis with ascites. Figure 3 shows the specific causes of 72 patients in the malignant effusion group. Besides, there were 14 patients of gastrointestinal malignant tumors with ascites, 44 patients of lung cancer with pleural effusion, 9 patients of breast cancer with multiple metastases and pleural effusion, 3 patients of ovarian cancer with ascites, and 2 patients of esophageal cancer with pleural effusion in the malignant effusion group. There was no statistical difference in the number of cases of each cause of the above patients ($P > 0.05$).

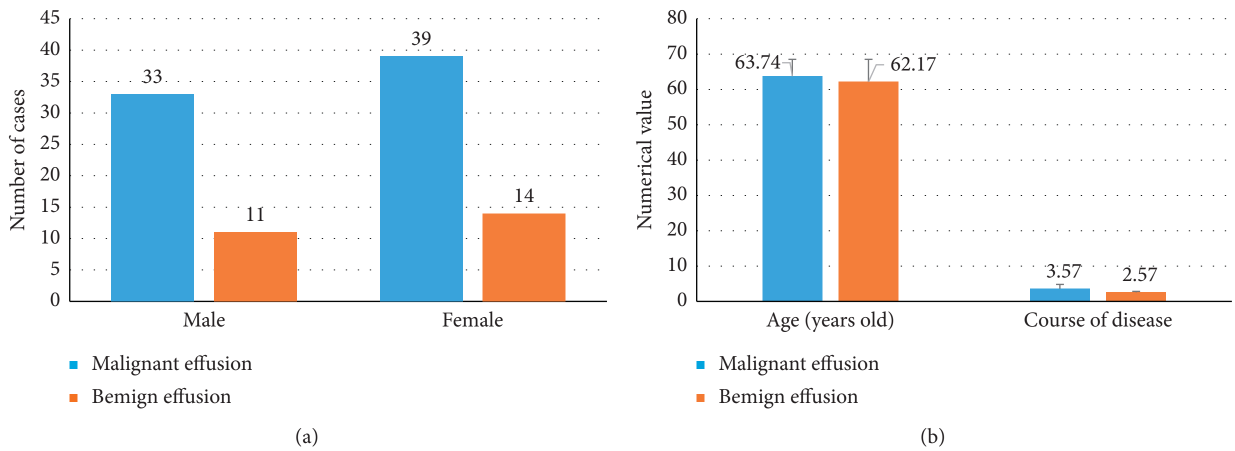

Figure 1: Comparison of the basic data of the patients in the two groups. (a) Comparison of the gender among the patients in the two groups; (b) comparison of the age and course of disease among the patients in the two groups.

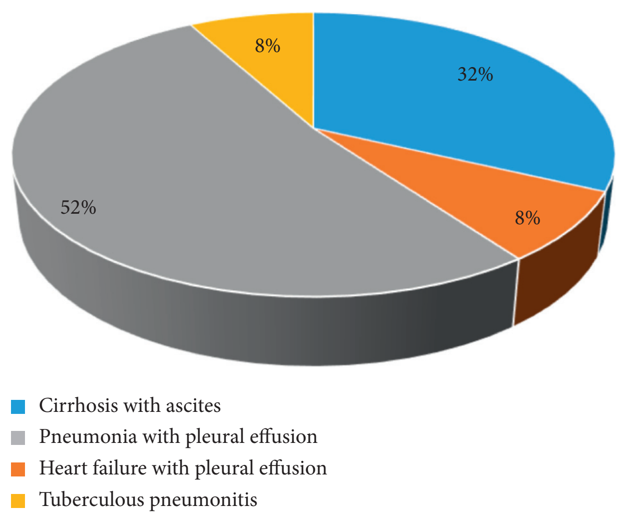

Figure 2: The disease causes of the patients with benign effusion.

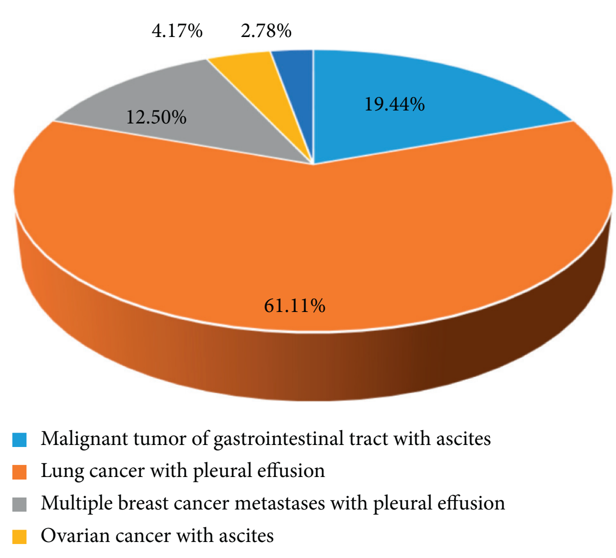

Figure 3: The disease causes of the patients with malignant effusion.

3.3. Comparison of the Physiological Conditions of the Patients in the Two Groups. The two groups of patients were subjected to immunohistochemical tests, and the representative results were selected for display shown in Figure 4. In addition, the immunohistochemical results of the benign effusion group showed that there was a small amount of positive cells; namely, the overall degree of cell malignancy was not high; meanwhile the immunohistochemical results of the malignant effusion group indicated that the positive cells were abundant in the effusion; namely, the whole cells had the high degree of malignancy.

3.4. Comparison of PET-CT Image Registration Values between Clone Selection Algorithm and Genetic Algorithm. Figure 5 discloses that the average difference of the maximum value of the normalized mutual information of PET-CT image registration of the clone selection algorithm is small, with no statistically huge difference ($P > 0.05$). Furthermore, the registration time and mismatching times were lower than those of genetic algorithm, and the differences were statistically substantial ($P < 0.05$).

The lungs were further taken as the comparison objects. The pneumonia with pleural effusion and lung cancer with pleural effusion were selected as the examples of the benign and malignant effusion group, respectively, as shown in Figure 6. In the PET-CT image of benign effusion, it is shown that there were concentrated shadows of radioactive distribution in lymph nodes and the larger range of lesion, so that they were presumed to be infectious lesions, and pneumonia was diagnosed based on medical history. There was no obvious radioactive concentrated area in the PET-CT image of malignant effusion, so as to speculate to be lung cancer with lymph node metastasis and diagnose lung cancer combined with medical history.

3.5. The CT Values of the Patients in the Two Groups under Different Energies. The differences in CT of the patients from the two groups were compared under different energies, and the results are expressed in Figure 7. Under the low energy (40–60 keV), the CT values of the benign effusion group were 41.24 ± 18.45 HU, 31.75 ± 12.8 HU, and 25.78 ± 11.12 HU; and the CT values of the malignant effusion group were 0.96 ± 19.45 HU, 7.99 ± 12.48 HU, and 12.57 ± 11.22 HU, with a statistical difference between the two groups ($P < 0.05$). Under 70–120 keV, the CT values of the benign effusion group were 21.15 ± 6.27 HU, 18.11 ± 6.33HU, 15.99 ± 5.24 HU, 15.24 ± 8.45 HU, 15.02 ± 4.21 HU, and 14.71 ± 6.66 HU; the CT values of malignant effusion group were 15.82 ± 7.67 HU, 17.55 ± 10.63 HU, 19.33 ± 11.27 HU, 20.01 ± 9.67 HU, 20.14 ± 10.44 HU, and 21.98 ± 10.57 HU, and the difference between the two groups was not statistically dramatic ($P > 0.05$). Under 130–140 keV, the CT values of the benign effusion group were 14.11 ± 6.17 HU and 13.56 ± 6.54 HU, while the CT values of the malignant effusion group were 21.44 ± 11.66 HU and 21.97 ± 12.57 HU; thus, there was a statistical difference in the two groups ($P < 0.05$).

3.6. The Paired Base Substances of the Patients in the Two Groups. Figure 8 illustrates that the contents of lipid/water, water/iodine, and water/calcium in malignant effusion were sharply higher than the contents of benign effusion. What is more, the content of lipid/water in malignant effusion was 221.44 ± 189.45 g/L, while its content in the benign effusion was 201.45 ± 197.56 g/L; the contents of water/iodine in the malignant and benign effusion were 1024.69 ± 19.48 g/L and 1008.48 ± 18.27 g/L, respectively; and the contents of water/calcium in the malignant and benign effusion were 1027.87 ± 11.66 g/L and 1009.48 ± 9.21 g/L, respectively. Therefore, there was a statistical difference between the two groups ($P < 0.05$).

Figure 9 demonstrates that the diagnostic sensitivity, specificity, and AUC of malignant effusion were 95.5%, 92.6%, and 97.7%, respectively, when the lipid/water concentration was over 104.34 g/L; when the water/iodine concentration was more than 1024.22 g/L, the diagnostic sensitivity, specificity, and AUC of malignant effusion were 86.4%, 77.8%, and 79.8%, respectively; and the diagnostic sensitivity, specificity, and AUC of malignant effusion were 86.4%, 92.6%, and 86.7%, respectively, when the water/calcium concentration was greater than 1028.44 g/L.

4. Discussion

Serous cavity refers to the human chest, abdominal cavity, pericardial cavity, and so forth. Under normal conditions, only a small amount of fluid in the serous cavity provides lubrication and protection (the fluid in the pleural cavity <20 mL, the fluid in the peritoneal cavity <50 mL, and the fluid in the pericardial cavity 10–50 mL). However, the increased volume of fluid in the cavity leads to the occurrence of effusion under pathological conditions, which is called SCE. Once the disease is complicated by SCE, it often indicates the severity of the disease [12, 13]. Based on the causes of the effusion, the effusion can be divided into benign and malignant. The study of Sherman-Samis et al. (2019) showed that many common causes of benign SCE were decompensation of liver cirrhosis, cardiac insufficiency, renal function failure, tuberculosis, and nonspecific inflammation. However, malignant SCE often existed in the late stages of various malignant tumors. This was because the blood vessels and lymph vessels were invaded by malignant tumor, or lymph nodes metastasis was to hinder the backflow and absorption of SCE; or tumor cells directly invaded blood vessels to increase the capillary permeability [14]. It was consistent with the pathological detection results of the study. The gold standard for diagnosing malignant effusion is to find tumor cells in SCE, but only when the malignant tumor invades the pleura or peritoneum or directly falls off in the effusion will a positive result be obtained. Moreover, its specificity is high, but the positive rate is low [15]. Das proved in a study that 58% was the positive rate of a single test in the pleural effusion. In addition, there was a false negative rate in the detection of malignant exfoliative cytology, and its sensitivity was only 40–60% [16]. Therefore, the PET-CT scanning detection proposed in the experiment plays an important role in assisting the diagnosis

of malignant effusion. It has great advantages in the diagnosis of tumors, and it can diagnose most tumors on the double-layer structure and functional metabolism through whole body imaging. What is more, it has very critical significance in finding the primary tumor lesion, and the nature diagnosis of patients with pleural and abdominal effusion is also relatively clear [17–19].

Harrison et al. summarized and sorted out the diseases that produced serous cavity effusion. The results illustrated that the main cause was malignant tumors in the chest and abdominal cavity, and pericardial effusion and tuberculosis also accounted for a large proportion, followed by connective tissue diseases, inflammatory infection, liver cirrhosis, heart function failure, hypothyroidism, and nephrotic syndrome [20]. The results were similar to the results of the study. However, there are certain differences in details, which may be caused by too few samples in the study. The PET-CT imaging based on the artificial intelligence algorithm of clone selection injects a small amount of positron nuclide tracer into the human body. The commonly used tracer is PF-FDG, which is adopted to detect the distribution of these positron nuclides in various organs of the human body. CT is employed to display the physiological metabolism of the main organs of the human body and to accurately locate, thereby fusing images. In this study, the clone selection algorithm was used to find that the registration time and mismatching times were both low, which achieved the optimal registration of PET-CT images and improved the accuracy of imaging results [21–23]. Zaucha et al. [24] stated that PET-CT was of great significance in finding primary tumor lesions and was more accurate in the diagnosis of patients with pleural and ascites effusion. It was also consistent with the experimental results of the study, showing that it is more sensitive to the diagnosis of malignant tumors. The paired base substances of lipid (water), water (iodine), and water (calcium) contents were selected for analysis, because the range of substances commonly used in medicine from fat to iodine contrast agents was included [25]. Knorr et al. have proved that free fatty acids in malignant ascites were 3 times higher than those in liver cirrhosis, and both saturated and unsaturated fatty acids in malignant ascites were higher than those in liver cirrhosis [26]. This is because fatty acids are the energy substrate for tumor cell metabolism, and malignant effusion contains dense and abundant tumor cells, which grow and metabolize vigorously, so lipids increase in malignant ascites [27–30]. It was reflected in the results of the study, indicating that the liquid concentration of the malignant effusion was higher than that of the benign effusion.

5. Conclusion

In this study, there was an investigation on the effect of PET-CT imaging detection image information and data information based on clone selection artificial intelligence algorithm in the diagnosis of serous cavity effusion in patients with different types of tumors. Besides, it was analyzed according to benign effusion and malignant effusion. It was found that the registration time and the times of mismatching of PET-CT images under the clone selection algorithm were both low, and the optimal registration of PET-CT images was realized. The image results indicated that benign and malignant serous cavity effusion could not be distinguished by CT values of routine mixed energy and 70–80 keV single energy (equivalent to mixed energy), while the CT value of low energy (40–60 keV) image played a critical role in the identification of benign and malignant effusions. However, the overall sample size of this study is small, and only relevant analysis for benign effusion and malignant effusion does not analyze many other clinical factors and the prognosis of patients. In the future, the sample size will be expanded to conduct more in-depth and comprehensive research and exploration in this direction. In short, PET-CT based on the artificial intelligence algorithm of clone selection has important diagnostic value in unexplained serous cavity effusion and has high sensitivity, specificity, and accuracy in the diagnosis of malignant pleural effusion.

Retracted: Application of Clavien–Dindo Classification System for Complications of Minimally Invasive Percutaneous Nephrolithotomy

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

In addition, our investigation has also shown that one or more of the following human-subject reporting requirements has not been met in this article: ethical approval by an Institutional Review Board (IRB) committee or equivalent, patient/participant consent to participate, and/or agreement to publish patient/participant details (where relevant).

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

Objective. To investigate the clinical applications of the Clavien–Dindo classification system (CDCS) in the assessment of perioperative complications in minimally invasive percutaneous nephrolithotomy (MPCNL). *Methods*. Totally, 390 patients with renal stones in our hospital from March 2015 to March 2020 were included for this study and then were divided into observation group (complication group, 78 cases) and control group (noncomplication group, 312 cases) according to the incidence of perioperative complications in CDCS. Single factor analysis and multivariate logistic regression analysis were used to analyze the risk factors of the perioperative complications of MPCNL. *Results*. The total incidence of complication in the 390 cases with MPCNL was 20.00% (78 cases) according to CDCS, among which the incidence of complications at grades I, II, III, IV, and V was 6.92% (27 cases), 8.21% (32 cases), 2.82% (11 cases), 1.79% (7 cases), and 0.26% (1 case), respectively. The proportion of patients, that aged >60 years, complicated with comorbidities, sophisticated calculi, the preoperative albumin level (<35 g/L), the operation time (>180 minutes), intraoperative bleeding volume (>300 mL), and hospitalization time (>7 days) in the observation group was significantly higher than that in the control group ((75.64% vs. 61.86%, 38.46% vs. 24.36%, 83.33% vs. 69.55%, 83.33% vs. 69.55%, 70.51% vs. 30.76%, 53.85% vs. 36.54%, and 60.26% vs. 43.27%), all $P < 0.05$). Multivariate logistic regression analysis showed that gender, associated comorbidities, preoperative albumin level, calculus complexity, operation time, and intraoperative bleeding volume (>300 mL) were correlated with the occurrence of complications ($P \leq 0.001$, 0.001, 0.001, 0.001, 0.003, and 0.001 respectively). *Conclusion*. The CDCS can give standard and more comparative criteria for the assessment of perioperative complications, which will provide reference data for reducing complications and ensuring safety profiles in these high-risk patients.

1. Introduction

Renal stones were one of the most common diseases in the urinary system, and it often occurs in the young and the middle-aged people; the morbidity was higher in males than females [1, 2]. Studies showed that, about 40% to 75% of patients with renal stones underwent different degrees of back pain, which is often taken as the primary clinical manifestation to visit doctors [3]. At the early stage, patients with small diameter stones and mild symptoms can alleviate the illness by drinking lots of water and physical exercises or other conservative treatments [4, 5]. However, with the influence of the patient's diets, environmental conditions, and other factors, the diameter of renal stones will be gradually enlarged in some people; consequently, the frequency and duration time of pain will increase, and hematuresis, hydronephrosis, or urinary tract obstruction would be found in some serious patients [6, 7]. When conservative treatment does not work for kidney stones, procedures such as transurethral ureteroscopic lithotripsy, percutaneous nephrolithotripsy, and laparoscopic ureterolithotripsy are often considered alternatives to conservative treatment. [8, 9].

Minimally invasive percutaneous nephrolithotomy (MPCNL) is a most common operation in urology, which was modified on the basis of percutaneous nephrolithotomy.

MPCNL had the advantage of small trauma, high discharging rate, rapid recovering course, and so on. MPCNL was effective for renal stones, but the complications in the perioperative period did not receive enough attention compared with its clinical efficacy. And, the evaluation of complications was usually based on operator's experience, but lacked consistent criteria [10]. How to carry out quantitative evaluation and reduce the incidence of perioperative complications in MPCNL are becoming surgical hotspots. In order to investigate the criteria of standardized assessment and the risk factors of the complications of MPCNL, 390 patients with renal stones from March 2015 to March 2020 in our hospital were collected in the study, and the Clavien–Dindo classification system (CDCS) was adopted to analyze the perioperative complications.

2. Patients and Methods

2.1. Patient Data. Totally, 390 patients with renal stones who underwent MPCNL from March 2015 to March 2020 in our hospital were collected, including 254 males and 136 females; aged from 40 to 70 years; 274 urban patients and 116 rural patients; 156 patients with diabetes, hypertension, chronic bronchitis, or other general comorbidities, and 234 patients without comorbidity; and 255 patients with simple renal stones and 135 patients with complex renal stones [11] (including stone diameter >25 mm, horn-like or multiple renal stones, stones that are difficult to remove caused by abnormal anatomy, etc.).

2.2. Surgical Methods. Epidural anesthesia or general anesthesia with endotracheal intubation were performed in operation, these patients were performed or supervised by a single surgeon who had previous experience of MPCNL. All patients were placed in the lithotomy position with conventional sterilization of surgery area, and the surgical towels were placed. The 5 Fr or 6 Fr ureteral catheter was inserted to the target ureter directed by ureteroscopic vision. After uretheral catheter insertion, the patients were replaced in a prone position, and percutaneous access was achieved by fluoroscopic guidance using an 18–20-gauge needle. Patients were punctured under the direction of B ultrasound. Then, the ureteroscope (Richard wolf, Germany) was placed in the renal pelvis, and the holmium laser (Litho, Italy) was used to fragment renal stones. The stones were discharged under the pressure of the irrigation solution or were taken out with basket catheter. At the end of surgery, a nephrostomy tube was inserted and removed 1 week after surgery, the double *J* ureteral catheter was inserted into the renal pelvis and removed 1 month after surgery, and the operation time was calculated from the insertion of ureteral catheter to the placement of nephrostomy tube.

2.3. Classification Standards and Evaluation Methods. Perioperative complications were divided into grade I, II, III, IV, and V according to CDCS [12]. Grade I: the complications had mild impacts on patients' recovery, but there is no threat to the life of patients, and these antipyretics, analgesics, antiemetics, diuretics, and physical therapy were allowed to application. Grade II: on the basis of grade I, other kinds of drugs, blood infusion, or total intravenous nutrition were required. Grade III: surgery, endoscope, or radiotherapy were required, including grade IIIa and grade IIIb; grade IIIa did not require general anesthesia, which could be performed by surgical intervention directly; grade IIIb required to carry out general anesthesia. Grade IV: it includes grade IVa and grade IVb; the former one's complications having life threats to the patients, who showed single organ failure and needed ICU care, and the latter one manifested as multiple organ failure. Grade V: patients' death was caused by complications. The incidence of perioperative complications in patients was observed and recorded.

2.4. Statistical Analysis. The data were analyzed with SPSS22.0 statistical software; the measurement data was expressed as mean ± standard deviation ($\bar{x} \pm SD$) and analyzed by the *t*-test; the numerical data were expressed as n (%) and analyzed by chi-square (χ^2) test; the single factor analysis and multivariate logistic regression analysis were used to analyze the risk factors of MPCNL complications; and P value <0.05 was considered to be statistically significant.

3. Result

3.1. Comparison of the Incidence of Complications of CDCS in MPCNL. According to CDCS, totally there were 390 cases in MPCNL complications; the cases of grade I, II, III, IV, and V complications were 6.92% (27 cases), 8.21% (32 cases), 2.82% (11 cases), 1.79% (7 cases), and 0.26% (1 case), respectively. Among these complications, the proportion of cases with fever (body temperature ≧ 39°C) was the largest (4.87%), the complications within grade III were 70 cases (89.74%), mainly including urinary infections and blood transfusion caused by intraoperative bleeding, and the proportion of infection and blood transfusion was 4.10% and 3.08%, respectively; there was 1 patient who died of acute myocardial infarction. The results are shown in Table 1.

3.2. Comparison and Analysis of Clinical Data in Two Groups. There were no significant differences in gender, BMI, demographic characteristics, and anesthesia between the two groups ($P > 0.05$). Age (>60 years), associated comorbidities, preoperative albumin level (<35 g/L), stone complexity, operation time (>180 min), intraoperative bleeding volume (>300 ml), and hospital stays (>7 days) of the observation group (complication group) were significantly higher than that of the control group (noncomplication group). The results are shown in Table 2.

3.3. Multivariate Logistic Regression Analysis of Complications. 78 patients with complications of MPCNL in perioperation were analyzed by multivariate logistic regression analysis, the results demonstrated that age (>60 years), associated comorbidities, preoperative albumin levels

Table 1: Comparison of CDCS of MPCNL complication in 390 patients (n (%)).

Grade	Complications	Incidence rate
Grade I		27 (6.92%)
	Body temperature ≧39°C	19 (4.87%)
	Increase of CCR, (alanine aminotransferase) ALT	5 (1.28%)
	Application of analgesic drugs	3 (0.77%)
Grade II		32 (8.21%)
	Blood transfusion caused by intraoperative bleeding	12 (3.08%)
	Urinary infections	16 (4.10%)
	Perirenal effusion	4 (1.03%)
Grade IIIa		8 (2.05%)
	Urinary tract obstruction	3 (0.77%)
	Closed drainage of thoracic cavity	2 (0.51%)
	Embolization of renal artery caused by bleeding	1 (0.26%)
	Renal pelvis perforation	1 (0.26%)
Grade IIIb		3 (0.77%)
	Renal abscess	2 (0.51%)
	Unilateral nephrectomy	1 (0.26%)
Grade IVa		6 (1.54%)
	Myocardial infarction	2 (0.51%)
	Cerebral stroke	2 (0.51%)
	Colonic injury	1 (0.26%)
	Acute renal failure	1 (0.26%)
Grade IVb		1 (0.26%)
	Shock	1 (0.26%)
Grade V		1 (0.26%)
	Death	1 (0.26%)

	General anesthesia	24 (30.77%)	111 (35.58%)		

Table 3: Results of multivariate logistic regression analysis of Clavien–Dindo classification of complications in perioperation.

Items	B	Sb	Wald	P	OR	95%CI
Age	1.082	0.075	205.618	≤0.001	1.142	0.985–3.420
Associated comorbidities	0.983	0.185	28.264	≤0.001	1.125	0.783–3.8404
Preoperative albumin levels	2.465	0.317	60.279	≤0.001	4.412	2.398–21.917
Stone complexity	2.146	0.224	92.159	≤0.001	3.126	2.017–13.252
Operation time	1.017	0.126	65.052	0.003	2.562	2.001–3.540
Intraoperative bleeding volume	2.016	0.220	83.936	≤0.001	3.765	2.446–11.557

(<35 g/L), the stone complexity, the operation time (>180 min), and intraoperative bleeding volume (>300 ml) were associated with complications in patients by Claivien–Dindo classification. The results are shown in Table 3.

4. Discussion

Currently, MPCNL is one of the most common clinical treatments for renal stones. Percutaneous renal channel is F16 ~ F20, which is far less than the traditional Fr 24 ~ Fr 34. Thus, MPCNL can greatly shorten the area of the incision, reduce surgical injury, and increase the stone discharging rate. Some previous studies have reported that MPCNL promoted clinical efficacy, while some new complications appeared, which can lead to the increasing trend of total incidence rate of complications [13, 14]. CDCS began to be applied for clinical assessment of complications, with the improvement and update of CDCS in past decades, and surgical complications can be more detailed, reasonable, and objective to evaluate [15].

One researcher [16] analyzed the perioperative complications of 172 stone patients undergoing MPCNL using CDCS and showed that the overall incidence of complications was almost as high as 30%, with 9.88%, 6.98%, 7.56%, 3.49%, and 0.58% of class I, II, III, IV, and V complications, respectively. Nevertheless, the total incidence of complication of this study was 20.00% (78/390), and the incidence of complication of grade I, II, III, IV, and V were 6.92% (27/390), 8.21% (32/390), 2.82% (11/390), 1.79% (7/390), and 0.26% (1/390), respectively. The total incidence of complications and the complications of grade III and IV were reduced, and the possible explanations may be related to the differences of surgeons' experience and improvements in technology and equipments. Zeng et al. [17] adopted the CDCS to classify the perioperative complications of 377 patients in MPCNL, and the results showed that the associated comorbidities, stone complexity, and urinary abnormal anatomy were closely correlated with occurrence of perioperative complications. In this study, part of the results was similar as the results of Zeng et al [17]; moreover, our results agreed that the age, preoperative albumin levels, operation time, and intraoperative bleeding volume were the risk factors of perioperative complications of stones in patients.

In this study, the major complications in MPCNL were fever, infections, and bleeding within grade III of CDCS, which were the most common three adverse reactions, but grade IV~V of CDCS were major threats to the life security of patients. Therefore, the analysis of factors related to the occurrence of complications of CDCS can provide reference data for the managements of preoperative assessment and surgical scheme. According to the results of multivariate logistic regression analysis, the possible reasons may be explained in terms of these risk factors. Firstly, patients with age >60 years were often complicated with one or more comorbidities, and this will result in the decrease of coagulation function, body organic function, and surgical tolerance [18, 19]. Secondly, albumin is the common protein in plasma, which can reflect the condition of liver function and body immunity at a certain extent [20], and once the liver function was impaired, albumin levels were also reduced; meanwhile, there were obstacles in coagulation function and body immunity. Thirdly, urinary abnormal anatomy, large size stones, and complex location stones will increase the difficulties of fragmenting and discharging of stones [21, 22]. Lastly, the longer operation time and wound exposure time will increase the risk of bacterial infections and the volume of bleeding, and these risk factors mentioned above were influenced each other and increased the probability of complications, and made an interactive effect to deteriorate the safety profiles on patients [23].

In this study, several viewpoints must be presented for prevention and management of complications in MPCNL. If severe skeletal deformities, urinary abnormal anatomy, or hydronephrosis were not obvious, puncture should be performed under the B ultrasonic or C-arm on necessity of avoiding the main blood vessels. Once the main renal blood vessels injured and large bleeding appeared, nephrostomy tube should be immediately closed, and immediate hemostasis must be taken [24, 25]. Referring to elderly patients with poor nutritional status or complicated with several comorbidities, the related examinations and preassessment should be well performed before operation [18]. In this study, one patient died of acute myocardial infarction, which reminded urologists that they must carry out more rigorous preoperative assessment for these elderly patients complicated with comorbidities.

In conclusion, the CDCS can give standard and more comparative criteria for the assessment of perioperative complications in MPCNL, and the urologists should pay more attention to these high-risk factors, which will provide reference data to ensure surgical safety and promote the clinical efficacy.

Academic Editor: Enas Abdulhay

This study aimed to analyze the effect of the deep learning algorithm on ultrasound elastography on the treatment of cervical cancer with clustered regularly interspaced short palindromic repeats (CRISPR) short hairpin ribonucleic acid (shRNA) nanoparticles, aiming to provide a reference for the clinical application of deep learning to analyze the therapeutic effect of the disease. In this study, CRISPR and shRNA plasmid nanoparticle drugs were used to treat 55 patients with cervical cancer in the experimental group, and normal saline was injected to another 53 patients in the control group, so compare the effect of nanoparticles in the treatment of cervical cancer. Professional doctors and the recurrent neural network (RNN) intelligent algorithm were used to score cervical cancer based on the ultrasound elastograph images by taking blue, green, and red (BGR) as diagnosis criteria. As a result, the experimental group had a total of 217 points before drug administration and a total of 224 points after drug administration. Each patient had an average increase of 0.13 points. The control group had a total of 200 points before drug administration and a total of 223 points after drug administration, and each patient had an average increase of 0.43 points. The experimental group was obviously different from the control group ($P < 0.05$). Each tissue image output by the RNN was clearer than the original image, and the score given by intelligent calculation was faster than that of professional doctors. The monitoring effect of the deep learning RNN intelligent algorithm on the therapeutic effect of nanomedicine was analyzed. It was found that the average accuracy of the experimental group and the control group was 98.95% and 90.34%, respectively; and the experimental group was greatly different from the control group ($P < 0.05$). In short, nano-CRISPR and shRNA drugs had remarkable effects on the treatment of cervical cancer, and the scores given by the deep learning intelligent algorithm were faster and more accurate, which provided theoretical guidance for the clinical application of deep learning algorithms to analyze the treatment effects of diseases.

1. Introduction

Cervical cancer is a common gynecological malignant tumor [1]. Carcinoma in situ is concentrated in the age of 30–35, and invasive cancer is concentrated in the age of 45–55. There is a trend of younger generation. With the development of imaging, examinations are becoming more and more common, enabling early detection and early treatment of cervical cancer, and its mortality significantly decline [2]. The etiology is related to viral infection, sexual behavior, number of childbirths, and other factors. Cervical smear cytology is the main method of cervical cancer screening. Others include the cervical iodine test and colposcopy. However, in some economically underdeveloped areas, early screening for cervical cancer is not universal, and women who have been vaccinated against human papillomavirus (HPV) are still at risk of getting the disease. Therefore, it is necessary to study a new type of drug to treat HPV to achieve the purpose of reversing cervical tissue lesions.

In recent years, with the development of the material field, nanomedicine has been widely reported in the treatment of cervical cancer. CRISPR is a repetitive sequence in the genome of prokaryotes, which can integrate its own genes into the genes of bacteria, and bacteria have evolved the CRISPR-Cas9 system to understand foreign genes [3]. It can make the genome more effective to produce changes or mutations, and the efficiency is higher than other gene editing techniques, but it may produce a large number of accidental targets in human cancer cells [4]. shRNA has two short inverted repeats, separated by a stem-loop sequence to form a hairpin structure [5]. When small interfering RNA is delivered in vivo, the siRNA sequence is cloned into a plasmid vector as a short hairpin; when it is delivered to an animal body, the hairpin sequence is expressed to form double-stranded RNA and processed by the RNAi channel. Transfection of cervical cancer tissue with nanoparticles containing clustered regularly interspaced short palindromic repeats (CRISPR) and short hairpin RNA (shRNA) plasmids can effectively inhibit the growth of cervical cancer cells [6].

Ultrasound-assisted elastography (ETE) can be roughly divided into two categories: intravascular elastography and tissue elastography, which can be used to analyze the therapeutic effect of cervical cancer [7]. Deep learning is a new research direction in the field of machine learning; it has achieved results in speech and image recognition, search technology, data mining, machine learning translation, and other related fields and has solved many complex pattern recognition problems and made great progress in artificial intelligence-related technologies [8]. The recurrent neural network (RNN) is one of the common deep learning algorithms. The RNN takes sequence data as input, recursively in the evolution direction of the sequence, and all nodes (cyclic units) are connected in a chain [9]. In this study, 108 patients with cervical cancer were randomly divided into an experimental group with 55 patents treated with CRISPR and shRNA plasmid nanoparticle drugs and a control group with 53 patients treated with the same amount of normal saline. The ultrasound elasticity of the two groups before and after administration was collected. In addition, the imaging results were compared to analyze the effect of CRISPR shRNA nanoparticles in the treatment of cervical cancer, aiming to provide data support and theoretical guidance for the clinical diagnosis and treatment of cervical cancer.

2. Materials and Methods

2.1. Research Objects and Their Grouping. In this study, 108 cervical cancer patients diagnosed by colposcopy biopsy in the hospital from January 2018 to January 2020 were selected as the research objects, with an average age of 43.2 ± 8.9 years old. 55 cases were randomly selected as the experimental group, and the remaining 53 cases were undertaken as controls. This study had been approved by the ethics committee of the hospital, and the patients and their families had understood the content and methods of the study and agreed to sign the corresponding informed consents.

The inclusion criteria were defined as follows: patients whose age was between 18 and 65, patients who were diagnosed with cervical cancer after clinical diagnosis, patients who had not received other drug treatment recently, patients had not received chemotherapy and radiotherapy, and patients who had no history of other treatments in the reproductive system.

The exclusion criteria were defined as follows: patients who had undergone tumor resection, patients with incomplete clinical data, and patients who did not cooperate with doctors throughout the treatment.

2.2. Nanoparticle Preparation and Drug Administration of CRISPR and shRNA. The poly β-amino ester (PBAE) and CRISPR/shRNA plasmid DNA were diluted in 25 mM of (pH = 5) sodium acetate solution. According to the different mass ratio (PBAE to plasmid), the PBAE solution was added dropwise to the same volume of the plasmid-containing solution and mixed gently for 30 seconds. The mixture was allowed to stand at room temperature for 15 minutes to completely synthesize PBAE/nanoparticles of plasmid deoxyribonucleic acid (DNA). 1% pentobarbital solution was intraperitoneally injected. The synthesized nanoparticles (containing 10 ug of plasmid) were injected into the vagina of patients with cervical cancer in the experimental group. Among the 55 cases in the experimental group, 25 cases were injected with PBAE/CRISPR plasmid DNA nanoparticle drugs, and 30 cases were injected with PBAE/shRNA plasmid DNA nanoparticle drugs, once a day for 20 days. The control group was injected with the same amount of normal saline, and then, the changes in the ultrasound elastography scores of the experimental group were observed.

2.3. Ultrasound Elastography. All patients underwent ultrasound elastography examination after vaginal ultrasound examination. The probe was moved to the cervix to observe the size of the cervix, the capsule, the characteristics of the gray-scale ultrasound, and the blood flow velocity of the cervix. Then, the probe was moved to the vaginal fornix and lightly attached to the external cervix for testing, the duration was 3–5 s, and the color coding ranged 0–180 kPa. The measurement should be repeated for 3 times to record and calculate the average of each group of data. All images were completed by an experienced professional imaging physician.

2.4. RNN under Deep Learning Algorithm. Convolutional neural network (CNN) models are widely used in image classification. Among them, the network neurons in the same layer are not independent of each other, but have a certain correlation. In the RNN model, the convolutional layer is built by combining the single-loop neural network and the convolutional layer, and the sampling layer is consistent with the same output layer. A simple RNN consisted of an input layer, a hidden layer, and an output layer. Its dynamic system had an input dynamic system and an input dynamic system, as shown in Figure 1. The equations of the dynamic system without input are (1) and

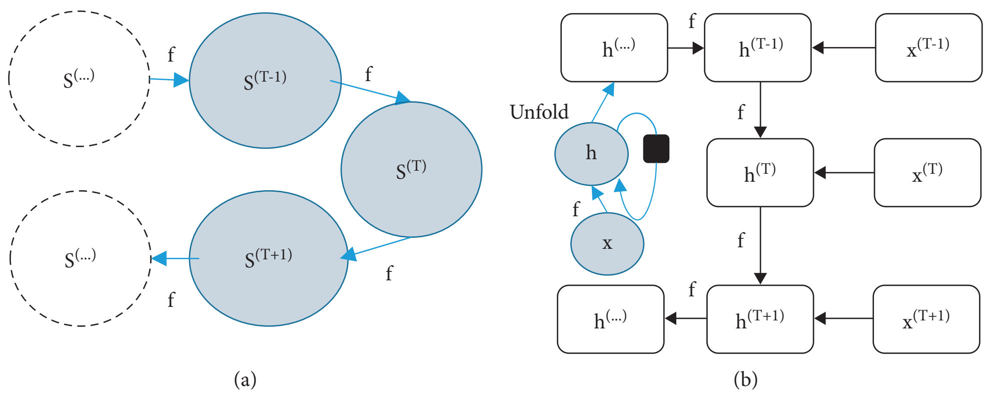

Figure 1: Dynamic system diagram. (a) A dynamic system without input. (b) A dynamic system with input.

(2); the equations for the dynamic system with input are (3) and (4). f represents the unit operation, the final state of the dynamic system with input is represented as h, the final state of the dynamic system without input is represented as S, X represents the input, T represents the state of the unit, T+1 and T–1 represent the increase or decrease of the unit state, and the ellipsis indicates the follow-up process can continue to run as such.

$$\begin{aligned} S^{(T)} &= f\left(S^{(T-1)};\theta\right),\\ S^{(3)} &= f\left(S^{(2)};\theta\right) = f\left(f\left(S^{(1)};\theta\right);\theta\right),\\ h^{(T)} &= f\left(h^{(T-1)}, X^{(T)};\theta\right),\\ h^{(T)} &= g^{(T)}\left(X^{(T)}, X^{(T-1)}, X^{(T-2)},\ldots, X^{(2)}, X^{(1)}\right)\\ &= f\left(h^{(T-1)}, X^{(T)};\theta\right). \end{aligned} \tag{1}$$

The following RNN algorithm was proposed by Hinton in 2015 [10], which uses ReLU to activate neurons and initializes the weights of the entire network to make the final model effect better than most existing algorithms. The location of the forget gate in the algorithm flowchart is shown in Figure 2, and the red circle area is shown in equation (2). f represents the internal unit operation, t represents the state of the unit, the unit operation on the state is defined as function f_t, A and Tanc represent the inputs of the vector, the final state of the forget gate is represented as h, the final state of the input gate is expressed as i, the final state of the total input is represented as C, O refers to the final state of the output gate, and T-1 represents the reduction of the unit state.

$$f_t = A\left(W_{fx}x_t + W_{Th}h_{t-1} + b_f\right). \tag{2}$$

The input gate positioning in the algorithm flowchart is shown in Figure 3 (the red circle area), and the equations are given as follows:

$$\begin{aligned} C'_t &= Tanh\left(W_{cx}x_t + W_{ch}h_{t-1} + b_c\right),\\ i_t &= A\left(W_{ix}x_t + W_{Th}h_{t-1} + b_i\right). \end{aligned} \tag{3}$$

The total input positioning in the algorithm flowchart is shown in Figure 4 (the red circle area) and equation (4).

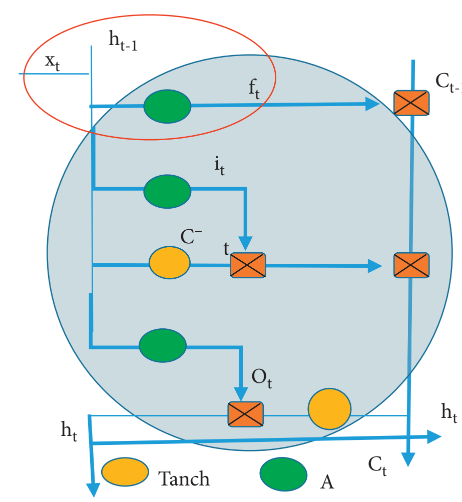

Figure 2: Diagram for location of the forgotten gate.

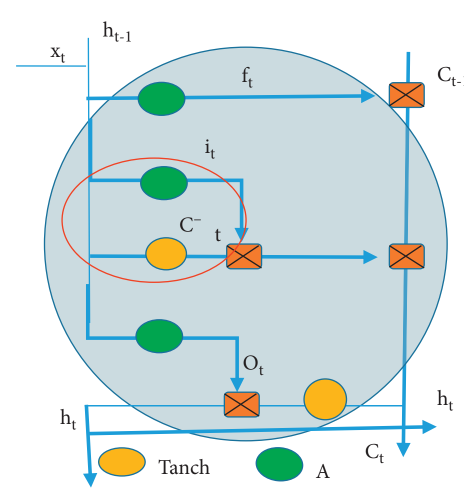

Figure 3: Diagram for location of the input gate.

$$C_t = f_t * C_{t-1} + i_t * C'. \tag{4}$$

The location of the output gate in the algorithm flowchart is shown in Figure 5 (the red circle area) and equations (5) and (6).

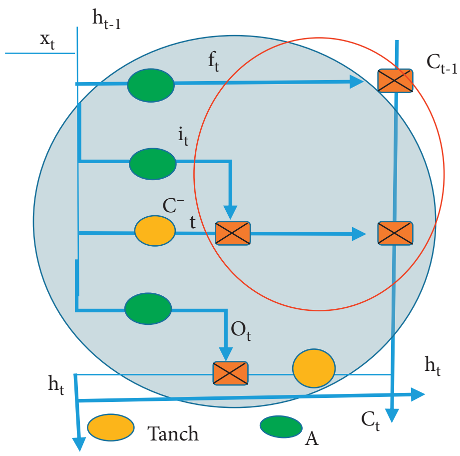

Figure 4: Diagram for location of the total input.

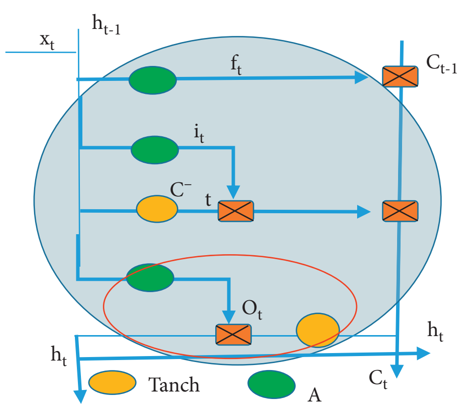

Figure 5: The location of the output gate in the algorithm flowchart.

$$o_t = A\left(W_{ox}x_t + W_{oh}h_{t-1} + b_o\right), \tag{5}$$

$$h_t = o_t * \mathrm{Tanh}\left(C_t\right)(f). \tag{6}$$

2.5. The Treatment and Efficacy Evaluation. ETE image evaluation was given as follows. The elasticity diagram used different colors to represent the hardness of different tissues, in which red indicates the average hardness was softer and the tissue was softer, green indicates the average elasticity of the tissue, and blue indicates the average hardness was harder. Generally, in normal cervical imaging, the display is mostly blue and green, and a small part of it is red. The specific scoring method studied in this study was defined as follows. If blue, green, and red were visible and blue area was ≤50%, the score was 1 point; if blue and green alternated without red and the blue area was ≤50%, the score was 2 points; if blue and green were visible with no red and the blue area was 50%–70%, the score was 3 points; if the image display was mainly blue, with a small part of green and no red and the blue area was more than 70%, the score was 4 points; and if the entire area of the cervix was shown in uniform blue, the score was 5 points.

In order to quantitatively evaluate the performance of the algorithm in this study, three commonly used evaluation indicators in medical image segmentation were used as the standard to measure the results of this experiment. Accuracy represented the ratio of all correctly predicted pixels to the total number of pixels. The specific calculation method is shown in equation (7), where TP represents the number of true positive, FP represents the number of false positive, FN represents the number of false negative, and TN represents the number of true negative.

$$A = \frac{\mathrm{TP} + \mathrm{TN}}{\mathrm{TN} + \mathrm{TP} + \mathrm{FP} + \mathrm{FN}}. \tag{7}$$

2.6. Statistical Methods. The software used for data processing in this study was SPSS 19.0. For statistical analysis, measurement data were expressed as mean ± standard deviation ($\overline{x} \pm s$), and count data were expressed as percentage (%). Pairwise comparison used analysis of variance. $P < 0.05$ means the difference was statistically significant.

3. Results

3.1. The Therapeutic Effect of CRISPR and shRNA Plasmid Nanoparticles on Cervical Cancer. As shown in Figure 6, 25 image scores of CRISPR nanoparticles before the drug administration were randomly selected, including 1 patient with 1 point, 2 patients with 2 points, 3 patients with 3 points, 12 patients with 4 points, and 7 patients with 5 points. After drug administration, there were 0 patient at 1 point, 1 patient at 2 points, 2 patients at 3 points, 13 patients at 4 points, and 9 patients at 5 points.

As shown in Figure 7, 30 cases of imaging scores before shRNA nanoparticle drug administration were randomly selected from the experimental group; there were 1 patient with 1 point, 3 patients with 2 points, 4 patients with 3 points, 14 patients with 4 points, and 8 patients with 5 points; after drug administration, there was 1 patient at 1 point, 2 patients at 2 points, 3 patients at 3 points, 15 patients at 4 points, and 9 patients at 5 points.

As shown in Figure 8, the image scores of the control group before drug administration were 3 patients at 1 point, 6 patients at 2 points, 5 patients at 3 points, 25 patients at 4 points, and 14 patients at 5 points. After drug administration, there were 2 patients at 1 point, 1 patient at 2 points, 2 patients at 3 points, 27 patients at 4 points, and 21 patients at 5 points.

As shown in Figure 9, the experimental group had a total of 217 points before drug administration and a total of 224 points after drug administration, with an average increase of 0.13 points per patient, and the control group had a total of 200 points before drug administration and a total of 223 points after drug administration, with each patient having an average increase of 0.43 points. Therefore, the experimental group was greatly different from the control group ($P < 0.05$).

3.2. Image Analysis of Ultrasound Elastography under RNN. Figure 10 shows a traditional ultrasound image of three random patients. The image was not in color. It can roughly

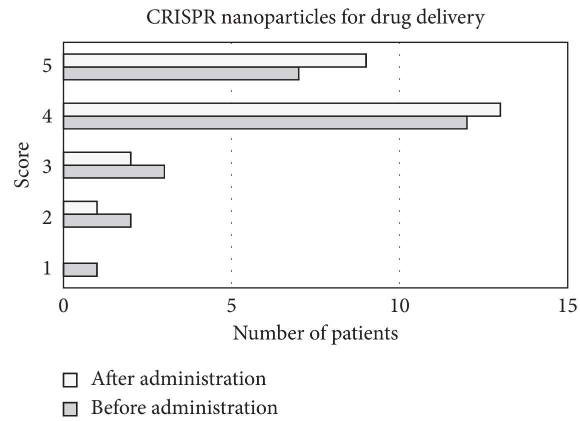

Figure 6: The CRISPR nanoparticles drug administration score for patients in the experimental group.

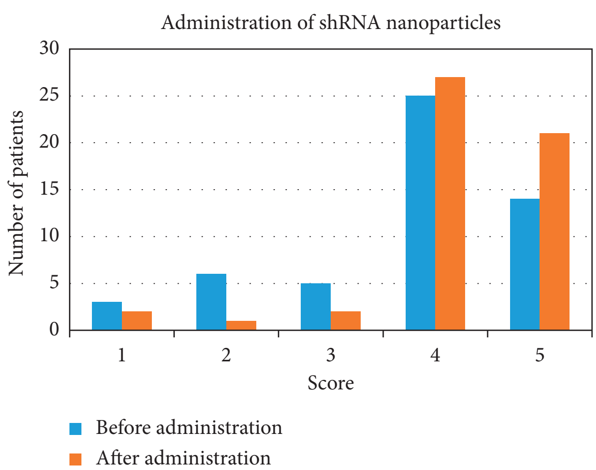

Figure 7: The drug administration score of shRNA nanoparticle of the experimental group.

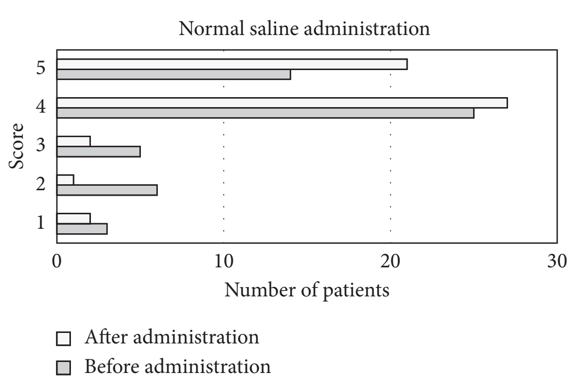

Figure 8: The scoring of drug administration with normal saline in the control group.

analyze cervical cancer qualitatively, but it was difficult to analyze cervical cancer quantitatively. With the development of technology, ultrasonic elastic imaging can simultaneously perform qualitative and quantitative analyses of cervical cancer.

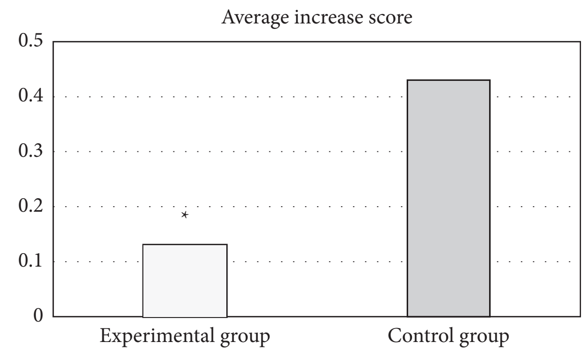

Figure 9: The scoring of drug administration with normal saline in the control group. *The difference was statistically great in contrast to the control group ($P < 0.05$).

Figure 11 shows the analysis process of the algorithm's influence on ultrasound elastography. The following figure is the image of five random patients, and A, B, C, D, and E in the figure refer to five different scores of 1–5, respectively. Figures A1, B1, and C1 are the original images of ultrasonic elastic imaging, and different colors represent tissues of different hardness. Figures A2, B2, and C2 show tissue images output by the deep learning algorithm based on the original ultrasound elastography image. Compared with the original image, the hardness of the tissue can be clearly distinguished. Figures A3, B3, and C3 show the blue area of the hardness output by the deep learning algorithm. The score was given through the calculation of the intelligent algorithm. Compared with professional doctors, this method was faster and more accurate.

The scores given by professional doctors and RNN intelligent algorithms were compared to analyze the monitoring effect of deep learning on the therapeutic effect of nanomedicine. Each test was performed three times, as shown in Figure 12. The data showed that the accuracy of the experimental group was 98.76%, 99.13%, and 98.96% for three times, respectively, and that for the control group was 89.43%, 91.15%, and 90.45%, respectively.

As shown in Figure 13, the average accuracy of the experimental group was 98.95%; the average accuracy of the control group was 90.34% and that in the experimental group was greatly different from that in the control group ($P < 0.05$).

4. Discussion

Persistent high-risk HPV infection is the main risk factor for cervical cancer. Even if the HPV vaccine has been vaccinated, the risk of other high-risk HPV infections faced by women still exists. Although the HPV vaccine can stimulate the body to produce antibodies to avoid infection, its therapeutic effect is minimal for women who already have cervical disease. Cervical screening can also be done on a regular basis, but in some economically underdeveloped areas, this type of examination is not universal and easy to achieve. Therefore, considering the actual needs of patients threatened by the HPV virus, this study combined PBAE and

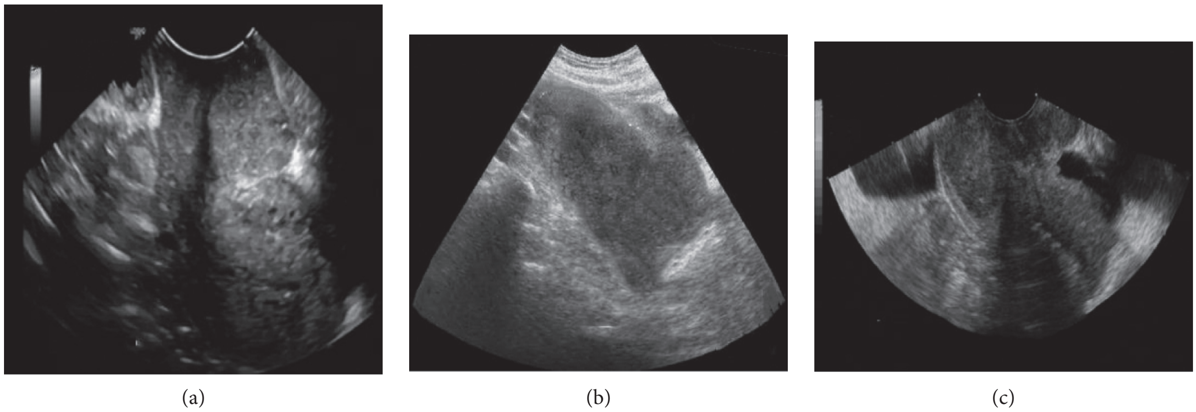

Figure 10: Traditional ultrasound image of cervical cancer. (a) An image of the early symptoms of cervical cancer. (b) The uterine cavity is closed and the periphery of the cervical lesion is blurred. (c) The cervical lesions are visible.

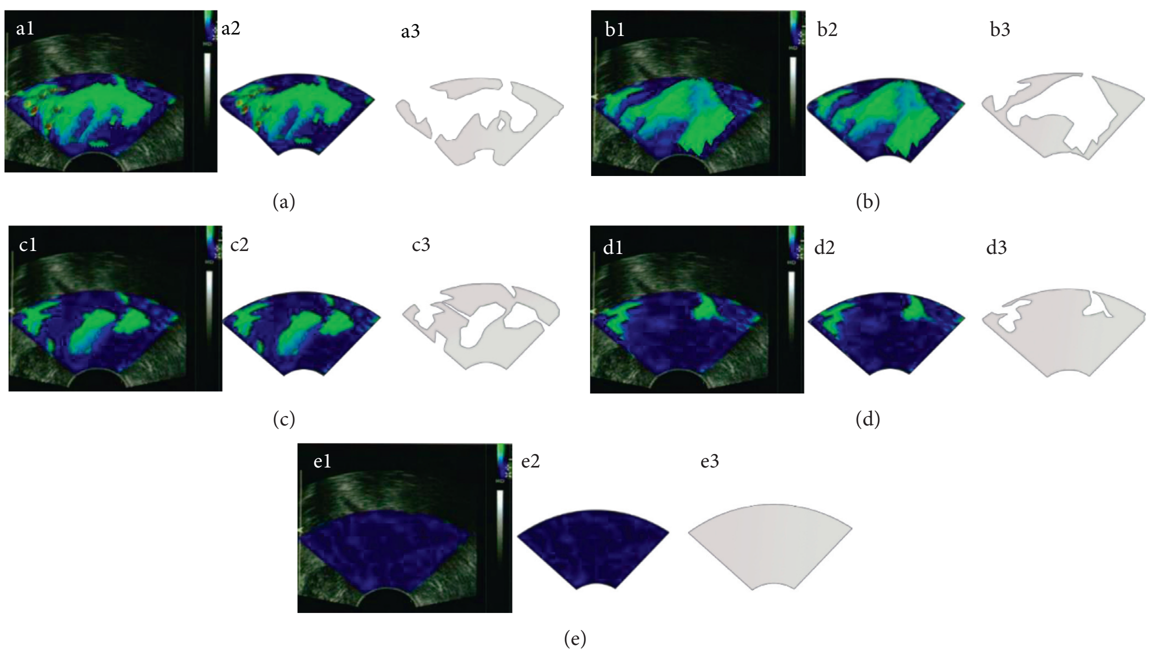

Figure 11: Diagram of ultrasonic elastic imaging analysis under the deep learning algorithm.

CRISPR shRNA to design a nanoparticle drug. In the field of molecular biology today, the silencing technology represented by shRNA can bind to mRNA encoding the protein at the mRNA level, so that the gene can be specifically degraded [11]. Knockout technology represented by CRISPR uses double-stranded DNA cutting and mismatch repair to prevent specific genes from achieving normal transcription and translation at the DNA level [12, 13]. Since these functional plasmids cannot penetrate the body's organs and tissues by themselves, an appropriate carrier system is needed [14]. In this study, PBAE with low toxicity, good degradability, high transfection efficiency, and excellent stability was used to complete plasmid delivery. It has currently shown good efficacy in the clinical treatment of some cancers.

Ultrasound-assisted elastography technology can detect tumors and spreading diseases that cannot be detected by traditional ultrasound and is an important imaging method to analyze and detect the therapeutic effect of cervical cancer [15, 16]. The RNN is one of the common deep learning algorithms. It is a type of algorithm that takes sequence data as input and recursively in the direction of sequence evolution, its nodes are connected in a chain, and it is featured with memory, parameter sharing, and Turing completeness [17, 18]. It has great advantages when learning the nonlinear features of the sequence. Under its optimization, ultrasound elastography can monitor the effect of disease treatment more accurately [19]. In this study, 108 patients with cervical cancer were selected and randomly divided into an experimental group with 55 patients treated with CRISPR and

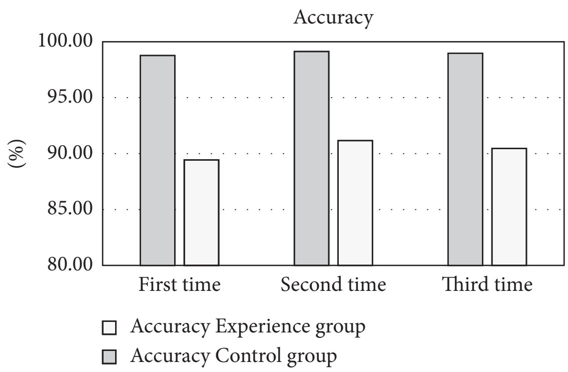

Figure 12: The comparison on accuracy in the experimental group and the control group.

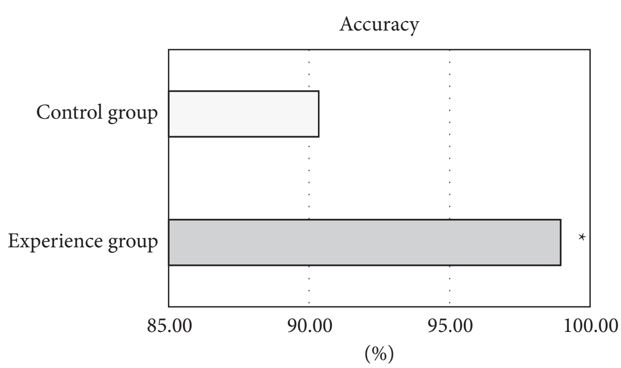

Figure 13: Comparison on average accuracy between the experimental group and the control group. *The difference was statistically great in contrast to the control group ($P < 0.05$).

shRNA plasmid nanoparticle drugs and a control groups (53 patients) treated with the same amount of normal saline. The ultrasound elastography image results before and after the administration of the two groups were collected and compared to analyze the effect of CRISPR shRNA nanoparticles in the treatment of cervical cancer, aiming to provide data support and theoretical guidance for the clinical diagnosis and treatment of cervical cancer. The results showed that the experimental group had a total of 217 points before drug administration and a total of 224 points after drug administration. Each patient had an average increase of 0.13 points. The control group had a total of 200 points before drug administration and a total of 223 points after drug administration. Each patient had an average increase of 0.43 points. Therefore, the experimental group was significantly different from the control group ($P < 0.05$). Each organization chart output by the RNN algorithm was clearer than the original image, and the score given by intelligent calculation was faster than that of professional doctors. The monitoring effect of the deep learning RNN intelligent algorithm on the therapeutic effect of nanomedicine was analyzed, it was found that the average accuracy of the experimental group and control group was 98.95% and 90.34%, respectively, and the experimental group was significantly different from the control group ($P < 0.05$). Such results were consistent with the research conclusions of Zhu et al. [20]. Nano-CRISPR and shRNA drugs are effective in the treatment of cervical cancer. Nano-CRISPR and shRNA drugs have significant effects on the treatment of cervical cancer, and the scores given by the deep learning intelligent algorithm are faster and more accurate, which can provide theoretical guidance for the clinical application of deep learning algorithms to analyze the treatment effects of diseases.

5. Conclusion

In this study, CRISPR and shRNA plasmid nanoparticle drugs were used to treat patients with cervical cancer, and the effects of nanoparticle treatment on cervical cancer were compared with those without drug treatment. In addition, the scores for cervical cancer were given by doctors and RNN intelligent algorithms to compare and analyze the monitoring effect of deep learning on the therapeutic effect of nanomedicine. The results suggested that nano-CRISPR and shRNA drugs can effectively inhibit the growth of cervical cancer cells and had a significant effect on the treatment of cervical cancer; each tissue image output by the deep learning algorithm was clearer and more identifiable, and the score given by the intelligent algorithm calculation was faster and more accurate. However, the sample size selected in this study was relatively small, which may have a certain impact on the final results of the experiment. Therefore, in future experiments, it is necessary to expand the sample size and further analyze and compare the effects of ultrasound elastography of deep learning algorithms on the treatment of cervical cancer with CRISPR shRNA nanoparticles. In short, it provided theoretical guidance for the clinical application of deep learning to analyze the therapeutic effect of diseases.

This work was aimed to explore the role of CT angiography information provided by deep learning algorithm in the diagnosis and complications of the disease focusing on congenital aortic valve disease and severe aortic valve stenosis. 120 patients who underwent ultrasound cardiography for aortic stenosis and underwent transcatheter aortic valve implantation (TAVI) in hospital were selected as the research objects. Patients received CT examination of deep learning algorithm within one week. The measurement methods were long and short diameter method, area method, and perimeter method. The deep learning algorithm was used to measure the long and short diameter, area, and perimeter of the target area before CT image processing. The results showed that the average diameter of long and short diameter measurement was 95% CI (0.84, 0.92), the average diameter of perimeter measurement was 95% CI (0.68, 0.87), and the average diameter of area measurement was 95% CI (0.72, 0.91). Among the 52 patients, 35 cases were hypertension (67%), 13 cases were diabetes (25%), 6 cases were chronic renal insufficiency ($Cr > 2$ mg/dL) (11%) (2 cases were treated with hemodialysis, 3.8%), 11 patients had chronic pulmonary disease (21%), 9 patients had cerebrovascular disease (17.3%) and atrial flutter and atrial fibrillation. Deep learning can achieve excellent results in CT image processing, and it was of great significance for the diagnosis of TAVI patients, improving the success rate of treatment and the prognosis of patients.

1. Introduction

Aortic valve stenosis is a common cardiovascular disease. Once clinical symptoms occurs, it develops rapidly, and the prognosis is extremely poor [1]. Current guidelines suggest that severe aortic stenosis patients with clinical symptoms should be treated as soon as possible. However, for elderly patients with multiple serious complications, postoperative mortality and incidence of complications increased significantly [2]. On this background, transcatheter aortic valve implantation (TAVI) came into being. The advantage of surgery is that there is no need to open the chest, so the trauma is small, and the postoperative recovery is quick. At present, China's TAVI is still in the primary stage and lacks experience [3]. Based on the particularity of TAVI surgery "high-risk requirements" and "nonvisualization," the clinical complications and aortic root anatomy of Chinese patients are different from those of western studies, but there is no systematic summary [4]. In recent years, TAVI became a new treatment method. Many studies reported that the annulus size measured by CT is the "gold" standard for the selection of valve rings, and the existing studies have confirmed that the use of CT in the diagnosis of TAVI disease can achieve excellent results [5]. CT angiography with deep learning algorithm can provide detailed anatomical image data of aortic root sinus and become a routine examination before operation for severe aortic stenosis [6]. In recent years, many studies showed that CT angiography based on deep learning algorithm is more accurate in the diagnosis of bicuspid aortic valve. In addition, it can also clarify the injury of ascending aorta [7]. For patients with aortic valve disease, CT angiography with deep learning algorithm can not only provide anatomical information but also quantitatively analyze aortic valve calcification [8]. The important role of deep learning algorithm CT angiography in aortic valve disease diagnosis and preoperative risk assessment sounded the clinical alarm for these patients in advance. Aortic valve interventional therapy became a research hotspot and direction of interventional therapy for structural heart disease [8].

These patients are mostly elderly, serious complications and cannot tolerate valve implantation surgery [9]. Studies indicated that TAVI can not only reduce aortic cross-valvular pressure in patients with aortic valve stenosis but also improve myocardial function and reduce mortality [10, 11]. China is rapidly entering an aging society, and patients with calcified aortic stenosis are increasing year by year [12]. TAVI has broad development prospects. Based on the particularity of surgery "high-risk requirements" and "nonvisualization" of TAVI, the preoperative clinical evaluation and imaging evaluation are to screen suitable patients and prevent intraoperative complications [13]. The purpose of this study was to investigate the role of CT angiography information provided by the deep learning algorithm in the diagnosis and complications of congenital aortic valve disease and severe aortic valve stenosis. The purpose of optimizing and improving CT scanning mode evaluation of deep learning algorithm before TAVI was to provide more safe and effective scanning methods for surgical patients.

2. Materials and Methods

2.1. Research Objects. 120 patients underwent ultrasound cardiography of aortic stenosis in the hospital from February 2018 to December 2020. The average age of them was 72.46 ± 6.75 years old, and there were 67 males. According to the comprehensive evaluation, the risk of surgery was too high to tolerate surgical valve ring replacement. Therefore, it was recommended that patients with severe aortic stenosis who had percutaneous main valve replacement and arterial replacement received cardiac enhanced CT examination within one week could be included. Patients with rheumatic heart disease who had undergone aortic valve replacement or the patients with infective endocarditis were excluded. A total of 120 patients were selected. General information, traditional risk factors, and other information of patients were collected by consulting medical records and telephone follow-up. The study was approved by the medical ethics committee, and patients signed informed consent.

2.2. CT Scanning. All patients who underwent cardiac scanning signed informed consent for scanning. The patient sat for 30 minutes before the examination, and the professional staff explained the precautions of the examination. CT scan included plain cardiac scan and prospective electrocardiogram-gated coronary spiral scan (anterior) (35–73% cardiac cycle) and dynamic large-pitch scan. The prospective electrocardiogram-gated trigger technique was used to scan the supine position of calcification, and the electrocardiogram-gated device was connected. The width of the collimator was 0.733 mm, the matrix was 500 × 500, and the thickness was 2.6 mm. The scanning range was from tracheal bulge to apex. After inhalation, breath hold twice had completed the scan, and the scan time was 7 s. The enhanced CT scan was performed with prospective electrocardiogram-gated (60% cardiac cycle) and dynamic large-pitch scanning. The scanning range was from the apex to the diaphragm. Onepak 370 (370 mg/mL, OP) was used as thw contrast agent. Dual-tube high pressure injection was used to connect the automatic injector to the elbow vein and measure the circulation time. The method was to select the level of aortic root, embed 17 cannula needles into the vein before scanning the elbow, inject 16 mL Onepak 370, with a flow rate of 6 mL/*s*, delay scanning of 7 s, and scan one layer with a thickness of 6 mm. The rotation time of the spherical tube was 1.3 s/circle. The scanning can be stopped when the density of the ascending aortic root changed from high to low. In the time-density curve obtained by dynamic analysis software, the actual delay time was obtained 5 s after the peak attenuation delay of contrast agent in the region of interest of ascending aorta. Two injection stages were conducted.

2.3. CT Images of Deep Learning Algorithm. In the Caffe environment, according to the existing experience and knowledge, combined with the CT image characteristics of aortic aneurysm, the CT performance of the aorta was analyzed (TJ-2 fully convolutional network model suitable for experiments was analyzed. The model structure was shown in Figure 1.). The TJ-2 fully convolutional network model can theoretically enter any size of the graph, for example, and generate the corresponding image output after calculation. The network model had good fault tolerance. The experimental data set was divided into training set and verification set, and these data were applied to the designed model for training in TJ-2. After training, the accuracy of the training results and other information can be obtained, and the problems in the experiment can be found by comparison. Image transmission to postprocessing workstations (syngo Imaging, Siemens, medical solution systems, Forchheim) was analyzed using three-dimensional software. Parameters were as follows: reconstruction layer thickness, 1.2 mm; reconstruction interval, 0.8 m; and convolution kernel, d32f. Image postprocessing techniques were intensity projection, multiplanar reconstruction, and surface reconstruction. Two experienced radiologists worked together to complete image analysis, discuss, and deal with different problems.

x samples $n_{\mathrm{i}} \in \mathrm{DX}$ ($i = 1, 2, \ldots,$ x) are controlled into q:

$$U_{I1} = \left\{ 1^{1st} 2^{\text{other}} \right. . \tag{1}$$

The property of matrix U is $U = (U_{il})$.

$$\begin{gathered} U_{i1} \varepsilon (1, 2), \\ \sum_{i=1}^{e} U_{I1} = 2 (1 = 2, 3, \ldots X). \end{gathered} \tag{2}$$

The overall difference is as follows.

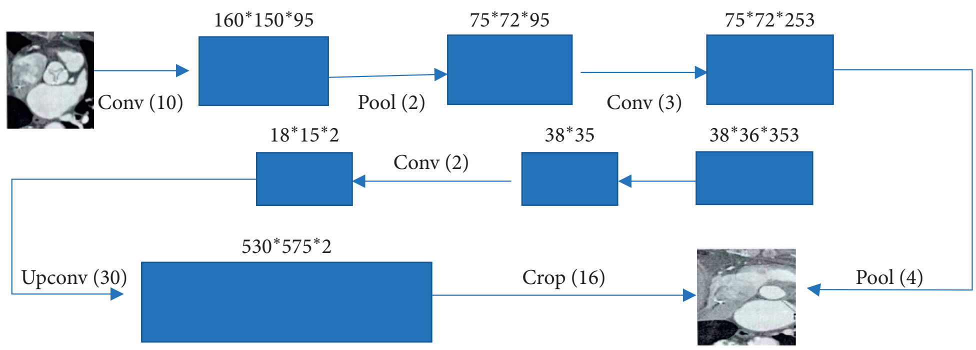

Figure 1: TJ-2 fully convolutional network model.

$$P(U) = \sum_{i=1}^{e} P(1)(u) = \sum_{i=1}^{e}\sum_{1=1}^{e} Uil\|n1 - \overline{ni}\|. \quad (3)$$

The TJ-2 deep learning piecewise network model is shown in Figure 1. The whole network structure experienced four convolution operations, two convolution pool operations, and one deconvolution operation. After this processing, the output image was the same size as the input image. The location of the aorta and aortic aneurysm was marked on the output image. TJ-1 full convolution network was mainly used for optimizing the experimental data, which greatly improved the computational efficiency. Although the TJ-1 full convolution network design was not as complex as the classical deep learning network, such as AlexNet and VGg segmentation network, the TJ-2 network can also complete the segmentation task well and had high operation efficiency and energy saving effect.

Obviously, such a small amount of data cannot be applied to deep learning algorithms. The square equation of translation and rotation was used to expand the dataset. The obtained original data were moved three times to the left and right, and the unit of each second translation was 20 pixels. On the basis of the obtained image, original data were moved three times to the up and down, and each translation was 15 pixels. After left and right translation and up and down translation, 1,617 slices were obtained. Next, the rotation operation was carried out. Each rotated 45° clockwise, a total of 7cycles. The dataset was expanded to 12,936 slices.

After 28 iterations, the trained TJ-2 full convolution network model was obtained. The trained TJ-21 model can be directly used for aortic image segmentation test. The specific experimental results can be explained as follows. GPU used NVIDIA GTX 1170 to conduct experiments in the Cafe environment of Ubuntu 13.02.

2.4. Image Measurement and Analysis. The acquisition phase of CT cardiac image was cardiac cycle, which was about 28%–71%. When the coronary image of the patient was recorded, in the case of arterial stenosis, as long as the stenosis rate of one coronary artery was >51%, the patient was defined as coronary heart disease. The two valves and two sinuses of the aortic valve were measured, and disappeared plane was measured simultaneously in the test. The long and short diameter measurement method was used to calculate the average diameter of the valve ring according to long diameter + short diameter. Ellipticity index (EI) was used to evaluate the ellipticity of the petal ring. EI was the maximum long diameter of ellipse divided by its minimum diameter. When EI ≤1, the measured plane was defined as a circle, the difference between the maximum diameter and the minimum diameter was less than 11% of the minimum diameter, and if EI > 1, the measured plane was defined as an ellipse (Figure 2 shows the measurement process).

As shown in Figure 2, the enhanced cardiac contraction image was selected for processing. In the coronal position, the long axis (a) of the ventricle was cut along the left side, and the sagittal oblique position (b) perpendicular to the long axis of the left ventricle was reconstructed to obtain the double oblique figure by axial cutting. The double oblique figure was obtained by axial cutting, and short axis of the aortic sinus was roughly flat (c). The lowest point of the adjusted cardiac sinus and the lowest point of the left sinus were determined by the whole tangent on the coronal line (the dotted line in (a) and (b)), respectively. The lowest point of the solid-free square sinus was determined at the sagittal oblique point, so that the lowest point of each valve in the triple aortic valve was flat ((e)–(g)). (g) showed the aortic valve ring on the double oblique transverse axis.

Figure 3 shows different measurement methods. Aortic rings were measured by long and short diameter method (a), perimeter method (b), and area method (c). All measurements were performed by two experienced doctors according to the blind method. Each observer measured the size according to the three methods shown in the diagram. In order to assess the observer's inherent reliability, at least one month later, the observer reconstructed and defined the measurement plane according to the original image. The size of the valve ring was measured, and then a second measurement was conducted.

2.5. Statistical Analysis. The general situation of the selected patients was classified and analyzed. Results were based on the mean, standard deviation, or frequency and percentage ratio representation, and the normal distribution was tested by continuous variables. Chi-square test or accurate test was used to compare the classification variables. The difference in

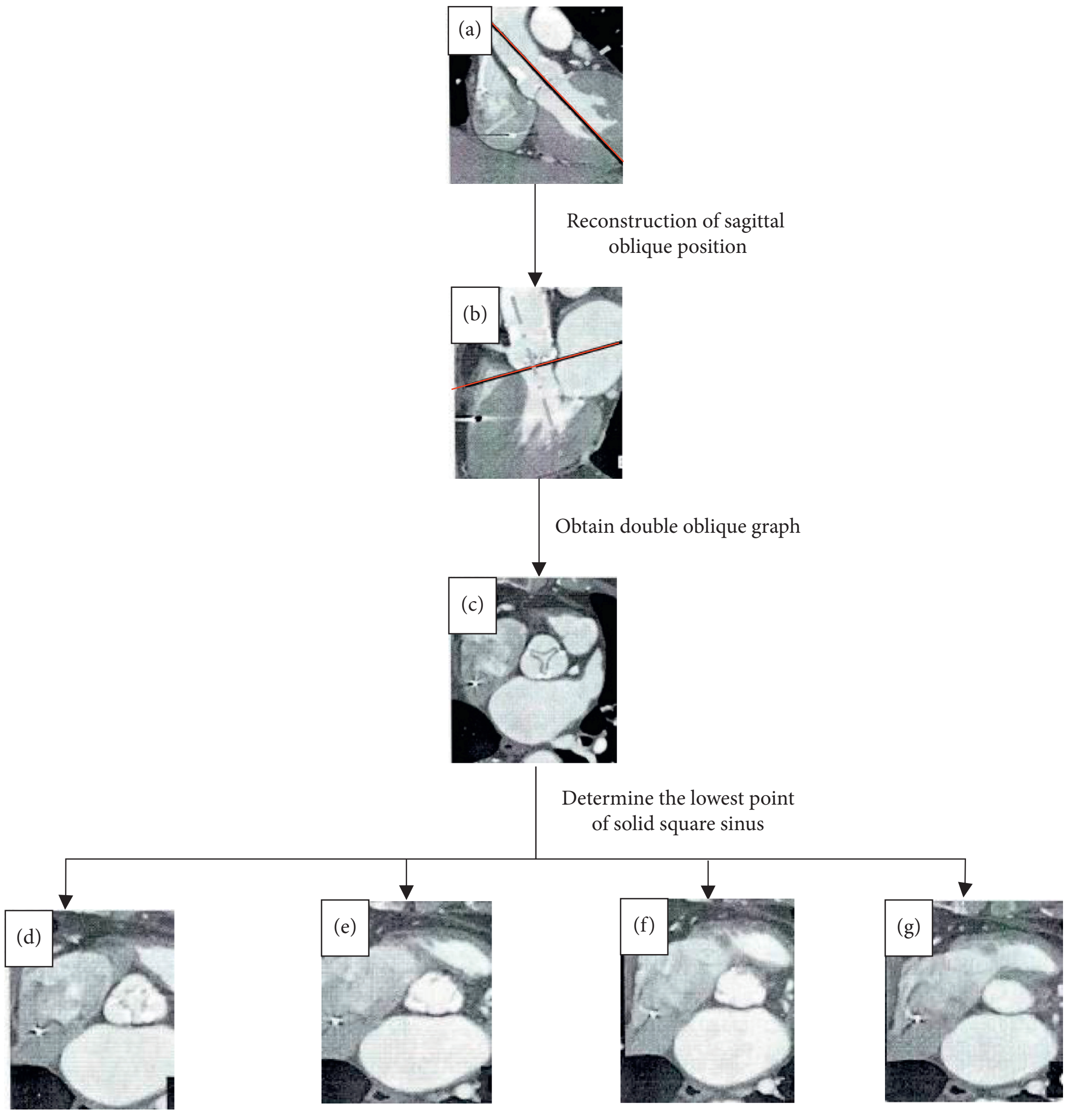

Figure 2: Measurement process.

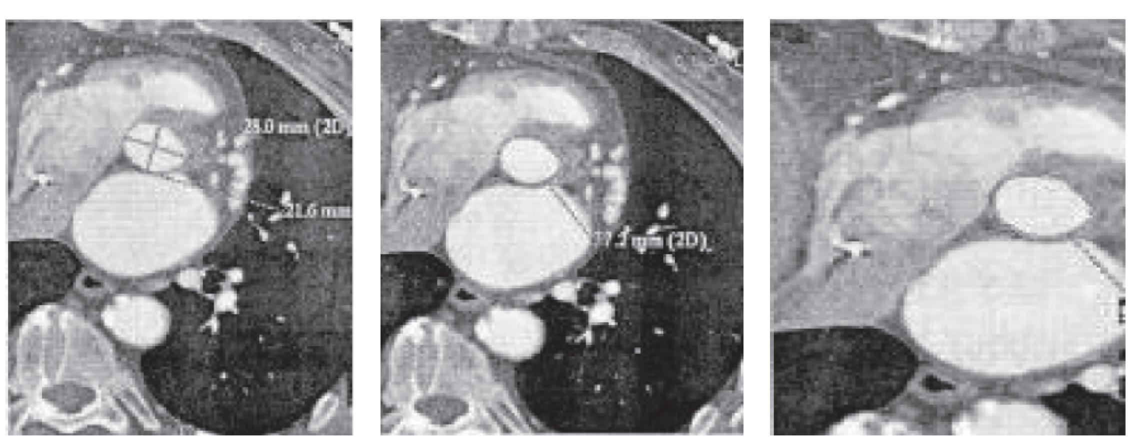

Figure 3: Results of three methods for measuring aortic valve ring.

average diameter measured by different methods was compared, and the paired test was adopted. Interclass correlation coefficient was defined as interobserver or the ratio intraobserver variability to overall variability. The 95% confidence interval was calculated by the data analysis method. Statistical analysis was performed in SPSS19, and $P < 0.05$ was considered statistically significant.

3. Results

3.1. Basic Data of Patients. 120 patients underwent CT examination. The average age was 72.46 ± 6.75 years. Male patients accounted for about 58%. 52 patients received TAVI eventually. All patients were successfully treated with TAVI after operation and had no valve ring rupture, leaflet embolism, or coronary artery occlusion (Table 1).

Table 1: HEBIN basic data of patients.

Variable	Patient ($n = 120$)
Mean transvalvular pressure gradient (mm/hg)	57.65 ± 15.3
Gender (male)	67 (58%)
Height (cm)	164 ± 8.2
Body surface area (m^2)	1.73 ± 0.15
Hypertension (%)	58 (48.3%)
Diabetes (%)	30 (25%)
Coronary heart disease (%)	32 (26.7%)
Peak velocity of aortic valve (m/s)	5.133 ± 0.65
Left ventricular ejection fraction (%)	54.3 ± 15.4

3.2. Effect Evaluation of Deep Learning Algorithm in CT Image Processing. In the training process, the convergence change of the loss function can be obtained. With the increase of training times, the accuracy of the verification data obtained by the entire TJ-2 network was getting higher and higher. However, when the accuracy reached 80%, the accuracy can increase little. Until the end of the training, the loss function also gradually converged and showed a constant trend. The final accuracy was 82%. The training process of the TJ-2 full convolution network was completed. The learning changes of training the TJ-2 full convolution network indicated changes of three kinds of learning in TJ-2 network during training. The learning rate can control the loss function of the whole TJ-2 volume product neural network to decrease smoothly (Figure 4). The following image was about the aortic valve CT image and algorithm for CT image target region segmentation results. It revealed that the application of deep learning to calculate and process can clearly show the specific area of the lesion (Figure 5).

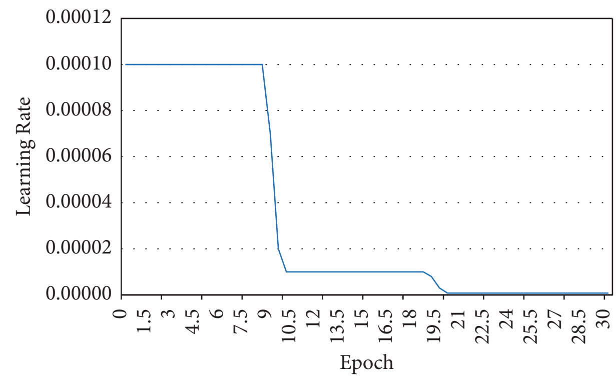

Figure 4: Training TJ-2 full convolution network learning rate changes.

3.3. Measurement of Aortic Root Anatomy Using CT Images of Deep Learning Algorithm. The mean diameter calculated by the long and short diameter, the mean diameter calculated by the perimeter, and the mean diameter calculated by the area were used for paired test in CT. The results showed that the size of annulus in CT was larger, and there was no significant difference in the average diameter measured by three CT methods (23.2 ± 3.85, 24.12 ± 3.52, and 23.74 ± 2.25, $P > 0.05$) (Figure 6).

The diameter results calculated by the CT of the deep learning algorithm according to the measurement methods such as long-short diameter, area, and perimeter are shown in Table 2.

3.4. Complications. Among the 52 patients, there were 35 cases of hypertension, accounting for 67%, 13 cases of diabetes, accounting for 25%, 6 cases of chronic renal insufficiency (Cr > 2 mg/dL), accounting for 11% (including 2 cases of hemodialysis maintenance, accounting for 3.8%), 11 cases of chronic lung disease, accounting for 21%, 9 cases of cerebrovascular disease, accounting for 17.3%, and atrial flutter and atrial fibrillation. There were no patients with infective endocarditis (Table 3).

4. Discussion

At present, the preoperative screening of patients to undergo CT plays an important role, which can be used to provide important information for clinical sheath approach. It also provides anatomical information for the weight of ascending aorta, the size of aortic root, and aortic ring [14]. TAVI requires preoperative examination to assess the size of aortic rings noninvasively and accurately, which is of great significance for the size selection of TAVI valve rings. If the size of the valve ring is not good, it will cause complications around the ring, such as aortic regurgitation, valve embolism, and ring tearing. Computer tomography can provide accurate anatomical shape and size of aortic rings [15]. Previous studies suggested that the valve diameter selected by CT and two-dimensional ultrasound is larger than the ring diameter measured by ECG, which reduces aortic regurgitation [16]. Deep learning was widely used in medical fields, such as image or data processing, and achieved excellent processing results [17]. In this study, the TJ-2 full convolution network in deep learning was used to process CT images of patients. The results showed that the lesions in CT images can be effectively identified, which laid a foundation for subsequent research. Such results were consistent with the excellent results obtained by Guo et al. [18] who

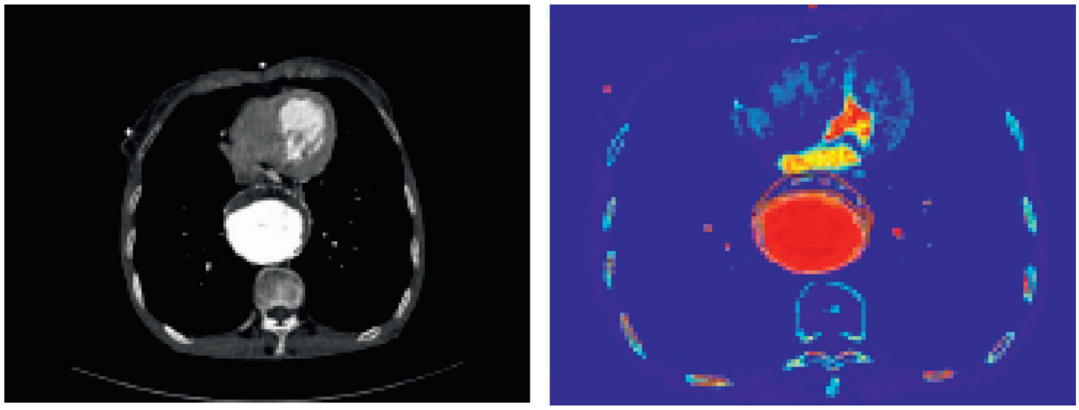

Figure 5: The CT images of aortic valves and the results of target region segmentation in CT images by the algorithm.

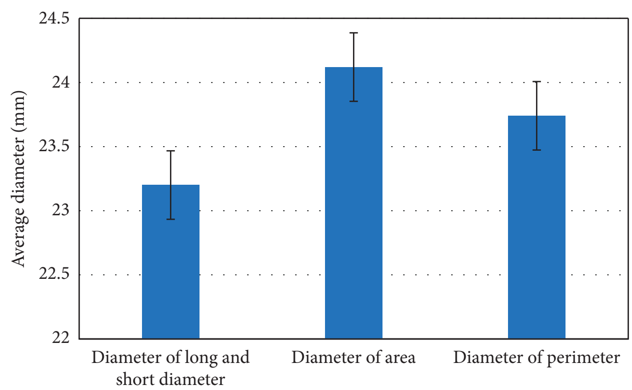

Figure 6: Average diameters measured by three CT methods.

Table 2: Measurement of aortic root anatomy using CT images of the deep learning algorithm.

Measurement	95% CI (lower limit, upper limit)
Mean diameter calculated by the long and short diameter (mm)	0.88 (0.84, 0.92)
Mean diameter calculated by the perimeter (mm)	0.76 (0.68, 0.87)
Mean diameter calculated by the area (mm)	0.85 (0.72, 0.91)

Table 3: Complication information.

Item	Cases ($n = 52$)
Hypertension (%)	35 (67.3)
Diabetes (%)	13 (25.0)
Chronic renal insufficiency (Cr > 2 mg/dL) (%)	6 (11.5)
Hemodialysis maintenance (%)	2 (3.8)
Chronic lung disease (%)	11 (21.2)
Cerebrovascular disease (%)	9 (17.3)

adopted the Elman neural network model in deep learning for image processing.

The repeatability of the diameter of the measured ring measured by the perimeter of scientific research evaluation is lower than that of the average diameter method and the area method. The average diameter measured by the area method is generally larger than that measured by the perimeter method in different cardiac cycles. In the contraction period, the elliptic index of the ring is minimal, which is closer to the circle than other cardiac cycles [19]. However, the diameter difference between the two calculated by the perimeter method and area method in the diastolic period is greater than that in the contraction period [20]. After stent implantation, especially after balloon implantation, the shape of the stent is round, and the same situation before and after surgery is the circumference of the ring. The ring diameter measured by the circle method may be more suitable for ring selection. The results of this study used the long-short diameter calculation, perimeter calculation, and area calculation in CT images to obtain the average diameter. The results represented that there was no significant difference in the average diameter measured by the three CT methods.

5. Conclusion

This study was to explore the use of deep learning in the measurement of information in CT images and its impact on surgical results. Of the 120 patients in this study, 52 eventually received TAVI treatment. The aortic ring diameter measured by three CT methods of deep learning algorithm is larger than that measured by CT, but there is no significant difference in the aortic ring diameter measured by their diameter measurement methods, and the area method and the long and short diameter method have high repeatability. Limitations are that although the size of the ring was chosen according to the different methods of measuring the ring, the most important thing is whether the final patient can undergo surgery, which is affected by many factors, including the vascular condition of the approach and the distortion angle of the blood vessel to the aorta, the diameter of the sinus orifice, and the width of the sinus orifice. This study summarizes and analyzes the characteristics of clinical complications and main influencing factors in patients with high-risk aortic valve stenosis and the preliminary experience according to moving root and anatomical data measurement. In the future, the sample size will be further expanded to integrate clinical data combined with intraoperative and clinical conditions, so that the preoperative evaluation results can better guide the screening of TAVI patients and standardize the success rate and prognosis of TAVI.

The study focused on the clinical diagnostic value of color Doppler ultrasound of dangerous placenta previa patients under the guidance of intelligent recognition algorithms. 58 patients with placenta previa and placenta accreta admitted to the hospital for treatment were selected as research subjects. The color Doppler ultrasound under the guidance of intelligent recognition algorithm was compared with the two-dimensional ultrasound for specificity, sensitivity, and accuracy. The color Doppler ultrasound results showed that, of the 58 patients, there were 32 cases of complete placenta previa and 26 cases of incomplete placenta previa, which were consistent with the surgical pathology results. It was found that patients with malignant placenta previa and placenta accreta had thickened placenta, disappeared posterior placental space, myometrium <2 mm, and increased incidence of cervical enlargement ($P < 0.05$). In conclusion, the recognition accuracy of color Doppler ultrasound under the guidance of the intelligent recognition algorithm is more than 90%, and it can effectively identify dangerous placenta previa, assisting doctors in diagnosis and treatment of dangerous placenta previa.

1. Introduction

Dangerous placenta previa may cause severe trauma, postpartum hemorrhage, blood clotting, etc., endangering the life of pregnant women [1]. Studies have shown that trophoblast cell invasion and dysplasia of uterine exfoliated tissue are serious causes of dangerous placenta. With the implementation of the second child policy, the number of patients with dangerous placenta previa has increased year by year [2, 3]. The maternal mortality rate is 7%, and the dangerous placenta previa is common in women with a cesarean section. There is likely to be placental implantation at the scar site of the last cesarean section. That is to say, placental villi have invaded part of the myometrium [4]. When women are at risk of dangerous placenta previa and placenta accreta, the placenta needs to be removed manually. It is the most serious complication of pregnancy, causing massive bleeding, uterine perforation, infection, and even death. Hence, early diagnosis and timely treatment are the key to improving the quality of delivery [5, 6].

Artificial intelligence [3] is a comprehensive discipline concerning control theory science, neuroscience, mathematics, information theory science, and game theory science. It is characterized by machines that can be as smart as human minds and can think and perceive like humans. Color Doppler ultrasound is a noninvasive diagnostic method. Under the guidance of electronic technology, it can detect the spatial information of the blood flow in the tested part in real time, and it can provide abundant blood circulation information. Therefore, it is highly valued clinically [7, 8]. Doppler color ultrasound has no radiation and minimizes the damage to pregnant women and fetuses. It is highly-safe, reliable, comfortable, and is easy to perform. The operator can see clear images and diagnose uterine differentiation, placenta, abnormalities, and the blood flow of pregnant women in time. Therefore, it is often used for early diagnosis of dangerous placenta previa. Malignant placenta can be detected by ultrasound in the middle and late stages of pregnancy, and active clinical treatment can reduce the risk of postpartum hemorrhage.

Two-dimensional ultrasound can directly observe the shape and thickness of the placenta, the space behind the placenta, and the condition of the myometrium, and Doppler ultrasound can be used to detect blood flow signals. The main content of ultrasound diagnosis [9–11] includes (i) placenta previa; (ii) a lacuna is formed in the placenta; (iii) the placenta attaches to the thin muscle layer and disappears; (iv) placenta partly or completely disappears from the posterior placenta space; and (v) the interface between the front wall of the uterus and the back wall of the bladder. Doppler ultrasound image of malignant placenta shows (i) vortex of blood flow in the placental blood pool; (ii) turbulent flow in the blood pool; (iii) rich blood flow at the interface between the uterus and bladder; and (iv) increased blood vessels around the placenta. The Doppler color ultrasound can monitor blood flow and is sensitive to placental accreta. Su Jilian et al. reported that the sensitivity of Doppler color ultrasound for placenta was 98%, and the negative predictive value was 100%, meeting the best classification and exclusion criteria.

When it comes to ultrasonic images, great progress has been made from the manual identification of the indicator diagram to the use of computer identification and diagnosis. Traditional machine learning models can be divided into shallow learning and deep learning according to their structural levels. Most machine learning models are shallow learning, which are only effective for some simple or limited problems but are obviously at a disadvantage in the face of complex problems with large data scale. Deep learning network, with multiple hidden layers, can realize mapping transformation from low-dimensional space to high-dimensional space through multilayer nonlinear transformation and to distinguish and classify complex input data features in high-dimensional space. The intelligent recognition algorithm based on deep learning has a good clinical application effect for dealing with a large number of complex and numerous medical images.

In the study, 58 patients with severe placenta previa were selected as research subjects, and they all accepted the Doppler color ultrasound examination under the guidance of an intelligent recognition algorithm. Then, the diagnosis accuracy and sensitivity of the intelligent algorithm were investigated.

2. Materials and Methods

2.1. Research Subjects. In the study, 58 patients with dangerous placenta previa admitted to a tertiary hospital from March 2019 to September 2020 were selected as research subjects. They were aged between 30 and 46 years old, with an average of 38.29 ± 2.59 years old. The gestational period was between 34 and 40 weeks, with an average of 36.62 ± 3.11 weeks. The number of cesarean sections was 1–3, and the lower uterine incision was a transverse incision. The number of pregnancies was between 1 and 4. The diagnostic criteria for dangerous placenta previa were as follows: with a history of cesarean section and placenta previa was diagnosed prenatally.

Inclusion criteria: (i) diagnosed with dangerous placenta previa as per *Obstetrics and Gynecology*; (ii) all underwent surgical delivery and pathological examination, of singleton pregnancy; (iii) patients and their families were aware of and voluntarily joined this study and signed informed consent form.

Exclusion criteria: (i) not undergoing surgical pathological examination; (ii) cooperating with the doctor in the study. Additionally, patients with coagulation dysfunction and incomplete data were excluded.

2.2. Intelligent Recognition SVM Algorithm. SVM classification method is to maximize the classification margin by discovering the hyperplane in the space. However, practical problems are often nonlinear, and it is very difficult to find a hyperplane in the spatial dimension to separate data. SVM can construct the optimal classification structure hyperplane through the core function, so as to realize the linear global optimal solution.

In the study, the SVM classifier is used, and the icons extracted from the self-encoding decomposition group represent different classifications. For example, if there are n categories, n SVM classifiers can be built. For example, x_i represents the sample, w represents the weight matrix, wj represents the weight vector of the jth classifier, b represents the bias matrix, bj is the bias term of the jth classifier, C represents the penalty factor, ξij is the slack variable, $\varphi(xi)$ has the nonlinear mapping function, and commonly, the kernel function $k(x)$ replaces the mapping function $\varphi(x)$ to simplify the mapping from the low-dimensional space to high-dimensional space. The ideal objective function can be expressed as follows.

$$
\begin{aligned}
& min\frac{1}{2}\left\|w_j\right\|^2 + C\sum_{i=1}^{l}\xi_i^j, \\
& s.t.\left(w_j\right)T\dot{\oint}\left(x_i\right) + b_j \geq 1 - \xi_i^j, if\, y_{i=}j, \\
& \left(w_j\right)\dot{T}\oint\left(x_i\right) + b_j \leq -1 + \xi_i^j, if\, y_i \neq j, \quad \xi_i^j \geq 0, \quad i = 1, 2, \cdots, l.
\end{aligned} \tag{1}
$$

By solving N optimization problems as equation (1), N decision functions are obtained, and f is the decision function as follows.

$$
\begin{cases}
f_1(x) = (w_1)T\dot{\oint}(x) + b_1 \\
\cdots \\
f_n(x) = (w_n)\dot{T}\oint(x) + b_n
\end{cases} \tag{2}
$$

Substituting the test sample iX into equation (2) can obtain the sample value belonging to the decision function of each classifier. By selecting the classifier represented by the largest decision function value, the classification category of the sample can be identified calculated as follows:

$$
class(x) = arg\,max\left(w_j\right)\dot{T}k(x) + b_j\big). \tag{3}
$$

2.3. Intelligent Identification Process. Pattern recognition is the scientific identification to describe and classify research subjects. A pattern is to quantitatively and structurally describe an entity object, and a set of similar things is called a pattern class. Through pattern recognition, data are processed and analyzed in various ways and then described and classified. This recognition and classification technology transfers various feature description information of objects to the machine and automatically classifies various objects to their pattern classes.

Traditional pattern recognition methods include linear regression, nearest neighbor classification, and principal component analysis clustering algorithms. In recent years, with the development of machine learning technologies such as artificial neural networks (ANN), ANN-based learning technologies have become a worldwide research hotspot. Figure 1 is the pattern recognition flow chart.

2.4. Ultrasound Examination. Color Doppler Ultrasound uses the top color Doppler ultrasound diagnosis system of Germany Siemens ACUSON Oxana series. Examination: the bladder of the patient should be full before the examination. The patient was in a supine position. The frequency of the probe for transabdominal examination is 2.5–5 MHz, and the frequency of the probe for transvaginal examination is 7–12 MHz. The patient was scanned for the position and thickness of the placenta, the echo of the placenta, the edges, borders, and thickness of the placenta, and the uterus. For patients whose placenta was at the bottom of the anterior wall, special attention should be paid to the continuity of the posterior wall and the correlation between the posterior bladder wall and the anterior uterine wall. The color ultrasound images of the placental substance and the posterior placenta were then analyzed.

Two-dimensional ultrasound examination: a two-dimensional ultrasound diagnosis and treatment instrument is used, and the frequency of the abdominal probe is set at 3.5 MHz. Before the examination, the patient was asked to drink water to keep the bladder full. The position of the placenta was determined by moving the probe to examine the fetus and its surrounding conditions and detect the distance between the placenta and the cervix, the uterine wall, the posterior wall of the bladder, the muscle layer, and the thickness of the placental implant.

2.5. Evaluation Index. The two-dimensional ultrasound and color Doppler ultrasound results were analyzed under the guidance of intelligent recognition algorithms. With the results of surgical examination as the "gold standard," the sensitivity, accuracy, and specificity of two-dimensional ultrasound and color Doppler ultrasound were evaluated.

2.6. Statistical Methods. The data in this study were processed by SPSS21.0 software, and $(x(-) \pm s)$ and n (%) were used to represent measurement data (t-test) and count data ($\chi 2$), respectively. $P < 0.05$ indicated that the difference was statistically significant.

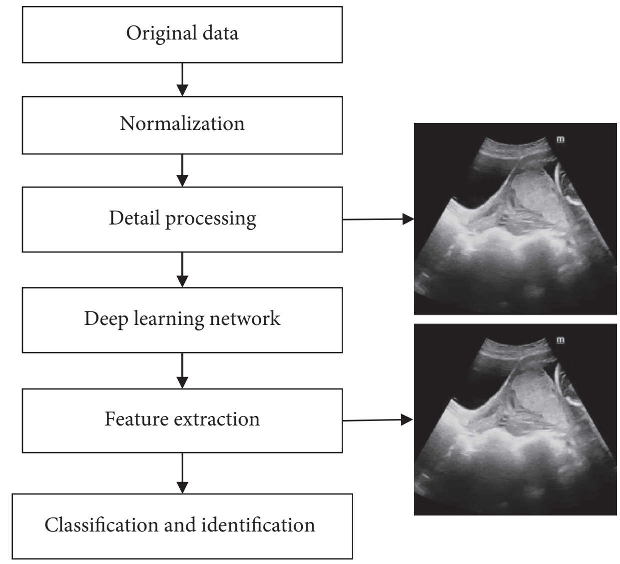

Figure 1: Intelligent recognition process.

3. Results

3.1. Routine Placenta Data. All the cases were confirmed by surgery, including 15 cases of marginal placenta previa, 11 cases of partial placenta previa, and 32 cases of central placenta previa. The placenta was attached to the anterior wall in 20 cases, the posterior wall in 8 cases, the anterior and right wall in 2 cases, and the anterior and left wall in 1 case. Ultrasound showed 15 cases of marginal placenta previa, 12 cases of partial placenta previa, and 31 cases of central placenta previa, as shown in Figure 2.

3.2. Color Doppler Ultrasound in the Examination of Dangerous Placenta Previa. Of the 58 patients, 32 had complete placenta previa, 11 had partial placenta, and 15 had marginal placenta. 47 cases were detected by color Doppler ultrasound, and the correct rate was 81.03%. There were 41 cases correctly detected by both of the two-dimensional and Doppler color ultrasound and 5 cases incorrectly detected by both of the two methods, as shown in Figures 3 and 4.

3.3. Abnormal Results of Placental Attachment Examined by Color Doppler Ultrasound. Of the 58 patients, there were 27 cases of abnormal placental attachment, and color Doppler ultrasound detected 30 cases of abnormal placental attachment. The detection rate of various abnormal placental attachments using Doppler color ultrasound and two-dimensional ultrasound showed $^{*}P > 0.05$, and there was no statistically significant difference, as shown in Figure 5.

3.4. Examination Results of Dangerous Placenta Previa by Color Doppler Ultrasound under the Guidance of Intelligent Recognition Algorithm. The ultrasound examination results were compared with the surgical pathology results. The ultrasound examination results showed that, of 58 patients, there were 52 cases of complete placenta previa and 6 cases

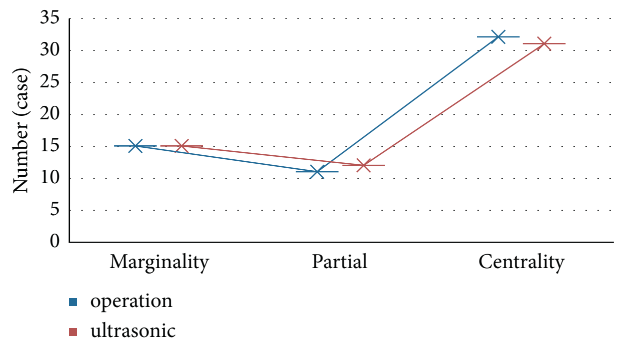

Figure 2: Placenta data of the subjects.

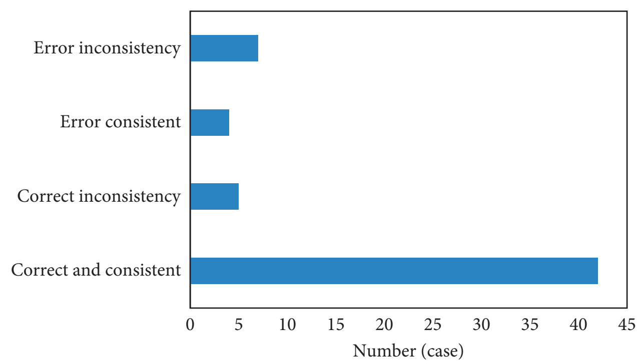

Figure 3: Color Doppler ultrasound in the diagnosis of malignant placenta previa.

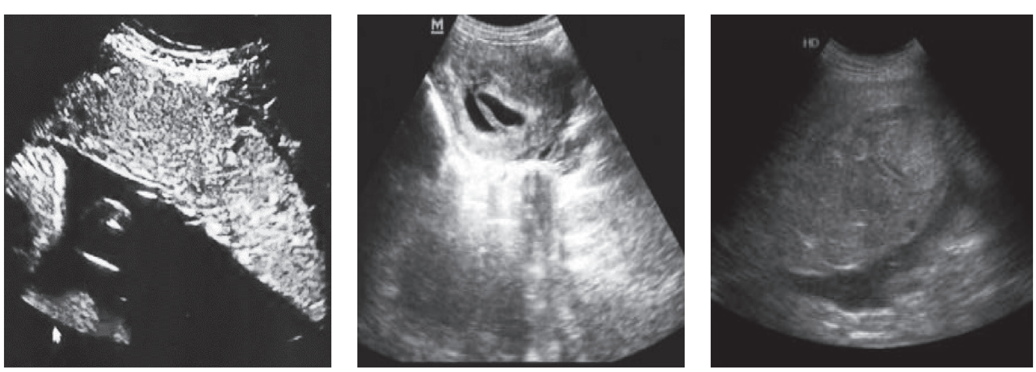

(a) (b) (c)

Figure 4: Ultrasound image characteristics of dangerous placenta previa.

of incomplete placenta previa, which were consistent with the surgical pathological results. Ultrasound diagnosis detected 54 cases of placenta accreta and 4 cases without placental accreta. The specific results of the ultrasound examination are shown in Figure 6.

3.5. Comparison of Results of Placenta Previa of Surgical Pathological Examination and Ultrasound Examination under the Guidance of Intelligent Recognition Algorithms. Figure 7 shows the results detected by the intelligent recognition algorithm. It was noted that the intelligent recognition algorithm proposed in this study can locate the placenta previa position accurately, and the positioning result was basically similar to the manual positioning result of the doctor.

The white dotted line represented the manual positioning result of the doctor, and the red dotted line represented the positioning result of the intelligent recognition algorithm.

The results of the ultrasound examination were then compared with the postoperative pathological results. The ultrasound examination detected 38 cases of complete placenta previa and 10 cases of incomplete placenta previa, in line with surgical pathology. The ultrasound examination results showed that 39 cases had placenta accreta and 9 cases

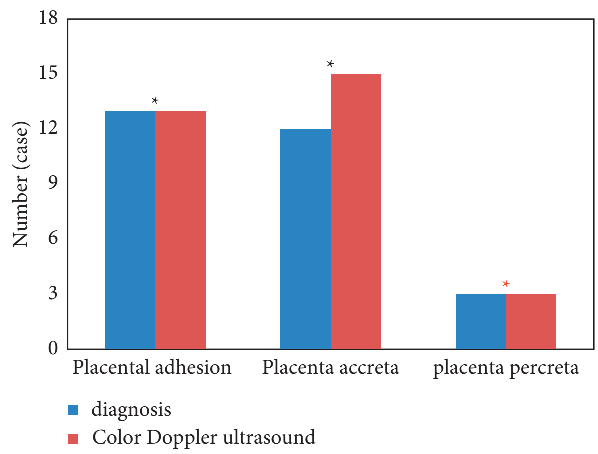

FIGURE 5: Abnormal results of placental attachment examined by color Doppler ultrasound ($^*P > 0.05$ indicated statistically significant difference between groups).

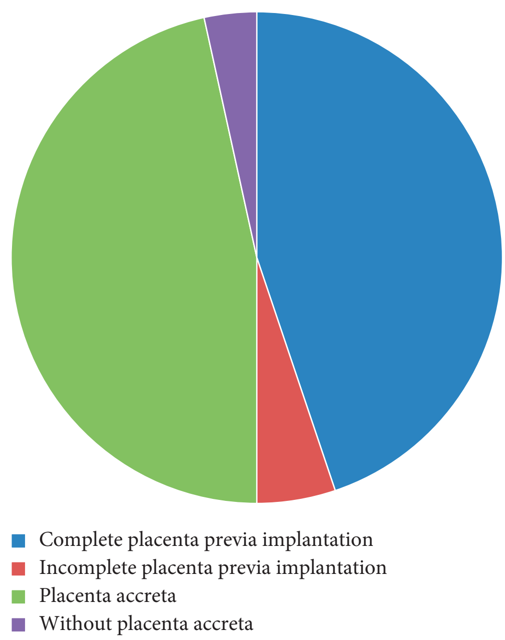

FIGURE 6: Ultrasound examination results.

FIGURE 7: Ultrasonic positioning of placenta previa based on the intelligent recognition algorithm.

had no placenta accreta. Compared with surgical pathology results, 2 cases were missed and 2 cases were misdiagnosed (Figure 8).

3.6. Application of Color Doppler Ultrasound in the Diagnosis of Cicatricial Placenta Previa. Surgical results showed that, of 58 suspected patients, 50 cases had placenta previa and

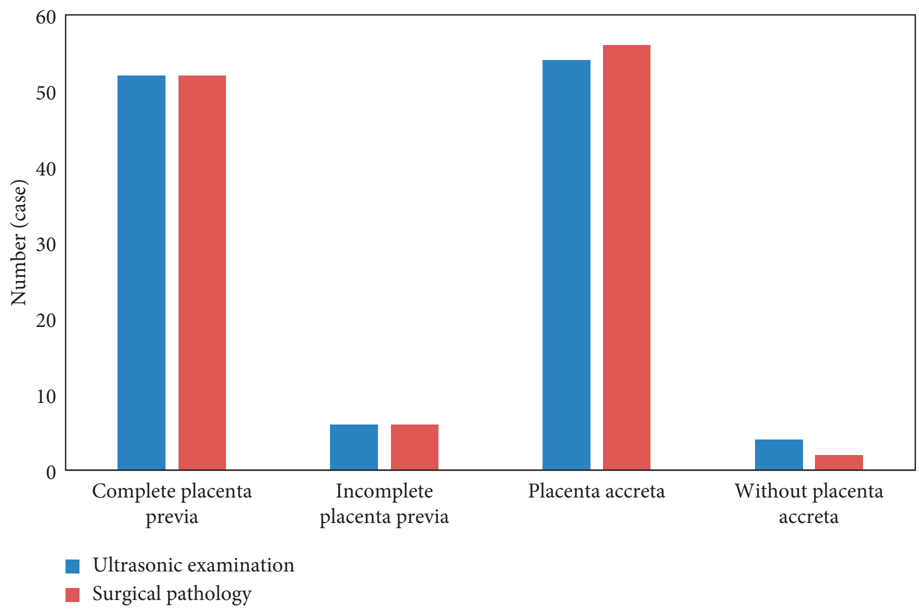

Figure 8: Comparison of ultrasound results and surgical pathology results for placenta previa.

placenta accreta. The diagnostic accuracy rate of two-dimensional ultrasound for placenta previa and placenta accreta was 78.57% (43/58), which was lower than 94.29% (54/58) of color Doppler ultrasound, and the difference was statistically significant ($X^2 = 7.368$, $P = 0.007$) (Figure 9).

3.7. Comparison of Conventional Two-Dimensional Ultrasound and Color Doppler Ultrasound Results. ROC curve analysis showed that the sensitivity and AUC of color Doppler ultrasound diagnosis were higher than those of conventional two-dimensional ultrasound, and the difference was statistically significant ($^{\theta}P < 0.05$) (Figure 10).

3.8. Features of Color Doppler Ultrasound with and without Placenta Implantation. Color Doppler ultrasound showed that dangerous placenta with placenta implantation has higher incidence of thickened placenta and loss of posterior placental space and significantly higher incidence of myometrium <2 mm and expanded cervical expanded than that without placenta implantation ($^{*}P < 0.05$), as shown in Figure 11.

3.9. Pregnancy Outcome. The amount of postpartum blood loss in pregnant women with placenta implantation was significantly higher than that in pregnant women without placenta implantation, with statistical significance ($^{*}P < 0.05$), as shown in Figure 12.

4. Discussion

Dangerous placenta previa refers to the presence or absence of placenta accreta on the basis of placenta previa. Placenta previa refers to the lower edge of the placenta away from the cervix, attached to the lower part of the uterus, or covering the cervix after 28 weeks of pregnancy [12]. According to the relationship between the placenta and the cervical foramen, placenta previa can be divided into 3 types: complete, partial, and marginal [13]. Studies have shown that compared with pregnant women without a history of cesarean section, the incidence of placenta previa in pregnant women with a history of cesarean section can increase by 5 times. Statistics show that the mortality rate of patients with malignant placenta previa can reach as high as 10%, seriously threatening the lives of pregnant women [14]. In order to reduce the mortality rate of pregnant women and improve their health, it is important to diagnose placenta previa and placenta accreta as soon as possible, so as to take timely measures to terminate the pregnancy.

For dangerous placenta previa, to diagnose placenta accreta or not before surgery has a great influence on the treatment effect [15]. Ultrasound is an economical and effective prenatal diagnosis method for malignant placenta previa. It can perform noninvasive multiangle examination and clearly show the relationship between placental thickness, fetal manifestations, and cervical and subuterine scars [5]. Furthermore, with the development of power Doppler and three-dimensional ultrasound technology, its sensitivity and specificity have been elevated. However, ultrasound cannot accurately assess the depth of placental accreta in patients with abnormal placental attachment.

At present, artificial intelligence algorithms have been widely used in the medical field [16]. Under the guidance of intelligent recognition algorithms, color Doppler ultrasound is used to detect malignant placenta previa. It is noninvasive, with high reproducibility and low cost [17–19]. Color Doppler ultrasound can be divided into transabdominal ultrasound and transperineal ultrasound. Transabdominal ultrasound is the simplest and a commonly used method. Color Doppler ultrasound images show that the posterior placenta space disappears, the placenta is thickened, and the myometrium at the placental attachment is significantly

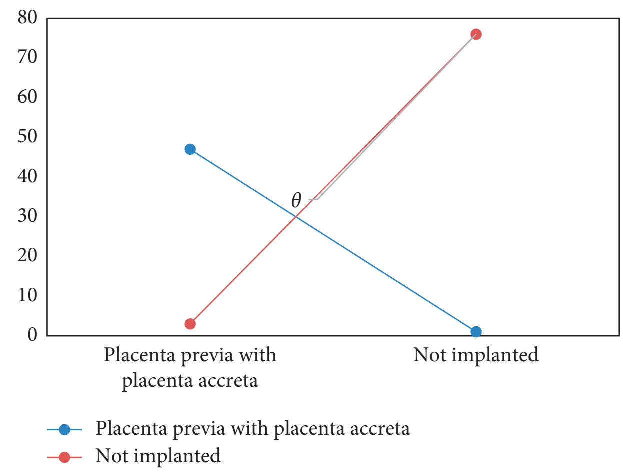

FIGURE 9: Application of color Doppler ultrasound in the diagnosis of placenta previa with placenta previa ($^{\theta}P < 0.05$ indicated that the difference between groups was statistically significant).

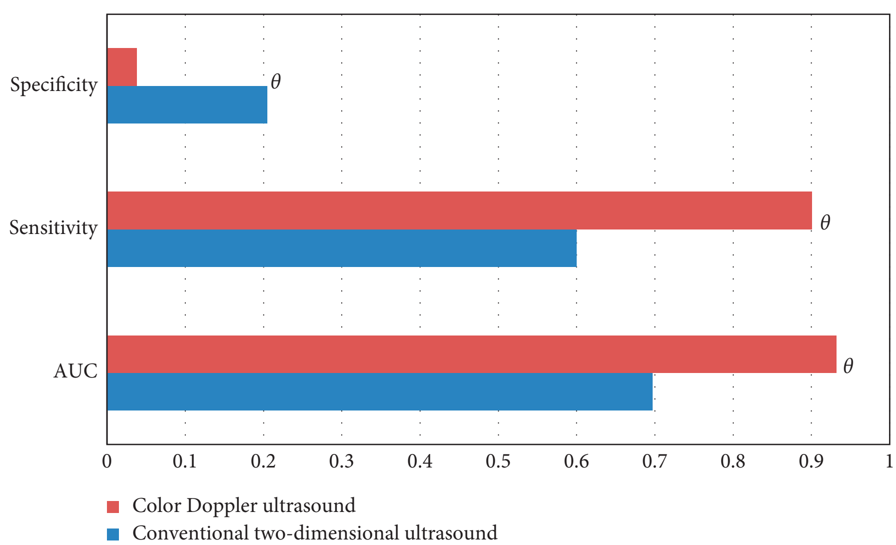

FIGURE 10: ROC curve analysis results of two-dimensional conventional ultrasound and color Doppler ultrasound ($^{\theta}P < 0.05$ indicated that the difference between groups was statistically significant).

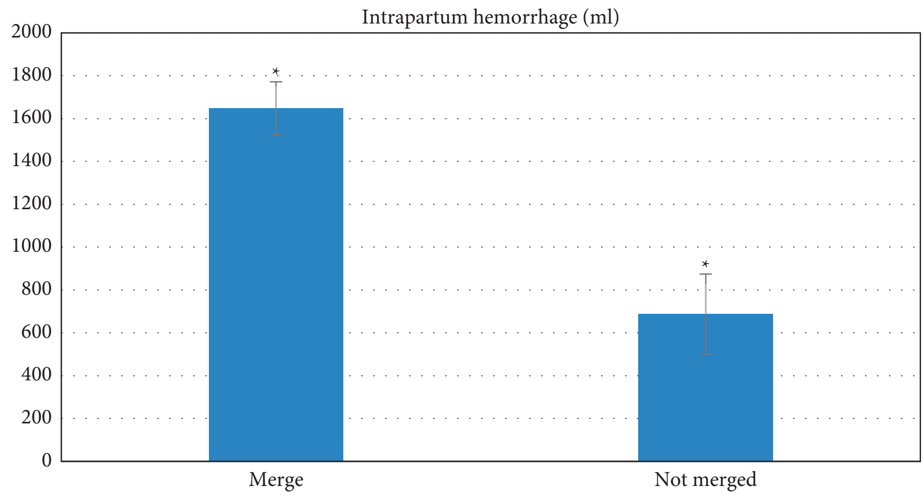

Figure 12: Pregnancy outcomes ($^*P < 0.05$).

thinned. The images can effectively determine whether there is a placenta accreta, which facilitates the diagnosis of the doctor [20–22]. For those with a thick abdominal fat layer, the accuracy of abdominal ultrasound is reduced, consistent with results of Guo et al. [23]. At this time, the perineum multisection examination can fully make up for the missed detection of the cervix and lower uterus. Transperineal ultrasound can effectively identify the relationship between the placenta and myometrium. Most ultrasound images show swelling of the lower part of the uterus, enlarged cervix, placenta coverage, and abundant blood flow in the lower part of the uterus.

The combination of abdominal examination and perineal examination can complement each other to improve the accuracy of the detection of malignant placenta previa with placenta accreta [24, 25]. In patients with malignant placenta previa and placenta accreta, ultrasound can display obvious blood flow changes, such as abnormal blood flow in the placental cavity, abundant blood flow signals, placenta accreta, thinned echo zone between the uterus and placenta, the enlarged cervix, and the thinned myometrium. Color Doppler ultrasound can accurately identify whether it is complete placenta previa. Compared with the postoperative pathological results, there are a few missed and misdiagnosed cases of placenta accrete, consistent with results of Yuwen et al. [26]. For pregnant women with placental accreta, the hysterectomy rate and blood loss are higher, indicating a great impact of placental accreta on mothers. Timely prenatal ultrasound examination can quickly screen the lesions in the early stage, which assists doctors in judging the severity of the disease in a timely manner, and can provide an accurate basis for further treatment.

Limitations: this article does not discuss the situation of patients with malignant placenta previa combined with placenta accreta, which needs to be continuously explored in the clinic. Despite the high accuracy of color Doppler ultrasound, it cannot completely replace ultrasound due to the high cost. Hence, an appropriate examination method is required according to the patient's specific condition.

In conclusion, under the guidance of intelligent recognition algorithms, color Doppler ultrasound has high accuracy in the detection of malignant placenta previa and can correctly assess the severity of malignant placenta previa and placenta accreta. This study is of great significance for improving the quality of pregnancy and ensuring the safety of mothers and babies.

Academic Editor: Enas Abdulhay

The study aimed to explore the diagnostic value of computed tomography (CT) images based on cavity convolution U-Net algorithm for patients with severe pulmonary infection. A new lung CT image segmentation algorithm (U-Net+ deep convolution (DC)) was proposed based on U-Net network and compared with convolutional neural network (CNN) algorithm. Then, it was applied to CT image diagnosis of 100 patients with severe lung infection in The Second Affiliated Hospital of Fujian Medical University hospital and compared with traditional methods, and its sensitivity, specificity, and accuracy were compared. It was found that the single training time and loss of U-Net + DC algorithm were reduced by 59.4% and 9.8%, respectively, compared with CNN algorithm, while Dice increased by 3.6%. The lung contour segmented by the proposed model was smooth, which was the closest to the gold standard. Fungal infection, bacterial infection, viral infection, tuberculosis infection, and mixed infection accounted for 28%, 18%, 7%, 7%, and 40%, respectively. 36%, 38%, 26%, 17%, and 20% of the patients had ground-glass shadow, solid shadow, nodule or mass shadow, reticular or linear shadow, and hollow shadow in CT, respectively. The incidence of various CT characteristics in patients with fungal and bacterial infections was statistically significant ($P < 0.05$). The specificity (94.32%) and accuracy (97.22%) of CT image diagnosis based on U-Net + DC algorithm were significantly higher than traditional diagnostic method (75.74% and 74.23%), and the differences were statistically significant ($P < 0.05$). The network of the algorithm in this study demonstrated excellent image segmentation effect. The CT image based on the U-Net + DC algorithm can be used for the diagnosis of patients with severe pulmonary infection, with high diagnostic value.

1. Introduction

At present, the incidence of postoperative pulmonary infection is very high [1]. If the diagnosis is not timely, it is easy to miss the best treatment time. Studies have shown that if the diagnosis can be made in advance, the survival rate of patients with pulmonary infection can be increased by about 40% [2, 3]. Therefore, early and accurate diagnosis of pulmonary infection has become a key issue to improve the cure rate [4, 5]. The main pathogens are bacteria, fungi, viruses, parasites, etc. In addition to pathogen testing, computed tomography (CT) imaging diagnosis has become a common and important method for medical diagnosis. However, as the main feature of judging pulmonary infection, lung CT signs are particularly important from the clarity of lung images and the accurate expression of lung information. Traditional medical image segmentation extracts lung information according to the shallow features of the image and depends on the judgment of the doctor [6]. The addition of subjective factors leads to inaccurate segmentation. Lu et al. [7] proposed a fuzzy logic technology to determine the threshold to achieve accurate segmentation of melanin, but the segmentation effect is poor and inefficient.

With the development of artificial intelligence and information, convolution neural network is introduced into the segmentation of medical images. Nasrullah et al. [8] proposed and used it in the semantic segmentation of natural images and made great progress at that time. In the past segmentation experience, it has exceeded the traditional segmentation method, but its shortcomings cannot be ignored. The excessive multiples adopted in the upsampling operation cause the segmentation accuracy to be not high enough, and the context information is not fully integrated, resulting in low accuracy and precision, which will have a great impact on the survival rate of subsequent diagnosis and posttreatment [9, 10]. The fully convolutional neural network has made great contributions to this problem. As a representative of fully convolutional neural networks, U-Net network can make good use of lower-level information and fuse high-level information when sampling operations [11]. In the following studies, some network structures with better performance are combined with the U-Net network. Baek et al. [12] modified the U-Net to strengthen the position of the feature map, so as to improve the accuracy of extracting the segmentation contour. The 3DU-Net model improves the segmentation performance again by learning the spatial information of the image [13]. In this work, a new lung CT image segmentation algorithm was proposed by adding cavity convolution on the basis of U-Net network. Compared with CNN algorithm, it is applied to the diagnosis of 100 patients with severe pulmonary infection. The sensitivity, specificity, and accuracy of diagnosis are compared with the traditional diagnostic method. It is hoped to provide some theoretical reference for the diagnosis of CT images based on cavity convolution U-Net algorithm in patients with severe pulmonary infection.

2. Materials and Methods

2.1. Research Objects. In this study, 100 patients with severe pulmonary infection in hospital from July 2019 to July 2021 were enrolled. There were 46 males and 54 females, aged 20–66 years. CT image features based on U-Net + DC algorithm were used to diagnose patients with severe pulmonary infection, which was compared with those of traditional diagnostic methods. The study was approved by the Medical Ethics Committee of Hospital. Patients and their families were informed of the study and signed informed consent.

Inclusion criteria were as follows: (1) separate the same pathogen twice in succession from patient sputum; (2) patients with lung invasive lesions showed by chest X-ray; (3) patients with cough, expectoration, and rales; (4) patients with pathogens isolated from blood or pleural effusion.

Exclusion criteria were as follows: (1) patients who did not sign the informed consent; (2) patients with incomplete clinical data; (3) patients who dropped out of the experiment for personal reasons.

2.2. Lung CT Image Segmentation Based on U-Net and Cavity Convolution. The ability of deep learning to extract features is beyond reach of previous machine learning. On account of the fact that the ability of U-Net network to process and integrate high-level and low-level information is better than that of CNN, it is widely used in medical image segmentation. In order to achieve the segmentation of lung CT images, this paper adds cavity deep convolution (DC) on the basis of U-Net network, simplifies and improves the U-Net network, and adds an activation function to increase the nonlinearity of the model. A new lung CT image segmentation algorithm (U-Net + DC) is proposed. The U-Net network is different from the convolution block of the network model proposed in this paper as shown in Figure 1. The convolution block of the network model proposed in this paper is less than the convolution block of the U-Net network by one convolution and an activation function, and the convolution block uses an empty convolution, which can simplify the structure, increase the receptive field, and improve the ability to extract information.

The convolution process of a two-dimensional image can be represented as

$$o(a,b) = (i \times k)(a,b) = \sum_{c}\sum_{d} i(c+a, d+b) \times k(c,d). \tag{1}$$

In equation (1), i is input, k is convolution kernel, and o is output. When (a, b), (c, d) is the size of the input image to select the convolution kernel, a smaller convolution kernel is usually selected, which can not only reduce the number of parameters but also increase nonlinearity. The total parameters p are as follows:

$$P = \omega + B = k^2 \times C \times N + N. \tag{2}$$

In equation (2), ω is the weight, B is the partial value, C is the number of characteristic channels, and N is feature mapping. As a special convolution, cavity convolution can increase the nonlinearity of the model. The essence is to add holes in the convolution and increase the receptive field under the condition of keeping the number of parameters unchanged, which is of great significance to improve the accuracy of image segmentation. Figure 2 shows the schematic diagram of cavity convolution [14].

Because of the interval of empty convolution, it may cause information discontinuity in practical applications, especially when the image is small and the interval is too large. To solve this problem, this paper designs the cavity size according to Hybrid Dilated Convolution (HDC) standard, which needs to meet the following equation:

$$m_n = mix\left[m_{n+1} - 2r_n, m_n - 2\left(m_{n+1} - r_n\right), r_n\right]. \tag{3}$$

In equation (3), m_n is the largest void spacing before the n layer and r_n is the void interval of the n layer. The last layer the void spacing selected in this article is (1,2,5).

The pooling layer is downsampling, and the reverse pooling layer is upsampling on the contrary. If it is the maximum pooling $m_n = r_n$ in the network transformation process, the location of the activation value is recorded. On the contrary, the location of the nonmaximum is set to 0. Maximum pooling and antipooling are shown in Figure 3.

In this study, the classification output uses *sigmoid* function, which is very sensitive between [−4,4], especially for subtle changes in data that feel very strong. It can be expressed as follows:

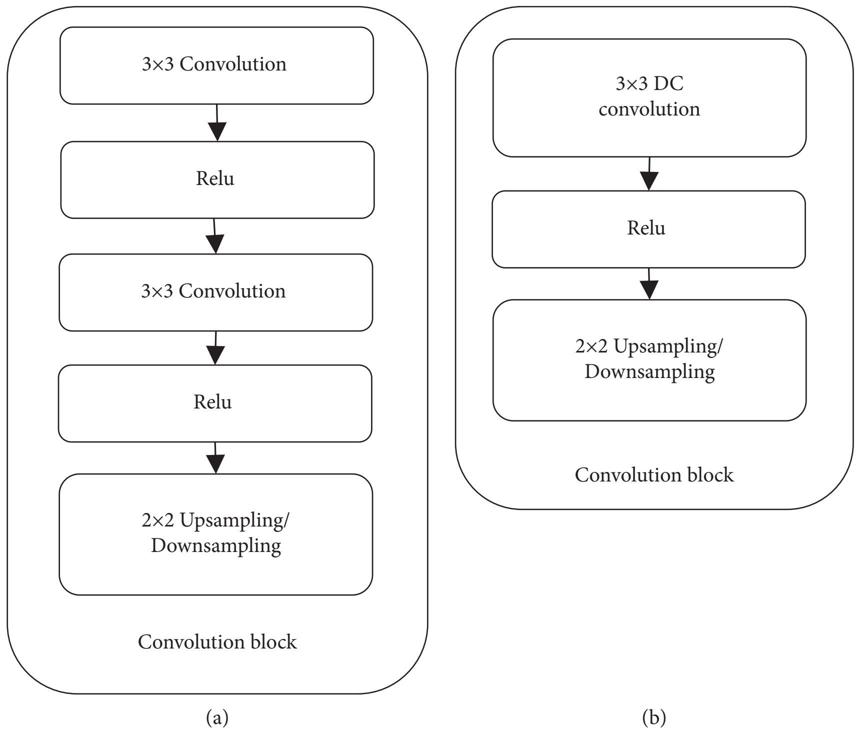

Figure 1: Comparison of two network convolution blocks. (a) U-Net network convolution blocks. (b) U-Net + DC model convolution block proposed in this paper.

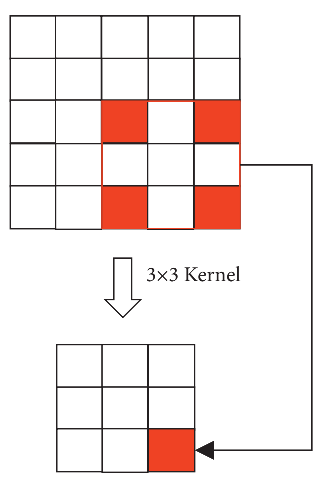

Figure 2: Schematic of cavity convolution.

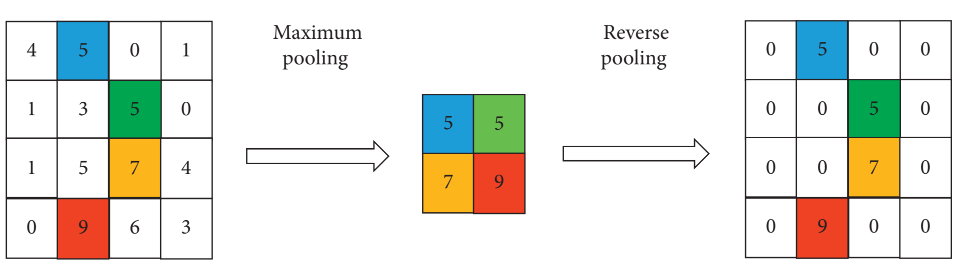

Figure 3: Maximum pooling and reverse pooling.

$$Sigmoid = \frac{1}{e^{-a}} = \frac{1}{1 + e^{-(\omega x + c)}},$$
$$Sigmoid'(a) = \frac{e^{-a}}{(1 + e^{-a})^2}. \tag{4}$$

There are also some problems in the *sidmoid* function. When the number of layers increases, the gradient disappears. The reverse transfer process is as follows:

$$\frac{\partial c}{\partial f_k} = Sigmoid'(a_k)\omega_{k+1} Sigmoid'(a_{k+1})\omega_{k+2} \ldots Sigmoid'(a_n)\frac{\partial c}{\partial h_k}, \tag{5}$$

$$h_k = Sigmoid(a_n) = Sigmoid(\omega_n a_{n-1} + f_n). \tag{6}$$

In equation (5), $\partial c/\partial f_k$ is the gradient of the function to the bias term and a_n is the output.

The Relu function can solve the problem of gradient disappearance, and the convergence rate is fast. The expression is as follows:

$$\mathrm{Relu}(x) = \max(0, x),$$
$$\mathrm{Relu}'(x) = \begin{cases} 0, x < 0 \\ 1, x > 0 \end{cases} \tag{7}$$

The loss function can increase the robustness of the model, which is crucial to the optimization of the model. The expression of mean square error loss D function is shown in the following equation:

$$D = \frac{1}{2n}\sum (y - F(i))^2. \tag{8}$$

In equation (8), $F(i)$ is the output of the model. Then, activation function is as follows:

$$Sigmoid(Z) = Sigmoid(\omega A + b). \tag{9}$$

In equation (9), A and Z are the input and output of the last layer and b is the offset. However, compared with the mean square error loss function, the cross entropy loss function and the Sigmoid function are better. So this paper selects the cross entropy loss function, and its expression is shown in the following equation:

$$D = \frac{1}{n}\sum [y \log(F(i)) + (1 - y)\log(1 - F(i))]. \tag{10}$$

Image denoising and data enhancement are needed before training. Curvature-driven denoising method is used in this paper. Curvature-driven minimization energy function is as follows:

$$G(v) = \lambda \int_\Omega |h_v| \mathrm{d}x + \int_\Omega (F - v)^2 \mathrm{d}x. \tag{11}$$

In equation (11), $(x, y, v(x, y))$ is a surface, $(x, y, F(x, y))$ is the input image, and λ is the parameter. The regularization h_v is expressed as follows:

$$h_v = \frac{1}{2}\nabla\left(\frac{\nabla v}{\sqrt{1 + |\nabla v|^2}}\right). \tag{12}$$

According to the corresponding Euler-Lagrange function, curvature smoothing is realized. In order to improve the convergence speed, we choose Z-score standardized processing:

$$x_1 = \frac{x_2 - \overline{x}}{\sigma}. \tag{13}$$

In equation (13), $\overline{x}$ is the mean and σ is the standard deviation. The data enhancement increases the robustness and generalization ability of the model to prevent the occurrence of overfitting. The enhancement methods selected in this paper are rotation, flip, offset, scaling, elastic transformation, and so on. The original data is extended to about 20,000, and it is trained. The image segmentation process constructed in this paper is shown in Figure 4.

2.3. Simulation Experiment. Simulation environment: the operating system is Windows 10 on LINUX, the processor is Xeon CPU E5-2630, the display card is NVIDIA Quadro K2200, the framework is TensorFlow and Keras, the language is Python 3.5, and the visual library is OpenCV, SimpleITK, CUDA9.0, cudnn, etc.

Network parameters: input image resolution is 256256, convolution block is a hole convolution and activation function, convolution kernel size is 33, according to HDC principle, hole interval is (1,2,5), activation function is Relu function, with 2×2 maximum pooling downsampling, 1×1 convolution layer for multichannel feature fusion, 3×3 convolution upsampling, and the number of training in this paper is 60.

In this study, the lung CT image data is used as the simulation object, and the CNN algorithm is introduced to compare with the algorithm in this paper. The measurement index is Dice coefficient [15].

$$\mathrm{Dice} = \frac{2|E \cap F|}{|E| + |F|}. \tag{14}$$

In equation (14), E is the gold standard for the segmentation of pulmonary nodules, F is the segmentation

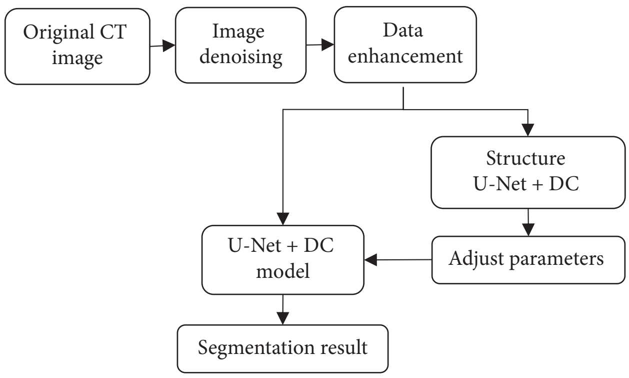

Figure 4: Construction of algorithm segmentation flow.

result, and the range of Dice coefficient is [0,1]. The larger the value is, the better the algorithm performance is.

2.4. CT Examination and Radiofrequency Ablation. At the beginning of scanning, the patient was supine in the center of the CT examination bed. The patient should maintain a peaceful state of mind, not move the body, and routinely inhale. Scanning ranges from chest entrance to diaphragm. Scanning parameters: CT tube voltage is 120 kV, tube current is 300 mAs, scanning field is 260~360 mm, matrix is 512512, layer thickness is 4 mm, and layer spacing is 4 mm. Siemens CT tube voltage is 120 kV, tube current is 380 mAs, scanning field is 220~280 mm, matrix is 512512, layer thickness is 2 mm, and layer spacing is 2 mm. All patients underwent plain scan. CT image is uploaded to Siemens for readings, window width of lung window is 1 600, window level of lung window is 400, and window width of Mediastinal window is 350. The CT images were reviewed by two experienced physicians respectively, and conclusions were reached through discussion in case of disagreement.

2.5. Observation Indicators. The types of pathogens, morphological characteristics of CT manifestations, and lesion distribution of patients with severe pulmonary infection were recorded, and the incidence of morphological characteristics of CT manifestations of pulmonary infection with different pathogens was compared. The sensitivity, specificity, and accuracy of traditional method diagnosis and CT image diagnosis based on U-Net + DC algorithm were compared and calculated.

$$\text{sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \times 100\%, \tag{15}$$

$$\text{specificity} = \frac{\text{TN}}{\text{TN} + \text{FN}} \times 100\%, \tag{16}$$

$$\text{accuracy rate} = \frac{\text{TP} + \text{TN}}{\text{Total}} \times 100\%. \tag{17}$$

In equations (15), (16), and (17), TP represents true positive, TN represents true negative, FP represents false positive, and FN represents false negative.

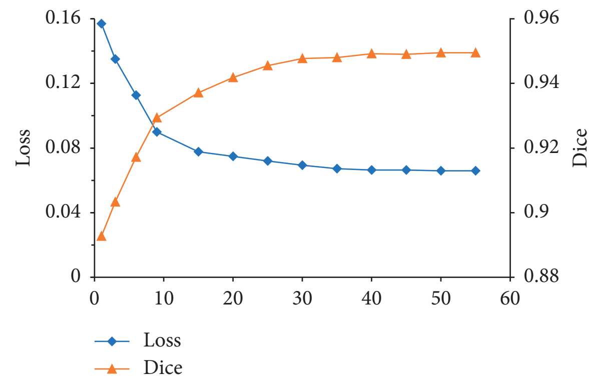

Figure 5: Changes in Loss value and Dice coefficient of U-Net + DC model under different iterations.

2.6. Statistical Methods. The data in this study were analyzed by SPSS 22.0 statistical software. The measurement data were expressed as mean ± standard deviation ($\overline{x} \pm s$), and the count data were expressed as percentage (%). The difference was statistically significant with $P < 0.05$.

3. Results

3.1. Algorithm Simulation Effects. Figure 5 shows the changes in the Loss value and Dice of the U-Net + DC model as the number of iterations increased. It was noted that when the number of iterations was 30, the Loss value tended to be stable, and finally, the Loss value reached 0.0659, and Dice increased with the number of iterations and, finally, reached 0.9495.

Figure 6 shows the single training time of the two algorithms. It was noted that the single training time of the CNN algorithm was 690 s, and the single training time of the U-Net + DC algorithm was 280 s. The single training time of the U-Net + DC algorithm was significantly less than the single training time of the CNN algorithm by 59.4%, and the difference was statistically significant ($P < 0.05$).

Figure 7 shows the Loss value and Dice coefficient of the two algorithms. It was noted that the Loss value and Dice of the CNN algorithm were 0.0731 and 0.9387, respectively, and the Loss value and Dice of the U-Net + DC algorithm were 0.0659 and 0.9495, respectively. The Loss value of the U-Net + DC algorithm was smaller than the Loss value of the CNN algorithm by 9.8%, and the difference was statistically significant ($P < 0.05$). The Dice of the U-Net + DC algorithm was larger than the Dice of the CNN algorithm by 3.6%, and the difference was statistically significant ($P < 0.05$). It showed that, with the gold standard as a reference, the Loss value and Dice of the U-Net + DC algorithm were improved versus the CNN algorithm, and its segmentation effect was better than that of the CNN algorithm.

3.2. Comparison of Lung CT Image Segmentation Effects of the Two Algorithms. Figure 8 shows the lung CT image segmentation effects of the two algorithms. It was noted that, with the gold standard as a reference, the edges segmented by the CNN algorithm were blurred, and the segmentation

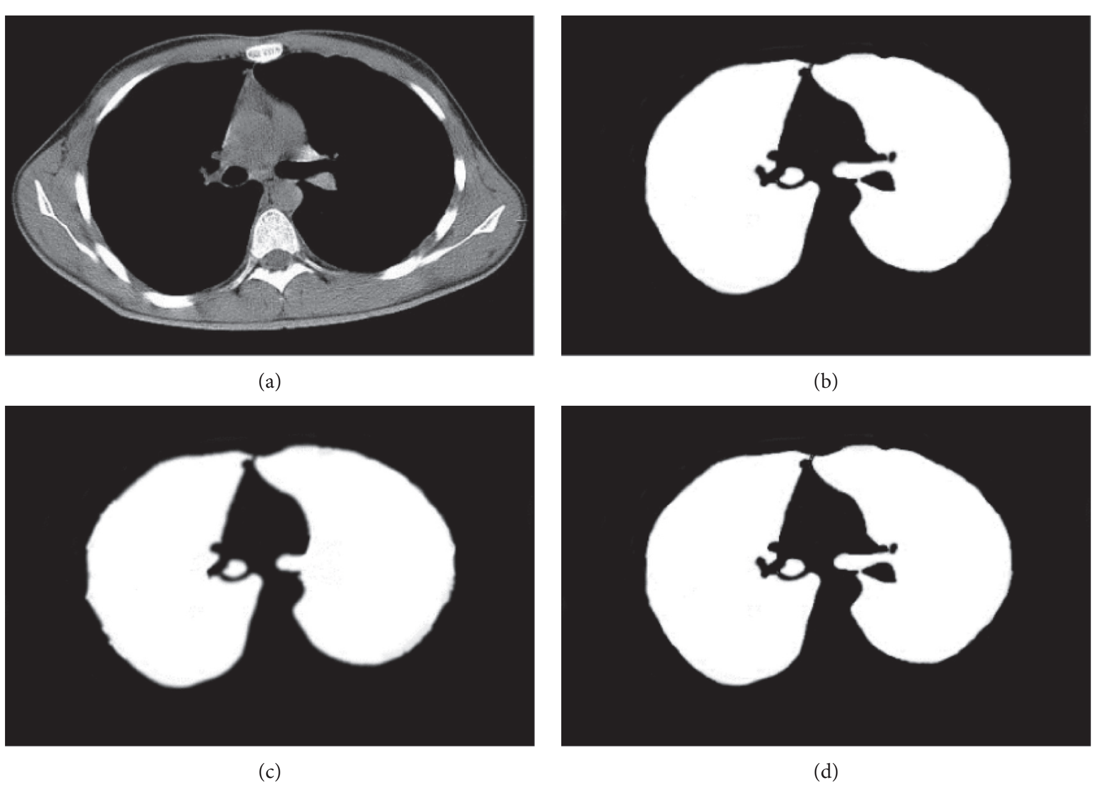

Figure 8: Comparison of lung CT image segmentation results of the two algorithms. (a) The original image, (b) the gold standard, (c) the CNN segmentation result, and (d) the U-Net + DC segmentation result.

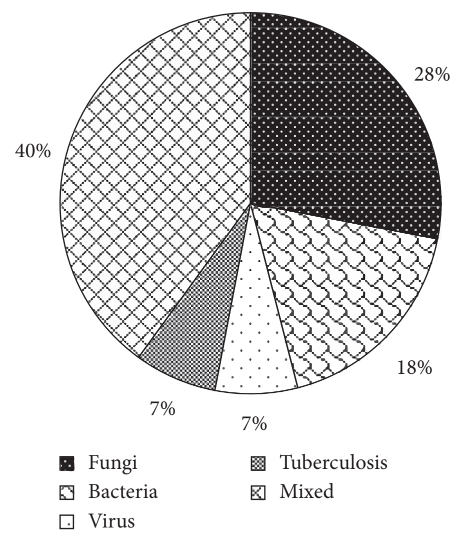

Figure 9: The types of pathogens in patients with severe lung infections.

was affected by the fine blood vessels of the lung organs and other tissue, while the outline of the lungs segmented by the U-Net + DC algorithm was more accurate, and the edges were smoother, which was closer to the gold standard.

3.3. Types and Morphological Characteristics of Pathogens in Patients with Severe Lung Infections. Figure 9 shows the pathogens in patients with severe lung infections. Of the 100 patients with severe lung infections, 28% (28 cases) had fungal infections, 18% (18 cases) had bacterial infections, 7% (7 cases) had viral infections, 7% (7 cases) had tuberculosis infections, and 40% (40 cases) had mixed infections, accounting for the highest proportion.

Figure 10 shows the CT morphological characteristics of severe lung infections. Of the 100 patients with severe pulmonary infections, 36% (36 cases) had ground-glass shadows, 38% (38 cases) had consolidation shadows, 26% (26 cases) had nodules or masses, 17% (17 cases) had reticulated or linear shadows, and 20% (20 cases) had hollow shadows.

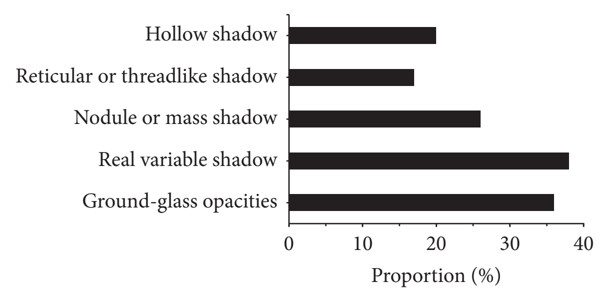

Figure 10: CT morphological characteristics of patients with severe lung infections.

3.4. Images of Various Morphological Features of Patients with Severe Lung Infections. Figure 11 shows images of various morphological features of patients with severe lung infections. Figure 11(a) shows the ground-glass shadow of the right lung. Figure 11(b) shows the large consolidation shadows of the lungs. Figure 11(c) shows the mass-like high-density shadows of the upper lobe of the left lung, and the lungs had multiple small nodules with clear boundaries. Figure 11(d) shows ground-glass shadows and fine mesh shadows. Figure 11(e) shows a hollow shadow in the upper right lung, with patches of increased density around it.

3.5. The Distribution of Lesions in Patients with Severe Lung Infections. Figure 12 shows the lesion distribution of patients with severe lung infections. It was noted that there were 20 cases, 10 cases, 3 cases, and 3 cases with subpleural distribution, middle internal zone distribution, diffuse distribution, and irregular distribution in patients with ground-glass shadows in CT; of the patients with consolidation shadows in CT, there were 21, 8, 5, and 4 cases with subpleural distribution, midinternal zone distribution, diffuse distribution, and irregular distribution, respectively; of the patients with nodules or masses in CT, there were 10 cases, 3 cases, 12 cases, and 1 case with the subpleural distribution, the middle and inner zone distribution, the diffuse distribution, and the irregular distribution, respectively; of the patients with network or line-like shadows in CT, there were 12 cases, 1 case, 3 cases, and 2 cases with the subpleural distribution, the middle inner zone distribution, the diffuse distribution, and irregular distribution, respectively; of the patients with hollow shadows in CT, there were 13 cases, 1 case, 4 cases, and 3 cases with subpleural distribution, midinternal zone distribution, diffuse distribution, and irregular distribution, respectively.

3.6. Comparison of the Incidence of Different CT Morphological Characteristics of Lung Infections with Different Pathogens. Figure 13 shows the incidence of different CT morphological characteristics lung infections with different

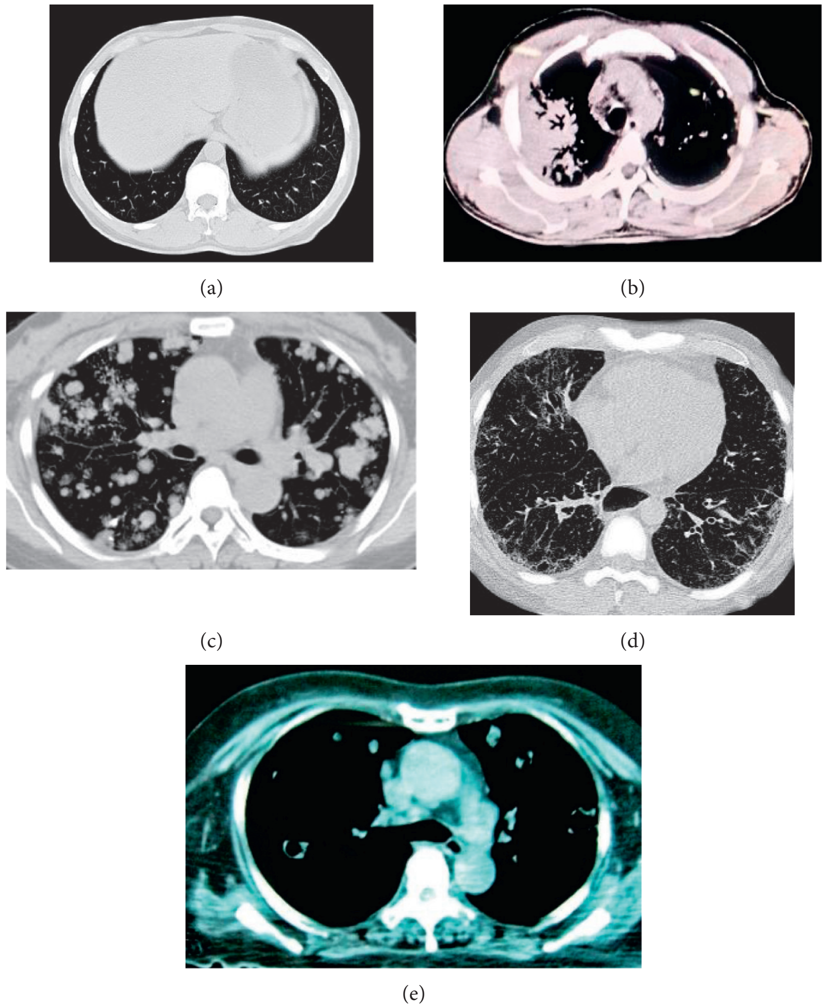

Figure 11: Various morphological feature images of patients with severe lung infections. (a) Ground-glass shadow, (b) consolidation shadow, (c) nodule or mass shadow, (d) network or line-like shadow, and (e) hollow shadow.

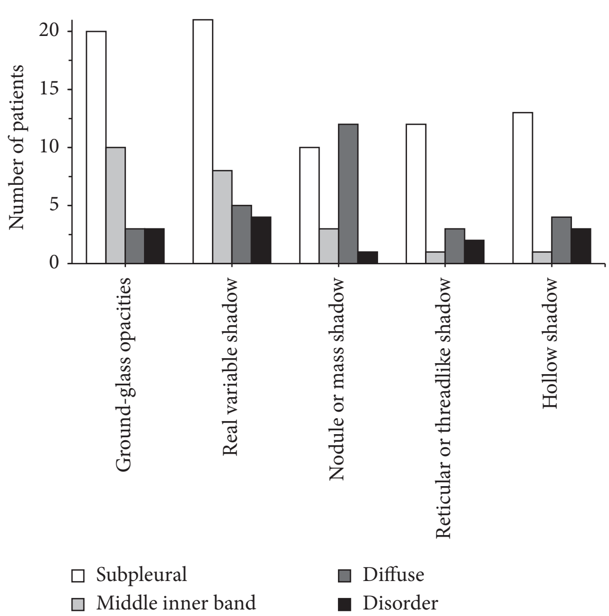

Figure 12: The distribution of lesions in patients with severe lung infections.

pathogens. It was noted that the incidence of ground-glass shadows, consolidation shadows, nodules or mass shadows, network or line-like shadows, and hollow shadows in patients with fungal infections was 25%, 25%, 14.3%, 7.1%, and 28.6, respectively; the incidence of ground-glass shadow, consolidation shadow, nodule or mass shadow, network or linear shadow, and hollow shadow in patients with bacterial infections was 16.7%, 5.6%, 44.4%, 22.2%, and 11.1%, respectively. There were statistically significant differences in the incidence of ground-glass shadows, consolidation shadows, nodules or mass shadows, network or line-like shadows, and hollow shadows in patients with fungal and bacterial infections ($P < 0.05$).

3.7. Diagnosis Accuracy of Patients with Severe Lung Infection in Two Ways. Figure 14 shows the sensitivity, specificity, and accuracy of the two methods of diagnosis. It was noted that the sensitivity of the traditional method was 88.31%, the specificity was 75.74%, and the accuracy was 74.23%; the sensitivity of CT image diagnosis based on the U-Net + DC algorithm was 98.13%, the specificity was 94.32%, and the

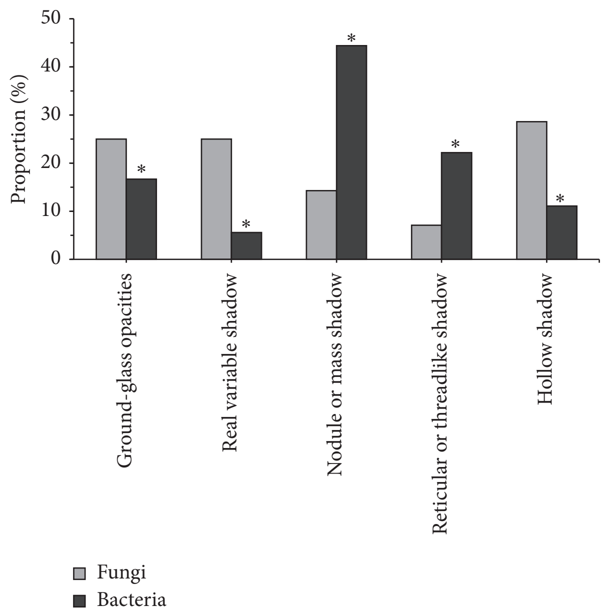

FIGURE 13: Comparison of the incidence of different CT morphological characteristics of lung infections with different pathogens. *Note.* * means the difference was statistically significant compared to fungal infections ($P < 0.05$).

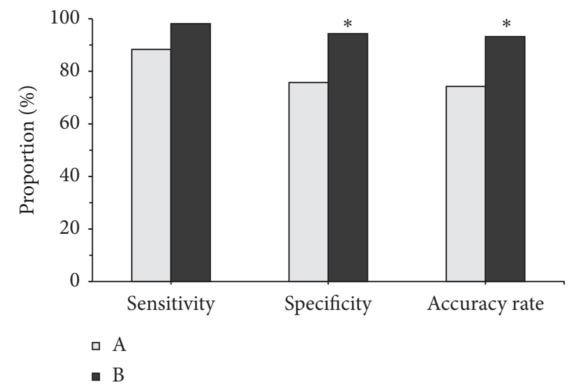

FIGURE 14: Comparison of the sensitivity, specificity, and accuracy of the two diagnosis methods. (a) Traditional method diagnosis. (b) CT image diagnosis based on U-Net + DC algorithm. *Note.* * indicates that, compared with the traditional method, the difference was statistically significant ($P < 0.05$).

accuracy was 97.22%; the specificity and accuracy of CT image diagnosis based on U-Net + DC algorithm were significantly higher than those of traditional method, and the difference was *statistically* significant ($P < 0.05$).

4. Discussion

At present, the morbidity and mortality of patients after the surgery are extremely high due to severe lung infections [16]. CT imaging plays an important role in the diagnosis of severe pulmonary infections and there are high requirements on the accuracy and resolution of the images. With the rapid development of artificial intelligence and information technology, the application of deep learning in medical imaging has made great contributions to the segmentation and diagnosis of medical images [17, 18]. In this study, DC was incorporated into the U-Net network to simplify and improve the U-Net network, and then the improved one was used to process the lung CT images, and its segmentation effect was compared with that of the CNN algorithm. The results showed that the U-Net + DC algorithm had shorter single training time and a lower Loss value than the CNN algorithm, and the difference was statistically significant ($P < 0.05$). Specifically, the single training time was reduced by 59.4% and the Loss value was reduced by 9.8%. The Dice of the U-Net + DC algorithm was larger than the Dice of the CNN algorithm by 3.6%, and the difference was statistically significant ($P < 0.05$). It showed that, with the gold standard as a reference, the U-Net + DC algorithm's various indicators were improved versus the CNN algorithm. It can segment the contours of the lungs more accurately, and the edges were smoother, which was closer to the gold standard.

After that, it was applied to the diagnosis of 100 patients with severe lung infections, and it was compared with the traditional method for the sensitivity, specificity, and accuracy of the diagnosis. The results found that, of the 100 patients with severe lung infections, 28% (28 cases) had fungal infections, 18% (18 cases) had bacterial infections, 7% (7 cases) had viral infections, 7% (7 cases) had tuberculosis infections, and 40% (40 cases) had mixed infections, accounting for the highest proportion. This was in line with the results of Suleyman et al. [19] that, of the 88 patients with lung infections after hematopoietic stem cell transplantation, 27 cases had fungal infections, 12 cases had bacterial infections, and 88 cases had viral infections. Of the 36 patients with ground-glass shadows in CT, there were 20 cases, 10 cases, 3 cases, and 3 cases with subpleural distribution, middle internal zone distribution, diffuse distribution, and irregular distribution; of the 38 patients with consolidation shadows in CT, there were 21, 8, 5, and 4 cases with subpleural distribution, midinternal zone distribution, diffuse distribution, and irregular distribution, respectively; of the 26 patients with nodules or masses in CT, there were 10 cases, 3 cases, 12 cases, and 1 case with the subpleural distribution, the middle and inner zone distribution, the diffuse distribution, and the irregular distribution, respectively; of the 17 patients with network or line-like shadows in CT, there were 12 cases, 1 case, 3 cases, and 2 cases with the subpleural distribution, the middle inner zone distribution, the diffuse distribution, and irregular distribution, respectively; of the 20 patients with hollow shadows in CT, there were 13 cases, 1 case, 4 cases, and 3 cases with subpleural distribution, midinternal zone distribution, diffuse distribution, and irregular distribution, respectively. This was consistent with the results of Ioannou et al. [20] that 4 out of 10 cases of *Aspergillus* infection had subpleural wedge-shaped consolidation shadows. The incidence of ground-glass shadows, consolidation shadows, nodules or mass shadows, network or line-like shadows, and hollow shadows in patients with fungal infections was 25%, 25%, 14.3%, 7.1%, and 28.6, respectively; the incidence of ground-glass shadow, consolidation shadow, nodule or mass shadow, network or linear shadow, and hollow shadow in patients with bacterial infections was 16.7%, 5.6%, 44.4%, 22.2%, and 11.1%, respectively. There were statistically significant differences in the incidence of ground-glass shadows, consolidation shadows, nodules or mass shadows, network or line-like shadows, and hollow shadows in patients with fungal and bacterial infections ($P < 0.05$). The specificity (94.32%) and accuracy (97.22%) of CT image diagnosis based on U-Net + DC algorithm were significantly higher than those of traditional method (75.74% and 74.23%), and the differences were statistically significant ($P < 0.05$). This is better than Chung et al. [21]. The addition of deep learning algorithm makes the diagnosis and segmentation of severe lung patients more accurate and helps medical staff to control the disease more effectively, so as to better treat it.

5. Conclusion

In this study, the DC was incorporated into the U-Net network to simplify and improve the U-Net network, and the improved algorithm was used to process lung CT images, and then it was compared with the CNN algorithm for the sensitivity, specificity, and accuracy of diagnosis. The results showed that the network of the algorithm in this study had better image segmentation effects; in medical diagnosis, CT images based on U-Net + DC algorithm can be used to diagnose severely infected patients, demonstrating high diagnostic value. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the followup, expanded sample size is necessary to strengthen the findings of the study. In conclusion, CT images based on hollow convolution U-Net algorithm are analyzed, which improves the segmentation effect of images and provides a new direction for the diagnosis of patients with severe pulmonary infection.

This study aimed to analyze the application of composite domain analysis algorithm for electroencephalogram (EEG) images of children with epilepsy and to investigate the risk factors related to poor prognosis. 70 children with neurological epilepsy admitted to the hospital were selected as the research objects. Besides, the EEG of the children during the intermittent and seizure phases of epilepsy were collected, so as to establish a composite domain analysis algorithm model. Then, the model was applied in EEG analysis. The clinical disease type and prognosis of children were statistically analyzed, and the risk factors that affected the prognosis of children were investigated. The results showed that the EEG signal values of the detail coefficients (d51 and d52) and the approximate coefficient (c5) during the epileptic seizure period were higher markedly than the signal values of the epileptic intermittent period; the EEG signal of the epileptic intermittent period was a transient waveform, which appeared as sharp waves or spikes. The EEG signal of epileptic seizures was continuous, with a composite waveform of sharp waves and spikes, and the change amplitude of the wavelet envelope spectrum during epileptic seizures was also higher hugely than that of intermittent epilepsy. The accurate identification rate, specificity, and sensitivity of EEG analysis with the composite domain algorithm were higher than those without the algorithm. Among the five types of epileptic seizures in children, the proportion of systemic tonic-clonic status was the largest, and the proportion of myoclonic status was equal to that of complex partial epileptic status, both of which were relatively small. The proportion of children with a better prognosis was 75.71% (53/70), which was higher than those with a poor prognosis 24.29% (17/70). Abnormal imaging examination (odds ratio (OR) = 3.823 and 95% confidence interval (CI) = 1.643–8.897); seizure duration greater than 1 hour (OR = 1.855 and 95% CI = 1.076–3.199); C-reactive protein (CRP) (OR = 5.089 and 95% CI = 1.507–17.187); and abnormal blood glucose (OR = 3.077, 95%CI = 1.640–5.773) were all independent risk factors for poor prognosis (all $P < 0.05$). The composite domain analysis algorithm was helpful for clinicians to find the difference in the EEG signals between the epileptic seizure period and the epileptic intermittent period in a short time, thereby improving the doctor's analysis of the results, which could reflect its marked superiority. In addition, abnormal imaging examinations, convulsion duration greater than 1 hour, CRP, and abnormal blood glucose were independent risk factors for poor prognosis in children. Therefore, the invasion of related risk factors could be reduced clinically by prognostic review with medical advice, attention to food safety and hygiene, and improvement of children's immunity.

1. Introduction

Children's neurological epilepsy is a common neurological syndrome caused by complex, recurrent, paroxysmal, and temporary brain dysfunction in children (0–18 years old). It is characterized by transient, rigid, paroxysmal, and repetitive central nervous system dysfunction. Its causes are mainly perinatal ischemia and hypoxia, cortical dysplasia, low-grade glioma, encephalitis, trauma, and so on, and it is a relatively common disease of children's nervous system [1]. Children can show sweating, convulsions, frequent convulsions, and even suffocation during the onset of the disease, which can easily cause loss of consciousness [2]. According to relevant epidemiological data, the prevalence of neurogenic epilepsy in children is about 6%, and there are at least 8.5 million children with epilepsy in China [3–5].

However, according to reports, the probability of intellectual impairment and structural abnormalities in epilepsy patients is about 20%–65%. Most of the patients have a chronic recurrent disease due to failure to detect and receive the appropriate treatment as early as possible and are accompanied by cognitive dysfunction, which seriously affects the healthy growth of children [6].

At present, the methods for detecting epilepsy in the clinic include computerized tomography (CT), magnetic resonance imaging (MRI), and EEG. What is more, EEG, the most commonly used technique in the clinic, uses electrical signals to record the activity of clusters of brain cells [7]. This examination technique appeared early in the 1970s, and a German professor named Hans Berger first recorded active currents from the human cerebral cortex in the 1990s. In 1935, researchers recorded 3 Hz pulses and ware complexes in the brains of epileptic patients such that slow comprehensive wave can further promote the application progress of EEG in clinical medicine [8]. Seizures will have physiological reactions similar to those of hysteria, syncope, migraine, and other diseases, which are easily confused [9]. Thus, it was necessary to use EEG inspection. According to relevant statistics, 83% of children with epilepsy have abnormal EEG. If proper EEG induction is performed, more patients will have abnormal EEG [10]. Epilepsy will not only damage the body of children but also leave children with sequelae and bring some social discrimination. Therefore, early detection and timely treatment are key to reducing children's neurological epileptic seizures [11].

The composite domain analysis algorithm was a multilead algorithm model that combined time-domain analysis, frequency-domain analysis, and time-frequency analysis. It can improve the efficiency of EEG data analysis and highlight its clinical application potential. In this study, 70 children with neurological epilepsy were selected, followed by EEG tracking. Then, the composite domain analysis algorithm was adopted to explore the clinical characteristics and prognostic factors of children with neurological epilepsy to provide a valuable reference for clinical treatment.

2. Materials and Methods

2.1. General Data. A total of 70 children with neurogenic epilepsy admitted to the hospital from June 2017 to March 2019 were selected as the research objects, including 38 male and 32 female children. Besides, they were from 1 month old to 17 years old, with an average age of 5.02 ± 1.24 years. There were 18 cases under 1 year, 20 cases between 1 and 3 years, 5 cases between 3 and 6 years, and 27 cases between 6 and 17 years. Based on the cause of the children, 23 cases suffered from central nervous system infection, 18 cases had hypoxic-ischemic encephalopathy, 14 cases had intracranial hemorrhage, and 15 cases suffered from head trauma. The diagnostic criteria were referred to the relevant diagnostic criteria in the 2006 International Anti-Epilepsy League Epilepsy Guidelines [12]. The inclusion criteria were defined to include children patients who met the above diagnostic criteria, did not take relevant antiepileptic drugs 3 months before treatment, were not contraindicated with antiepileptic drugs, were not allergic to the relevant treatment and examination drugs used in the treatment or examination in this study, and knew and signed the informed consent (their family members were aware of this study and also signed the informed consent). The exclusion criteria were defined to include children patients who were combined with cognitive impairment; had poor compliance and were unable to cooperate with the researchers; were accompanied by congenital heart disease, meningitis, and cerebrovascular malformations; suffered from abnormal liver and kidney function or were in a stressful state, and switched to other antiepileptic drugs during this study.

2.2. Research Methods

2.2.1. EEG Collection. Before the examination, the children needed to remove their hair and wash their scalp, which should be kept clean and dry. The 16-lead video EEG system produced by Siemens, Germany, was used for examination. The electrodes, 2 reference electrodes, and the anti-interference ground wire were placed in 19 recording electrodes according to the l0–20 system. The scalp resistance of each electrode should be lower than 4.5 kW, the amplitude was 100 uV/cm, the speed of paper skip was 11 mm/s, and there was the routine unipolar lead tracing and the routine flash stimulation test. The monitoring should be continued for 18 hours, and one complete sleep cycle should be recorded at least. Then, the method of continuous playback was employed to intercept the complete EEG during the awake, sleepy, and nonrapid eye movement (NREM) phases. The videos of EEG after 3 months and 6 months of treatment of all children were rechecked to observe the change of EEG discharge frequency.

2.2.2. Composite Domain Analysis Algorithm Model. Based on the children's EEG data, an epileptic EEG signal analysis algorithm of wavelet envelope spectrum was designed under composite domain analysis to better record and analyze the children's EEG data, and the valuable information could be extracted as the basis of clinical treatment.

First, the double-density discrete wavelet transform function was established, and the specific equation was as follows:

$$W(i) = \sqrt{2}\sum_{n} l_0(n)W(2i-n), \tag{1}$$

$$P(i) = \sqrt{2}\sum_{n} l_1(n)W(2i-n). \tag{2}$$

$W(i)$ represented the scale function, l_0 expressed the low-pass filter, l_1 stood for the high-pass filter, and $P(i)$ meant the wavelet number. $ls(n)$, $s = 0, 1, 2$ should meet the following reconstruction conditions, which were presented as follows:.

$$L_0(t)L_0\left(\frac{1}{t}\right) + L_1(t)L_1\left(\frac{1}{t}\right) + L_2(t)L_2\left(\frac{1}{t}\right) = 2, \quad (3)$$

$$L_0(t)L_0\left(-\frac{1}{t}\right) + L_1(t)L_1\left(-\frac{1}{t}\right) + L_2(t)L_2\left(-\frac{1}{t}\right) = 2. \quad (4)$$

Thus, the following equations could be obtained:

$$W_r = W(i-r), \quad (5)$$

$$P_{1,z,r}(i) = P_1\left(2^z i - r\right), \quad (6)$$

$$P_{2,z,r}(i) = P_2\left(2^z i - r\right). \quad (7)$$

Among them, there was $\{z, r \in a, z \geq 0\}$, so the signal to be processed $y(i)$ could be expressed as follows:

$$y(i) = \sum_{r=-\infty} f(r)W_r(i) + \sum_{s=1}^{2}\sum_{z=0}^{\infty}\sum_{r=-\infty}^{\infty} q_s(z,r)P_{s,z,r}(i). \quad (8)$$

In the following equations, f and q stood for the low-frequency coefficient and the high-frequency coefficient, respectively:

$$f(r) = \int v(i)W_r(i)qi, \quad (9)$$

$$q_s(z,r) = \int v(i)P_{s,r,z}(i)qi, \quad s = 1,2. \quad (10)$$

Envelope spectrum analysis, also known as envelope demodulation analysis, is a very effective method for detecting periodic effects of signals, which is extensively used in mechanical fault diagnosis. In order to obtain a clearer and smoother envelope curve, the Hilbert transform formula was required as follows:

$$\begin{aligned}\overline{y}(i) &= y(i) * \frac{1}{\Pi\Gamma} \\ &= \frac{1}{\Pi}\int_{-\infty}^{\infty}\frac{y(\Gamma)}{i-\Gamma}a\Gamma.\end{aligned} \quad (11)$$

$y(i)$ indicated the continuous-time signal, and Γ represented the transformation parameter. Moreover, an analytical signal was constructed by $\overline{y}(i)$ and $y(i)$ in the above equation, as follows:

$$F(i) = y(i) + z\overline{y}(i). \quad (12)$$

Then, the amplitude function could be obtained by taking the modulus value of $F(i)$, which was expressed as follows:

$$O(i) = \lfloor F(i) \rfloor = \sqrt{[y(i)]^2 + [\overline{y}(i)]^2}. \quad (13)$$

The two were combined to analyze the wavelet envelope spectrum of epileptic brain signals, to effectively demodulate the low-frequency signal of each subband from the high-frequency signal in the wavelet domain.

2.2.3. Algorithm Index. The commonly used indexes to evaluate the accuracy of the algorithm are accuracy (Acc), sensitivity (Sen), and specificity (Spe):

$$\begin{aligned}\mathrm{Acc} &= \frac{\mathrm{TP}+\mathrm{TN}}{\mathrm{TP}+\mathrm{TN}+\mathrm{FP}+\mathrm{FN}} \times 100\%, \\ \mathrm{Sen} &= \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FN}} \times 100\%, \\ \mathrm{Spe} &= \frac{\mathrm{TN}}{\mathrm{TN}+\mathrm{FP}} \times 100\%.\end{aligned} \quad (14)$$

TP is the amount of positive data predicted as positive data, TV is the amount of negative data predicted as negative data, FP is the amount of negative data predicted as positive data, and FN is the amount of positive data predicted as negative data.

The double-density discrete wavelet transform decomposition coefficients and the corresponding coefficient envelope spectrum of the EEG signals in children patients were recorded during the intermittent and seizure periods of epilepsy. Since frequency components higher than 70 Hz lacked application value in research and analysis, the Butterworth low-pass filter was adopted to filter EEG signals to remove high-frequency interference. The EEG signals could be decomposed into several different frequency segments by using the compound domain analysis algorithm. These segments could not only separate the mutation signals of the EEG signals but also retain the time information of each segment, which can provide reference materials for the follow-up research. The wavelet envelope spectrum obtained in this study contained not only time-frequency information but also frequency-modulation and amplitude-modulation information, which better revealed the frequency and variation law of the mutation signal in the time-frequency domain. Moreover, the application of dual-density discrete wavelet transform also increased the ability to capture the signal details.

2.2.4. Simulation Algorithm Flow. First, the epileptic EEG signal is processed, and the processing flow is shown in Figure 1.

Epilepsy EEG detection can be formalized as EEG signal classification. The classifiers used in this study are SVM, KNN, LDA, and DT. The four classifiers are introduced as follows.

SVM: Map the data to a higher dimensional feature space, and then determine a hyperplane in this projection space to maximize the classification interval.

KNN: The test sample category is determined based on the category of the K samples closest to it in the feature space; that is, the sample category belongs to most of the k nearest neighbor samples. The number of nearest neighbors K is the only parameter in the KNN model. If $k = 1$, the test sample category will be marked as the nearest neighbor sample category.

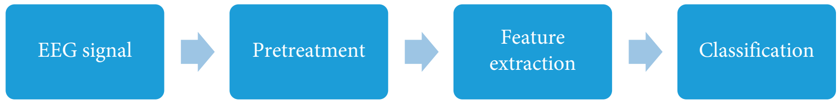

Figure 1: Algorithm flow of epileptic EEG signal analysis.

LDA: It is a classical linear learning method, which projects historical data onto a straight line. After projection, it ensures that the distance between similar data is as close as possible and the distance between different types of data is as far as possible.

DT: It is a nonparametric classifier, which derives decision rules according to the characteristics of training data. Its structure is similar to the flow chart, which is a directed tree composed of root nodes, internal nodes, and leaf nodes. Branching starts from the root node, where each internal node represents the test of a certain attribute of the data, and each leaf node represents the class or its distribution. Once the decision rules are generated and the tree structure is formed, the test data can be input into the tree and divided into different categories.

2.3. Statistical Processing. The collected data were sorted, summarized, and analyzed by SPSS 23.0. Measurement data were expressed as mean ± standard deviation ($\pm s$), and single sample data were represented by t test. In addition, $P < 0.05$ indicated that the difference was statistically substantial.

3. Results

3.1. Double-Density Discrete Wavelet Transform Decomposition Coefficients of EEG Signals and the Corresponding Coefficient Envelope Spectrum. Figures 2 and 3 show that the EEG signal values of the detail coefficients (d51 and d52) and the approximate coefficient (c5) of the epileptic period rose obviously in contrast to the signal values of the epileptic intermittent period. The interphase EEG signal was a transient waveform, which appeared as sharp waves. Besides, the EEG signal of epileptic seizures was continuous, with a composite waveform of sharp waves and spikes, and the change amplitude of the wavelet envelope spectrum in the seizure period was also greatly higher than that in the epileptic intermittent period.

3.2. Recognition Performance of the Composite Domain Analysis Algorithm. Figure 4 indicates that the correct recognition rate, specificity, and sensitivity of EEG analysis after using the algorithm were greater than the analysis value without using the algorithm, and the difference was statistically remarkable ($^*P < 0.05$).

3.3. Statistics of Types of Epileptic Seizures in Children. Among the five types of epileptic seizures in children, the proportion of systemic tonic-clonic status was the largest, the proportion of myoclonic status and complex partial status of epileptic status was equal to each other, and the difference was statistically obvious after comparison ($^*P < 0.05$) (Figure 5).

3.4. The Prognosis of all the Child Patients. Figure 6 reveals that the proportion of children with a good prognosis was 75.71% (53/70), which was higher than that of patients with a poor prognosis 24.29% (17/70), with a statistically marked difference ($^*P < 0.05$).

3.5. Single-Factor Analysis on the Prognosis of Children Patients. The single factor analysis showed that the proportion of imaging examination, convulsion duration, CRP, and blood glucose in children with good prognosis was statistically significant compared with the proportion of children with poor prognosis ($P < 0.05$), as shown in Table 1.

3.6. Multiple-Factor Analysis and Logistic Multiple-Factor Regression Analysis on Middle-Aged and Elderly Bronchial Asthma. The independent risk factors for poor prognosis in children included abnormal imaging examination, convulsion duration greater than 1 hour, CRP, and abnormal blood glucose (Table 2).

3.7. Comparison of EEG and Discharge Index in Children with Epilepsy before and after Treatment. The EEG discharge index of 70 children with epilepsy was 62.8 ± 12.567 before treatment and decreased significantly after treatment. There was a significant difference before and after treatment, $t = 5.766$, $P = 0.000$ ($^*P < 0.005$). Figures 7 and 8 and Table 3 show the details.

4. Discussion

The clinical pathogenesis of epilepsy is relatively complicated, and a clear conclusion has not yet been obtained. Some studies believe that the disease is mainly caused by neurotoxicity, which leads to disorders of intracellular energy, thereby triggering the functions of breathing, liver, and kidney innervated by nerves. Obstacles cause the patients to have cognitive, behavioral, and local neurological deficits, which reduce the quality of life of the children and shorten the survival time of the child patients [13, 14]. Special examinations for children in the clinic include EEG and MRI, and EEG is critical evidence for the diagnosis of epilepsy. Therefore, most clinical doctors recommend that children's family members receive this examination, and the examination process will not make the child patient feel pain. Moreover, the clinical use rate is relatively high [15–17].

In order to improve the accuracy of the EEG examination results, the composite domain analysis algorithm was adopted in this study, the algorithm idea of wavelet envelope analysis

was introduced into the field of epilepsy identification to reduce the influence of excessive fluctuation between single recognition data when the EEG signal analysis algorithm processed fixed classification tasks. Through systematic analysis of formic acid, the results of this study found that the interphase signal was a transient waveform, manifested as

Table 1: Single factor analysis on prognosis of children (cases (%)).

Relevant factors		Good prognosis ($n = 53$)	Poor prognosis ($n = 17$)	P value
Gender	Male	25 (47.17)	9 (52.94)	>0.05
	Female	28 (52.83)	8 (47.06)	
Age (years old)	<6 years old	32 (60.38)	11 (64.71)	>0.05
	≥6 years old	21 (39.62)	6 (35.29)

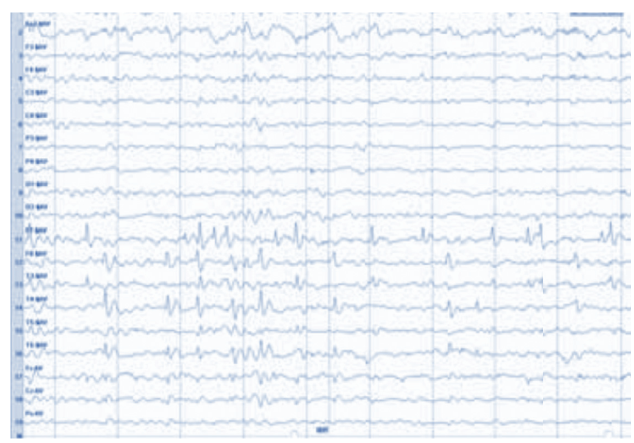

Figure 8: EEG after six months of treatment.

sharp waves or spikes, and the EEG signal of epileptic seizures is continuous, with a composite waveform consisting of sharp waves and spikes. Besides, the latter was brain waves to move more than the former, indicating that brain activity was relatively active in children with epilepsy. However, there were still differences between the intermittent EEG of epilepsy and the normal EEG because the intermittent EEG signal of epilepsy and the EEG signal of epilepsy were abnormal EEG. In this study, algorithm analysis was used, so that persevering clinicians could quickly differentiate and draw conclusions, which shortened the time of clinical diagnosis and promoted the treatment efficiency.

In this study, the clinical data and prognosis of the children were also analyzed. It was found that the generalized tonic-clonic status accounted for the largest proportion among the five types of epileptic seizures in children. Myoclonic status and complex partial status epilepticus accounted for the same proportion, and both had a smaller proportion. Furthermore, the proportion of children with a good prognosis was 75.71% (53/70), higher than that of patients with a poor prognosis (24.29%) (17/70). Statistical analysis of factors affecting the prognosis revealed that abnormal imaging examination, convulsion duration >1

Table 3: Changes of the EEG discharge index before and after treatment in 70 cases of children with epilepsy.

Discharge index	62.8 + 12.567	< 50	5.766	0.000

hour, CRP, and abnormal blood glucose were all independent risk factors for poor prognosis in children patients.

According to a study by Hamano et al. [18], children with epilepsy with abnormal brain CT had a higher risk of poor prognosis, which corresponded to the results of this study. It might be because epilepsy was in a dynamic and constantly changing development process, so abnormalities occurred in daily cranial imaging examinations. According to the results of neuropathological studies, the continuous point activity abnormality of the central nervous system might result in irreversible neuronal damage and even death [19]. Children with recurrent clinical manifestations such as vomiting, nausea, vertigo, limb pain, headache, and abdominal pain, especially school-age patients, should be questioned on medical history in detail. If necessary, the corresponding auxiliary examination should be given. On the basis of excluding common diseases such as pediatric surgery, the disease should be highly suspected. Children should be treated immediately after their diagnosis, followed up, and observed, with paying attention to the toxic and side effects of drugs. They should be given early intervention and treatment in time, and their dose should be mastered. Half an hour after the onset of epilepsy, the child patient had brain hypoxia and decreased metabolic rate, and more than 1 hour could lead to permanent and irreversible brain damage. Therefore, the duration of convulsions longer than 1 hour was also one of the risk factors affecting the prognosis of children. Seizures can trigger a rapid stress response in the body, which increases the possibility of infection. What is more, CRP abnormalities are more common in infections, such as bacterial meningitis, sepsis, and other related encephalopathy. At the same time, studies have pointed out that blood glucose levels are not normal. The prognosis of children within the range is poor, and previous studies have confirmed that hypoglycemia can lead to brain damage [20]. Some children with poor prognosis in this study also suffered from hypoglycemia. Relevant researchers have also found that hyperglycemia is associated with the poor prognosis of patients with epilepsy. Therefore, it is necessary to understand whether children have the above risk factors during treatment and to diagnose and treat them in time [21].

5. Conclusion

To sum up, the composite domain analysis algorithm was applied in this study to analyze the EEG images of 70 children with neurogenic epilepsy, suggesting the difference between the EEG signals in the epileptic intermittent period and the epileptic period, which improved the doctor's understanding of the results. It also reflected the significant superiority of the composite domain analysis algorithm. In this study, the influencing factors of the patient's poor prognosis were also analyzed and sorted out, indicating that abnormal imaging examination, convulsion duration >1 hour, CRP, and abnormal blood glucose were independent risk factors for the poor prognosis of children patients. Therefore, the invasion of related risk factors could be reduced clinically through the prognostic review with medical advice, attention to food safety and hygiene, and improvement of children's immunity. In addition, researchers should continue to investigate the risk factors of poor prognosis in children patients with epilepsy and introduce them into the preventive treatment process to enhance rapid recovery of children patients.

The shortcomings of this study are that the description of the EEG research process is simple, and no more in-depth analysis has been carried out. Therefore, further in-depth discussions are needed in future research to better provide a clinical reference.

Academic Editor: Enas Abdulhay

This paper aimed to study the application value of Internet of Things (IoT) edge computing algorithm-based ultrasound-guided erector spinae plane block combined with edaravone anesthesia in thoracoscopic lobectomy. A total of 110 patients undergoing thoracoscopic resection were selected as subjects. The patients were anesthetized with erector spinae plane block combined with edaravone before surgery and underwent chest ultrasound scan. IoT edge computing algorithm was constructed and applied to ultrasound images of patients to enhance and denoise the images. It was found that, in different mixed noise mixtures (Gaussian noise 10% + speckle noise 90%; Gaussian noise 30% + speckle noise 70%), the edge computing algorithm can still maintain the edge information of the output image, showing better performance on edge information detection and denoising compared with the Prewitt and Canny operator. In addition, visual analog scale (VAS) scores decreased with postoperative time after edaravone anesthesia induction and erector spinae plane block lobectomy and reached the lowest level after five days. In short, erector spinae plane block combined with edaravone showed good sedative and analgesic effects on patients undergoing thoracoscopic lobectomy. Ultrasound images processed by IoT edge computing algorithm showed high accuracy in the identification of lung lesions, which was worth applying to clinical diagnosis.

1. Introduction

Lobectomy is mainly used for lobectomy of malignant tumors limited to the lung, pulmonary damage caused by tuberculosis, severe bullae, bronchiectasis, interstitial lesions, trauma, and dysplasia. Lobectomy is a kind of routine pulmonary resection [1]. The human body has five lobes in the chest cavity. The right lung is made up of the upper lobe, the middle lobe, and the lower lobe. The left lung is made up of two lobes, the upper lobe and the lower lobe. Lobectomy is suitable for lung cancer and irreversible lesions confined to the lung lobe. It mainly includes right upper lobectomy, right middle lobe lobectomy, right lower lobectomy, left upper lobectomy, and left lower lobectomy. If the lesion involves two lobes or the middle bronchus, upper-middle or lower-middle lobe, two-lobe lung resection is feasible [2]. In general, the quality of life of patients after surgery is good. In normal survival, postoperative patients need to pay attention to climate changes, keep warm, pay attention to diet, and avoid irritating gases [3]. In addition, patients need to exercise properly to enhance their resistance, closely observe their symptoms and signs, and go to the hospital for comprehensive examination and treatment as soon as possible if there is an abnormality [4, 5]. Thoracoscopic lobectomy means that, with the assistance of thoracoscopy, the surgeon only observes the situation in the thoracic cavity in real time through a TV screen and completes the operation through one to four hole-like incisions (without spreading the ribs) with the longest length not exceeding 5 cm. The veins, arteries, and bronchi are cut off anatomically to completely remove the lung lobes. At present, video-assisted thoracic surgery (VATS) lobectomy has basically matured and gained wide acceptance. The surgical technique is also gradually refined and perfected day by day [6, 7]. The

National Comprehensive Cancer Network (NCCN) lung cancer treatment guidelines clearly point out that "VATS lobectomy is a viable option for resectable lung cancer," which means that the role of thoracoscopic lobectomy for the treatment of benign lung lesions or early malignant lesions has been confirmed [8].

However, the postoperative pain of this type of surgery is relatively strong. Insufficient intraoperative anesthesia or insufficient postoperative analgesia will affect the patient's cough, sputum, and so on, which may easily lead to adverse events and affect the patient's recovery process. Edaravone is a new type of free radical scavenger, which can scavenge oxygen-free radicals, inhibit lipid peroxidation of cell membranes, and reduce tissue edema and damage. Studies have shown that edaravone can reduce the production of inflammatory factors in the human body and has a protective effect on the lungs of patients [9]. In recent years, an interfascial plane block technique has gradually been used clinically, that is, ultrasound-guided erector spinae plane block (ESPB). It was first applied to severe acute postoperative pain and neuropathic pain in 2016, and it was successful. Studies have shown that ESPB is easy to operate, has high safety, low error rate, good analgesic effect, and few adverse reactions, and shows broad clinical application prospects [10].

With the full integration and adoption of cutting-edge technologies such as big data, Internet+, AI, and Internet of Things (IoT), AI-assisted medicine has shown strong influence and vitality. It plays an important supporting role in deepening the reform of the medical and health system, accelerating the construction of "healthy China," and promoting the development of the medical and health industry [11]. At present, medical imaging such as ultrasound (scanning the human body with ultrasound beam and obtaining images of internal organs by receiving and processing reflected signals) and magnetic resonance have gradually developed from auxiliary examination methods into the most important clinical diagnosis and differential diagnosis methods in modern medicine [12, 13]. Through big data plus artificial intelligence technology solutions, AI-assisted diagnosis and treatment adoptions are built, medical imaging data are modeled and analyzed, and conditions and lesions are analyzed to provide decision support for doctors and improve medical efficiency and quality [14, 15]. In this way, the high rate of misdiagnosis and missed diagnosis due to the limitation of doctors' experience in the field of medical imaging can be better solved, so did the long reading time, slow speed, and many other problems [16].

In the process of thoracoscopic lobectomy, some small pulmonary nodules cannot be accurately located during thoracoscopic surgery, and the boundary of pulmonary nodules is not easy to be identified. Ultrasonic guidance based on IoT edge detection algorithm was used to identify and locate hilar vessels and to surround small nodules in thoracoscopic lobotomy, to study the adoption value of the intelligent algorithm and ultrasound image in thoracoscopic lobectomy, aiming to provide more reference for the diagnosis and treatment of lobectomy and the sedation and analgesia methods of postoperative patients.

2. Materials and Methods

2.1. General Information. In this study, 110 patients who received thoracoscopic lobotomy in hospital from September 2019 to September 2020 were collected as subjects, including 58 male patients and 52 female patients aged 25~68 years (43.7 ± 5.2 years on average). This study had been approved by the Medical Ethics Committee. The patients and their families understood the content and methods of the study and agreed to sign the corresponding informed consent.

Inclusion criteria were as follows: (i) patients who underwent lobectomy after prepathological and imaging diagnosis of lobectomy; (ii) patients aged between 45 and 65 years; (iii) patients with no pulmonary metastasis, mediastinal lymph node enlargement, or pleural hypertrophy; (iv) patients who had not received any other drugs or antibiotics recently; (v) patients with normal coagulation function and platelets.

Exclusion criteria were as follows: (i) patients with other system or organ lesions; (ii) patients who did not cooperate with treatment due to personal or other factors; (iii) patients with incomplete clinical data and medical history.

2.2. Patient Anesthesia and Surgical Methods. All patients were fasting and abstaining from drinking 6 h before anesthesia induction, and all vital signs were monitored before surgery, including heart rate, diastolic blood pressure, systolic blood pressure, pulse oxygen saturation, and mean arterial pressure. 0.5 mg/Kg edaravone was added to 100 mL normal saline, and the infusion was completed within 30 min. A conventional disinfection towel was taken from the surgical position, and an erector spinae plane block was performed under the guidance of ultrasound. The puncture was performed after local anesthesia with 1% lidocaine at the puncture site. Local anesthetic drugs were injected after a puncture to the designated location, and a two-point block was selected according to the intercostal incision. Each puncture site was injected with 10 mL of drugs, and 0.5 mg/Kg edaravone was used as an anesthetic. The results of nerve block were tested by alcohol cotton ball 10 minutes after injection.

In lobotomy, an incision was made in the fifth intercostal area between the midaxillary line and the anterior axillary line, approaching the hilum at a small angle to facilitate the operation of hand instruments along the longitudinal axis. During the operation, the hemodynamic indexes of patients were monitored in real time, and the corresponding vasoactive drugs were timely corrected in case of intraoperative hemodynamic instability.

All patients included in the study underwent lung ultrasound examination. The patient was placed in a lateral position, and a high-frequency linear array probe was used for sagittal scanning. After the T4 spinous process was positioned, the probe was moved 3–5 cm to the outside to show the T5 transverse process, pleura, and transverse costal ligament. The ultrasound images were interpreted by two attending physicians or imaging physicians with rich clinical experience. The specific location of pulmonary lesions, the maximum diameter of the lesion site, and hilar and mediastinal lymph node enlargement were mainly observed and analyzed by ultrasound.

2.3. IoT Edge Computing. The image edge generally refers to the position where the grayscale change rate of the image is the largest. Edge detection refers to the process of detecting edge points and edge segments from the image and describing the edge direction. The image is regarded as a binary function $f(x, y)$, (x, y) is the position of the pixel, and $f(x, y)$ is the gray value at that point so that the image is regarded as a curved surface. The edge of the image is the most drastically changing position on the curved surface, and this position is also the position of the local extreme point of the curved surface. The basic idea of the image segmentation method based on edge detection is determining the edge pixels in the image first. Then, these pixels are connected together to form the required area boundary. Figure 1 shows the image edge type and its derivative curve law.

The brightness change of the image can be processed and enhanced by the difference between adjacent points. Differential processing of adjacent points in the horizontal direction can detect the brightness change in the vertical direction, that is, the horizontal edge detector (horizontal edge detector). Differential processing of adjacent points in the vertical direction can detect the brightness change in the horizontal direction, that is, the vertical edge detector (vertical edge detector). The expressions are shown in

$$E_x = \left|P_{x,y} - P_{x+1,y}\right|, \tag{1}$$

$$E_y = \left|P_{x,y} - P_{x,y+1}\right|. \tag{2}$$

Among them, E_x represents the vertical edge and E_y represents the horizontal edge. The horizontal edge detection operator and the vertical edge detection operator are combined, and the vertical edge and the horizontal edge can be detected at the same time, as shown in

$$E_{x,y} = \left|P_{x,y} - P_{x+1,y} + P_{x,y} - P_{x,y+1}\right|. \tag{3}$$

From the above equation, equation (4) is obtained:

$$E_{x,y} = \left|2 \times P_{x,y} - P_{x+1,y} - P_{x,y+1}\right|. \tag{4}$$

If a pixel is inserted between two adjacent difference points to achieve this, it is equivalent to using two adjacent first-order differences as the new horizontal difference, as in

$$\begin{aligned} E_{xxx,y} &= E_{xx+1,y} + E_{xx,y} = \left|P_{x+1,y} - P_{x,y} + P_{x,y} - P_{x-1,y}\right| \\ &= \left|P_{x+1,y} - P_{x-1,y}\right|. \end{aligned} \tag{5}$$

Here, E_{xx} represents the new level difference.

A gradient operator is defined by the method of first-order differentiation. The gradient is a vector, which indicates the direction of the most dramatic change in the gray level of the image.

$$\nabla f = \left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}\right). \tag{6}$$

The gradient can be expressed as

$$\|\nabla f\| = \sqrt{\left(\frac{\partial f}{\partial x}\right)^2 + \left(\frac{\partial f}{\partial y}\right)^2}. \tag{7}$$

The direction of the gradient is shown in

$$\theta = \left(\frac{\partial f/\partial y}{\partial f/\partial x}\right). \tag{8}$$

In actual image processing, the difference method is used for calculation. However, the use of the differential method for edge detection must make the direction of the difference perpendicular to the direction of the edge. Therefore, it is necessary to perform difference calculations in different directions of the image, which increases the amount of calculation. Generally, the edges are divided into horizontal edges, vertical edges, and diagonal edges.

2.3.1. Roberts Operator. The Roberts gradient operator uses the difference between the values of two adjacent pixels in the diagonal direction as a measurement standard, and its calculation method is shown in

$$G_x = f(i, j) - f(i-1, j-1), \tag{9}$$

$$G_y = f(i-1, j) - f(i, j-1), \tag{10}$$

$$|G(x, y)| = \sqrt{G_x^2 + G_y^2}. \tag{11}$$

Equation (11) is written in the form of convolution operation, and the convolution kernels are the following equations:

$$G_x = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \tag{12}$$

$$G_y = \begin{bmatrix} 0 & 11 \\ 1 & 0 \end{bmatrix}. \tag{13}$$

2.3.2. Prewitt Operator. The Prewitt operator combines the method of difference operation and neighborhood averaging, and its convolution template is shown in

$$G_x = \begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix}, \tag{14}$$

$$G_y = \begin{bmatrix} -1 & -1 & -1 \\ 0 & 0 & 0 \\ 1 & 1 & 1 \end{bmatrix}. \tag{15}$$

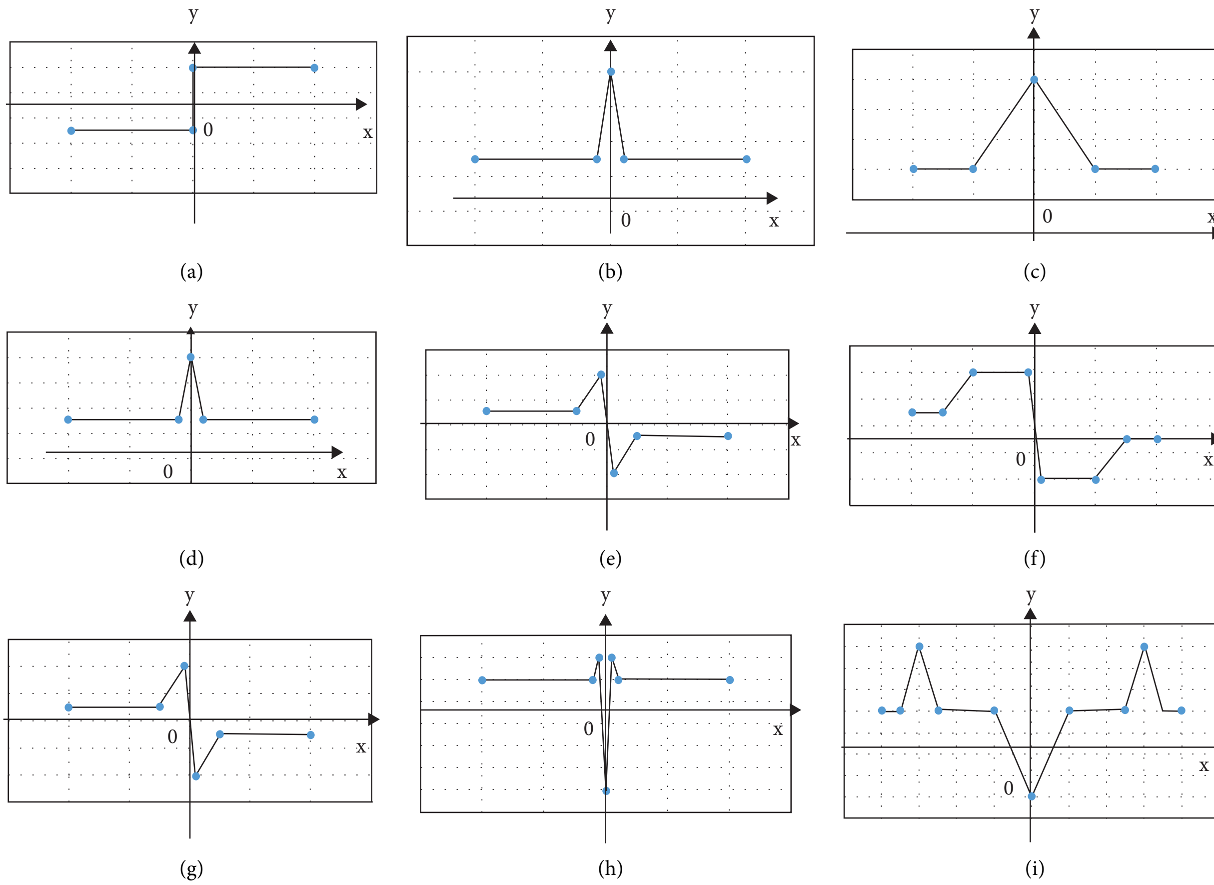

Figure 1: Image edge type and its derivative curve law. (a) Gray cross section-step shape; (b) gray cross section-thin line shape; (c) gray cross section slope gradient; (d) first-order differential-step shape; (e) first-order differential-thin line shape; (f) first-order differential-slope gradient shape; (g) second-order differential-step shape; (h) second-order differential-thin line shape; (i) second-order differential-slope gradient shape.

2.3.3. Soble Operator. The two Soble operators are for detecting horizontal edges and detecting vertical edges. It weighs the influence of the position of the pixel, which can reduce the degree of edge blur. Since the Soble operator is a form of filter operator, it is used to extract the edge and can use the fast convolution function, which is simple and effective. However, the Soble operator does not strictly distinguish the main body of the image from the background; that is, it is not based on image grayscale processing. Figure 2 shows the template of the Soble operator.

2.3.4. Prewitt Edge Detection Operator. If the weights of the center pixels of the two Prewitt template operators are doubled, the well-known Soble edge detection operator is obtained. It is composed of two masks that determine the edge in a vector manner. Soble has better performance than other edge detection operators in the same period as the Prewitt operator (Figure 3).

2.4. Evaluation of Edge Detection Effect of Ultrasonic Images. Ultrasound uses the difference between echo and original sound waves to produce images. The ultrasonic wave will change after being reflected by the object. The change is related to the shape characteristics of the object, and the shape of the object is determined according to the reflected wave. Ultrasound is injected into the body through the organs and tissues with different acoustic impedance and different attenuation characteristics from the surface to the deep, resulting in different reflections and attenuations. However, the existing ultrasound imaging technology is susceptible to interference from image noise, and the detection effect of blur and discontinuous edges is not good. Therefore, the IoT edge detection algorithm processes the ultrasound image and then judges its blur and discontinuous edge detection effect on the ultrasound image by setting the direction of the edge detection and the edge gray threshold.

2.5. VAS Evaluation Criteria. VAS is used for pain assessment and is widely used in clinical practice. The basic method is to use a moving ruler about 10 cm long with 10 scales on one side, and the two ends are "0" and "10" points, respectively. 0 points mean no pain, and 10 points mean the most severe pain that is unbearable [17].

2.6. Statistical Methods. The data processing in this study was analyzed by SPSS 19.0 version statistical software, some

measurement data were expressed by the mean ± standard deviation ($\overline{x} \pm s$), and the count data were expressed by the percentage (%). Pairwise comparison used analysis of variance. $P < 0.05$ indicated that the difference was significant.

3. Results

3.1. Lung Ultrasound Signs. Figure 4 shows the ultrasound signs of the lungs. In a normal lung ultrasound image, a hyperechoic line that slid back and forth with breathing motion was seen on the deep surface of the rib line, which was called the "pleural line." When the ultrasound was projected perpendicularly to the pleura-lung surface, reverberation artifacts may appear, which were manifested as multiple echoes arranged at equal distances. Its intensity decreased successively, called "A line," so the normal lung ultrasound image features were "slip sign" and "A line."

3.2. Signal-to-Noise Ratio of the Output Image. The signal-to-noise ratio of the filtered image can represent the denoising effect of the algorithm on the image with noise. Figures 5 and 6 show the signal-to-noise ratio (SNR) of the output image processed by different filters under Gaussian noise 10% and speckle noise 90% and Gaussian noise 30% and speckle noise 70% of the noise mixed conditions, respectively. Under different mixed noise conditions and signal-to-noise ratio conditions, the edge detection algorithm can still better maintain the edge information of the output image, and the image enhancement effect was ideal.

3.3. Lung Ultrasound Edge Detection. Figure 7 shows the ultrasound images of the lung and the image after image enhancement and noise processing were performed by the edge detection algorithms of the Canny operator, Prewitt operator, and Soble operator. The improved filter of the edge detection algorithm can not only maintain the original texture details and edge information of the input and output images in the image processing process but also process and suppress the noise pollution of the background of the image and the internal noise of the organization to a higher degree. Moreover, the Soble operator had better edge detection performance than the Prewitt operator and Canny operator in the same period and had better edge information detection and denoising performance for ultrasound images.

3.4. Detection Rate of Lung Nodules by Three Edge Detection Operators. Figure 8 shows the comparison results of the detection rates of lung nodules of different sizes after the Canny operator, Prewitt operator, and Soble operator edge

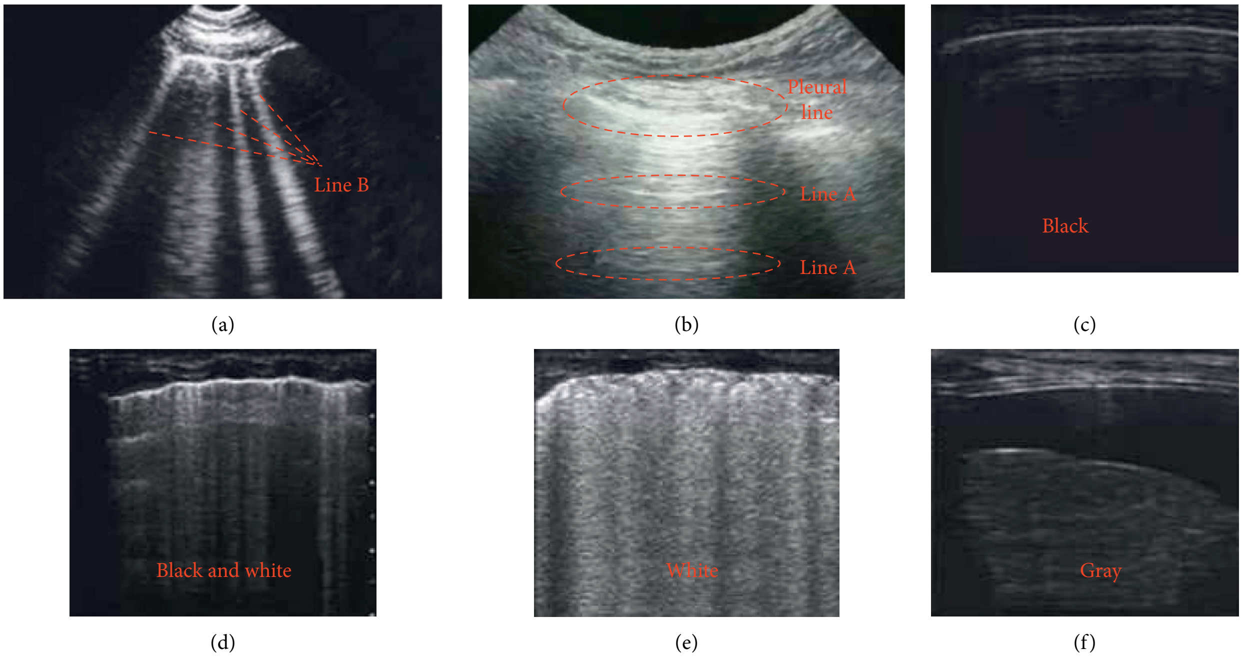

FIGURE 4: Ultrasound signs of the lungs. (a) A line; (b) B line; (c) normal; (d) mild-to-moderate interstitial edema; (e) severe interstitial edema and alveolar edema; (f) lung consolidation.

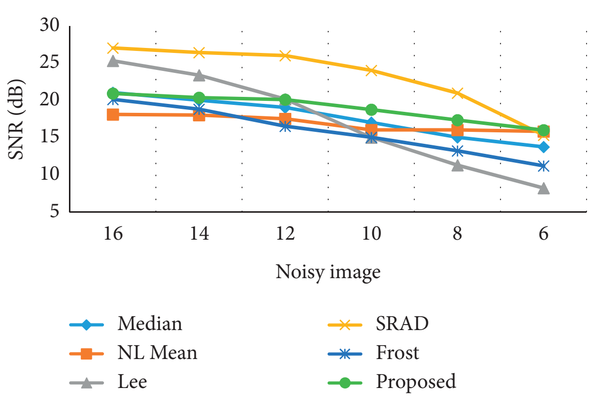

FIGURE 5: Signal-to-noise ratio of the output image of the edge detection filter (Gaussian noise 10%; speckle noise 90%).

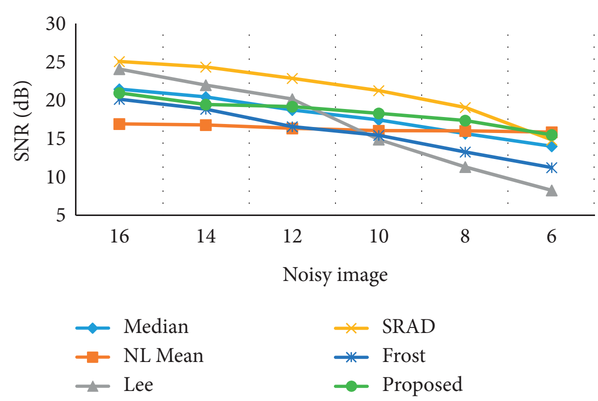

FIGURE 6: Signal-to-noise ratio of the output image of the edge detection filter (Gaussian noise 30%; speckle noise 70%).

detection algorithms processed lung ultrasound images. For lung nodules smaller than 6 mm, the detection rates of the three edge detection operators were 90.98%, 87.53%, and 92.35%, respectively. For lung nodules from 6 to 30 mm, the detection rates of the three edge detection operators were 88.32%, 90.87%, and 95.44%, respectively. The detection rate of the Soble operator for lung nodules of different sizes was significantly higher than that of the Canny operator and Prewitt operator edge detection algorithm ($P < 0.05$).

3.5. VAS Score after the Patient's Operation. Figure 9 shows the visual analog score (VAS) of patients in different periods after thoracoscopic lobectomy. Figure 9(a) shows the VAS score result in the resting state, and Figure 9(b) shows the VAS score result in the patient's exercise state. After edaravone was used for induction of anesthesia and lobectomy after erector spinae plane block, the patient's VAS score decreased with the prolongation of postoperative time. After five days, the patient's VAS score was reduced to a lower level.

4. Discussion

Edge detection of medical image is an important basis for image segmentation, object recognition, region shape extraction, and other image processing fields. In the process of image understanding and analysis, the first step is often edge detection to identify the points with obvious brightness changes in digital images [18]. The so-called edge refers to the set of pixels with sharp changes in the gray level of the surrounding pixels, which is the basic feature of the image. Edge exists between target, background, and region, which is

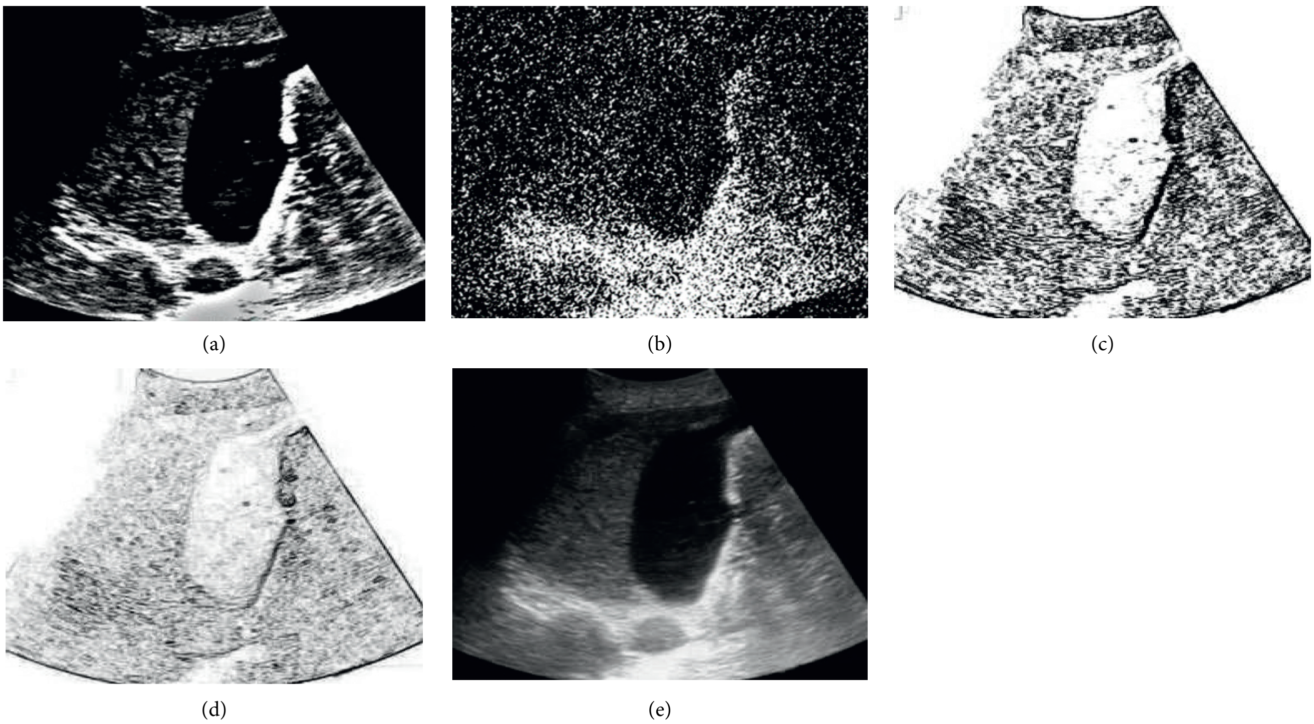

Figure 7: Ultrasonic edge detection of lungs. (a) The original image; (b) the image contaminated by noise; (c–e) edge detection and image processing of Canny operator, Prewitt operator, and Soble operator, respectively.

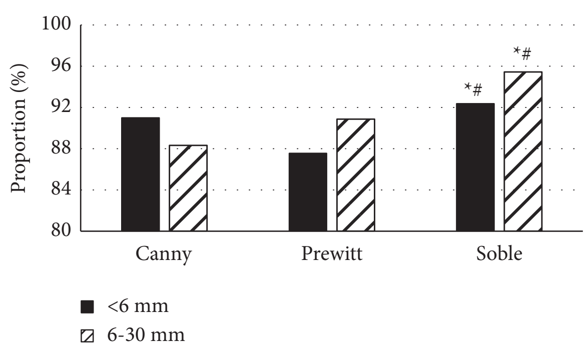

Figure 8: Detection rate of lung nodules by three edge detection operators. Note: * means significant difference compared to Canny operator ($P < 0.05$); # means significant difference compared to Prewitt operator ($P < 0.05$).

the most important basis for image segmentation. As an indicator of position, edge is insensitive to changes in gray level, so it is an important feature of image matching [19]. Image edge contains the useful information used for identification in the image, which greatly reduces the amount of data, eliminates the irrelevant information, and retains the important structural attributes of the image. The use of edge detection technology for visual detection has become the latest trend in image sensor adoptions. In addition, as edge detection plays an important role in image analysis such as computer vision and ultrasound, it provides valuable feature parameters for people to describe or identify objects and to interpret images. Cao et al. [20] found that ultrasound-guided erector spinae plane block technology had the advantages of simple operation and high safety factor. In addition, ultrasound-guided erector spinae plane block lobectomy was performed with high recognition of intermuscular images and no risk of spinal cord injury compared with other blocking methods. Erector spinae plane block has a long duration of action and a wide range of action. To a certain extent, it can effectively shorten the hospital stay of patients undergoing lobectomy and accelerate the postoperative recovery speed, which has a high adoption value.

In this study, patients undergoing laparoscopic lobectomy were selected as subjects, and lung ultrasound examination was performed on the included patients. The ultrasonic image was filtered, enhanced, and denoised by IoT edge detection algorithm. Ultrasound images were processed and used in erector spinae plane block combined with edaravone anesthesia-induced lobectomy. It was found that, under different mixed noise conditions and SNR conditions, the edge detection algorithm can still maintain the edge information of the output image well and the image enhancement effect was good. The Soble operator had better edge detection performance than the Prewitt operator and Canny operator at the same period and had better edge information detection performance for ultrasonic images. Edge detection and filtering had a good effect on noise removal of ultrasonic images. The detection rate of the Soble operator for pulmonary nodules of different sizes was significantly higher than that of the Canny operator and Prewitt operator ($P < 0.05$). VAS scores decreased with postoperative time after edaravone anesthesia induction and erector spinae plane block lobectomy. After five days, the VAS score of the patients was reduced to a low level. The results of this study were in line with expectations. A number of previous studies have shown that erector spinal muscle plane block combined with edaravone has a positive sedative and analgesic effect on patients undergoing thoracoscopic lobectomy. Ultrasound images based on IoT edge computing algorithm are more accurate in the identification of lung lesions. This was similar to the results of Williams et al. [21], indicating that erector spinae plane block combined with edaravone anesthesia induction had good sedative and analgesic effects on patients undergoing thoracoscopic lobectomy, which also improved the prognosis of patients.

5. Conclusion

In this study, three edge detection algorithm models were constructed and applied in the ultrasound images of 110 patients with lung disease. The results found that the erector spinal muscle plane block combined with edaravone had a better sedative and analgesic effect on patients undergoing thoracoscopic lobectomy. The ultrasound image based on the IoT edge computing algorithm showed higher accuracy in identifying lung lesions, and it was worth applying to clinical diagnosis. The disadvantage was that it lacked comparison with other intelligent algorithms, and the representativeness was low. Therefore, in subsequent experiments, an improvement and optimization would be made in this area, and more in-depth exploration of this direction would be carried out. In summary, this study provided a reference for the application of intelligent algorithms such as edge detection in medical imaging.

Academic Editor: Enas Abdulhay

Based on the ordered subsets (OS), a linear augmentation Lagrangian method (OS-LALM) was constructed, which was then combined with the optimized gradient method (OGM) to construct the OS-LALM-OGM, so as to discuss application of the computed tomography (CT) images based on OS-LALM-OGM in evaluation of clinical manifestations and complications of patients before transcatheter aortic valve implantation (TAVI). The OS-LALM-OGM was compared with the filtered back projection (FBP) and OS-LALM. In addition, it was applied to evaluate the conditions of 128 patients before TAVI. It was found that the peak signal-to-noise ratio (PSNR) of OS-LALM-OGM was greater than that of the FBP and OS-LALM when the number of iterations was 5, 20, and 40, while the root mean square error (RMSD) was the opposite ($P < 0.05$). The proportion of dyspnea was the highest, 38.28%, followed by angina (19.53%) and fainting (21.09%). The long diameter of the annulus and the average inner diameter of the annulus measured by the CT image based on the OS-LALM-OGM algorithm were greatly larger than the inner diameter of the aortic annulus measured by the CT based on the FBP algorithm ($P < 0.05$); the evaluation sensitivity (95.24%) and specificity (85.85%) of CT based on the OS-LALM-OGM algorithm were obviously greater than those of X-ray, which were 84.43% and 76.77%, respectively ($P < 0.05$). In short, the OS-LALM-OGM proposed had a relatively excellent effect on CT image reconstruction. The CT image based on the OS-LALM-OGM algorithm showed a better evaluation performance for patients before TAVI than the traditional FBP algorithm, showing higher sensitivity and specificity.

1. Introduction

The aortic valve is a "valve" located between the left ventricle and the aorta. When the ventricles contract, the aortic valve opens and blood flows into the aorta. Aortic valve stenosis refers to the abnormality of the aortic valve structure or function caused by rheumatic fever, congenital malformations, and valve calcification, which causes restricted aortic valve opening and causes left ventricular ejection disorders [1, 2]. The disease progresses slowly, and there may be no obvious symptoms for a long time. As the disease worsens, symptoms such as angina and dizziness may appear [3]. If aortic valve stenosis cannot be treated in time, it can also lead to complications such as heart failure, arrhythmia, congestive heart failure, infective endocarditis, systemic embolism, and gastrointestinal bleeding [4]. TAVI is an interventional therapy that has emerged in recent years to treat aortic valve stenosis. It can deliver an interventional catheter through the femoral artery to deliver the artificial heart valve to the aortic valve. The area is opened to complete the implantation of the artificial valve and restore the valve function. This operation does not require thoracotomy and has the advantages of less trauma to the patient and quick recovery after surgery [5, 6]. The current clinical preoperative evaluation of TAVI patients includes clinical and aortic root anatomical indication evaluation. Imaging examinations can be used to assess the aortic root morphology and anatomical adjacency, locate the aortic valve annulus, and help doctors select patients for surgery.

CT mainly uses precisely collimated X-ray beams, gamma rays, and ultrasound together with extremely sensitive detectors to scan a certain part of the human body one by one, with fast scanning time, clear image, and other characteristics [7, 8]. The clinical use of CT will use high radiation doses to obtain high-quality images with higher resolution and better display effects, but high radiation can cause damage to the patient's body, causing cancer, gene mutations, leukemia, and other diseases [9]. Therefore, how to use the obtained noise image and incomplete projection data to reconstruct a higher-quality CT image is a hot topic for current scholars. OS is a method that uses only a subset of observation data to perform gradient calculations. Momentum terms can be introduced to speed up the convergence of the algorithm and improve system performance [10]. Gradient algorithm is a kind of momentum technology, which can solve large-scale optimization, including signal and image processing, machine learning, and communication. LALM is generally used to solve compound convex optimization, but it has the disadvantages of difficult reference selection and slow convergence [11, 12]. Therefore, the OS was adopted to optimize the LALM and then combined the OGM to construct a CT image reconstruction algorithm, so as to provide help for patient evaluation before TAVI.

In summary, CT imaging has a wide range of applications in the field of medical screening, but there are also some urgent problems to be solved. Based on this, the ordered subset (OS) was adopted to optimize the linear augmentation Lagrangian iterative algorithm into OS-LALM, which was then combined with the optimized gradient method (OGM) to construct the OS-LALM-OGM. The OS-LALM-OGM was compared with the filtered back projection (FBP) and OS-LALM and applied to evaluate the 128 patients before TAVI. The application of CT images in the evaluation of clinical manifestations and complications of patients before TAVI was comprehensively evaluated, so as to provide a good theoretical basis for imaging detection of patients before TAVI.

2. Materials and Methods

2.1. Research Objects. 128 high-risk patients with severe aortic valve stenosis who were admitted to the hospital from May 2018 to March 5, 2021, were selected as the research objects, including 91 males and 59 females, aged 60–90 years old. The study had been approved by the Ethics Committee of Hospital, and the patients and their families had understood the situation of the study and signed the informed consent forms.

The inclusion criteria were defined as follows: patients with area of arterial valve less than 0.8 cm2, patients with transvalvular pressure difference of aortic valve greater than 40 mmHg, and patients with surgical contraindications.

The exclusion criteria were defined as follows: patients with incomplete clinical data, patients with psychiatric diseases, patients with transvalvular peak flow rate less than 4 m/s, and patients who withdrew from the experiment due to personal reasons.

2.2. CT Examination. In this study, the third-generation 192-slice force dual-source spiral CT scanner produced by Siemens (Germany) was used for retrospective ECG-gated coronary scans and large-pitch total aortic scans. The contrast agent was 370 mgI/mL iopromide. The contrast agent and saline were injected into the vein sequentially, and then the dynamic continuous same-layer monitoring scan was performed. The monitoring level was 1 cm below the tracheal bifurcation. The region of interest (ROI) was selected in the ascending aorta for CT value monitoring, and the scan was automatically triggered when the 100 HU threshold was reached. The scanning range was defined as follows: the aortic root scan covered the entire heart, and the full aortic scan extended from the entrance of the thorax to the lesser trochanter of the femur. The scanning parameters were as follows: the matrix was 512×512, the tube voltage was 110 kV, the tube current was 60 mAs, the CARE Dose4D automatic current was used, the layer spacing was 0.75 mm, and the layer thickness was 0.75 mm. The original images obtained were sent to the workstation for image reconstruction processing, and two senior physicians were selected for evaluation. The ALD and the annulus short diameter (ASD) of annulus were recorded, and the calculated averages of ALD and ASD can represent the AID of annulus. The diameters of the sinus and sinus tube junction, the diameter of the ascending aorta, and the height of the coronary artery opening were measured and recorded.

2.3. Construction of OS-LALM-OGM. Firstly, the CT image was set to the following model:

$$y = Mx + \theta. \tag{1}$$

In equation (1), y represents the measurement data, M represents the forward projection operator, x represents the image to be reconstructed, and θ referrs to the noise. The penalty weighted least squares (PLWS) were incorporated to reconstruct image x; then, the following equation could be obtained:

$$\overline{\overline{x}} = \arg\min_{x \geq 0} \left\{ \varphi(x) \triangleq \frac{\|\overline{\overline{y}} - Nx\|_P^2 + Q(x)}{2} \right\}. \tag{2}$$

In the above equation, N represents the system matrix, $\overline{\overline{y}}$ represents the sine graph with noise, P refers to the statistical weight matrix, and Q means the regular term retaining the edges. Then, the edge preservation regularization function can be expressed as follows:

$$Q(x) \triangleq \sum_i \lambda_i \sum_n u_r u_{r+e_i} \eta_i [(B_i x)_r]. \quad (3)$$

In equation (3), λ_i, e_i, and η_i refer to the regularization parameter, the corresponding offset, and the potential function, respectively; B_i is the finite difference matrix in the ith direction, and u_r represents the voxel-related weight. The following equation could be obtained by converting it into a compound convex optimization:

$$(\overline{\overline{x}}, \overline{\overline{t}}) \in \arg\min_{x,t} \{p(t) + q(x)\}. \quad (4)$$

In the above equation, $p()$ and $q()$ are convex functions, p represents the weighted quadratic data fitting term, and q represents the edge retention regularization term. Then, the LALM was incorporated [13] for solution; then the following equations could be obtained:

$$x^{(u+1)} \in \arg\min_x \left\{ q(x) + \vartheta_u(x) + \frac{\rho \left\| x - x^u \right\|_R^2}{2} \right\}, \quad (5)$$

$$k^{(u+1)} \in \arg\min_x \left\{ p(t) + \frac{\rho \left\| Mx^{(u+1)} - k - d^{(u)} \right\|_2^2}{2} \right\}, \quad (6)$$

$$d^{(u+1)} = d^{(u)} - Mx^{(u+1)} + t^{(u+1)}. \quad (7)$$

In equations (5)–(7), R represents the diagonal optimization matrix, $p()$ is set as a quadratic loss function, and ρ represents the penalty parameter; then the previous equation could be transformed into a least squares regularization matter as follows:

$$\overline{\overline{x}} = \arg\min_x \left\{ \varphi(x) \triangleq \frac{\rho \| y - Mx \|_2^2}{2} + q(x) \right\}. \quad (8)$$

If $T(x) \triangleq p(Mx)$ was defined as a quadratic data fitting term and can be accelerated by an OS, then the following could be obtained:

$$\Delta T(x) \approx W \Delta T_W(x). \quad (9)$$

In equation (9), W represents the number of quadratic functions and $\Delta T(x)$ represents the gradient of the subset. In consideration that that the near-end mapping of the quadratic function was linear, the update of k can have a closed solution, which was written as follows:

$$t^{(u+1)} = \frac{\rho \left(Mx^{(u+1)} - d^{(u)} \right) + y}{\rho + 1}. \quad (10)$$

The following equation could be obtained by combining equations (7) and (10):

$$t^{(u+1)} + \rho d^{(u+1)} = y. \quad (11)$$

Then, new equations could be found after d was initialized:

$$d_{(o)} = \frac{y - t_{(0)}}{\rho}, \quad (12)$$

$$\overline{\overline{t}} \triangleq t - y. \quad (13)$$

In equations (12) and (13), $\overline{\overline{t}}$ represents the split residual; then the initial LALM can be obtained:

$$\begin{aligned} e^{(u+1)} &= M' \left(\rho \left(Mx^{(u)} - y \right) + (1 - \rho) \overline{\overline{t}}^{(u)} \right), \\ x^{(u+1)} &\in \operatorname{prox}_{(l/\rho)q} \left(x^u - \left(\frac{l}{\rho} \right) r^{(u+1)} \right), \\ \overline{\overline{t}}^{(u+1)} &= \frac{\rho \left(Mx^{(u+1)} - y \right) + \overline{\overline{t}}^{(u)}}{\rho + 1}. \end{aligned} \quad (14)$$

Then, $p \triangleq M\imath(t)$ was set as the split gradient; it can be optimized as follows:

$$\begin{aligned} e^{(u+1)} &= \rho \Delta T\left(x^{(u)} \right) + (1 - \rho) p^{(u)}, \\ x^{(u+1)} &\in \operatorname{prox}_{(l/\rho)q} \left(x^u - \left(\frac{l}{\rho} \right) e^{(u+1)} \right), \\ p^{(u+1)} &= \frac{\rho \Delta T\left(x^{(u+1)} \right) + p^{(u)}}{\rho + 1}. \end{aligned} \quad (15)$$

The previous process was the OS-based LALM, which only needed the gradient of T to be updated to accelerate the ordered subset. However, there was still a problem with this algorithm; that is, the penalty parameter ρ value was not fixed. The deterministic downward continuation technique was applied to determine the optimal size of the parameter ρ value, so it could be written as follows:

$$\varpi(u) \triangleq \left(p^{(u)} - \Delta T\left(x^{(u+1)} \right) \right) \left(\Delta T\left(x^{(u+1)} \right) - \Delta T\left(x^{(u)} \right) \right). \quad (16)$$

It was assumed the iteration was restarted at the z^{th} iteration, and then the optimal penalty parameter ρ can be expressed as follows:

$$\rho_i = \begin{bmatrix} 1, & g = 0 \\ \max\left[\dfrac{\pi}{g+1}\sqrt{1-\left(\dfrac{\pi}{2g+2}\right)^2}, \rho_{\min}\right], & \text{otherwise} \end{bmatrix}. \tag{17}$$

In equation (17), g represents the number of iterations. This method can effectively solve the regularized least squares and simplify the selection of parameters through the deterministic downward continuation method based on the second-order damping system. However, it only used the current gradient to estimate the search direction will accumulate gradient errors, so that the reconstructed images were unstable. Based on this, the OGM was incorporated; then the CT image reconstruction can be expressed as follows:

$$\begin{cases} M \leftarrow E^{1/2} M \\ y \leftarrow E^{1/2} y \\ p \leftarrow Q + \kappa_\Omega \end{cases} \tag{18}$$

In equation (18), κ_Ω was the characteristic function of the convex set Ω. The above process was the constructed OS-LALM-OGM.

2.4. Design of Simulation Experiment. This experiment run on a real data platform. The operating environment was defined as follows: Virtual Box centos 6.6–32 bit system was installed, central processing unit (CPU) was AMD Athlon 2.99 GHz, memory was 1.75 GB, and the video resolution was 480 × 320. The (FBP) [14] and OS-LALM [15] were compared with the OS-LALM-OGM algorithm constructed. The number of OS was 40, and the PSNR and RMSD of the three algorithms under different function iteration times (5, 20, and 40) were recorded and compared:

$$\text{PSNR} = 10\log_{10}\frac{255 * 255}{\left[\sum_{i=1}^{A}\sum_{j=1}^{N}\left(x(i,j) - y(i,j)\right)^2 / A * C\right]}, \tag{19}$$

$$\text{RMSD} = \frac{\left\| x^{v} - \overleftarrow{x} \right\|}{\sqrt{O_\alpha}}. \tag{20}$$

In equations (19) and (20), $A * C$ represents the image size and x, y, and A refer to the original image, the noisy image, and the number of iterations, respectively. The larger the PSNR value meant the better the image reconstruction effect, and the smaller the RMSD value meant the better the image reconstruction effect.

2.5. Observation Indicators. The observation indicators included the clinical manifestations (angina, fainting, and dyspnea), complications (hypertension, diabetes, renal insufficiency, cerebrovascular disease, atrial flutter, and atrial fibrillation), CT image data, and the anatomical data of the aortic root of patients with bicuspid and tricuspid valve (ALD, ASD, AID, sinus inner diameter (SID), sinus junction inner diameter (SJID), ascending aorta inner diameter (AAID), left coronary opening height (LCOH), and the right coronary opening height (RCOH)) of the patients. In addition, the evaluation sensitivity and specificity of CTs under different algorithms were calculated, respectively.

2.6. Statistical Methods. The data processing was analyzed by SPSS19.0 version statistical software. The measurement data was indicated as mean ± standard deviation ($\overline{x} \pm s$), and the count data was displayed as percentage (%). The PSNR and RMSD of OS-LALM-OGM, FBP, and OS-LALM were compared in pairwise with single-factor analysis of variance. The difference was statistically significant at $P < 0.05$.

3. Results

3.1. Comparison on Image Reconstruction Effects of Three Algorithms. Figure 1 and 2 show the PSNR and RMSD comparisons of the three algorithms under different iteration times. The PSNR of the OS-LALM-OGM algorithm was much greater than that of the FBP and OS-LALM algorithms, and the differences was statistically obvious ($P < 0.05$), while the RMSD of the OS-LALM-OGM algorithm was smaller greatly than that of the FBP and OS-LALM algorithms, showing remarkable different in statistics ($P < 0.05$). In addition, the PSNR and RMSD of FBP and OS-LALM algorithms showed no statistical difference ($P > 0.05$).

3.2. Image of a Patient with Aortic Valve Stenosis. Figures 3–6 and Table 1 show the analysis of a patient with aortic valve stenosis. The diagnosis was a TYPE0 bicuspid valve, the leaflets were significantly thickened and severely calcified, the size of the French sinus was reasonable, the ascending aorta was slightly wider, the heart was horizontal, double crown height was normal, the left ventricle was small, and the myocardium was thickened, so it was determined as right femoral artery was clinically recommended as the main approach.

3.3. The Clinical Manifestations and Complications of Patients. Figure 7 illustrates the clinical manifestations of patients, in which 1 refers to angina, 2 refers to fainting, and 3 refers to dyspnea. It can be seen that there were 25 cases of angina in 128 patients, accounting for 19.53%, 27 cases of fainting (accounting for 21.09%), and 49 cases of dyspnea (accounting for 38.28%). Among them, the proportion of patients with dyspnea was much more than the proportions of patients with angina and fainting ($P < 0.05$).

Figure 8 illustrates the complications of patients, in which 1 indicates hypertension, 2 indicates diabetes, 3 refers

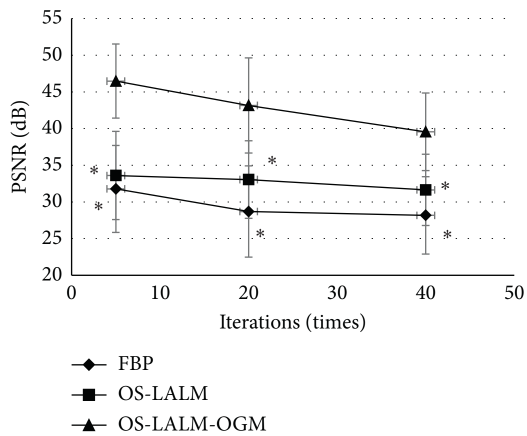

FIGURE 1: Comparison on PSNR of three algorithms under different iteration times. * indicates that the difference was remarkable in statistics in contrast to OS-LALM-OGM ($P < 0.05$).

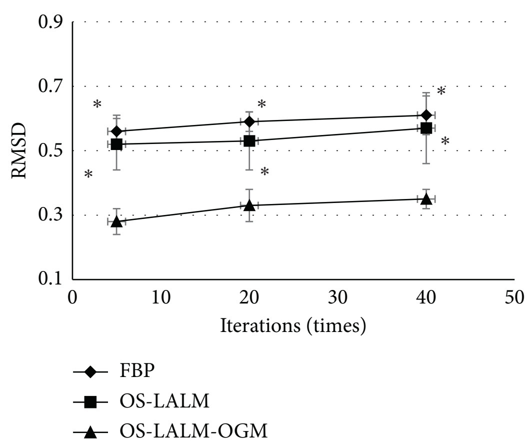

FIGURE 2: Comparison on RMSD of three algorithms under different iteration times. * indicates that the difference was remarkable in statistics in contrast to OS-LALM-OGM ($P < 0.05$).

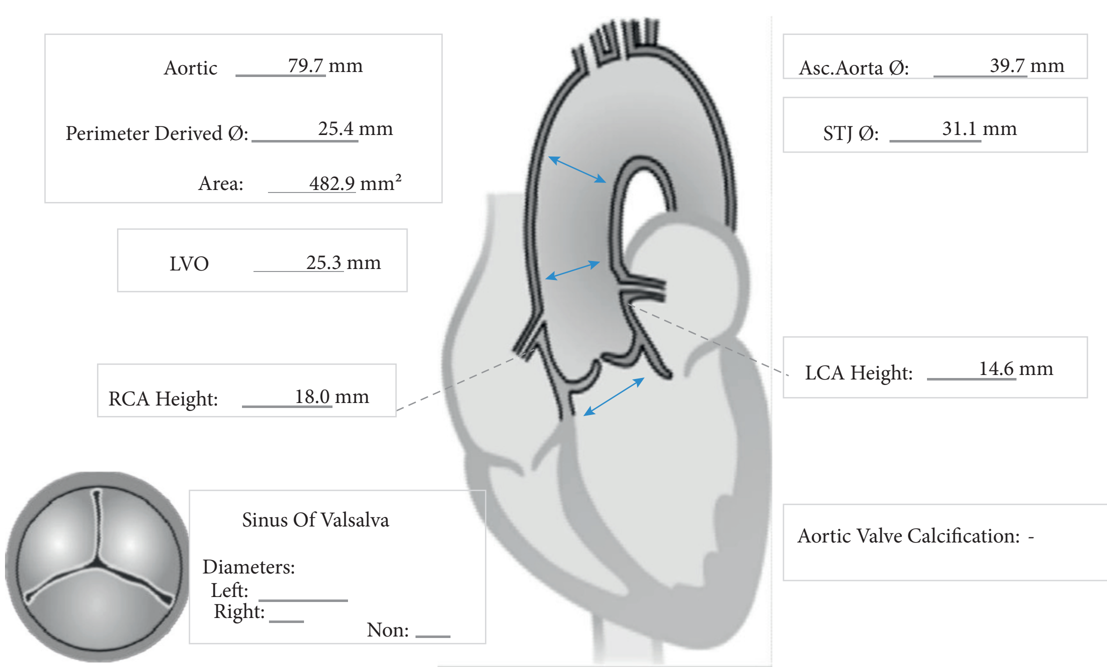

FIGURE 3: The aortic valve and measurement results of various indicators of patients.

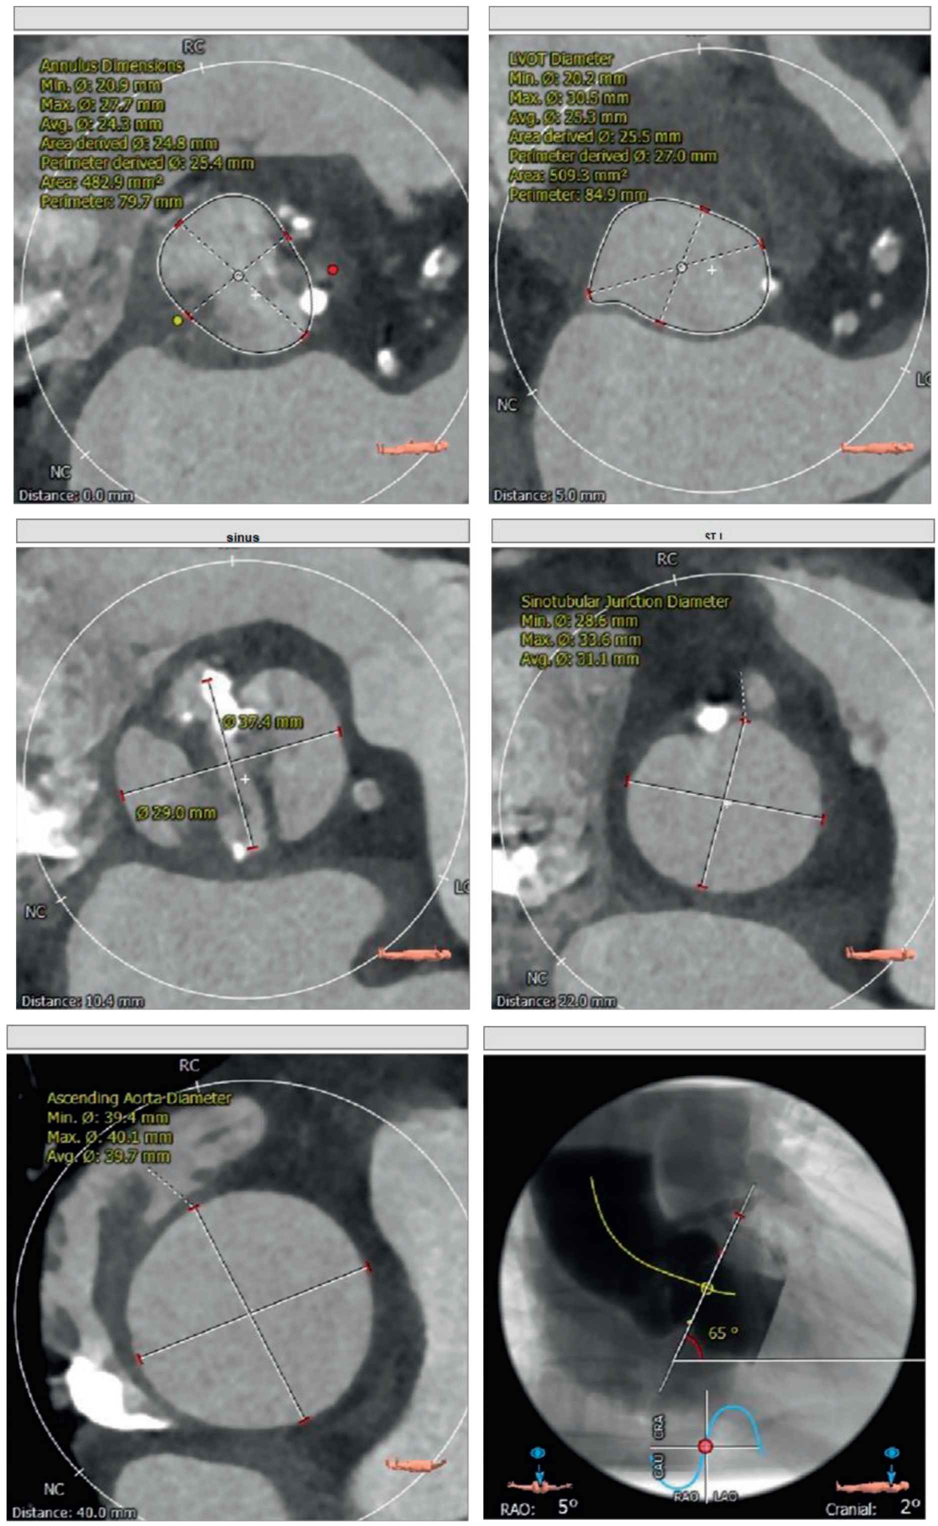

Figure 4: CT image and index measurement of patients.

to renal insufficiency, 4 refers to cerebrovascular disease, and 5 represents atrial flutter and atrial fibrillation. It revealed that 59 of 128 patients had hypertension (accounting for 46.1%), 26 had diabetes (accounting for 20.31%), 9 had renal insufficiency (accounting for 7.03%), 21 cases had cerebrovascular disease (accounting for 16.41%), and 19 cases had atrial flutter and atrial fibrillation (accounting for 14.84%). Thus, the proportion of patients with hypertension was much higher in contrast to that of patients with diabetes, renal insufficiency, cerebrovascular disease, and atrial flutter

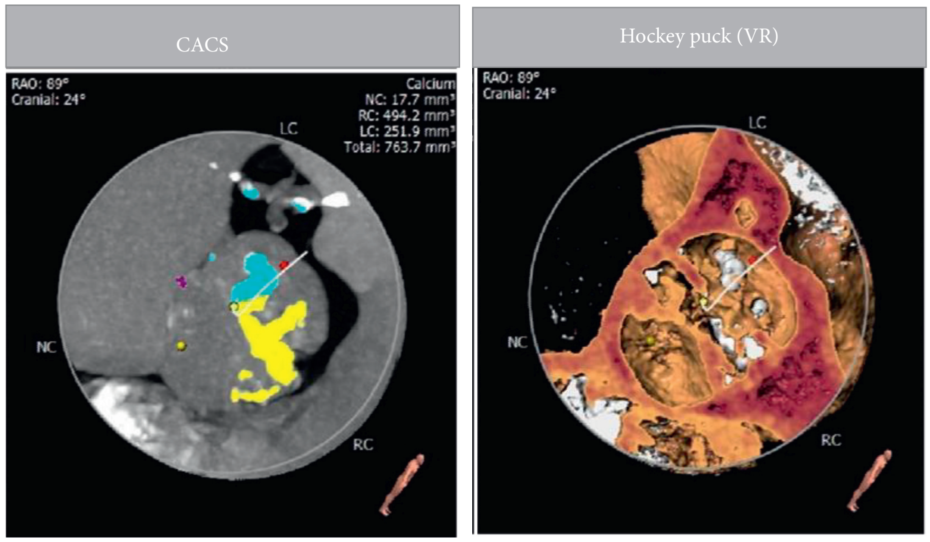

FIGURE 5: The coronary artery calcification score of patients.

Aortomitral continuity length	
Annulus to apex	

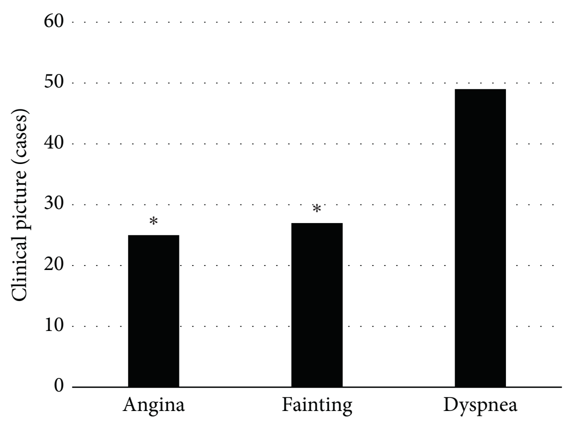

Figure 7: The clinical manifestations of patients. * suggests that the difference was obvious in statistics in contrast to dyspnea ($P < 0.05$).

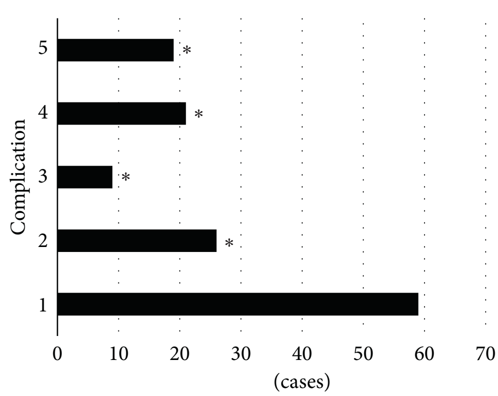

Figure 8: The complications of patients (1: hypertension; 2: diabetes; 3: renal insufficiency; 4: cerebrovascular disease; 5: atrial flutter and atrial fibrillation). * suggests that the difference was obvious in statistics in contrast to hypertension ($P < 0.05$).

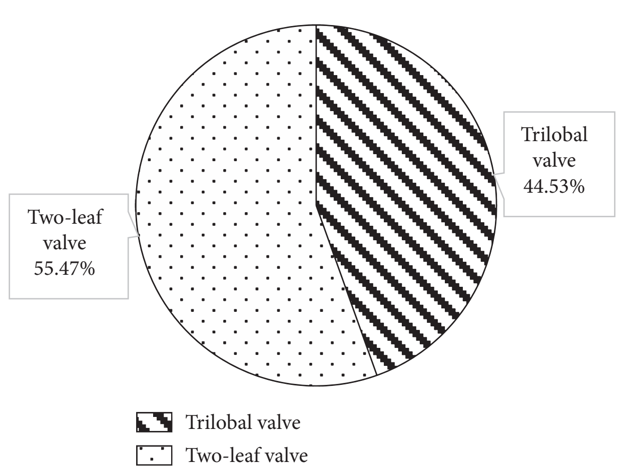

Figure 9: CT measurement results of the aortic root of the patient.

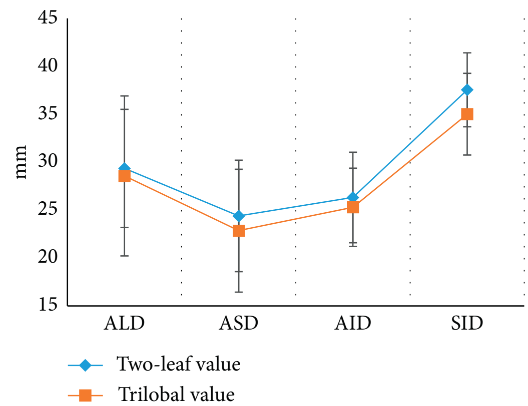

Figure 10: Comparison on ALD, ASD, AID, and SID of patients with bicuspid valves and trilobular valves.

and atrial fibrillation, showing observable and meaningful differences ($P < 0.05$).

3.4. CT Measurement Results of the Aortic Root of the Patient. Figure 9 shows the CT measurement results of the aortic root of the patient. It discloses that among the 128 patients, 71 were bicuspid valves (accounting for 55.47%) and 57 cases were trilobular valves (accounting for 44.53%).

3.5. The Anatomical Data of the Aortic Roots of Bicuspid Valves and Trilobular Valves of the Patients. The anatomical data of the aortic roots of the patient's bicuspid valves and trilobular valves were shown in Figures 10 and 11. It was clear that the ALD was 29.35 ± 6.17 mm, ASD was 24.38 ± 5.82 mm, AID was 26.31 ± 4.71 mm, SID was 37.55 ± 3.86 mm, SJID was 36.24 ± 5.11 mm, AAID was 41.49 ± 4.02 mm, LCOH was 17.46 ± 3.82 mm, and RCOH was 16.37 ± 3.51 mm for patients with bicuspid valves. The ALD, ASD, AID, SID, SJID, AAID, LCOH, and RCOH of patients with trilobular valves were 28.56 ± 8.34 mm, 22.86 ± 6.41 mm, 25.29 ± 4.08 mm, 35.01 ± 4.26 mm, 32.86 ± 4.27 mm, 38.35 ± 5.21 mm, 12.85 ± 4.24 mm, and 16.02 ± 4.05 mm. The data here indicated that the patients with bicuspid valve showed no great differences in ALD, ASD, AID, SID, SJID, AAID, and RCOH ($P > 0.05$) but great difference in LCOH ($P < 0.05$) in contrast to the patients with trilobular valves.

3.6. Comparison on CT Image of Aortic Valve Annulus Measurement Results Based on OS-LALM-OGM Algorithm and FBP Algorithm. Figure 12 shows a comparison of CT image aortic valve annulus measurement results based on OS-LALM-OGM algorithm and FBP algorithm. It could be observed that the annulus long diameter and the average inner diameter of the annulus measured by the CT image based on the OS-LALM-OGM algorithm were significantly larger than the aortic annulus inner diameter measured by the CT based on the FBP algorithm, and the difference was statistically obvious ($P < 0.05$), while the difference between the short diameter of the valve annulus and the inner diameter of the aortic annulus measured by CT based on the OS-LALM-OGM algorithm and the inner diameter of the aortic annulus measured by CT based on the FBP algorithm was not statistically observable ($P > 0.05$).

3.7. Comparison on the Evaluation Performance of CT Images for Patients Based on OS-LALM-OGM Algorithm and FBP Algorithm. Figures 13 and 14 show the comparisons on the evaluation performance of CT images based on OS-LALM-OGM algorithm and FBP algorithm for patients. The sensitivity and specificity of CT evaluation based on OS-LALM-OGM algorithm were 95.24% and 85.85%, respectively, and those for CT evaluation based on FBP algorithm were 84.43% and 76.77%, respectively. Thus, the sensitivity and specificity of CT evaluation based on OS-LALM-OGM algorithm were dramatically greater than those based on FBP algorithm, and the differences were statistically great ($P < 0.05$).

4. Discussion

The evaluation of preoperative clinical conditions and comorbidities of TAVI has always been an important reference for clinical judgment of surgical indications. The aortic valve annulus is the key to the parameters of the aortic root. Excessive aortic diameter can cause aortic root rupture and coronary ostia, while stenosis or too small aortic diameter can cause severe valve regurgitation. As a commonly used clinical examination method, CT also plays a crucial role in the evaluation of patients before TAVI [16]. Therefore, the LALM was optimized based on OS and then combined the OGM to construct the CT image reconstruction algorithm OS-LALM-OGM, which was applied in evaluation of 128 patients with severe aortic valve stenosis. Simulation experiments found that the PSNR of the OS-LALM-OGM algorithm was much greater in contrast to that of the FBP and OS-LALM algorithms, while the RMSD was much smaller, and the differences were statistically meaningful ($P < 0.05$). Such results were similar to Østergaard et al. [17], indicating that the OS-LALM-OGM algorithm proposed had a relatively excellent effect on CT image reconstruction, so it can be used as one of the algorithms that can effectively improve the quality of CT images in the future.

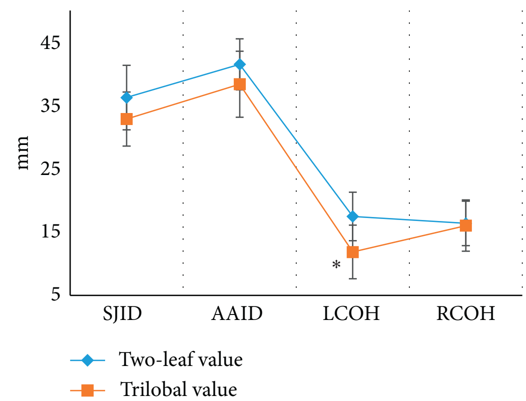

Figure 11: Comparison on SJID, AAID, LCOH, and RCOH of patients with bicuspid valves and trilobular valves. * indicates that obvious difference can be found in contrast to patients with bicuspid valves ($P < 0.05$).

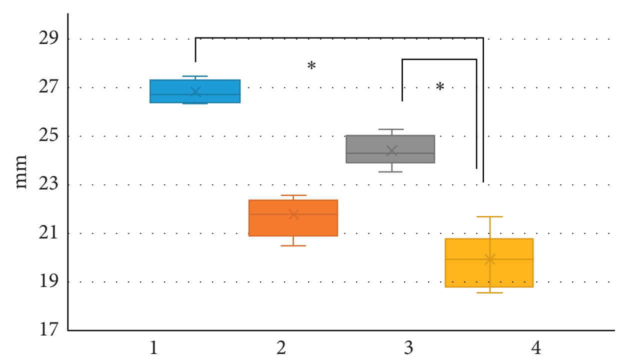

Figure 12: Comparison on CT image aortic annulus measurement results based on OS-LALM-OGM algorithm and FBP algorithm. *Note.* 1, 2, and 3 in the figure refers to the annulus long diameter, annulus short diameter, and average inner diameter of annulus measured by CT based on the OS-LALM-OGM algorithm, respectively, and 4 represents the inner diameter of the aortic annulus measured by CT based on the FBP algorithm. * indicates that visible difference could be found in contrast to 4 ($P < 0.05$).

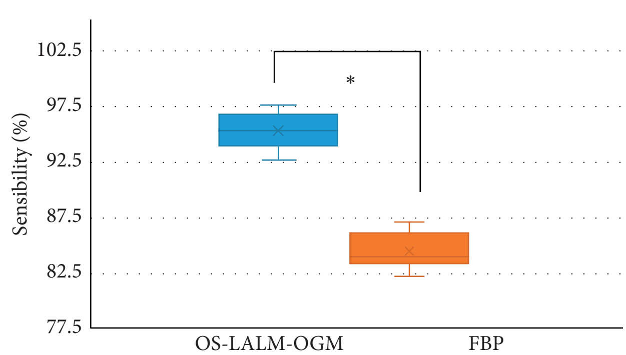

Figure 13: Comparison on the sensitivity of CT images to patients based on OS-LALM-OGM algorithm and FBP algorithm. * indicates that the different in contrast to CT results under FBP algorithm was meaningful in statistics ($P < 0.05$).

Of the 128 patients, 49 had dyspnea, accounting for the highest proportion (38.28%), followed by angina (19.53%) and fainting (21.09%). This suggested that CT and ultrasound screening should be performed as soon as possible for patients with related symptoms, so as to accurately diagnose the aortic valve stenosis. Among the 128 patients, 71 cases had bicuspid valves (accounting for 55.47%) and 57 cases had tricuspid valves (accounting for 44.53%). This indicated that the proportion of severe aortic valve stenosis caused by the bivalve deformity was higher, which may be due to the difficulty of intraoperative valve release caused by calcification of the valve leaflets and uneven leaflet force in patients with bicuspid valve, and the incidence of paravalvular leakage after release was higher than that of patients with tricuspid valve [18]. The height of the left coronary opening of the bicuspid valve was greater obviously than that of the

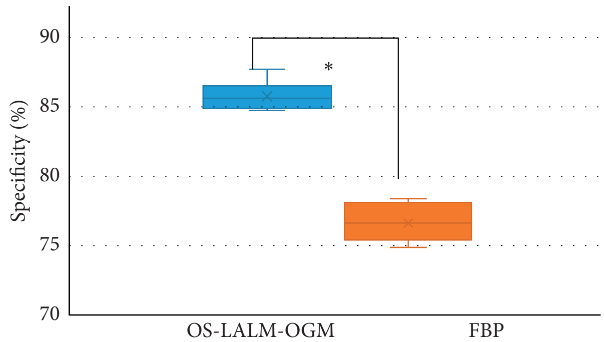

Figure 14: Comparison on the specificity of CT images to patients based on OS-LALM-OGM algorithm and FBP algorithm. * indicates that the different in contrast to CT results under FBP algorithm was meaningful in statistics ($P < 0.05$).

tricuspid valve ($P < 0.05$), which was different from the results of Singh et al. [19]. The reason of such difference may be that abnormal development of the left main stem may aggravate the degree of coronary artery obstruction during the operation, and the widening of the ascending aorta could lead to the occurrence of intraoperative dissection. The ALD and annulus AID of measured by CT image based on OS-LALM-OGM algorithm were significantly larger than the aortic annulus diameter measured by CT based on FBP algorithm, and the difference was statistically significant ($P < 0.05$), which may be due to the three-dimensional shape of the aortic root and the oval shape of aortic valve, and measuring the ALD and ASD separately could more closely reflect the actual inner diameter of the aortic annulus [20]. The sensitivity and specificity of CT evaluation based on the OS-LALM-OGM algorithm were significantly greater than those based on the FBP algorithm, and the differences were statistically significant ($P < 0.05$), which suggested that CT images based on the OS-LALM-OGM algorithm had better evaluation performance for patients before TAVI than CT based on the FBP.

5. Conclusion

Based on the OS, OS-LALM was constructed, which was then combined with the OGM to construct the OS-LALM-OGM. The OS-LALM-OGM was compared with the FBP and OS-LALM and applied to evaluate the 128 patients before TAVI. It was found that the OS-LALM-OGM algorithm proposed had a relatively excellent effect in CT image reconstruction. The CT image based on the OS-LALM-OGM algorithm showed better evaluation performance for patients before TAVI than the traditional FBP and OS-LALM algorithms, showing higher sensitivity and specificity. However, the sample size for the study was small, and there was a lack of relevant registration data for patients with severe aortic stenosis. In the future, the selection of patient samples will be increased to further explore the reconstruction effect of OS-LALM-OGM on CT images. In short, the results of this study could provide a good theoretical basis for imaging detection of patients before TAVI.

This research was aimed to study CT image features based on the backprojection filtering reconstruction algorithm and evaluate the effect of ropivacaine combined with dexamethasone and dexmedetomidine on assisted thoracoscopic lobectomy to provide reference for clinical diagnosis. A total of 110 patients undergoing laparoscopic resection were selected as the study subjects. Anesthesia induction and nerve block were performed with ropivacaine combined with dexamethasone and dexmedetomidine before surgery, and chest CT scan was performed. The backprojection image reconstruction algorithm was constructed and applied to patient CT images for reconstruction processing. The results showed that when the overlapping step size was 16 and the block size was 32×32, the running time of the algorithm was the shortest. The resolution and sharpness of reconstructed images were better than the Fourier transform analytical method and iterative reconstruction algorithm. The detection rates of lung nodules smaller than 6 mm and 6–30 mm (92.35% and 95.44%) were significantly higher than those of the Fourier transform analytical method and iterative reconstruction algorithm (90.98% and 87.53%; 88.32% and 90.87%) ($P < 0.05$). After anesthesia induction and lobectomy with ropivacaine combined with dexamethasone and dexmedetomidine, the visual analogue scale (VAS) decreased with postoperative time. The VAS score decreased to a lower level (1.76 ± 0.54) after five days. In summary, ropivacaine combined with dexamethasone and dexmedetomidine had better sedation and analgesia effects in patients with thoracoscopic lobectomy. CT images based on backprojection reconstruction algorithm had a high recognition accuracy for lung lesions.

1. Introduction

Lobectomy is mainly used for malignancies confined to the lobes, lung damage caused by tuberculosis, severe bullae, bronchiectasis, interstitial lesions, trauma, and dysplasia, which refers to routine removal of the lungs [1]. There are five lobes in the chest. The right lung is made up of the upper, middle, and lower lobes. The left lung is made up of two lobes, the upper and lower lobes. Lobectomy is used for lung cancer and irreversible disease confined to the lung lobe. It mainly includes right upper lobe resection, right middle lobe resection, right lower lobe resection, left upper lobe resection, and left lower lobe resection. If the lesion involves both lobes or intermediate bronchial tubes, upper middle or lower middle lobe pneumonectomy is feasible [2]. In general, the postoperative quality of life of patients is not bad. Postoperative patients need to pay attention to the change of climate and pay attention to diet and avoid irritant gases in normal survival [3]. In addition, it is necessary to take proper exercise to strengthen resistance and closely observe the symptoms and signs of oneself. If abnormal, it is necessary to go to the hospital for comprehensive examination and treatment as soon as possible [4, 5]. Thoracoscopic lobectomy is a kind of lobectomy in which the thoracoscopic surgeon only watches the thoracoscopic situation through the TV screen in real time and performs the operation through one to four hole-like incisions no longer than 5 cm (without repositioning the ribs). Veins, arteries, and bronchial tubes were dissected anatomically, and the lung lobe was completely removed. At present, video-assisted thoracic surgery (VATS) lobectomy is basically mature and widely accepted. Its surgical techniques are also gradually refined and improved [6, 7]. The National Comprehensive Cancer Network (NCCN) guidelines for the treatment of lung cancer clearly state that "VATS lobectomy is a viable option for resectable lung cancer," which means that the role of thoracoscopic lobectomy in the treatment of benign or early malignant lung lesions has been confirmed [8, 9].

With the continuous breakthrough of medical imaging technology, the revolution of life science is promoted, such as CT, which provides great help for doctors' clinical diagnosis and treatment [10]. CT is widely used in the diagnosis of lung and other lesions due to its advantages of nonoverlapping cross-sectional imaging, high density resolution, and easy detection of small lesions, as well as energy spectrum and perfusion functional imaging [11, 12]. However, the current segmentation of conventional CT images has great limitations and challenges, and there are problems such as blurred boundary of lesions and insignificant brightness difference [13, 14]. Image reconstruction technology plays an important role in many fields. In the research and implementation of reconstruction algorithms, there are a series of extremely complex image processing and mathematical calculation problems [15, 16]. The essence of backprojection reconstruction refers to evenly erasing (backprojection) the ray projection from the finite object space onto all points in the infinite space reached by the ray, including the original pixel value of 0 points. At present, algorithms such as image reconstruction and computer-assisted medical image analysis have obvious advantages in major breakthroughs in technology and improvement of the medical level and have also become an effective way to solve medical image problems [17].

Therefore, it was attempted to construct a filtering backprojection reconstruction algorithm. The ramp-Lak filter was convolved with $\sin(x)/x$ to obtain the Shepp-Logan filter. Reconstruction of CT images and noisy data was carried out through the sheep-Logan filter to evaluate the effect of ropivacaine combined with dexamethasone and dexmedetomidine on assisted thoracoscopic lobectomy using CT image features based on reconstruction algorithm.

2. Materials and Methods

2.1. The General Information. In this study, 110 patients undergoing laparoscopy-guided lobectomy admitted to the hospital from January 2019 to September 2020 were collected as the research objects. There were 58 male patients and 52 female patients, aged 52.37 ± 5.68 years. The study had been approved by the Ethics Committee of the hospital. Patients and their families understood the content and methods of the study and signed corresponding informed consent forms.

The inclusion criteria were as follows: (i) patients who underwent lobectomy after prepathological and imaging diagnosis of lobectomy; (ii) patients aged between 45 and 65 years old; (iii) patients without metastasis of lung lesions, mediastinal lymph node enlargement, or pleural hypertrophy occurred; (iv) patients who were not recently treated with other drugs or antibiotics in the study; (v) patients with normal coagulation function and platelets.

The exclusion criteria were as follows: (i) patients with other systemic or organ lesions; (ii) patients who did not cooperate with treatment due to personal or other factors; (iii) patients with incomplete clinical data and medical history.

2.2. Anesthesia and Surgical Methods of Patients. All patients were fasting and abstaining from drinking six hours before anesthesia induction, and all vital signs including heart rate, diastolic blood pressure, systolic blood pressure, pulse oxygen saturation, and mean arterial pressure were monitored before surgery. 0.5% ropivacaine combined with 30 mL 1 μg/Kg DEX was used. Routine disinfection and towel laying were performed on the surgical position, nerve block was performed under ultrasound guidance, and puncture was performed after local anesthesia with 1% lidocaine at the puncture site. After puncture to the specified location, local anesthesia was injected, and two-point blocking method was adopted according to the intercostal space of the surgical incision.

10 mL of drugs was injected into each puncture site, and a mixture of 0.5% ropivacaine and 1 μg/Kg DEX was used as an anesthetic. The nerve block results were tested with alcohol cotton balls ten minutes after the injection.

The lobectomy incision was made between the mid-axillary line and the front of the axillary line in the fifth intercostal area, which was close to the hilum at a small angle to facilitate the operation of hand instruments along the longitudinal axis. Hemodynamic indexes of patients were monitored in real time during surgery, and corresponding vasoactive drugs were used to correct intraoperative hemodynamic instability.

All patients enrolled in the study underwent chest enhanced CT scans, which were interpreted by two attending physicians or radiologists with extensive clinical experience. If there was a difference between the two, a third physician should be asked to interpret. CT was used to observe and analyze the specific location of lung lesions, the maximum diameter of the lesion site, and hilar and mediastinal lymph node enlargement.

2.3. Backprojection Reconstruction Algorithm. When the backprojection reconstruction algorithm processes medical image data, the processed image is regarded as a two-dimensional matrix x. The image reconstruction process is as shown in the following equation:

$$T_{(x)} = d\left(\sum_{n=1}^{y} H_x + p\right). \tag{1}$$

In equation (1), $T_{(x)}$ is the feature map obtained by weighting the image matrix by the convolution kernel, H

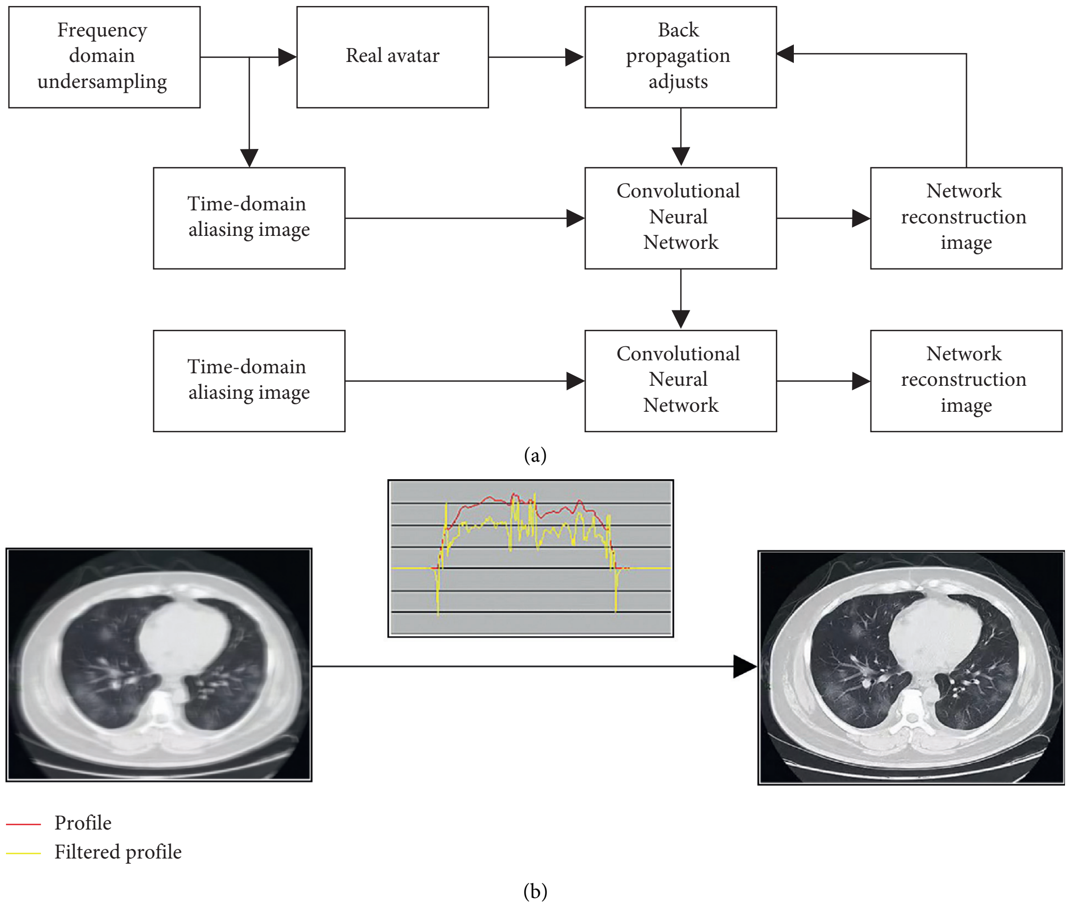

FIGURE 1: Medical image reconstruction (a) and reconstruction effect (b) based on backprojection.

represents the convolution kernel, p is the bias, n is the square of the size of the convolution kernel, and d represents the activation function. The backpropagation algorithm can accurately identify the optimal parameters in the network during the process of training the neural network. It is currently commonly used and effective. The update rule of each layer of convolution kernel H is as shown in the following equation:

$$H_{\alpha+1} = H_{\alpha} + \Delta H_{\alpha+1}, \tag{2}$$

$$\Delta H_{\alpha+1} = \beta H_{\alpha} - \theta\sigma\nabla a H_{\alpha}. \tag{3}$$

In equations (2) and (3), H is the convolution kernel, α is the number of layers, β is the weight of the gradient value of the previous layer, δ is the learning factor, θ is the momentum, and a is the loss function. The medical image reconstruction process based on backprojection is shown in Figure 1.

The network parameters are adjusted by backpropagation by minimizing the residuals of the reconstructed image and the corresponding real image, as shown in Figure 1, which is the network training process. The optimized network is obtained by training, and the aliased image is input in it to perform image reconstruction so that the obtained high-quality images can be used in clinical medical diagnosis.

Neural networks have independent connection and calculation methods, but they are all based on backpropagation algorithms, on which network parameters are adjusted and optimized.

$$T(n) = \int_{-\infty}^{+\infty} I(x)O(n-x)Y_x. \tag{4}$$

It is supposed that $f(a, b)$ is the image to be reconstructed, $T(s, \alpha)$ denotes a parallel projection of $f(a, b)$ acquired at an angle, and c is the coordinate axis of the projected X-ray parallel to the angle α. The coordinate axis is perpendicular to the coordinate axis where S is located; then, there is the following equation:

$$T(s, \alpha) = \int_{-\infty}^{+\infty} f(s, c)\mathrm{d}s. \tag{5}$$

In equation (5), s represents the distance from the projected ray to the center of symmetry (i.e., the center of rotation). One-dimensional Fourier transform is performed on $T(s, \alpha)$ of equation (5).

$$T(\varpi, \alpha) = \int_{-\infty}^{+\infty} T(s, \alpha)e^{-2jn\varpi s}\mathrm{d}t. \tag{6}$$

Equation (1) is substituted into equation (2) to get the following equation:

$$T(\varpi, \alpha) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(s, c)e^{-2jn\varpi s}\mathrm{d}t\mathrm{d}s. \quad (7)$$

In equation (7), ω represents the filter function, c is the coordinate axis parallel to the projected X-ray under the angle α, and s represents the distance from the projected ray to the center of symmetry (i.e., the center of rotation). Figure 2 shows the reconstructed image space coordinate system and projection space coordinate system.

In Figure 2, the coordinates of point n in the a-o-b coordinate system are shown in equations (8) and (9).

$$a = R\cos\beta, \quad (8)$$

$$b = R\sin\beta. \quad (9)$$

In the equations, R represents the distance between the point n and the origin in Figure 2. Similarly, the coordinates of point n in s-o-c are shown in equations (10)–(13).

$$s = R\ \cos(\beta - \alpha), \quad (10)$$

$$R\ \cos(\beta - \alpha) = a\ \cos\ \alpha + b\ \sin\ \alpha, \quad (11)$$

$$c = R\ \sin(\beta - \alpha), \quad (12)$$

$$R\ \sin(\beta - \alpha) = b\ \cos\ \alpha + a\ \sin\ \alpha. \quad (13)$$

R represents the distance between the point n and the origin in Figure 2. The above equations are substituted into equation (7) to get the following equation:

$$T(\varpi, \alpha) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(a, b)e^{-2jn\varpi(a\ \cos\ \alpha + b\ \sin\ \alpha)}\mathrm{d}a\mathrm{d}b. \quad (14)$$

The two-dimensional Fourier transform of the image $f(a, b)$ to be reconstructed is set as $F(i, j)$; then, $F(i, j)$ is expressed as follows:

$$F(i, j) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(a, b)e^{-2jn(ia + jb)}\mathrm{d}a\mathrm{d}b. \quad (15)$$

It is supposed that equations (16) and (17) are true.

$$i = \varpi\ \cos\ \alpha, \quad (16)$$

$$j = \varpi\ \sin\ \alpha. \quad (17)$$

Then, there is the following equation:

$$F(\varpi\ \cos\ a, \varpi\ \sin\ a) = T(\varpi, a). \quad (18)$$

According to the Fourier transform, the image function $f(a, b)$ can be restored by its inverse Fourier transform $F(i, j)$.

$$f(a, b) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} F(i, j)e^{2jn(ia + jb)}\mathrm{d}i\mathrm{d}j. \quad (19)$$

$i = \varpi\ \cos\ \alpha$ and $j = \varpi\ \sin\ \alpha$; then, there is equation (20) after the calculation of equation (18).

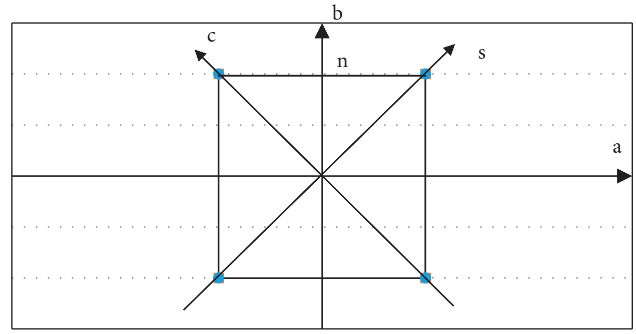

Figure 2: Image space coordinate system and projection space coordinate system.

$$f(a, b) = \int_{0}^{2n}\int_{-\infty}^{+\infty} T(\varpi, a)e^{j2n\varpi(a\ \cos\ \alpha + b\ \sin\ \alpha)}\varpi\mathrm{d}\varpi\mathrm{d}\theta. \quad (20)$$

Equation (19) is transformed into the following form using symmetric relationship (21), as shown in equation (22).

$$T(\varpi, \alpha + \pi) = T(-\varpi, \alpha), \quad (21)$$

$$f(a, b) = \int_{0}^{\pi}\mathrm{d}\alpha\int_{-\infty}^{+\infty} T(\varpi, a)|\varpi|e^{j2n\varpi(a\ \cos\ \alpha + b\ \sin\ \alpha)}\mathrm{d}\varpi, \quad (22)$$

$$g(a\ \cos\ \alpha + b\ \sin\ \alpha) = \int_{-\infty}^{+\infty} T(\varpi, a)|\varpi|e^{j2n\varpi(a\ \cos\ \alpha + b\ \sin\ \alpha)}\mathrm{d}\varpi, \quad (23)$$

$$f(a, b) = \int_{0}^{\pi} g(a\ \cos\ \alpha + b\ \sin\ \alpha)\mathrm{d}\alpha. \quad (24)$$

Equations (23) and (24) are the main equations for filtering backprojection, $|\omega|$ in (22) represents the filter function, and $f(a, b)$ is the reconstructed image.

2.4. Image Reconstruction and Effect Evaluation. In this study, a backprojection image reconstruction algorithm was used to reconstruct the lung lesions of patients undergoing lobectomy, and filtering function was added to solve the problem of image sharpness. In addition, the iterative reconstruction algorithm (using the method of solving linear equations to reconstruct the image) and Fourier transform analytical method were introduced. In the arterial phase of chest enhanced CT, the pulmonary artery, pulmonary vein, lesion, and blood-supplying artery were reconstructed. Through the reconstruction of 3D images, the lesions were presented more clearly in the form of three dimensions and visualization, so as to realize the simulation effect.

2.5. Statistical Methods. SPSS 19.0 was employed for data statistics and analysis. Mean ± standard deviation (□$x \pm s$) was how measurement data were expressed, and percentage was how count data were expressed. The pairwise comparison was performed by analysis of variance. The difference was statistically considerable with $P < 0.05$.

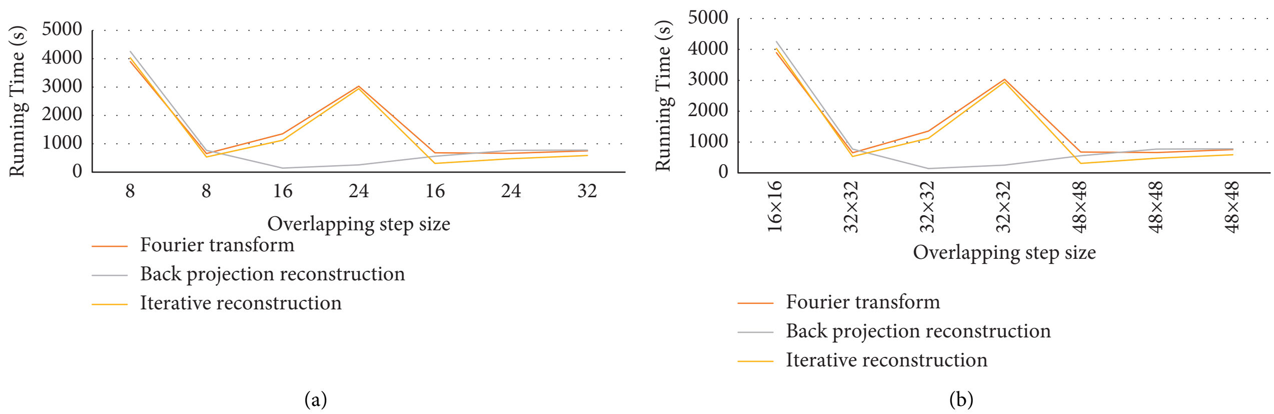

FIGURE 3: Image reconstruction running time. (a) The running time of different overlapping steps. (b) The running time of different block sizes.

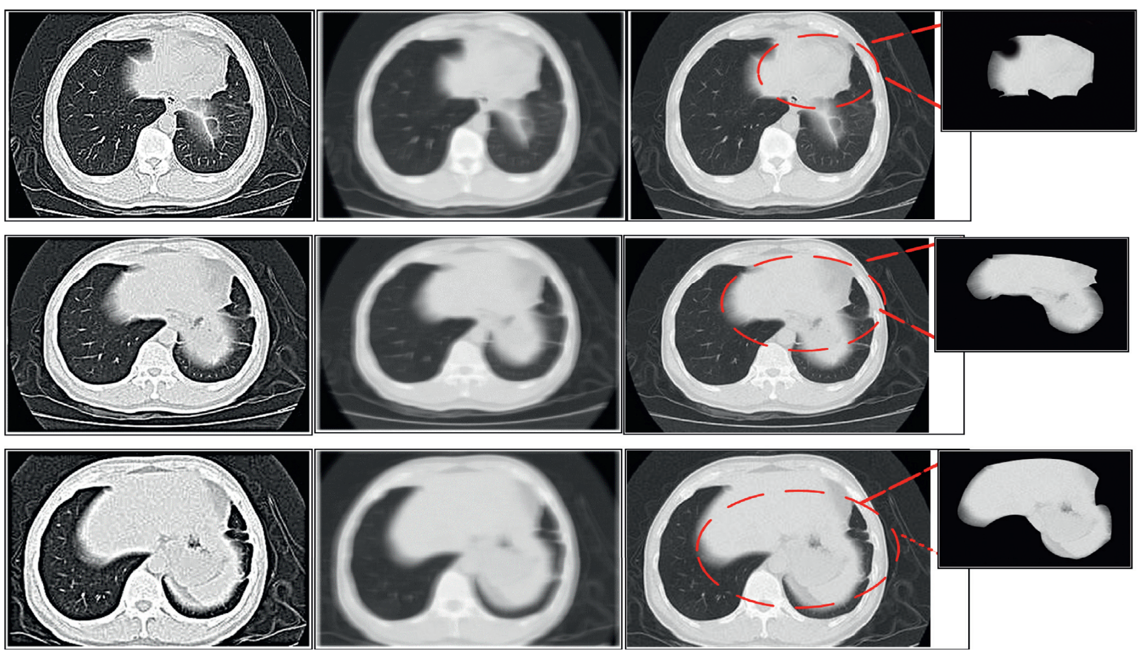

FIGURE 4: Reconstruction of CT images of lungs by backprojection.

3. Results

3.1. Running Time of the CT Image Reconstruction Algorithm. Figure 3 shows the running time of CT image reconstruction by Fourier transform analysis, iterative reconstruction algorithm, and backprojection image reconstruction algorithm. Figures 3(a) and 3(b) show the calculation time under different block and different overlap step parameter settings, respectively. The Fourier transform analysis had the shortest running time when the overlap step was 8, the block size was 32×32, and the overlap step was 16. The iterative reconstruction algorithm had the shortest running time when the overlap step was 16 and the block size was 48×48. When the overlap step was 16 and the block size was 32×32, the backprojection image reconstruction algorithm had the shortest running time.

3.2. Analysis of the Effect of CT Image Reconstruction. According to the noise characteristics in the data, the filtering function was applied to the original data, and the signal in the image was filtered, removing noise and artifacts to reconstruct the image. In Figure 4, there were patchy, subsegmental, and segmental ground-glass density shadows in the CT images of pulmonary lesions, which were separated into paving stone-like changes by the thickening of small honeycomb-like interlobular septa. In addition, large consolidation in the middle lobe of the right lung and patchy consolidation in the posterior basal segment of the lower lobe were observed. The density shadow of ground glass and the thickening of interlobular interval were seen obviously after image removal and processing by the backprojection filter reconstruction algorithm.

3.3. Analysis of the Reconstruction Effect of Three Algorithms. Figure 5 shows the CT images of a central lung cancer patient and a right upper lobe lung cancer patient, as well as the results of reconstruction by Fourier transform analysis, iterative reconstruction algorithm, and backprojection image reconstruction algorithm. Through adaptive image selection and super-resolution reconstruction, the backprojection reconstruction algorithm continuously corrected the structural information of the target image block, so as to obtain high definition and clear image edge. High-resolution images with dramatically enhanced details can eliminate the interference of image noise and artifacts and reconstruct clear CT images. The image clarity and resolution obtained by the backprojection reconstruction algorithm were superior to those of Fourier transform analysis and iterative reconstruction algorithm.

3.4. Detection Rate of Pulmonary Nodules by Three Reconstruction Algorithms. Figure 6 shows the comparison of the detection rates of pulmonary nodules of different sizes after the three algorithms, namely, Fourier transform analysis method, iterative reconstruction algorithm, and backprojection image reconstruction, processed the lung CT images. For pulmonary nodules smaller than 6 mm, the detection rates of the three algorithms were 90.98%, 87.53%, and 92.35%, respectively. For 6–30 mm lung nodules, the detection rates of the three algorithms were 88.32%, 90.87%, and 95.44%, respectively. The detection rate of pulmonary nodules of different sizes by backprojection image reconstruction algorithm was significantly higher than that by the Fourier transform analytical method and iterative reconstruction algorithm ($P < 0.05$).

3.5. Patient's Lung Disease Types. Figure 7 shows the types of lung lesions and their proportion in patients undergoing lobectomy. Patients with central lung tumors and right upper lobe tumors accounted for a relatively high proportion of 43.21% and 29.54%, respectively, followed by tuberculosis, severe lung infection, and pulmonary fibrosis, accounting for 8.11%, 8.93%, and 10.21%, respectively.

3.6. VAS Scores of Patients at Different Postoperative Periods. Figure 8 shows the VAS scores at different periods after thoracoscopic lobectomy. Figure 8(a) shows the VAS score under the resting state, and Figure 8(b) shows the VAS score under the exercise state. Ropivacaine combined with dexamethasone and dexmedetomidine was used for anesthesia induction and lobectomy after nerve block, and VAS scores decreased with the extension of postoperative time. The VAS score decreased to a low level after five days.

4. Discussion

The basis of CT image reconstruction is as follows. The same X-ray intensity passes through different substances, and different substances in the human body are distinguished by using this law [18, 19]. The structures that X-rays pass through each layer of the body in a CT scan are broken up into small cubes called voxels. Each cube corresponds to a separate attenuation signal, and this signal is fed into the corresponding cell in the image plane matrix called pixel. The attenuation signal of each voxel is input into the corresponding pixel and then reflected in different gray scales, which is the process of CT image reconstruction [20, 21]. For the backprojection image reconstruction algorithm, the problem of image sharpness is solved by adding a filter function. The reconstructed image is blurred when the filter function is not added, and the reconstructed image after the filter function is added can make it clear. Due to the fast reconstruction speed and high image quality of the backprojection filter, it has become the most commonly used CT image reconstruction method. Although the iterative reconstruction algorithm has been proposed very early, due to its large amount of calculation and slow reconstruction speed, it depends on the breakthrough of computer performance. Therefore, the backprojection reconstruction algorithm is widely used in current applications [22, 23]. In this study, a backprojection image reconstruction algorithm was used to reconstruct the lung lesions of patients undergoing lobectomy by CT three-dimensional reconstruction, and a filter function was added to solve the problem of image sharpness. In addition, iterative reconstruction algorithm and Fourier transform analysis method were introduced. Aiming at the arterial phase of enhanced CT of the patient's chest, the pulmonary artery, pulmonary vein, lesion, and blood supply artery were reconstructed, and the lesion was visualized more clearly through the reconstructed three-dimensional image, achieving the effect of simulation.

Through the backprojection reconstruction algorithm to process the CT image, it was found that when the overlap step was 16 and the block size was 32×32, the backprojection image reconstruction algorithm had the shortest running time. Therefore, to ensure that a higher-quality image was obtained after reconstruction, the setting of image block parameters should not affect the reconstruction result. The image separation parameters of this study were set as follows. The block size was 32×32, and the overlap step length was 16 pixels. The detection rate of backprojection image reconstruction algorithm for lung nodules smaller than 6 mm and 6–30 mm was significantly higher than that of the Fourier transform analytical method and iterative reconstruction algorithm ($P < 0.05$). The results were similar to those of Yoshida et al. [24], which showed that the backprojection image reconstruction algorithm can continuously modify the structure information of the target image through super-resolution reconstruction, make the image clear, and facilitate the identification of the lesion. The patients included in this study were treated with ropivacaine combined with dexamethasone and dexmedetomidine for induction of anesthesia and lobectomy for nerve block. The patient's VAS score decreased with the extension of postoperative time. After five days, the patient's VAS score can be reduced to a lower level. This was similar to the results of Williams et al. [25]. It was verified that combined induction of anesthesia and nerve block had a positive effect on postoperative pain and postoperative recovery.

5. Conclusion

In this study, a backprojection image reconstruction algorithm was established and applied to CT images of patients undergoing thoracoscopic lobectomy. The image was reconstructed to remove noise and artifacts to obtain a clear image and identify lesions. Then, the effect of ropivacaine combined with DXM and DEX in blocking thoracoscopic lobectomy was studied by evaluating CT image features based on reconstruction algorithm. The results showed that ropivacaine combined with dexamethasone and dexmedetomidine had ideal sedation and analgesia effects in patients with thoracoscopic lobectomy. The CT image based on the backprojection reconstruction algorithm had a high recognition accuracy for lung lesions, which was worth applying to clinical diagnosis. However, this study lacked comparison with other intelligent algorithms and was less representative. Therefore, this aspect will be improved and optimized in the subsequent experiments, and the CT image features based on reconstruction algorithm will be further analyzed to evaluate the effect of ropivacaine combined with dexamethasone and dexmedetomidine in the treatment of video-assisted thoracoscopic lobectomy. In conclusion, this study provides a reference for the application of intelligent reconstruction algorithms such as backprojection filtering in medical images.

This study aimed to explore the application value of three-dimensional (3D) convolutional neural networks (3D-CNN)-based computed tomography (CT) image intelligent segmentation model in the identification of lesions of patients with hepatitis B virus-associated acute-on-chronic liver failure (HBV-ACLF). A total of 30 patients with HBV-ACLF, 30 patients with chronic HBV hospitalized in hospital, and 30 healthy volunteers were selected as subjects. Liver function and serum inflammatory factors were measured in each group, and the 3D-CNN algorithm model was applied to CT imaging. The results showed that the levels of interleukin (IL)-6, IL-26, and IL-37 in the HBV-ACLF group were the highest, which were 128.43 ± 45.16 pg/mL, 1237.47 ± 536.22 pg/mL, and 50.83 ± 7.62 pg/mL, respectively. Total bilirubin (TBIL) ($P = 0.035$) and IL-26 ($P = 0.013$) were independent predictors that affected the prognosis of HBV-ACLF patients. The results of lesion segmentation showed that the Dice coefficient of 3D-CNN low-density focus and enhanced focus segmentation was the highest (0.821 ± 0.07 and 0.773 ± 0.071), and the marked area was close to the area manually drawn by the doctor. 3D CNN was superior to other algorithms in the number of nodular lesions detected (533), sensitivity (97.5%), and missed detection rate (0.52%) ($P < 0.05$). In short, IL-26 may become a useful biomarker in the treatment of HBV-ACLF. The 3D-CNN model improved the segmentation performance of lesions in CT images of HBV-ACLF patients, which provided a reference for the diagnosis and prognosis of HBV-ACLF.

1. Introduction

Acute-on-chronic liver failure (ACLF) refers to the acute deterioration of liver failure syndrome in patients with chronic liver disease whose liver function is originally stable under the action of various acute injury factors [1, 2]. Related research pointed out that more than 30% of ACLF patients are caused by infection, and the main cause of ACLF in China is hepatitis B virus (HBV) infection [3]. The patient's infection index has risen greatly, which is directly proportional to the severity of the disease and the mortality rate. This type of infection is mainly caused by bacteria such as Gram-negative bacilli. However, in recent years, with the abuse of antibiotics and the increase in the types of multidrug resistant bacteria, the infection range of HBV-ACLF patients is gradually expanding [4]. Bacteria generally induce inflammation through pathogen-associated molecular patterns (PAMPs) and virulent factors [5]. Studies found that the possible involvement in the pathogenesis of HBV-ACLF includes immune damage, inflammation, and cell apoptosis. It shows that the level of inflammatory factors in serum will change when HBV-ACLF occurs [6, 7], and its expression has potential clinical treatment and prognostic evaluation value.

Image omics is a technology that deeply mines data features from medical images through high-throughput multidimensional analysis [8]. The use of advanced image analysis tools and various data statistics and analysis tools for accurate diagnosis provides a powerful tool for modern medicine [9, 10]. In recent years, with the development of big data and medical imaging, imaging omics has been widely used in the prediction of the internal microscopic manifestations, pathological manifestations, and gene expression of clinical lesions [11]. Among them, computed tomography (CT) is the most valuable examination method at present. CT plain scan can describe the morphological characteristics of the lesion and clarify the status of the lesion, while the enhanced CT scan can reflect the characteristics of the blood supply of the lesion and the relationship with the surrounding tissue structure [12]. However, it is not ideal for the segmentation of low-density or nodular lesions in the liver of HBV-associated ACLF patients. CT images have many slices, and the size, location, and shape of low-density lesions are inconsistent. Manual reading is time-consuming and laborious, and there is no uniform standard for segmentation results. It is easy to have inconsistent diagnosis results from different doctors [13, 14]. Therefore, more intelligent algorithms are needed for image segmentation.

Convolutional neural network (CNN) has demonstrated more substantial effects and better clinical application prospects than traditional shallow learning methods in image segmentation and classification [15]. However, most of them are based on 2D cross section for feature extraction, and it is difficult to make full use of the data correlation in the vertical axis [16]. On this basis, an automatic segmentation algorithm based on 3D CNN for dual-channel 3D dense connection network is proposed. Convolution kernels of different sizes are used to extract multiscale features under different scale receptive fields. Then, the densely connected blocks of each channel were used for feature learning and transmission. After the features were connected, they were input to the classification layer to classify the target volume element [17, 18], and finally the automatic segmentation of the lesion was realized.

To sum up, the use of 3D-CNN model to optimize medical CT images to assist physicians in detecting low-density foci or nodular lesions in the liver of patients with HBV-associated ACLF has become a hot topic of current research by scholars. In this study, liver function and serum inflammatory cytokine levels were detected in 30 HBV-associated ACLF patients, 30 CHB patients, and 30 healthy volunteers. The end-to-end neural network architecture was designed based on 3D-CNN and applied to CT image analysis, to comprehensively evaluate the application value of 3D-CNN algorithm combined with CT imaging in the level of inflammatory factors and prognosis of HBV-associated ACLF patients.

2. Materials and Methods

2.1. Research Objects. A total of 30 patients with HBV-associated ACLF hospitalized in hospital from May 2019 to May 2020 were collected, with an age range of 30–80 years. Chronic active hepatitis B (CHB) patients were 30 cases, aged 31–77 years. Thirty healthy volunteers who underwent physical examination in this hospital during the same period were selected as healthy control group, aged 20–67 years.

Inclusion criteria for HBV-associated ACLF were as follows: patients who were in line with the diagnostic criteria of Guidelines for Diagnosis and Treatment of Liver Failure published by Liver Failure and Artificial Liver Research Group of Chinese Association of Infectious Diseases in 2018 [19] and serum total bilirubin in patients being 10 times or more than the normal value or increased by 17.1 μmol/L/day. Exclusion criteria were as follows: patients who had coinfection with other hepatitis viruses or immunodeficiency viruses, patients with drug-induced hepatitis and alcoholic liver, patients who had liver disease caused by parasitic infection, patients with hyperthyroidism, women in pregnancy or lactating period, and patients with liver metastasis of primary liver cancer or malignant tumor.

Inclusion criteria for CHB patients were the following: patients who were in line with the diagnostic criteria of Guidelines for Prevention and Treatment of chronic hepatitis B published by the Chinese Society of Liver Diseases and the Chinese Society of Infectious Diseases in 2015 [20] and the history of infection being more than six months. Exclusion criteria were the following: patients complicated with other viral hepatitis; patients with alcoholic liver, cirrhosis, drug-induced hepatitis, or fatty liver; patients with genetic metabolic liver disease; patients with autoimmune liver disease or parasitic liver disease; and patients with liver metastasis of primary liver cancer or malignant tumor.

Inclusion criteria of healthy volunteers were the following: all examination indexes and biochemical indexes being normal, and the patients not taking any drugs in the past week. Exclusion criteria were the following: those with organic diseases.

This experiment had been approved by the ethics committee of the hospital. All the experimental matters had been informed to the subjects and their families, who had signed informed consent.

2.2. Main Instruments and Reagents. Automatic blood coagulation analyzer was from Nanjing VEDENG Medical Co., Ltd. Centrifuge was from Nanjing Yiruoda Instrument Equipment Co., Ltd. Low-temperature refrigerator was from Jinan OLABO Instrument Equipment Co., Ltd. Microplate reader was from Jinan Laobao Medical Equipment Co., Ltd. Interleukin- (IL-) 26 kit was from Shanghai Yiyan Biotechnology Co., Ltd. IL-6 kit was from Shanghai Tongwei Industrial Co., Ltd. IL-27 kit was from Shanghai Jichun Industrial Co., Ltd. Enzyme conjugate was from Shanghai Rayzbio Biotechnology Co., Ltd. Termination fluid was from Shanghai Acmec Biochemical Co., Ltd.

2.3. Liver Function and Inflammatory Factor Detection. 5 mL of fasting venous blood was collected from all participants in the morning. After the blood sample was coagulated, it was centrifuged at a frequency of 3,500 rpm for 10 minutes. If the sample did not show hemolysis or lipemia, the upper serum was taken and stored in a refrigerator at −80°C. Routine detections were implemented for alanine aminotransferase (ALT), aspartate aminotransferase (AST), serum total bilirubin (TBIL), prothrombin time (PT), and activated partial thromboplastin time (APTT) using automatic serum coagulation analyzer. IL-26 was measured by double-antibody sandwich enzyme-linked immunosorbent assay (ELISA). The kit was taken out from the 4°C refrigerator and cooled to room temperature. The distilled water was diluted in a ratio of 1 : 20, and washing solution was prepared. The standard material was diluted to different concentrations, and 100 μL of the tested serum sample was injected into the well of the ELISA plate. The plate was sealed and left standing at 37°C for 1 hour; then, the plate was thoroughly cleaned for five times and dried. 100 μL biotinylated antibody was injected into each well, and the sealed plates were stood at 37°C for 1 hour. The plate was cleaned five times and dried. 100 μL enzymatic conjugate was added into each well, standing at 37°C for 15 min. The plate was cleaned five times and dried. Then, 50 μL of substrates A and B was added into each well, standing for 15 minutes at 37°C in dark. One drop of terminating solution was added to each well to terminate the experimental reaction. The absorbance was measured at 450 nm using a microplate analyzer. The operation for the determination of IL-6 and IL-27 was the same as above.

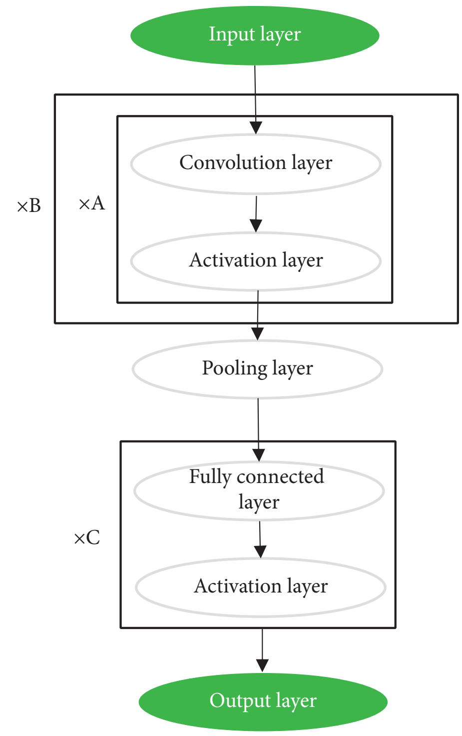

Figure 1: Structure diagram of CNN.

2.4. CNN Algorithm. Convolutional network is a kind of neural network structure, which is regarded as a special artificial neural network. The input data is calculated through the multilayer nonlinear mapping, and the prediction result is output. Its essence is a regression optimization calculation, which introduces a feedback layer into the traditional multilayer perception network structure to optimize the prediction results. It mixes A convolutional layer-activation layer, extracts image feature information, connects a pooling layer for downsampling, and repeats it many times until the image is minimized. Then, it connects a fully connected layer to convert all feature images into feature vectors. Finally, the result is obtained through the output layer. The basic network structure is shown in Figure 1.

The convolutional layer extracts the feature information of a certain area, and the image obtained after convolution is the feature map. In the CNN, the convolutional layer has two key characteristics of local connection and weight sharing. The meaning of local connection is that each point in the back layer only connects the corresponding area in the front layer. Weight sharing means that it inputs a picture and scans it with a convolution kernel. The number in the convolution kernel is called the weight. Each position in this picture is scanned by the same convolution kernel, so the weight is the same; that is, it is shared. The structure diagram is roughly as shown in Figure 2.

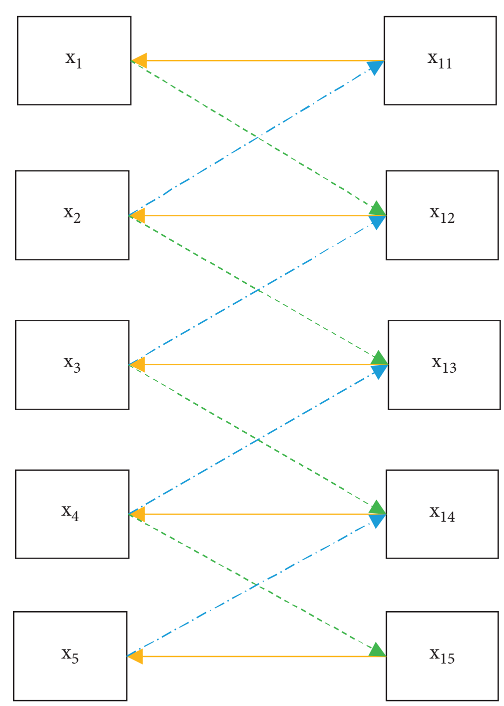

Figure 2: Local connection and weight sharing.

In the CNN, the definition of the 3D convolutional layer is as follows:

$$I_n^j(a,b,c) = \sum_h \sum_{e,f,g} I_h^{j-1}(a-e, b-f, c-g) M_{\mathrm{hn}}^j(e,f,g) + p_n^j. \tag{1}$$

Here, $I_n^j \in \theta^3$ is the nth feature image representing the jth layer, $M_{\mathrm{hn}}^j \in \theta^3$ is the 3D convolution kernel connecting I_h^{j-1} and I_n^j, and $p_n^j \in \theta^3$ is the offset of connecting $_I^{j-1}$ and I_n^j. A convolution kernel moves in the layer of the neural network, thereby obtaining a feature image of the next layer. The expression of the size of the image is as follows:

$$O_{\text{out}} = \frac{O_{\text{in}} - Q + 2R}{T} + 1. \tag{2}$$

Here, O_{in} is the size of the input feature image, Q is the size of the corresponding convolution kernel, R is the number of boundary zero padding, and T represents the length of the convolution kernel when it moves. In the neural network, there are two main types of pooling layers, the largest pool and the average pool. The calculation method of the maximum pool is as follows:

$$I_n^j(a,b,c) = \max_{0\le e,f,g\le w}\left\{I_n^{j-1}(a\cdot w+e, b\cdot w+f, c\cdot w+g)\right\}. \tag{3}$$

The average pool is expressed as follows:

$$I_n^j(a,b,c) = \frac{1}{w^3}\sum_{e=0}^{w}\sum_{f=0}^{w}\sum_{g=0}^{w} I_n^{j-1}(a\cdot w+e, b\cdot w+f, c\cdot w+g). \tag{4}$$

Here, w is the size of pooling. After passing through the pooling layer, the number of feature maps does not change, and the size of the image is calculated by the following equation:

$$O_{\text{out}} = \frac{O_{\text{in}} - w}{T} + 1. \tag{5}$$

Here, O_{in} is the size of the input feature image, w is the pooling size, and T is the pooling step size. For the fully connected layer, each neuron in it will be connected to the previous layer, and the Softmax layer is often used as the output layer of the CNN. Its expression is as follows:

$$I_u^N = \frac{x^{I_u^{N-1}}}{\sum_{v=1}^{v} x^{I_v^{N-1}}} \text{ for } u = 1,\cdots,V. \tag{6}$$

Here, V represents the total number of categories, N is the total number of layers of the neural network, I_V^{N-1} is the v th node in the $N-1$ th layer (usually a fully connected layer), and I_u^N represents the uth node in the Nth layer (i.e., the output layer). The sum of the probabilities of all categories is 1.

Since most of the low-density areas of the liver occupy a small area in the image, the channels in the network are usually used to sample under the pooling layer to avoid excessive loss of small information. The convolution module is employed to extract the information of this layer, and then deconvolution is performed to generate cascade with the feature image, which enables multilevel feature learning, thereby helping to detect low-density areas of different sizes.

2.5. 3D-CNN. 2D-CNNs mainly focus on 2D neighborhood information, while 3D-CNN is calculated through three dimensions and extracts features in 3D space. The main content of this study is applying 3D-CNN to the segmentation of low-density lesions in the liver area.

CNNs are individually estimated according to the neighborhood and context of each volume element in the image, and feature extraction is completed by cascading a series of convolution operations. 3D-CNN uses a 3D convolution kernel, facing the initial 3D data, which completes the convolution calculation through the input layer and the convolution kernel. After addition of the bias term, the nonlinear excitation function is used to obtain the output characteristic image. The basic network structure is shown in Figure 3.

The calculation method is expressed as follows:

$$y_{z-1}^u = g\left(\sum q_z^{u,v} \otimes y_{z-1}^v + d_z^u\right). \tag{7}$$

Here, each $q_z^{u,v}$ is the learned hidden weight, u represents the number of convolution kernels (the dimension of the output feature), v represents the dimension of the input feature, y_{z-1}^v represents the output 3D feature map, d_z^u represents the bias term, $\otimes$ is the convolution calculation, and g represents the nonlinear activation function. In 3D-CNN, if features are input to the network layer with a higher level, complex features will appear, which are used for classification. The end of the CNN is the classification layer, which is compared with the labels used for classification. This layer generally uses a normalized exponential function, which is defined and expressed as follows:

$$x_s = \frac{r^{O_s}}{\sum_s^N r^{O_s}}. \tag{8}$$

Here, O_s represents the output of the previous layer, s represents the index number of the estimated category, N is the number of categories in the layer, and x_s represents the ratio of the index of the estimated category at this time to the sum of all category factors. With the help of Softmax, the output value of each category is adjusted to the estimated probability compared with it.

2.6. Low-Density Foci Segmentation Based on 3D-CNN. The low-density stove segmentation process based on 3D-CNN is shown in Figure 4. In the training stage, the training set image is input, and the volume elements are normalized through preprocessing. Then, the features of each dimension are learned and extracted. According to the estimated conclusion and classification label, the patches generated by the loss function in the training and test set images are counted and then normalized. The categories of the volume elements are calculated through the network model one by one, and the segmentation result image is output.

2.7. CT Examination. A Brilliance 64-row helical scanner (GE Company, USA) was employed for inspection. The layer thickness was 5 mm, the spacing was 5 mm, and the reconstruction layer thickness was 0.625 mm. The tube current was 380 mA, the tube voltage was 125 kV, and the collimator width was 0.625 mm. In the enhanced scan, 80–100 mL (350 mg/100 mL) of the contrast agent iohexol

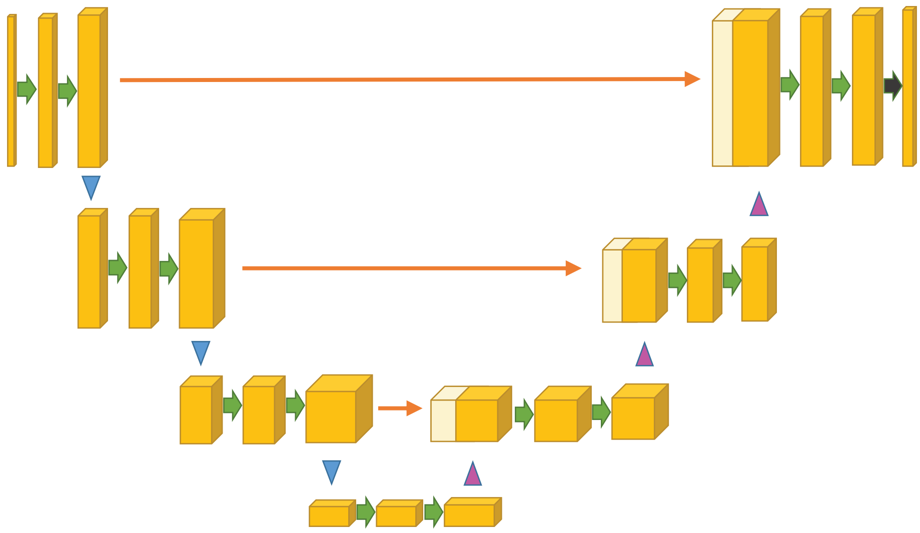

Figure 3: Basic network structures of 3D-CNN.

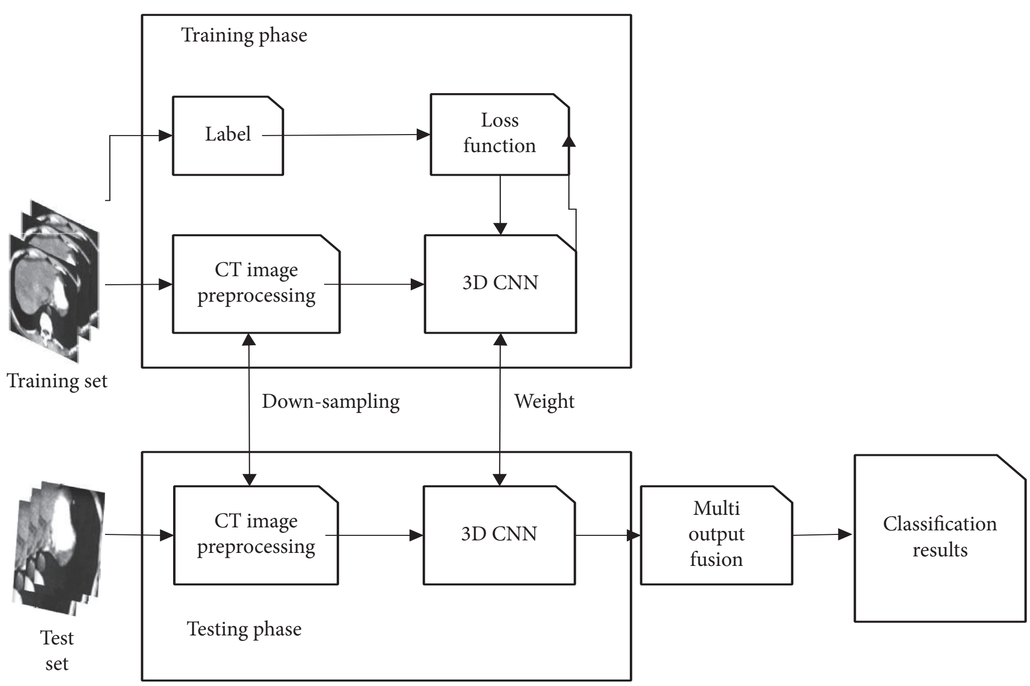

Figure 4: 3D-CNN's low-density foci segmentation process.

was injected at a flow rate of 3-4 mL/s. Scanning phases were 20–25 s in the arterial phase, 65–70 s in the venous phase, and 180 s in the delayed phase. The image data was processed by the system's own imaging workstation.

2.8. Statistical Analysis. SPSS 24.0 was used for statistical analysis of all experimental data. The continuous variables conforming to normal distribution were represented as mean ± standard deviation ($\overline{x} \pm s$), and the t-test was used for comparison between groups. One-way analysis of variance was used for comparison between multiple groups. Multivariate analysis was performed using logistic regression equation analysis. The correlation was assessed by Pearson test. $P < 0.05$ was considered statistically considerable.

3. Results

3.1. Comparison of the Levels of Inflammatory Factors among the Three Groups of Objects. In Figure 5, IL-6, IL-26, and IL-37 in the HBV-ACLF group were 128.43 ± 45.16 pg/mL, 1237.47 ± 536.22 pg/mL, and 50.83 ± 7.62 pg/mL, respectively, which were higher than those of 89.17 ± 28.39 pg/mL, 689.14 ± 351.7 pg/mL, and 31.19 ± 5.82 pg/mL in CHB group and those of the healthy group 58.45 ± 13.22 pg/mL,

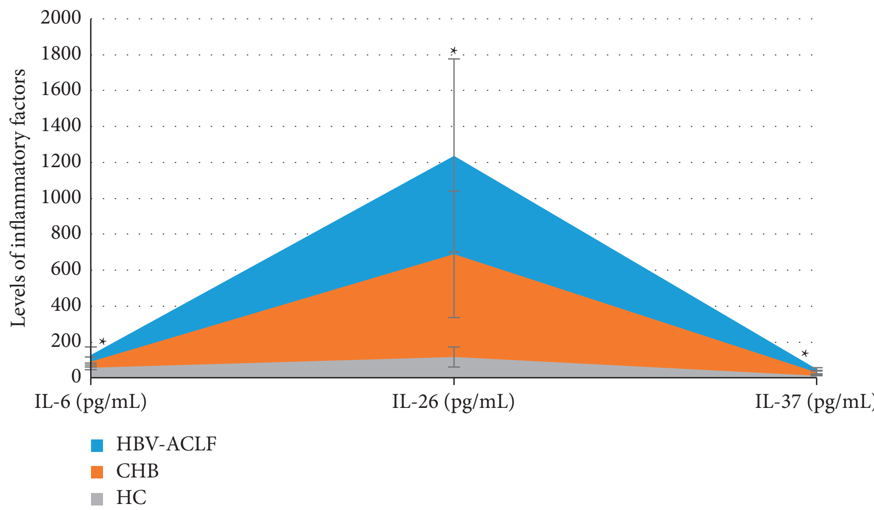

Figure 5: Comparison of the levels of inflammatory factors among the three groups of objects. Note: * indicates that the level of inflammatory factors in the HBV-ACLF group had a considerable difference compared with the CHB group and the HC group ($P < 0.05$).

Table 1: Prognostic risk factors of HBV-associated ACLF patients.

	P	Univariate analysis OR	95% CI	P	Multifactor analysis OR	95% CI
ALT (U/L)	0.291	1.000	0.987–1.000			
AST (U/L)	0.698	1.000	0.995–1.000			
TBIL (μmol/L)	0.004	1.0078	1.004–1.021	0.035	1.015	1.000–1.026
PT (s)	0.012	1.136	1.031–1.215	0.388	1.356	0.682–2.521
APTT (s)	0.005	1.043	1.008–1.098	0.891	1.002	0.936–1.054
IL-6 (pg/mL)	0.077	1.253	0.998–1.561	0.605	0.187	0.001–1.298
IL-26 (pg/mL)	≤0.001	1.004	0.936–1.006	0.013	1.005	1.000–1.006
IL-37 (pg/mL)	0.340	0.991	0.972–1.008	0.072	1.015	0.993–1.066

116.43 ± 56.29 pg/mL, and 14.14 ± 2.18 pg/mL, respectively. The differences were considerable ($P < 0.05$).

3.2. Prognostic Risk Factors of HBV-Associated ACLF Patients. Table 1 shows the single-factor and multifactor logistic regression analysis. In the univariate analysis of the prognosis of HBV-associated ACLF patients, TBIL ($P = 0.004$), PT ($P = 0.012$), APTT ($P = 0.005$), and IL-26 ($P < 0.001$) were considerable. In the multivariate analysis, TBIL ($P = 0.035$) and IL-26 ($P = 0.013$) were independent predictors of the prognosis of patients with HBV-associated ACLF.

3.3. Analysis of CT Image Low-Density Foci Segmentation Results Based on Three Algorithms. In Figure 6, the machine learning-based algorithms Deep Medic and Seg Net were compared with the 3D-CNN model. According to the Dice coefficient of the segmentation results, the Dice coefficient of 3D-CNN (0.884 ± 0.068) in the overall segmentation of low-density stoves was slightly lower than Deep Medic algorithm (0.900 ± 0.077) and higher than Seg Net algorithm (0.846 ± 0.072). In the core segmentation of low-density foci, the Dice coefficient of 3D-CNN was 0.821 ± 0.07, which was higher than Deep Medic algorithm (0.763 ± 0.069) and Seg Net algorithm (0.754 ± 0.076). In the segmentation of enhanced lesions, the Dice coefficient of 3D-CNN (0.773 ± 0.071) was higher than that of Deep Medic algorithm (0.731 ± 0.074) and Seg Net algorithm (0.694 ± 0.078), and the difference was considerable ($P < 0.05$).

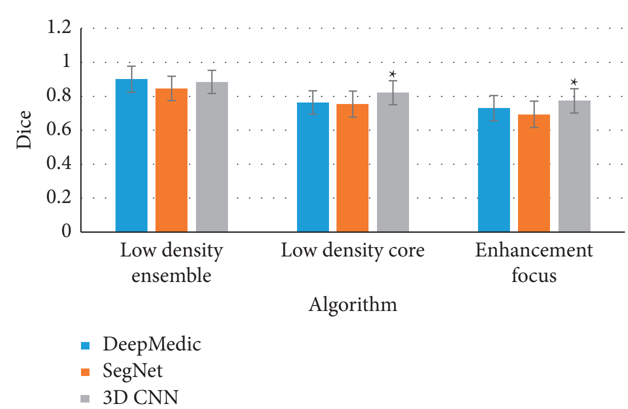

Figure 6: Analysis of CT image low-density lesion segmentation results based on three algorithms. Note: * indicates that the Dice coefficient of the 3D-CNN model was considerable compared to the other two algorithms ($P < 0.05$).

A 53-year-old male patient presented with intermittent abdominal distension for two years with exacerbation and yellowing of eyes and skin for two weeks. CT examination two years ago showed cirrhosis. That time, the patient visited the hospital due to abdominal distension and fatigue. HBsAg (+),

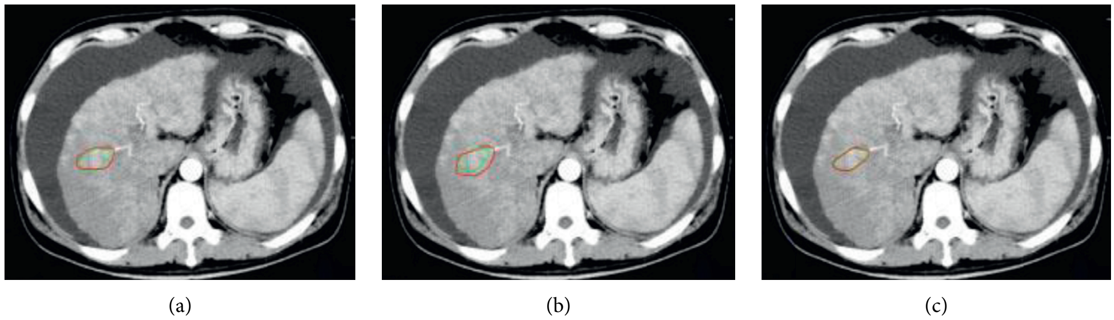

FIGURE 7: Different algorithm models segmentation results of low-density foci. (a) The CT image marked by the Deep Medic algorithm model, (b) the CT image marked by the Seg Net algorithm model, and (c) the CT image marked by the 3D-CNN model.

FIGURE 8: Comparison of CT image candidate detection results based on three algorithms. (a) The comparison of the number of nodular lesions detected by the three algorithms. (b) The comparison of the sensitivity and missed detection rate of the three algorithms. Note: *indicates that the detection performance of the 3D-CNN model was considerable compared to the other two algorithms ($P < 0.05$).

HBeAg (−), and HBV DNA 2.46×10^5 IU/mL were examined. Figure 7 shows the results of segmentation of low-density foci by different algorithm models. Green was the lesion area marked by the doctor, and red was the lesion area automatically marked by the three algorithm models. The 3D-CNN marked the area more closely to the area the doctor had sketched by hand.

3.4. Comparison of CT Image Candidate Detection Results Based on Three Algorithms. The results of candidate detection of nodular lesions using different algorithms are shown in Figure 8. The number of nodular lesions detected by 3D-CNN was 533, which was higher than that of Deep Medic algorithm (506) and Seg Net algorithm (482). Sensitivity (97.5%) of 3D-CNN was higher than that of Deep Medic algorithm (95.6%) and Seg Net algorithm (93.8%). The missed detection rate (0.52%) of 3D-CNN was lower than that of Deep Medic algorithm (0.76%) and the Seg Net algorithm (1.25%), and the difference was considerable ($P < 0.05$).

4. Discussion

HBV-associated ACLF is a reaction after a series of injuries, such as systemic immune disorders due to various inducements of acute liver injury based on chronic liver disease [21, 22]. It causes severe liver damage or failure. HBV-ACLF can lead to rapid deterioration of liver function, circulatory system, and organ dysfunction in the course of disease development, which is of high mortality and poor prognosis [23]. Many studies deemed that immune dysfunction is the main cause of ACLF. In the early stage, immune overexcitation and continuous inflammatory response cause a large number of liver cell necrosis [24, 25], while inflammatory cell infiltration and microcirculation disorder also exist. With the progress of the disease, liver failure, toxin accumulation in the body, internal environment disorder, and other consequences gradually appear [26]. In clinical practice, experts usually segment lesions manually based on their professional knowledge and work experience. The method based on computer automatic segmentation can effectively help doctors relieve working pressure and quickly and accurately obtain the feedback of the lesion area to doctors [27], which provides good diagnostic conditions and recommendations for treatment options. In clinical practice, CNN is usually used to build a medical image segmentation algorithm model to assist physicians to greatly improve the analysis effect of imaging features [28]. In this study, liver function and serum inflammatory cytokine levels were detected in 30 HBV-ACLF patients, 30 CHB patients, and 30 healthy volunteers. The end-to-end neural network architecture based on 3D-CNN was designed and applied to CT image analysis.

The results showed that the levels of IL-6, IL-26, and IL-37 were the highest in HBV-ACLF group, and TBIL and IL-26 were independent predictors of the prognosis of HBV-ACLF patients. The results of focal segmentation showed that the Dice coefficient of low-density focal core and enhanced focal segmentation was the highest in 3D CNN, and the labeled regions were closer to the regions delineated manually by doctors. Moreover, 3D CNN was superior to other algorithms in the number, sensitivity, and missed detection rate of nodular lesions detected ($P < 0.05$). In short, IL-26 may be a useful biomarker in the treatment of HBV-ACLF. The 3D-CNN model improved the segmentation performance of lesions in CT images of patients with HBV-ACLF, providing a reference for the diagnosis and prognosis of HBV-ACLF. This is consistent with the research results of Osuna-Coutiño and Martinez-Carranza [29]. 3D-CNN model makes full use of the interlayer information of CT images to improve the continuity of CT image segmentation. Hamidian et al. [30] pointed out that 3D-CNN combined the advantages of 2D and 3D models and significantly improved the segmentation performance of the model. It was found that TBIL and IL-26 were independent predictors of prognosis in patients with HBV-ACLF, and IL-26 may be a useful biomarker in the treatment of HBV-ACLF.

5. Conclusion

In this study, an intelligent CT image segmentation model based on 3D-CNN algorithm was established to integrate 2D and 3D models, which was applied to CT images of HBV-ACLF patients. The results showed that the 3D-CNN algorithm model had ideal performance in CT image segmentation of HBV-ACLF patients. However, there are still some shortcomings in this study. The experimental results have certain limitations and one-sidedness, so it is necessary to increase the sample size in the future and conduct further exploration in this direction. In conclusion, 3D-CNN model greatly improves the segmentation performance of CT images of patients with HBV-ACLF, which provides a reference for the diagnosis and prognosis of HBV-ACLF.

Gait and posture studies have gained much prominence among researchers and have attracted the interest of clinicians. The ability to detect gait abnormality and posture disorder plays a crucial role in the diagnosis and treatment of some diseases. Microsoft Kinect is presented as a noninvasive sensor essential for medical diagnostic and therapeutic purposes. There are currently no relevant studies that attempt to summarise the existing literature on gait and posture abnormalities using Kinect technology. The purpose of this study is to critically evaluate the existing research on gait and posture abnormalities using the Kinect sensor as the main diagnostic tool. Our studies search identified 458 for gait abnormality, 283 for posture disorder of which 26 studies were included for gait abnormality, and 13 for posture. The results indicate that Kinect sensor is a useful tool for the assessment of kinematic features. In conclusion, Microsoft Kinect sensor is presented as a useful tool for gait abnormality, postural disorder analysis, and physiotherapy. It can also help track the progress of patients who are undergoing rehabilitation.

1. Introduction

Microsoft's Kinect sensor is a motion-sensing device that gives users the features to interact with game consoles and computers via ways such as gestures, spoken commands, or movement [1]. Kinect sensors provide new and enhanced features for motion detection and 3D reconstruction. Kinect sensors also introduce many features that allow for more accurate research into the movement of the human body and its gestures. The sensors allow for interaction through voice commands that is a unique component of the technology. It has detectors and infrared emitters to capture human physical activities.

The key components of Microsoft Kinect sensors are the RGB cameras, IR depth sensors, and the multiple microphone array. The second version of Kinect has some enhanced features compared to earlier Kinect [2]. The colour camera of Kinect v2 has $1{,}920 \times 1{,}080$ @30fps while that of Kinect v1 has 640×480 @30fps. In terms of the depth camera capabilities, Kinect v2 uses 512×424 pixels, while Kinect v1 uses 320×240 pixels, and as a result, Kinect v2 has better image recognition compared to the earlier version. Kinect v2 is noted to have a wider area view compared to Kinect v1. Another key feature is that Kinect v2 has better skeletal joint tracking where it is able to capture 26 joints, whereas Kinect v1 can only capture 20 joints. The unique feature of Kinect sensors can be applied to the medical field for the purposes of diagnosing diseases and physiotherapy rehabilitation of people who may have walking disabilities due to physical injury or related diseases.

As stated above, Kinect has found application in many areas related to posture and motion capturing. The major bulk of studies are related to Kinect research in the areas of motion tracking, monitoring, diagnosis, and rehabilitation. Some representative studies with Kinect technology include: Lavanya et al. [3] presented dynamic finger gestures with skeletal data extracted from the depth sensor. A unique technique was designed for the recognition of dynamic gestures that can be used in auditoriums and classrooms. This approach allowed for more dynamic hand gestures to be developed that can be used in different environments. An example is a tutor using this technique to instruct students in a classroom who have speech problems to assist in their studies.

The use of Kinect for medical monitoring and diagnosis has also been trialed by researchers. Ales Prochazka et al. [4] presented a novel technique of using Kinect for heart rate estimation and breath monitoring to determine the likelihood of any medical condition. The mean thorax movement was monitored within a selected area to estimate the breathing of patients. Huy-Hieu et al. [5] presented a real-time system for the detection of objects for patients who are visually impaired. A unique system was designed that allowed visually impaired people to move freely and to detect any obstructions. Object detection was based on the 3D information captured with a depth sensor. However, the designed system was limited to only indoor use. Xin Dang et al. [6] presented a novel interactive system with an electroencephalogram and depth sensor for people with dementia. Skeletal data captured from the depth sensor were extracted to determine the motion of a user and their mental state. The designed system using a deep neural network can be used to aid patients with dementia. Torres et al. [7] provided a novel approach to assist physicians in the diagnosis of Parkinson's disease using posture and movement captured with Kinect. The characteristics of movements such as frequency and amplitude were essential to study tremors in people with Parkinson's. The results achieved in the study can assist clinicians to diagnose Parkinson's based on the tremors intensity and the postural changes.

Kinect sensors are also widely used for the purposes of rehabilitation. Capecci et al. [8] demonstrated an innovative approach in the evaluation of dynamic movement in a rehabilitation scenario. They were able to track skeletal joints in evaluating the performance of patients during a low back pain physiotherapy exercise. Postolache et al. [9] developed a unique framework for physiotherapy assessment based on a mobile application using skeletal data. The designed system assists physiotherapists to improve the effectiveness of the training sessions for patients undergoing rehabilitation. Monique Wochatz et al. [10] illustrated a reliable and valid assessment of the lower extremity rehabilitation of exercises using Kinect v2 sensors. The authors demonstrated the Kinect sensor as a reliable tool in assessing the lower limb position and the joint angles during exercises. Sanjay et al. [11] developed a unique framework for stroke rehabilitation of patients in a home environment. A framework was designed to aid patients who have suffered a stroke in their treatment process. The designed system can be used indoors to help patients who have difficulty in movement.

Abnormal gait is the asymmetric movement of a person that is most likely to be caused by disease or physical injuries. This could be a result of nerves damage, injuries, weakness of muscles, or joint problems. The detection of gait abnormalities at an early stage can help prevent other complications. There are traditional wearable sensors for gait abnormal detection; however, these conventional methods are quite cumbersome to use. Kinect is seen as a better alternative to wearable sensors in gait abnormal detection.

As such, gait analysis has also received wide interest among researchers [12–14]. Kinematic features such as the step length, walking speed, and cadence are useful to determine the gait of an individual. This will normally be cyclical and symmetric unless there are some forms of abnormalities. The human gait could be affected by the musculosketal and neurological systems as well as the motions habits [15]. Hassain Bari et al. [16] presented a novel method by designing a deep neural network for gait recognition. This was then evaluated with a 3D skeletal gait data set. Another study by Wan Zharfan et al. [17] illustrated an economic technique of gait analysis based on pixel coordinates of body joints. The technique served as an alternative method to determine gait parameters in a Vicon motion analysis.

The human posture is the physical positioning by which the body takes at a particular time. Posture is the arrangement of the structure of the human body and its position. Correct body posture can help reduce pressure on the human body by keeping it balanced. The human body posture may be intentional or unintentional due to natural causes. There are several techniques for postures recognition with skeletal data. Samiul Monir et al. [18] presented a novel technique with a rotation and scale-invariant for posture recognition from skeletal features. This technique for posture recognition used skeletal data and angle rotation of an individual. A set of vectors and manipulation of angles were used to determine the posture. Zequn et al. [19] developed a novel posture recognition model that can be used to identify different postures captured. The depth sensor was used to generate features of different body parts of an individual. The captured features were then fed into the support vector machine (SVM) to identify the posture.

Although there are quite a number of studies available using Kinect for the assessment of gait and posture abnormalities, to the best of our knowledge, there is no overall review study that attempts to summarise articles on the use of the Kinect sensor for gait abnormality and posture disorder assessment. Our review adopts a systematic approach similarly used by Shmuel Springer et al. [20]. The study provides up-to-date review of the articles for analysis and discussion.

2. Methods

In this section, we retrieve articles that meet the inclusion criteria for our study. The existing articles identified were summarised into tables indicating the methods used and the sampling area. The sample area stated the source from which the article was retrieved, the authors of the article, and the year it was published. Our focus was on articles that used Kinect sensors for assessing gait and posture abnormalities.

2.1. Search and Identification of Articles. The scholarly database used to identify the articles were: IEEE Xplore, ScienceDirect, CINAHL plus, and PubMed. The search was done in two different parts as follows:

(i) Part 1: the use of Kinect sensors for the detection of gait abnormality or disorder

(ii) Part 2: the use of Kinect sensors for detection posture disorder or instability

The key terms used in part 1 of the search were: "Kinect sensor," "gait abnormality," "gait disorder," and "walking abnormality." In the second part, the key terms used were: "Kinect sensor," "posture disorder," "posture abnormality," and "posture instability." The search was conducted between January and May 2021 to retrieve the most recent articles.

2.2. Eligibility Criteria of the Identified Articles. In identifying the articles for the study, we conducted two different searches for the database by two independent authors. The authors were able to identify and remove duplicate articles from the various database. The elimination of irrelevant articles was done without bias or oversight in order to get all relevant articles that meet the inclusion criteria. A number of diseases that could affect gait and posture abnormalities were included. They were: Parkinson's, ataxia, multiple scoliosis, stroke, and depression.

The exclusion criteria were for articles that only discussed gait detection and postures without considering abnormality. In the second part, articles that only discuss posture assessments without examining posture disorder or deformity were also not included. Articles that used wearable sensors for gait abnormality and posture disorder detection were not included. Figure 1 is a flowchart diagram of the search methodology.

3. Results

The initial search and retrieval of all articles from the various database were 458 for gait and 283 for posture, all using Kinect technology. The articles were further screened to ensure they meet the eligibility criteria for this study. In the end, a total of 26 articles were included for gait abnormality and 13 articles for posture disorders.

Table 1 summarises all the studies that were included for the review for gait abnormality, the journals where the articles were retrieved and the year of publications. In Table 1, the methodology describes the sampling method applied, the statistical method, and the descriptive approach used. That sampling method describes the number of participants in the study, gender, and age distribution. The disease associated with the abnormality was stated. The sampling methods from the reviewed articles were categorised as fully stated, partially, or not stated. The statistical method describes the statistical techniques that were used in the analysis of the data. The statistical methods were either sufficiently used or partially used. It describes the models and mathematical equations that were used in the analysis of skeletal data. The description method used refers to capturing of the skeletal data, processing of data, algorithms used, and the analysis of the results. It also includes the tools used in the analysis of results and a detailed discussion of the findings. Finally, the description method was either adequate or partial description.

The approach used in Table 1 was also similarly adopted in Table 2 except that it summarised the various articles for identifying posture disorders using Kinect. The sampling methods, statistical methods, and the description method are also indicated in this table.

In Table 3, the details of each article included in the study were categorised into two major phases. The first phase deals with the sampling technique used in each study while the second phase describes the key gait features captured with the major findings of each study. The limitations for each study were also included in the table.

A total number of 26 articles were reviewed. Most of the articles stated the number of participants in the study except in [26,28,37,42,43,45]. The majority of the studies used Kinect v2 as the main tool for capturing skeletal data for gait abnormality assessment, while a few articles used the older Kinect v1. In [37,44], the Asus Xtion PRO was used as a gold standard with a Kinect sensor for capturing skeletal data. Most of the reviewed articles did not state the data analysis tool. However, in [22,25,29,31,35,39,40], MATLAB was explicitly stated as the main tool for data analysis. In [23], the SPSS package was used as the data analysis tool. The gait features captured were mainly the step/stride length (m), stride time (s), gait speed (m/s), gait cycle (deg), gait rhythm (m/s), and step time (s). Some of the key joint angles measured were the hip, knee, and the ankle. Various algorithms were used to train the models for gait abnormality detection.

A total number of 13 articles were included for the assessment of posture abnormality or disorder. Some of the reviewed articles [42,46,50,51] did not state the participants in the studies. In Table 4, Kinect v2 was mostly used for skeletal data capturing, except in a few studies that used Kinect v1. Nine of the reviewed articles used Kinect v2 while four used Kinect v1. Most of the studies did not state any medical condition that resulted in posture abnormality. However, in [47], Parkinson's disease was stated, and in [56], a case of chronic traumatic brain injury was present. In [50,58], patients with suspected multiple scoliosis were also assessed for posture abnormality. The majority of the reviewed articles did not state the data analysis tool except in [47,48,50] that stated MATLAB. In [58], the IBM Watson Analytics was used to analyse the data for posture abnormality for patients with suspected cases of multiple scoliosis.

4. Discussion

4.1. Gait Abnormality or Disorder. The purpose of this study is to review the available studies using Microsoft Kinect for the assessment of gait and posture abnormalities. The key features measured included the angles formed by leg swing, speed, and distance of each gait step. These parameters were useful in detecting gait asymmetry in order to distinguish normal from abnormal gait. Some other components from the summarised studies were the algorithms used, the major findings of each study, and limitations.

From the reviewed articles, various methods were employed in assessing and detecting gait abnormality. The gait features captured were mainly the step/stride length (m), gait speed (m/s), gait cycle (deg), and step time (s). Some other gait features captured from the studies were angles of knee joints, ankle joints, and hip angles joints. The measured

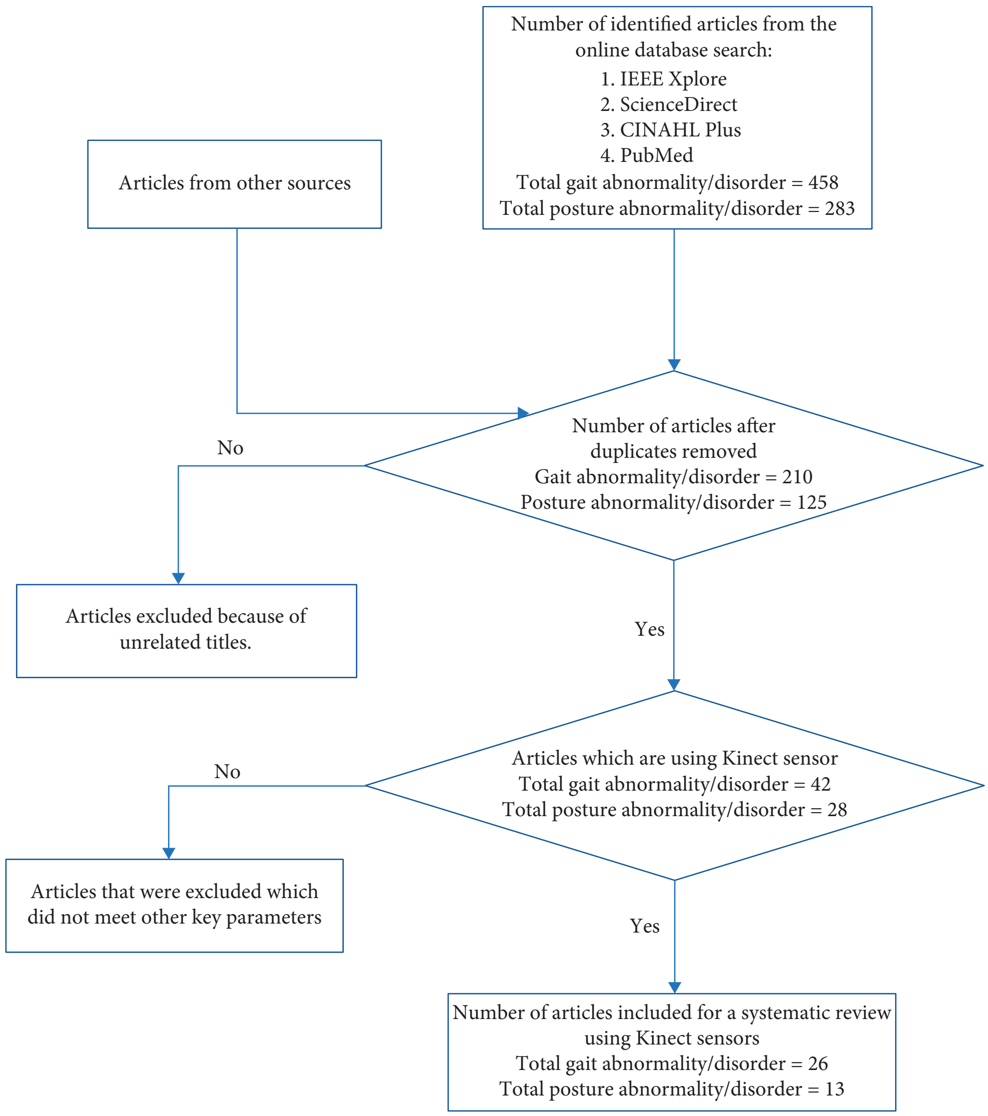

Figure 1: Flowchart for the search methodology of articles included.

joint angles were used to train the models in detecting gait abnormalities. The measurement of joint angles helped improve the efficiency and robustness of the trained models to detect gait abnormality.

They were various algorithms used to train the models for gaits abnormality detection. Some of the algorithms used in Table 3 were machine learning algorithms. The machine learning algorithms were either supervised or unsupervised, depending on the approach used. Supervised machine learning algorithms use classifications and regressions, while unsupervised use clustering and associations to determine outliers in the data. Algorithms that were used in the designed models for gait abnormality were: Bayesian algorithm, K-nearest neighbors algorithm (KNN), convolutional neural network (CNN), recurrent neural network (RNN), long short-term memory (RNN-LSTM), isolated forest (IF) algorithm, and one-class support vector machine (OC-SVM) algorithm. Depending on the algorithm that was used and the mythological approach, different accuracy were achieved. The Bayesian algorithm was commonly used in [15, 19, 23, 33] for the assessment of gait abnormalities. RNN-LSTN algorithm was used in three of the studies [20, 36, 37, 40]. Amr Elkholy et al. used unsupervised one-class support vector machine (OC-SVM) and isolated forest algorithms for abnormal detection in [31, 33]. Some other algorithms such as the EDSS and MSWS were also applied in [27]. The algorithms used in the various studies cannot be compared to determine which is more efficient and robust. This is because different methods and data sets were used to achieve the desired accuracy.

The general limitation of the summarised studies has to do with the relatively small data set used. Most of the studies did not use a large data set to test the robustness of the trained model except in [21, 22, 25, 29, 33, 34, 44] that used large data sets. Another limitation was some gait parameters were not used in training the models for abnormal gait assessment. Some studies did not also include key joint angles in the trained model. Therefore, some of the models

did not give high precision and robustness in assessing gait abnormalities. Also, the use of Kinect v1 has limited capabilities compared to Kinect v2 that has more enhanced 3D skeletal tracking capabilities.

4.2. Posture Abnormality or Disorder. From Table 4, some body features were measured to determine the posture abnormality of a person. They were the body center mass position and the shoulder position angulation. The head

position and the neck angles were also essential to detect postural instability. In [47,49], the center of body mass was used to determine the postural instability. The rapid upper limb assessment (RULA) method was commonly used to assess postural instability in [52,57]. The distance between the neck, shoulder blade, and angles was very essential in determining the abnormal posture of a person. In [52], the height, hips, and shoulder position were measured as well as the shoulder angles. In [53], the knee joints, ankle joints, the lateral joints, and interior joints were computed. The spine angle was also used in [47] to determine the abnormal posture of an individual.

Different algorithms were used to determine postural disorder from the summarised studies. The algorithms that were used included pattern recognition neural algorithm, CoVNet model, Berg balance scale (BBS) method, and the RULA technique. These algorithms were used to track the static body position features and key joint angles to determine the postural instability of a person. The accuracy in the detection of posture disorder was not considered because the studies focused only on determining if there was posture abnormality.

The limitations of the various summarised studies largely depended on the small data set used in the various studies.

4.3. Mathematical Analysis of Gait Abnormality. In Sun Bie et al. [21], the spatial position was used with the associated joints for each subject walking. The extracted joint angle formed were then calculated. The equations used in the joint angle computation were given by the following equation:

$$\begin{aligned} \mathrm{len}(i,k) &= \|J[i]-J[k]\|, \\ \theta(i,k,j) &= \cos^{-1}\frac{(J[i]-J[k])*(J[j]-J[k])}{\|J[i]-J[k]-J[j]-J[k]\|}, \end{aligned} \tag{1}$$

where *J[i]* represents the joints, *len (i,k)* represents the distance between joint *i*, and *k* θ *(i, k, j)* describes the angle formed by joint *i*, *k*, and *j*. Therefore, the angles formed by the left leg and the right leg were calculated by the following equation:

$$\begin{aligned} R_s &= \rho(\theta_l,\theta_r) \\ &= \frac{\mathrm{E}[(\theta_l-m_{\theta l})*(\theta_r-m_{\theta r})]}{\sqrt{\mathrm{E}(\theta_l-m_{\theta l})*\mathrm{E}(\theta_r-m_{\theta r})}}, \end{aligned} \tag{2}$$

where θ_l and θ_r represents the angles formed on the left and right leg, respectively, of a subject walking and E(∗) represents the expected value of the operation for the simulation. The equations were used in computing the key joint angles to determine gait asymmetry. The angles calculated were the hip angle, knee angle, and the ankle angle. The challenge with this technique is that there may be some difficulties in measuring the inner joint angles of subjects. The gait cycles were computed and given by the following equation:

Table 3: Detailed features of articles on gait abnormality or disorder.

Sampling techniques			Key gait features and aims of the identified articles							
Authors	Gender and age range of participants	Abnormality or disease	Kinect sensor version	Data type capture	Gait parameters measured	Data analysis tool	Algorithm used	Accuracy achieved (%)	Major findings	Limitations of study
Bei et al. [21]	Gender and age not stated	70 normal walking and 50 walking disorder	Kinect v2	Skeletal data	Leg swing angle (deg), knee and ankle joint angle (deg), step length (m), gait cycle (deg)	Not stated	K-means algorithms, Bayesian algorithms	Not stated	A novel technique was designed to demonstrate movement disorder through gait symmetry analysis	Some key gait parameters and joint angle were not considered. Only a small data set was used to test the model
Wang et al. [22]	98 individuals; gender and age not stated	Depression	Kinect v2	Skeletal data	Gait velocity (m/s), *Joint angles (deg)*	MATLAB	t-SNE algorithm	93.75	A nonintrusive framework was designed to detect depression	Some gait features are required to improve the robustness of the model in a real environment
Tsukagoshi et al. [23]	Ataxia (male = 14 female = 11); age 54.1 ± 14.6 years. Parkinson's (male = 10 female = 15); age 68.4 ± 8.1 years. Healthy people (male = 13 female = 12), age 62.0 ± 13.9 years	25 Patients with ataxia, 25 patients with Parkinson's, and 25 health people	Kinect v2	Skeletal data	Stride length (m), feet length (m), gait rhythm, (m/s)	SPSS package suit	Clinical scale	Not stated	Kinect depth sensor to quantitatively evaluate gait interference for patients who have a movement disorder	Body joint gaits angulation were not considered and thus there may be less precision with this model
Amini et al. [24]	15 participants (12 male and 3 female); average age 54–92 years	People with Parkinson's	Kinect v2	Skeletal data	Gait cycle (deg), knee angle (deg), number of footsteps (m)	Not stated	Heuristic fall detection algorithm	Not stated	A unique model was designed to detect freeze of gait for people with Parkinson's	The developed system is limited to only the x-axis for the freeze of gait detection
Aleš prochazka et al. [25]	51 individuals; gender not stated; age: Parkinson's, 52–87 years, healthy mature: 32–81 years, young: 23–25 years	18 Individuals with Parkinson's, 18 healthy matured, and 15young ones	Kinect v1	Not stated	Step length (m), gait length (m/s), stride length (m)	MATLAB	Bayesian algorithm	94.1	A novel technique was developed using Bayesian classification algorithm to recognise gaits disorder for people with Parkinson's disease	Some key joint angles were excluded in developing an abnormal gait recognition model and thus not so efficient

Sampling techniques			Key gait features and aims of the identified articles							
Authors	Gender and age range of participants	Abnormality or disease	Kinect sensor version	Data type capture	Gait parameters measured	Data analysis tool	Algorithm used	Accuracy achieved (%)	Major findings	Limitations of study
Cesar et al. [26]	Gender and age not stated	Not stated	Kinect v2	Skeletal data	Step speed (m/s), stride speed	MATLAB	LSTM algorithm	98.1	A model was designed to detect gait abnormality using the LSTM algorithm	Body joint angles are required to test and improve the accuracy of the model
Gholami et al. [27]	MS (male = 1, female = 9); age = 41–79 years. NP (male = 1, female = 9); age 36–80 years	10 multiple scoliosis and 10 normal people	Kinect v2	Skeletal data	Gait velocity (m/s), stride length (m), stride time (s), step time (s)	Not stated	EDSS algorithm and MSWS algorithm	Not stated	A novel framework was designed to evaluate the gaits abnormality of people with multiple scoliosis	The designed framework does not provide enough reliability to detect the disease. There is less accuracy with the designed model.
Devanne et al. [28]	Gender and age not stated	Not stated	Kinect v2	Skeletal data	Step length (m), body joint angles (deg)	Not stated	Riemannian manifold algorithm	Not stated	A model is designed to detect gait abnormality using motion trajectories	The method is not able to identify static gait abnormality such as a freeze of gait
Latorre et al. [29]	45 healthy individuals (men = 31, women = 14); age 30.6 ± 7.6 years. 38 stroke survived people (men = 22, women = 16); age = 56.1 ± 13.2 years	45 Healthy individuals and 38 stroke surviving people	Kinect v2	Skeletal data	Gait speed (m/s), stride length (m), stride time (s), swing time (s), step time (s), step asymmetry	MATLAB	Bayesian algorithm	Not stated	The authors illustrated the reliability of using Kinect-based methods to estimate gait disorder for poststroke adult individuals	The method used in the study were limited which influenced some errors with the gait parameters measured
Prakash et al. [30]	24 individuals (13 males and 11 females); age not stated	Not stated	Kinect v2	Skeletal data	Left knee angle (deg), right knee angle (deg)	Not stated	IR-UMB algorithm	Not stated	A model was developed to detect gait abnormality using contactless IR-UWB	Only the knee angle was considered and this may not give accuracy of the designed model

Table 3: Continued.

Sampling techniques					Key gait features and aims of the identified articles					
Authors	Gender and age range of participants	Abnormality or disease	Kinect sensor version	Data type capture	Gait parameters measured	Data analysis tool	Algorithm used	Accuracy achieved (%)	Major findings	Limitations of study
Nguyen et al. [31]	20 individuals; gender and age not stated	10 healthy people and 10 abnormal (Parkinson's/stroke)	Kinect v2	Skeletal data	Left hip angle (deg), right hip angle (deg), left knee angle (deg), right knee (deg), left ankle (deg), right ankle (deg)	MATLAB	HMM algorithm	90.12	A novel approach was designed for gait abnormality detection using skeletal-based data with no prior knowledge of individual gait	The method used in the study provided enough precision of the results achieved
Shrivastava et al. [32]	24 individuals; gender and age not stated	12 Normal walking and 12 abnormal walking	Kinect v1	Skeletal data	Step length (m), gait cycle (s), hip left foot angle (deg), right foot angle (deg)	MATLAB	KNN algorithm, SVM algorithm, and decision tree algorithm	83.33	The authors developed a model using machine learning for gaits abnormality detection using data from Kinect	The model used does not provide high precision and efficiency for detecting gait abnormality
Prochazka et. Al [33]	36 individuals; gender not stated; people with Parkinson's: age = 52–87 years, healthy control: age = 32–81 years	18 Individuals with Parkinson's. 18 healthy control	Kinect v1	Skeletal data	Stride length (m),	MATLAB	Skeletal tracking algorithm	90	A system was designed to detect Parkinson's disease based on the gaits features. This could be used for early detection of Parkinson's.	Only a few parameters such as stride length were used and this does not provide enough efficiency and reliability of the model
Fang et al. [34]	3,669 individuals (1555 males and 2114 females); age range 22–28 years	Suspected cases of depression	Kinect v2	Skeletal data	Walking speed (m/s), arm swing (mm), stride length (m), vertical head position (deg)	MATLAB	SVM algorithm; KNN, RF, and LR algorithms; linear discriminant analysis (LDA)	91.58	A novel model was designed using different ML to detect depression prevalence among students	Different viewing points were not considered in developing a model to detect depression
Ismail et al. [35]	11 individuals; gender not stated; age = 21–25 years	11 healthy control individuals	Kinect v2	Skeletal data	Gait speed (m/s), stride length (m), right knee angle (deg), left knee angle (deg), right ankle (deg), left ankle (deg), hip angle (deg)	MATLAB	Angle average algorithm	Not stated	A novel system is developed to determine gait abnormalities using gait cycle	There were some marginal errors in the data set used that does not provide enough efficiency of the model used in detecting abnormality

Authors	Gender and age range of participants	Abnormality or disease	Kinect sensor version	Data type capture	Gait parameters measured	Data analysis tool	Algorithm used	Accuracy achieved (%)	Major findings	Limitations of study
Menget al. [45]	Gender and age not stated	Not stated	Kinect v2	Skeletal data	Interskeletal joint distance	Not stated	Random forest classifier	Not stated	A system was developed using a skeletal inter-joint distance to detect abnormal gait and normal gait	The developed system may not be robust because only a few gait features were used on small data sets for abnormal gait detection
Jun et al. [46]	9 individuals; gender and age not stated	1 normal person and 8 abnormal gait	Kinect v2	Skeletal data	Left hip angle (deg), right hip angle (deg), left knee angle (deg), right knee (deg), left ankle (deg), right ankle (deg)	Not stated	RNN algorithm and LSTM algorithm	Not stated	An extraction method feature was developed using RNN to increase the performance of gait abnormality from a skeletal base system	A small data set was used to test the model, and this does not provide high efficiency for gait abnormal detection

RNN: recurrent neural network; LSTM: long short-term memory; GRU: gated recurrent units; OC-SVM: one-class support vector machine; IF: isolation forest; HMM: hidden Markov model; and KNN: k-nearest neighbors.

Table 4: Detailed features of articles on posture abnormality or disorder.

	Sampling techniques				Key body features and aims of the identified articles				
Authors	Gender and age of participants	Abnormality/ disease	Kinect sensor version	Data type capture	Body features measured	Data analysis tool	Algorithm used	Major findings	Limitations of the study
Ferrais et al. [47]	14 individuals (8 male and 6 female); age = 53–80 years	Parkinson's disease	Kinect v2	Skeletal data	Centre of body mass (m)	MATLAB	KNN algorithm	A system is designed for the automatic posture analysis of people with Parkinson's to determine postural instability	More subjects are required to test the model to improve its reliability and efficiency
Jawed et al. [48]	Gender and age not stated	Not stated	Kinect v1	Skeletal data	Body joint angles (deg), body position (m)	MATLAB	Pattern recognition neural algorithm	A system was developed using pattern recognition neural network model that is capable of analysing the whole body of a patient to determine if there is any postural disorder	Not much efficiency with this model in detecting postural disorder with high accuracy
Yang et al. [49]	18 individuals, 9 males and 9 females; age = 24.0 ± 0.7 years	Not stated	Kinect v2	Skeletal data	Centre of body mass (m)	Not stated	RSM algorithm	A system was designed to evaluate the standing balance to determine posture instability	There may be some variations in the calibration to measure the COM
Castroa et al. [50]	98 individuals (males = 50 and females = 48) average; age 24.7 years	Suspected scoliosis disease	Kinect v2	Skeletal data	Shoulder angulations (deg)	MATLAB	SA method	The Kinect sensor was used to quantitatively evaluate the posture of the spine to determine if there is any posture instability	The challenge was that the S2's spinal exposition process was unassured
Chin-Hsuan Liu et al. [51]	45 individuals (15 youth and 30 elderly); age of youth = 24.06 ± 2.02 years; age of elderly = 71.13 ± 4.56 years	Not stated	Kinect v2	Skeletal data	Body joint angles (deg), center of body mass (m)	Not stated	Mediolateral (ML) algorithm	A system was designed to investigate the postural instability using the body joint coordination patterns	Only the mediolateral (ML) motion direction is considered in determining impairments of an individual

BBS: Berg balance scale; CNN: convolutional neural networks; RULA = rapid upper limb assessment; and SA: shoulder angulation.

$$T_s = \frac{1}{n-1}\sum_{i=2}^{i=n}\left|x_i - x_i - 1\right| * 0.0333, \tag{3}$$

where $|*|$ is the absolute value from the operation and 0.0333 is the conversion factor from the Kinect sensor.

In [37], the gait energy image (GEI) was used based on the Gaussian mixture model (GMM) for each pixel in the simulation. The GEI was the image captured with the Kinect sensor of an individual in a walkway. It can be used to determine the dynamic information of a gait sequence. The gait cycle was then extracted and computed at the point where a normalised autocorrelation from the silhouette image was high in the GEI.

$$C(N) = \frac{\sum_{x,y}\sum_{n=0}^{k} S(x,y,n)S(x,y,n+N)}{\sqrt{\sum_{x,y}\sum_{n=0}^{k} S(x,y,n)^2}\sqrt{\sum_{x,y}\sum_{n=0}^{k}(x,y,n+N)^2}}, \tag{4}$$

where *C(N)* represents the autocorrelation for *N* frameshift, and the *N* value is chosen to empirically represent all the abnormal gait cycles that exist in the tested data sets; $K = N_{Total}-N-1$ where N_{Total} represents the total number of frames sequence. *S(x, y, n)* indicates the pixel values at a position *(x,y)* in the silhouette frame *n*. The GEI was then computed as an average of the normalised and aligned silhouette over the gait cycle in the following equation:

$$G(x,y) = \frac{1}{n_{\text{cycle}}}\sum_{i=1}^{n_{\text{cycle}}} S_i(x,y), \tag{5}$$

where n_{cycle} represents the frame of the gait cycle while S_i is the silhouette frame of *x*, y pixel coordinates of the image captured. The extracted gait energy image (GEI) and the gait cycle were used to determine gait abnormality from different viewing points based on the colour image sequence. However, this technique does not consider factors that may affect the colour image sequence such as clothes variations.

In [32], the Euclidian distance was used to compute the joints and dynamic body parts for a subject to determine gait abnormality. The Euclidian distance is defined in the following equation, where the distance *r* and *s* are the shortest distance between the line segment *rs*:

$$\begin{aligned} d(r,s) &= d(s,r) \\ &= \sqrt{(r_x - s_x)^2 + (r_y - s_y)^2 + (r_z - s_z)^2}. \end{aligned} \tag{6}$$

Hero's formula was then used to calculate the triangular area of the gait cycle. The area obtained by Hero's formula is given by the following equation:

$$\text{Area\_of\_triangle} = \sqrt{(r_x - s_x)^2 + (r_y - s_y)^2 + (r_z - s_z)^2}. \tag{7}$$

The step length was then calculated between the right foot from left foot in the Euclidian distance as follows:

$$\text{step\_length} = \sum_{i=1}^{n}\sqrt{A+B}, \tag{8}$$

where *A* and *B* are defined as the area formed by the joint angles.

The areas and angles were formed between the hip right foot and the left foot. A triangle was generated to get the area and angle between the right foot. Therefore, the Euclidean distance to compute for the maximum foot distance lifted from the ground is given by the following equation:

$$\text{Ground}_{\text{clearance}} = \max\left(\text{right\_foot}_y\right) - \min\left(\text{right\_foot}_y\right). \tag{9}$$

The limitations in using the Euclidean distance for computation has to do with the multiple dimensions and the sparse nature of data. This presents some variations in trying to measure the gait distances for subjects in a walkway.

In [44], asymmetry features were used to detect walking abnormality in a subject. The motion asymmetry between the right body parts and the left body parts of the skeletal data was extracted. The average distance extracted from the skeletal data for a pair of joint angles was then computed. The Euclidean distance used to represent the asymmetry feature was calculated from the following equation:

$$D_{ij}^{p} = \frac{\sum_{t=1}^{n}\sqrt{\left(x_{it} - x_{jt}\right)^2 + \left(y_{it} - y_{jt}\right)^2 + \left(z_{it} - z_{it}\right)^2}}{n}, \tag{10}$$

where D^{ρ} represents the left and right of the average distance of a subject while x_{it}, y_{it}, and z_{it} represents the 3D coordinates of the joint *i* of a subject of frame *t* and *n* is the number of frames of action sequence. N_p is the set of joints for the left and right body parts of an individual. The velocity magnitude feature was computed in the study to detect slow action performed by the subject. The equation used to calculate is as follows:

$$V = \frac{\sum_{t=1}^{n-1}\sum_{i=1}^{N}\sqrt{\left(x_{i(t+1)} - x_{it}\right)^2 + \left(y_{i(t+1)} - yit\right)^2 + \left(z_{i(t+1)} - z_{it}\right)^2}}{(n-1)N}. \tag{11}$$

Equation (11) is essential in computing the displacement magnitude for each body joint between two successive frames where *N* represents the number of joints and *n* represents the number of frames.

In [27], gait assessment of a patient was evaluated by extracting the time series for the knee angles and the gait cycle of dynamic time warping (DTW). The knee DTW distance and the hip were then calculated and averaged to get the mean DTW distance of individual patients. The mean DTW distance for the hip joints and the knee that are denoted by D_{HP} and D_{KP} are defined by the following equations:

$$D_{KP} := \frac{1}{2}\left[\frac{1}{m_p n_c m_c}\sum_{j=1}^{m_p}\sum_{q=1}^{n_c}\sum_{r=1}^{m_c}\mathrm{DTW}\left(\theta_{LK_{i,t}}, \phi_{LK_{q,r}}\right) + \frac{1}{m_p n_c m_c}\sum_{j=1}^{m_p}\sum_{q=1}^{n_c}\sum_{r=1}^{m_c}\mathrm{DTW}\left(\theta_{RK_{i,t}}, \phi_{RK_{q,r}}\right)\right], \tag{12}$$

$$D_{HP} := \frac{1}{2}\left[\frac{1}{m_p n_c m_c}\sum_{j=1}^{m_p}\sum_{q=1}^{n_c}\sum_{r=1}^{m_c}\mathrm{DTW}\left(\theta_{LH_{i,t}}, \phi_{LH_{q,r}}\right) + \frac{1}{m_p n_c m_c}\sum_{j=1}^{m_p}\sum_{q=1}^{n_c}\sum_{r=1}^{m_c}\mathrm{DTW}\left(\theta_{RH_{i,t}}, \phi_{RH_{q,r}}\right)\right]. \tag{13}$$

4.4. Equations for Postural Abnormality Assessment. Several researchers have proposed different techniques for the recognition of the human posture and 3D human reconstruction. The posture probability density is used to reconstruct the posture of human beings [60]. It is based on human body measurement that can be used to determine posture. This is used as a density estimator in the following equation:

$$\widehat{p}(x; h, \gamma) = \sum_{n=1}^{N} \gamma_n \kappa\left(\frac{x - x_n}{h}\right), \tag{14}$$

where *K(.)* is the kernel, *h* is the bandwidth of the kernel, and *d* is the degree of freedom of the data. The probability density estimate is then given by the function where the weights γ in each kernel are based on the reduced set density estimation (RSDE).

The RULA-based method is a common technique for posture assessment of an individual. This technique can be used to determine the postural abnormality of an individual. Two techniques are used to calculate the joint angles, which are input from a module score. These techniques use a voxel-based angle estimation in which the RULA score for the upper joints is computed based on their location. The joint angles are computed using vectors that are dependable on the location of each joint with correspondence to the parent joint location. This is given by the angle between two vectors of the parents' joints and the child's joints in the following equation:

$$\theta = \cos^{-1}\frac{p_1 \cdot p_2}{\|p_1\| \cdot \|p_2\|}. \tag{15}$$

The magnitude of the two vectors P_1 and P_2 are calculated by:

$\|p_1\| = \sqrt{p_1 \cdot p_1}$ and $\|p_2\| = \sqrt{p_2 \cdot p_2}$, where the computed value is then submitted into equation (15). The RULA method is a good technique for posture assessment because it is easy and fast to use. This can be used in the evaluation of posture disorder without the need to conduct any experimental measurements. This technique is, therefore, significant to conduct risks of musculoskeletal disease with regard to the posture of an individual.

5. Conclusion

In this study, we presented Microsoft Kinect as a noncontact tool for the assessment of gait abnormality and posture disorder. While there are several studies on gait recognition, only a few have dealt with the assessment of gait and posture abnormalities. Early detection of gaits and posture abnormalities plays a significant role for clinicians to provide corrective rehabilitation measures. Even though this is a comprehensive study, there may be some articles that are not included.

In our study, we presented 26 studies for gait abnormality assessment and 13 articles for posture disorder. The summarised studies differ by the methodology used, the gait features extracted, and the analytical tools used to process the skeletal data. Different algorithms were applied in the summarised studies, and some of them made use of machine learning algorithms. The results showed what has been done so far in the area of gait and posture abnormality assessment.

From our analysis, Kinect sensors have a high success rate of approximately 87% in abnormalities assessment. It has an accuracy ranging between 83% and 98.1% from the summarised articles for gait abnormality. This is quite acceptable in the clinical settings for the purposes of diagnosis of diseases associated with gait and posture disorders. Although Microsoft has stopped the release of Kinect sensors, it is still an important tool for diagnostic purposes. It can be concluded that Kinect sensor is an essential monitoring tool for use in medical diagnostics and can also help track the progress of patients who are undergoing rehabilitation.

Data Availability

The data that support the findings of this review paper can be sourced from the summarised table in the study and the references provided.

Conflicts of Interest

The authors declare that there are no conflicts of interest in this paper.

Academic Editor: Enas Abdulhay

This research was to explore the adoption value of computed tomography (CT) images based on adaptive statistical iterative reconstruction (ASIR) algorithm in the evaluation of probiotics combined with ursodeoxycholic acid in the treatment of intrahepatic cholestasis of pregnancy (ICP). A total of 82 patients with ICP were selected as the research subjects and they were randomly rolled into experimental group (380 mg probiotics enteric-soluble capsule twice a day, combined with 90 mg ursodeoxycholic acid soft capsule three times a day) and control group (90 mg ursodeoxycholic acid soft capsule three times a day), with 41 cases in each. The treatment course was four months. The ASIR algorithm was constructed and applied to the CT image analysis and diagnosis of ICP patients. The effects of filtering back projection (FBP) reconstruction and ASIR algorithm on CT image quality, denoising degree, and artifacts of ICP patients were compared. Moreover, blood indicator levels of ICP patients before and after treatment were assessed. The results showed that the SD values of liver and gallbladder (20.77 Hu and 27.58 Hu) in the reconstructed image of the ASIR algorithm were significantly lower than those of the FBP algorithm (40.58 Hu and 45.63 Hu) ($P < 0.05$). The SNR values of the liver and gallbladder (3.68 and 2.05) of the reconstructed image were significantly higher than those of the FBP algorithm (1.91 and 1.19) ($P < 0.05$). The overall image quality after ASIR reconstruction (3.92 points) was significantly better than that of the FBP algorithm (2.36 points), and the image noise score (3.21 points) reconstructed by the FBP algorithm was higher than that by the ASIR algorithm (1.83 points). The artifact score of FBP reconstructed image (4.47 points) was greatly higher than that of ASIR algorithm (2.26 points) ($P < 0.05$). Before treatment, there was no remarkable difference in the indexes between the two groups of patients ($P > 0.05$). After treatment, the γ-glutamyltransferase (γ-GT) and alkaline phosphatase (ALP) levels (327.55 U/L and 778.15 μmol/L) of the experimental group of ICP patients were higher than those of the control group (248.63 U/L and 668.43 μmol/L), with substantial difference between the two groups ($P < 0.05$). The blood ammonia (BA) level (151.09 μmol/L) of the experimental group was lower than that of the control group (178.46 μmol/L), and the difference between the two groups was remarkable ($P < 0.05$). To sum up, the CT image denoising degree based on ASIR algorithm was high, with few artifacts and good overall quality. Probiotics combined with ursodeoxycholic acid in the treatment of ICP can effectively improve the liver function and intestinal flora of patients, which was of great significance in the clinical diagnosis and treatment of the disease.

1. Introduction

Intrahepatic cholestasis of pregnancy (ICP) is a female disease occurring during pregnancy, which will endanger the fetus and lead to the increase of neonatal morbidity and mortality [1]. Patients with ICP typically experience problems such as elevated blood and bile acids and abnormal liver function. For pregnant women, these symptoms usually disappear immediately after delivery, but they are harmful to the fetus, and fetal intrauterine compression causes premature delivery, leading to neonatal asphyxia or death [2]. The incidence of this disease is up to 0.8%–12.0%, and it disappears immediately after delivery. However, the recurrence rate is high, and the patients will relapse again when they become pregnant again or take contraceptive drugs [3]. The pathogenesis of ICP is complex and not yet clear. Treatment is mainly through choleretics and hepatoprotective drugs, such as ursodeoxycholic acid and choline [4]. At present, researchers usually combine adenosylmethionine with ursodeoxycholic acid for research, but there are some shortcomings such as small sample size and complex control. Studies pointed out that probiotics can improve the microecological environment in vivo, with low cost and no invasion, which can prevent and cure hepatobiliary diseases and reduce the harm [5]. At present, there are few studies combining ursodeoxycholic acid and probiotics to treat IPC.

Nowadays, computed tomography (CT) is widely utilized in clinical medicine. Because of its fast scanning speed and clear images, it has become the main imaging tool for medical auxiliary diagnosis and scientific research. CT liver scan can choose any time phase for continuous scan. After a lot of clinical practice, CT scan has become a routine method for examination of liver and gallbladder diseases, and it has played an important role in the diagnosis and treatment of IPC [6]. The CT image reconstruction method is an important technology in the image imaging process, and the optimization of the image is particularly important. At present, the filtered back projection (FBP) method is the main algorithm for CT image reconstruction. The algorithm reconstructs quickly, but the noise is obvious, the imaging is not detailed enough, and it will aggravate the patient's radiation. The iterative reconstruction (IR) algorithm also has problems such as noise and artifacts [7]. Adaptive statistical iterative reconstruction (ASIR) can improve imaging quality, reduce radiation dose, and overcome the shortcomings of the above technologies, which is the most widely utilized iterative reconstruction technology at present [8]. ASIR image reconstruction algorithm can reduce imaging noise and artifact, improve image quality without interfering with clinical diagnosis, and is utilized for clinical treatment, which has been approved by the American medical management system [9]. In this study, ICP patients were taken as the research object, and the ASIR algorithm was applied to the CT image analysis and diagnosis of ICP patients by constructing the ASIR algorithm. The effects of filtering back projection (FBP) reconstruction and ASIR algorithm on CT image quality, denoising degree, and artifacts of ICP patients were compared. Blood indicator levels of ICP patients before and after treatment were detected to evaluate the clinical effect of probiotics combined with ursodeoxycholic acid in ICP treatment. It was hoped to provide a reliable basis for the application of ASIR based CT imaging in clinical diagnosis and treatment.

2. Materials and Methods

2.1. Research Objects. A total of 82 patients, ranging in age from 24 to 36 years, with an average age of 26 years, who underwent ICP specific detection in our hospital from July 2019 to May 2020, were selected for CT imaging examination. They were randomly divided into experimental group and control group, with 41 patients in each group. There was no statistical difference in general information between the two groups ($P > 0.05$). This study had been approved by the Ethics Committee of the Hospital, and informed consent was signed by the patients and their families.

Inclusion criteria were as follows: (i) clinically confirmed ICP patients (the ICP diagnostic criteria of *Chinese Journal of Obstetrics and Gynecology* edited by Cao [10]); (ii) skin pruritus being the main symptom during pregnancy; (iii) abnormal liver function, mainly slightly increased serum transaminase; (iv) the patient being in good general condition without obvious vomiting, weakness, or other diseases; (v) pruritus quickly subsiding after delivery, and liver function quickly returning to normal; and (vi) patients with elevated bile acid level.

Exclusion criteria for subjects were as follows: (i) those who had liver or gallbladder disease, or skin diseases before pregnancy which affected the observation indicators; (ii) patients who had received treatment that affected the observation indicators before inclusion; (iii) only statistical results without specific data listed; (iv) those who utilized the combination of drugs which affected the judgment of the results and could not be excluded by the control.

2.2. Grouping. The included IPC patients were randomly divided into experimental group and control group, with 41 patients in each group. Patients in the experimental group were given probiotic enteric-coated capsules 380 mg twice a day, combined with ursodeoxycholic acid soft capsules 90 mg three times a day for four months. Patients in the control group were given ursodeoxycholic acid soft capsule 90 mg three times a day for four months. During the treatment, neither group of patients took other drugs.

2.3. Observation Indicators and Detection. The blood sample test was as follows: 5 mL of venous blood was extracted from the patients on an empty stomach in the morning and placed in an anticoagulant tube. Levels of γ-glutamyl transferase (γ-GT), blood ammonia (BA), alkaline phosphatase (ALP), and total cholesterol (TC) were detected by Hitachi automatic biochemical analyzer.

2.4. Inspection Method and Reconstruction Method. All patients were scanned using a General Electric 256-bar widebody detector CT (Revolution, General Engine, GE, USA). Prior to the CT scan, the patients underwent inhalation and breath-holding training to reduce breathing movements and removed clothing at the site of examination, including various items with metallic substances, such as earrings and keys. During the examination, the patients were supine with their arms raised above their heads, and they were required not to move freely to avoid artifacts. Patients were first examined with a conventional dose scan, with a preset noise index (NI) of 14. FBP was utilized for image reconstruction. The NI was set at 24, and the image was reconstructed by ASIR. Scanning was under 120 KV and 150 mAs, reconstruction layer thickness was 0.625 mm, field of view was 220 mm, scanning time was 0.5 s, cycle time was 1 s, and matrix was 512 × 512.

2.5. CT Image Reconstruction Based on ASIR Algorithm. The main idea of the ASIR iterative reconstruction algorithm is making all currently estimated images satisfy an equation in each update. In the iterative correction process, only the projection value of one projection unit is considered at a time. The calculation process of the reconstruction algorithm is shown in Figure 1.

The specific reconstruction steps of the ASIR algorithm are as follows:

(I) Assign an unknown image vector, and k is a constant.

$$R_k = R_k^{(0)} \, (k = 1, 2, 3 \ldots n). \tag{1}$$

(II) The estimated projection values of all equations are calculated, where Z_{kc} is the relaxation parameter.

$$Y_c^* = \sum_{k=1}^{n} Z_{kc} R_k^{(0)} \, (k = 1, 2, 3 \ldots n). \tag{2}$$

(III) The error is calculated, and $\boldsymbol{\Phi}$ is the error parameter.

$$\Phi_c = Y_c - Y_c^* \, (k = 1, 2, 3, \ldots n). \tag{3}$$

(IV) The correction value of the k-th pixel is calculated.

$$E_k = \frac{1}{Z_{kc}} \sum_{k=1}^{N} \Phi_c \frac{1}{Z_{ik}}. \tag{4}$$

Among them, i is the ray passing through pixel k, and all rays passing through the pixel are summed at the same time.

(V) The k-th pixel value is corrected.

$$R_k = E_k + R_k^{(0)}. \tag{5}$$

To sum up, all rays passing through the pixel are utilized to correct it to complete the first iteration. The average value of each projection band can reduce the error, thereby avoiding the influence caused by the reconstruction result, which has a noise reduction effect in the image reconstruction process.

2.6. Image Objective and Subjective Evaluation Indicators. After reconstruction, two kinds of noise reduction images of each patient were obtained, and all the images were transmitted to GE workstation (General Engine Advantage Workstation 4.7). The patient's personal information and scan and reconstruction information were hidden. The patient's CT value (the relative density of tissue structure on the CT image, in Hu) and the SD value (the background noise value of the abdominal fat on the same plane) were

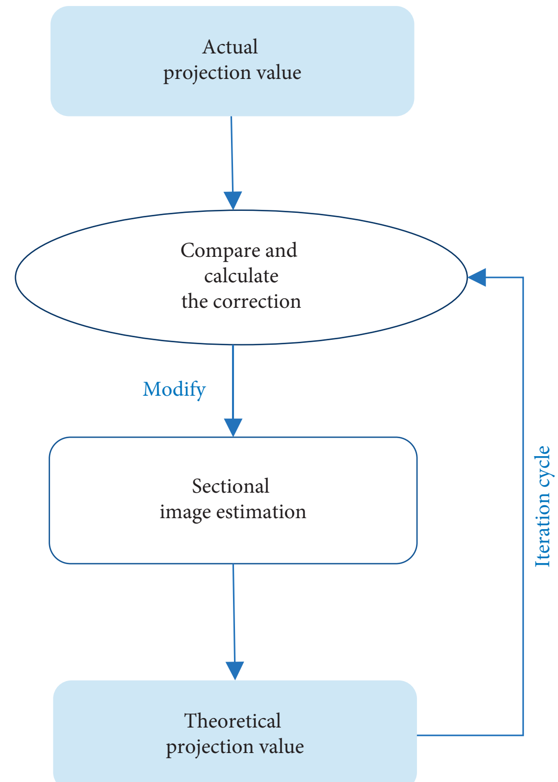

Figure 1: Schematic diagram of the calculation process of ASIR iterative reconstruction algorithm.

measured. The signal-to-noise ratio (SNR) was calculated. SNR = CT value/SD value. All data were measured three times, and the average value was taken as the final statistical result.

Subjective evaluation was performed by radiologists using a double-blind method to evaluate all images. A 5-point system was adopted to evaluate the overall image quality (unclear texture, blurred contrast, and unclear image indicated 1 point; the texture was fuzzy, the contrast was fuzzy, and the image roughly indicated 2 points; the texture was not clear, the contrast was not clear, and the image was not fine, indicating 3 points; the texture was clear, the contrast was clear, and the image was delicate, indicating 4 points; clear texture, clear contrast, and fine image indicated 5 points). A 5-point Likert method [11] was adopted to evaluate image noise (image noise was completely acceptable, 1 point; less than average noise, 2 points; average noise, 3 points; above average noise, 4 points; unacceptable image noise, 5 points). Each artifact was also scored by a 5-point method (no artifact, 1 point; small artifacts did not affect the organizational structure, 2 points; slight effects on the structure, 3 points; the artifact was large, affecting the main structure, 4 points; the artifact was extremely heavy, and the image was unacceptable, 5 points).

2.7. Statistical Analysis. SPSS 24.0 was utilized for statistical analysis. All experimental data were represented as mean ± standard deviation ($\overline{x} \pm s$). One-way analysis of variance was utilized for statistical data. Friedman rank-sum test was utilized to compare the subjective scores of overall image quality, noise, and artifacts, and the test level was $\alpha = 0.05$. $P < 0.05$ was statistically remarkable.

3. Results

3.1. Abdominal CT Images of ICP Patients with Different Reconstruction Algorithms. Figure 2 shows a 28-year-old ICP patient with a thin-slice CT scan of the lower abdomen with two reconstruction algorithms. A, B, and C represent the plain scan phase, arterial phase, and portal phase, respectively, and A1, B1, and C1 represent FBP, while A2, B2, and C2 represent ASIR. Observed from the CT image, the image reconstructed by the ASIR algorithm shows that the lesion area is relatively clear, and the edge contrast is high. The FBP reconstructed image has blurry edges and poor contrast. The overall quality of the FBP reconstructed image is worse than that of ASIR, the image noise is high, and the artifacts are obvious.

3.2. Objective Indicator Analysis of CT Image Based on Reconstruction Algorithm. Routine CT scans of the abdomen of 30 ICP patients were performed, and the initial images were reconstructed by two reconstruction algorithms, FBP and ASIR. The unreconstituted images with a thickness of 0.625 mm were obtained. According to the obtained images, the data of different organs in the abdomen of ICP patients were measured and analyzed, and the CT, SD, and SNR values of the reconstructed image under different reconstruction algorithms were obtained.

3.2.1. CT Value Analysis of Reconstructed Image. The CT value analysis results are shown in Figure 3. For the CT value of the liver, the CT values of the reconstructed image of FBP and ASIR were 77.43 Hu and 76.51 Hu, respectively, and there was no considerable difference between the two ($P > 0.05$). For the CT value of the gallbladder, the CT values of the reconstructed images of FBP and ASIR were 54.37 Hu and 56.58 Hu, respectively, and the difference between the two was not remarkable ($P > 0.05$).

3.2.2. SD Value Analysis of Reconstructed Image. The SD value analysis results are shown in Figure 4. The SD value of the liver was analyzed. The SD values of the reconstructed image of the FBP and ASIR algorithms were 40.58 Hu and 20.77 Hu, respectively. The SD value of the reconstructed image of the ASIR algorithm was notably lower than that of the FBP algorithm ($P < 0.05$). The SD value of the gallbladder was analyzed. The SD values of the reconstructed image of FBP and ASIR were 45.63 Hu and 27.58 Hu, respectively. The SD value of the reconstructed image of the ASIR algorithm was notably lower than that of the FBP algorithm ($P < 0.05$).

3.2.3. SNR Value Analysis of Reconstructed Image. The SNR value analysis results are shown in Figure 5. The SNR value of the liver was analyzed. The SNR values of the reconstructed image of the FBP and ASIR algorithms were 1.91 and 3.68, respectively. The SNR value of the reconstructed image of the ASIR algorithm was notably lower than that of the FBP algorithm ($P < 0.05$). The SNR value of the gallbladder was analyzed. The SNR values of the reconstructed image of the FBP and ASIR algorithms were 1.19 and 2.05, respectively. The SNR value of the reconstructed image of the ASIR algorithm was notably lower than that of the FBP algorithm ($P < 0.05$).

In summary, in the CT image of the ASIR algorithm, the noise value (SD value) of the abdominal liver and gallbladder of ICP patients was notably lower than that of the FBP reconstruction algorithm, while the signal-to-noise ratio (SNR) was considerably higher than that of the FBP reconstruction image. There was no considerable difference in the CT value of the reconstructed image between the two algorithms.

3.3. Subjective Evaluation of CT Images Based on Reconstruction Algorithm. Figures 6 and 7 show partially enlarged views of CT images of a certain ICP patient's abdominal CT reconstructed by FBP and ASIR, respectively.

Figure 8 shows the mean statistical graph of the overall quality, noise, and artifacts of the reconstructed CT image scored by the radiologist. The scoring results showed that the image quality scores of the FBP and ASIR algorithms were 2.36 and 3.92, respectively. The overall image quality after ASIR reconstruction was substantially better than that of the FBP algorithm ($P < 0.05$). In the evaluation of image noise, the scores of FBP and ASIR were 3.21 and 1.83, respectively. Compared with the ASIR algorithm, the FBP reconstructed image had higher noise, and the difference was remarkable ($P < 0.05$). The evaluation of image artifacts showed that FBP had more image artifacts than the ASIR algorithm, and the difference was remarkable ($P < 0.05$).

3.4. Observation Indicators of Experimental Group and Control Group before and after Treatment. The ICP patients in the experimental group were treated with probiotics combined with ursodeoxycholic acid, and the ICP patients in the control group were treated with ursodeoxycholic acid. The blood indicators of the two groups of patients before and after treatment were recorded, including γ-glutamyl transferase (γ-GT), blood ammonia (BA), alkaline phosphatase (ALP) levels, and total cholesterol (TC). The changes of these indicators were analyzed to draw a graph of the changes of blood indicators in each group before and after treatment. The results showed that, before treatment, there was no statistical difference in each indicator between the two groups of patients ($P > 0.05$). After treatment, the γ-GT and ALP levels of ICP patients in the experimental group were higher than those in the control group, and the difference was remarkable ($P < 0.05$). The BA level of the experimental group greatly was lower than that of the control group ($P < 0.05$). The difference in TC values between the two groups after treatment was not remarkable ($P > 0.05$). Figure 9 shows a graph of the changes of blood indicator levels before and after treatment in the experimental group and the control group.

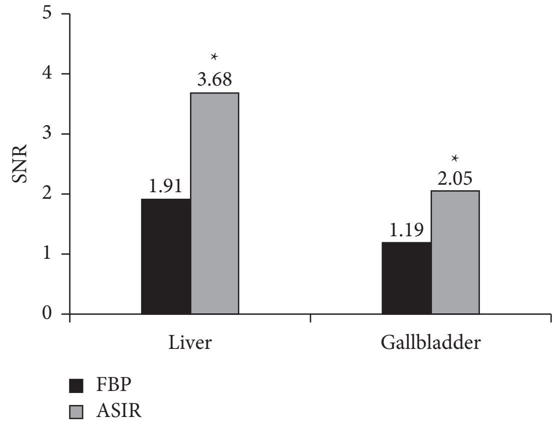

FIGURE 5: SNR values of reconstructed images. *indicates that the SNR value of the reconstructed image of FBP and ASIR algorithm is substantially different ($P < 0.05$).

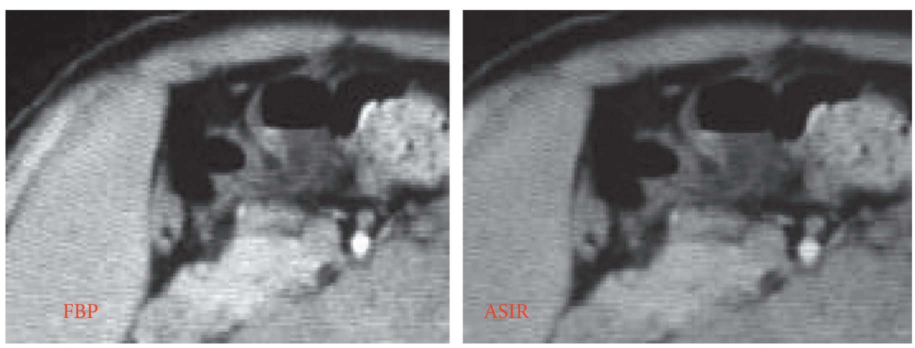

FIGURE 6: The partially enlarged views of liver imaging after reconstruction of the abdominal CT image of an ICP patient in two ways. *Note.* The average scores of subjective evaluations of FBP reconstructed images show image quality of 2.34 points, noise of 2.33 points, and artifacts of 4.45 points; the average scores of subjective evaluations of ASIR reconstructed images show image quality of 3.9 points, noise of 1.85 points, and artifacts of 2.34 points.

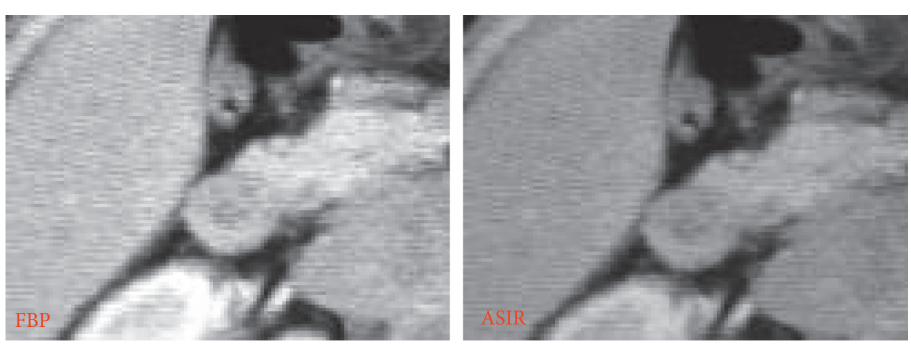

FIGURE 7: The partially enlarged views of gallbladder imaging after reconstruction of the abdominal CT image of an ICP patient in two ways. *Note.* The average scores of subjective evaluations of FBP reconstructed images show image quality of 2.38 points, noise of 2.29 points, and artifacts of 4.49 points; the average scores of subjective evaluations of ASIR reconstructed images show image quality of 3.94 points, noise of 1.81 points, and artifacts of 2.38 points.

4. Discussion

ICP generally has familial clusters, and the rate of recurrence is high. Medically, it is generally treated with liver protection and choleretic treatment [1]. The liver and gallbladder in the human body and the gastrointestinal system have the same embryonic origin, so there is a close relationship between tissue composition and organic function [12]. Probiotics can improve the microecological environment in the body, are cheap and noninvasive, which can prevent and treat liver and gallbladder diseases, reduce harm, and are nonpathogenic. Ursodeoxycholic acid can induce the massive secretion of endogenous bile acid in the treatment of IPC, regulate the concentration of hydrophilic bile acid, and prevent the functional damage of liver cells in the body. In this way, the liver's blocking structure is adjusted to alleviate the degree and progression of IPC patients [13].

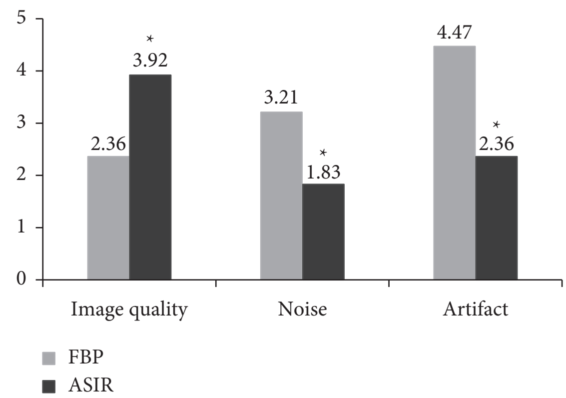

Figure 8: Subjective scoring results of reconstructed images. *Note.* * indicates that the subjective scores of the reconstructed images of FBP and ASIR algorithms are substantially different ($P < 0.05$).

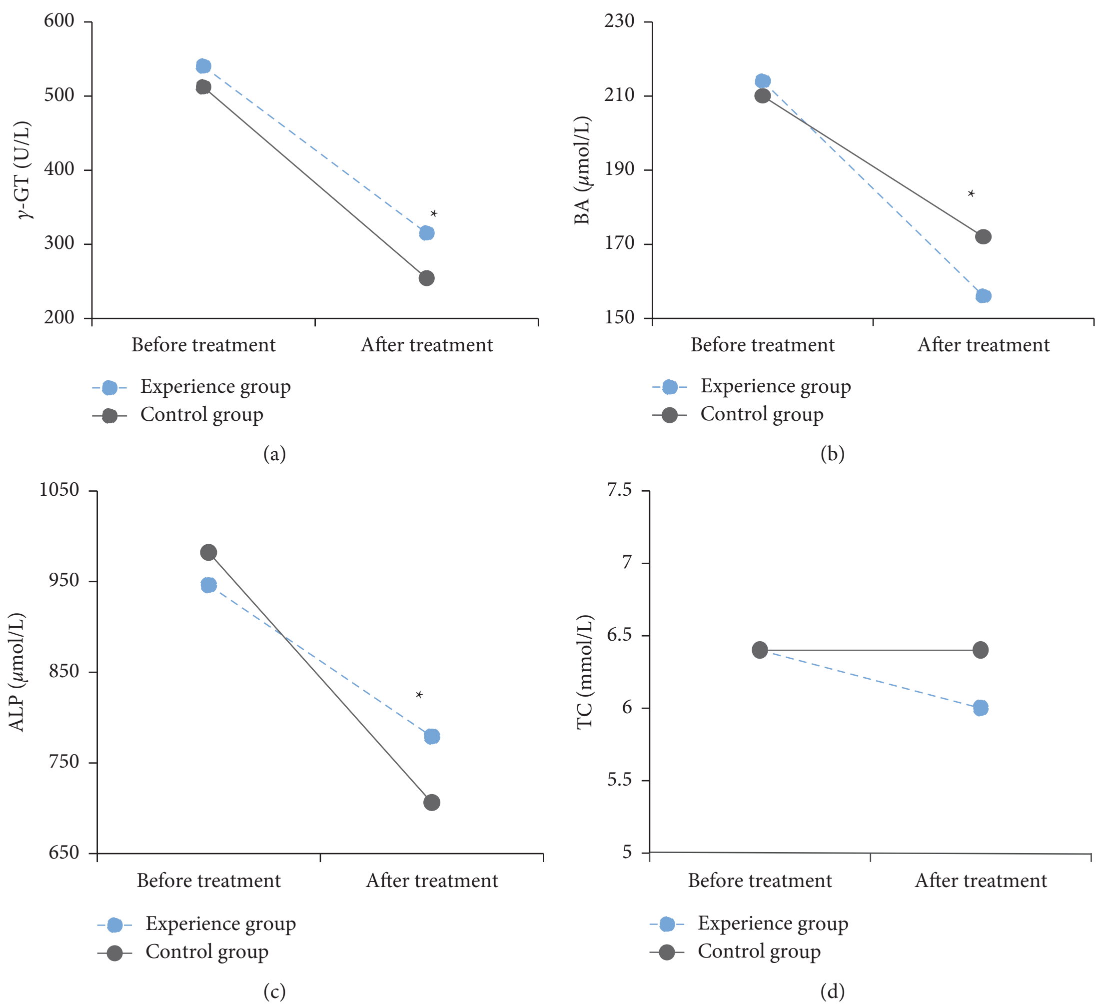

Figure 9: Changes of blood indicators in the experimental group and the control group before and after treatment. (a) The changes of γ-GT in the two groups of patients, (b) the changes in BA of the two groups of patients, (c) the changes in ALP of the two groups of patients, and (d) the changes in TC of the two groups of patients. *indicates considerable differences in blood indicators between the experimental group and the control group ($P < 0.05$).

This study combined probiotics and ursodeoxycholic acid to treat IPC. The results showed that, before treatment, there was no statistical difference in each indicator between the two groups of patients ($P > 0.05$). After treatment, the γ-GT and ALP levels of ICP patients in the experimental group were greatly higher than those in the control group ($P < 0.05$). The BA level of the experimental group was lower than that of the control group, and the difference was remarkable ($P < 0.05$). There was no considerable difference in TC values between the two groups after treatment ($P > 0.05$). It was proved that the combined application of ursodeoxycholic acid and probiotics was effective in improving liver function in patients with ICP, which may be related to the antioxidant and antiapoptotic effects of ursodeoxycholic acid in the above-mentioned mechanism [14]. Probiotics can regulate the intestinal flora, avoid excessive growth of small intestinal bacteria, and reduce intestinal endotoxemia and BA levels. They can also improve the liver function of patients and reduce the occurrence of mild HE and the possibility of mild HE progressing to clinical symptoms of HE [15]. There were no adverse reactions in all cases in this study, which also suggested that the drug had good safety.

Nowadays, CT is widely utilized in clinical medicine. Because of its advantages such as fast scanning speed and clear images, it has become the main imaging tool for medical auxiliary diagnosis and scientific research, which has played an important role in the diagnosis and treatment of IPC [16]. FBP, which is often utilized in image inspection, has heavy artifacts, great noise, and insufficient image quality [17]. ASIR can improve the image quality, reduce the radiation dose, and overcome the shortcomings of the above technologies and is currently the most widely utilized iterative reconstruction [18]. ASIR uses the resources obtained by FBR as the initial image for reconstruction, changes the measured values of different pixels into new estimated values, and then compares the target value with the new value. In the subsequent iterative reconstruction, the process is repeated until the new pixel value is wirelessly close to the expected value [19]. In recent years, iterative reconstruction has gradually been introduced into the field of image noise reduction. A series of current studies have also observed that ASIR has better image quality than FBP [20]. In this study, the subjective evaluation results of CT images showed that, in terms of image quality, the scores of FBP and ASIR were 2.36 and 3.92, respectively. The overall image quality after ASIR reconstruction was substantially better than that of the FBP algorithm ($P < 0.05$). In the evaluation of image noise, the scores of FBP and ASIR were 3.21 and 1.83, respectively. Compared with the ASIR algorithm, the FBP reconstructed image had higher noise, and the difference between the two was remarkable ($P < 0.05$). In the evaluation of image artifacts, FBP had more image artifacts than ASIR algorithm reconstruction, and the difference was remarkable ($P < 0.05$). It was shown that the image noise of ASIR at the aorta and skeletal muscle was notably lower than that of traditional FBP and ASIR, and the image quality can meet clinical needs. The objective indicator analysis results of the CT image showed that, in the CT image of the ASIR algorithm, the noise value (SD value) of the abdominal liver and gallbladder of ICP patients was notably lower than that of the FBP reconstruction algorithm ($P < 0.05$). However, the SNR was considerably higher than the FBP reconstructed image ($P < 0.05$). These results were consistent with the research conclusions of Dimmitt et al. (2019) [21]. It was proved that the noise of the CT image reconstructed by the ASIR model was considerably reduced, the image quality was improved, and the advantages of image quality and lesion detection were obvious.

5. Conclusion

In this study, patients with intrahepatic cholestasis of pregnancy (ICP) were selected as the research objects. ASIR reconstruction algorithm was established, which was applied to the CT image analysis and diagnosis of ICP patients, and the influence of the reconstruction algorithm on the CT image of ICP patients was discussed. Then, the clinical effect of probiotics combined with ursodeoxycholic acid in the treatment of ICP was evaluated. The results showed that SD and SNR values of liver and gallbladder reconstructed by ASIR algorithm were significantly lower than those of FBP algorithm. The overall image quality, image noise score, and pseudofilm review score after ASIR reconstruction were significantly better than those of FBP algorithm ($P < 0.05$). Before treatment, there was no statistical difference in all indicators between the two groups ($P > 0.05$). After treatment, the levels of γ -glutamyl transferase (γ-GT) and alkaline phosphatase (ALP) in the experimental group were higher than those in the control group, while the level of serum ammonia (BA) in the experimental group was lower than that in the control group, both with substantial differences ($P < 0.05$). It was proved that CT images based on ASIR reconstruction algorithm had high denoising degree, fewer artifacts, and good overall quality. Probiotics combined with ursodeoxycholic acid in the treatment of ICP can effectively improve the liver function and intestinal flora of patients. This study can provide a reliable basis for the adoption of CT imaging technology based on ASIR reconstruction algorithm in the diagnosis and treatment of ICP. However, the deficiency is that only abdominal CT images based on ASRI reconstruction algorithm at conventional doses are discussed. In future clinical studies, the influence of ASRI reconstruction algorithm on low-dose CT images needs to be discussed, so as to further illustrate its noise reduction efficiency in CT images.

Academic Editor: Enas Abdulhay

This study focused on the application of deep learning algorithms in the segmentation of CT images, so as to diagnose chronic kidney diseases accurately and quantitatively. First, the residual dual-attention module (RDA module) was used for automatic segmentation of renal cysts in CT images. 79 patients with renal cysts were selected as research subjects, of whom 27 cases were defined as the test group and 52 cases were defined as the training group. The segmentation results of the test group were evaluated factoring into the Dice similarity coefficient (DSC), precision, and recall. The experimental results showed that the loss function value of the RDA-UNET model rapidly decayed and converged, and the segmentation results of the model in the study were roughly the same as those of manual labeling, indicating that the model had high accuracy in image segmentation, and the contour of the kidney can be segmented accurately. Next, the RDA-UNET model achieved 96.25% DSC, 96.34% precision, and 96.88% recall for the left kidney and 94.22% DSC, 95.34% precision, and 94.61% recall for the right kidney, which were better than other algorithms. The results showed that the algorithm model in this study was superior to other algorithms in each evaluation index. It explained the advantages of this model compared with other algorithm models. In conclusion, the RDA-UNET model can effectively improve the accuracy of CT image segmentation, and it is worth of promotion in the quantitative assessment of chronic kidney diseases through CT imaging.

1. Introduction

At present, chronic kidney disease has affected approximately 10% of the world's population, killing millions of people every year, and hundreds of thousands of people undergo dialysis to maintain their lives [1]. Chronic kidney disease refers to changes in the structure and function of the kidney that have occurred for more than three months. Renal cysts are one of them, but renal cysts are benign structural changes. Renal cysts grow slowly and will not have an impact on patients in the short term. However, as the cysts increase, they will compress the gastrointestinal tract. As a result, the volumes of the stomach and intestine shrink, and the patient will feel full all the time. Some patients also have symptoms of fever, vomiting, and abdominal pain, so they will have a negative impact on the patient's psychology and physiology [2–4]. During treatment, it is difficult to accurately distinguish renal cysts from small cystic renal cell carcinoma, which affects the formulation of appropriate treatment plans for patients [5]. Hence, finding a safe and reliable way to detect renal cysts is important for the treatment of patients. In clinical practice, X-rays, CT, and B-ultrasound are commonly used to diagnose patients with the kidney disease. CT scans a part of the human body with X-ray beams to obtain a cross-section or stereo image of the part being examined. It can provide complete three-dimensional information of the part of the body being examined, clearly displaying the organs and structures, as well as the lesions. The biggest advantage is that it can be viewed in layers so that more organizational information can be displayed after calculation [6]. Therefore, the application of CT in kidney examination is a hotspot of current research.

Deep learning is the core of artificial intelligence technology, and it is a research hotspot in recent years. In 2006, Dong first proposed the concept of deep learning. In order to optimize the deep structure, they proposed a greedy layer-by-layer training algorithm on the basis of the deep belief network [7]. Deep learning algorithms have also been widely used in medical image segmentation. Song et al. used the kernel fuzzy C-means algorithm and the improved GrowCut algorithm to segment kidney images, and the automatically generated seed labels heightened the segmentation efficiency [8]. Xiang et al. used cortical models and nonuniform maps to depict the kidney structure in CT images [9]. Xiong et al. proposed a tumor segmentation method based on adaptive partitioned firework level sets, which effectively segmented kidney tumors in ultrasound images [10]. Gao incorporated the level set into image segmentation to process images with uneven gray values and achieved good segmentation results [11]. Hu introduced the target tracking mechanism into the traditional image segmentation and achieved good segmentation results [12].

In this study, the U-shaped fully convolutional neural network (CNN) segmentation model was optimized by incorporating a residual dual-attention module to the model to elevate the accuracy of locating the edge of the cyst, thus to accurately and quantitatively assess chronic kidney diseases.

2. Experimental Principles and Methods

2.1. UNET Segmentation Model Based on the RDA Module. The RDA module is incorporated into the UNET model, so the optimized one is called RDA-UNET, and the structure is shown in Figure 1.

2.1.1. RDA Module. Heet al. deepened the network by stacking residual units to ensure the integrity and safety of the information and reduce the learning difficulty [13]. Woo et al. proposed a convolution algorithm that combines the channel with spatial information to extract information features, but the convolutional features are messy, so the attention mechanism can only focus on meaningful features extracted from a certain dimension [14]. In this study, a residual attention module is proposed based on the residual unit structure and attention mechanism, as shown in Figure 2.

For the input image, after going through the convolutional operation twice in the RDA module, it is processed by the channel and spatial attention mechanism, and then elements are added to it, followed by the residual connection with the original image, and finally, it is processed by the ReLU function. The original image is $Y \in Ww \times w \times c$, y is the size of the image, and C is the number of channels. The specific process of the dual-attention mechanism is as follows. According to the position of the pixel, the spatial attention mechanism identifies its contribution, and then the 1×1 convolution and sigmoid activation function are used to calculate the single-channel spatial attention mask $Q \in Ww \times w \times 1$ of each position pixel. Then, the original image Y is multiplied with the single-channel spatial attention mask Q. For the channel spatial attention mechanism, the contribution of each channel is firstly identified, and then 1×1 convolution and sigmoid activation function are used to calculate out-channel attention code $P \in W1 \times 1 \times c$, and finally, the original image is multiplied by the channel attention code. The steps of the dual-attention mechanism can be expressed as follows:

$$Y' = Q(Y) \otimes Y + P(Y) \otimes Y, \tag{1}$$

where Y' represents the output image, $\otimes$ represents element-wise multiplication, and $Q(Y)$ and $P(Y)$ represent the size same as Y in the channel and space, respectively. The RDA module has two advantages. One is to repeatedly use the features, and the other is the adaptive learning feature table. Hence, the module can learn the features of the image more effectively.

2.1.2. RDA-UNET Network Structure. According to the structural characteristics of UNET, the RDA module is introduced to design a new deep segmentation model, and its network structure is shown in Figure 1. It is mainly composed of four parts of encoder, bottleneck layer, decoder, and classifier. The encoder mainly includes the RDA module and the maximum pooling layer. The main function is to extract the semantic features of the original image. The pooling layer is mainly used for image downsampling, so as to increase the neuron sensor to obtain more detailed semantic feature information. The bottleneck layer is mainly composed of two convolutional layers, which are mainly used during the transition from the encoder to the decoder. Two deconvolutional layers and an RDA template form the decoder part, which is mainly used for image feature reconstruction, and the deconvolution layer is used for upsampling to improve the resolution of the image. The classifier is composed of a convolution layer and a softmax layer. This part can be used to estimate the background image before and after. In this part, the convolution layer can reduce the number of channels. Softmax is used to calculate the probability of the pixel belonging to a certain category. In the decoder and encoder, images of the same level can be jump-connected, thus providing rich pixel-level information for feature reconstruction. In addition, zero-filling convolution is used in each convolutional layer to obtain feature maps of the same size. In order to prevent the gradient from rising and disappearing, BN is used for all convolutional layers (the parameter settings used by the encoder and decoder are similar).

The probability map is the ratio of each pixel on the kidney and not on the kidney. The loss function is obtained by manually labeling the mask and the probability map. In this study, Dice loss is used to optimize training [15]. Dice coefficient is to evaluate the similarity, which can be expressed as follows.

$$\text{Loss} = 1 - \frac{2\sum_y^N h_i(y)k_i(y)}{\sum_y^N h_i^2(y) + \sum_y^N k_i^2(y)}, \tag{2}$$

where N represents the number of pixels, $h_i(y)$ represents the estimated probability that the yth pixel belongs to category i, and $k_i(y)$ represents the probability that the true yth pixel belongs to category i.

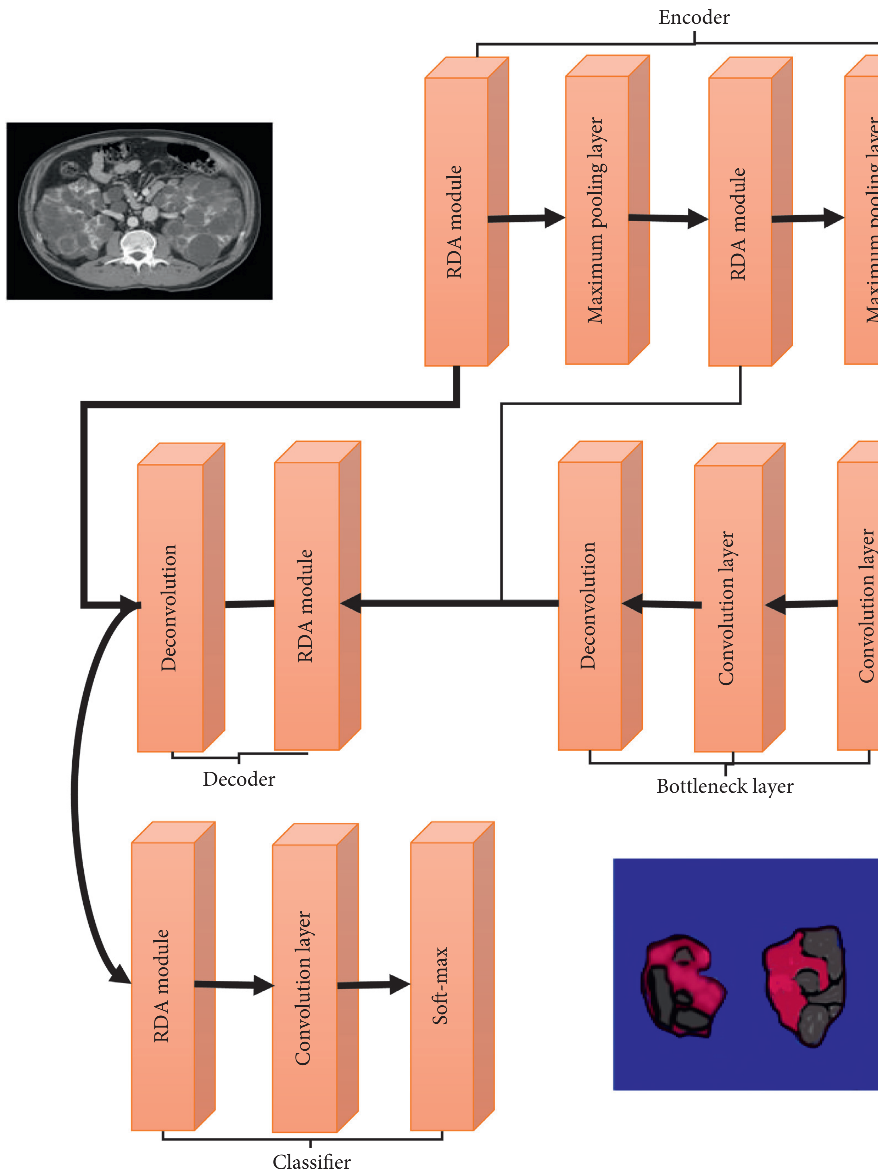

Figure 1: RDA-UNET network structure.

2.2. Experimental Settings. Dataset: the clinical abdominal plain CT images of patients with renal cysts were collected, and the images with obvious renal cyst lesions were manually marked by experienced experts. The data format is set to DICOM format, the distance between pixels is 0.625 mm, the thickness of image slices is generally 1.0 mm, and the distance between slices is about 0.5 mm. The resolution of Tuqiang is set to 512×512. A total of 79 patients with renal cysts were selected, and 6000 slice images were obtained. 27 cases were defined as the test group, and 52 cases were defined as the training group.

Preprocessing: the image needs to be processed before the experiment. First, the window width and window position of the image are adjusted to 420 hu and 60 hu, and then the size of the image is reduced to increase the number of images for each training. The image size is adjusted to 256×256. In order to make the network training more adequate, it is necessary to double the training set data by horizontal flipping. Finally, the image is normalized.

Hardware configuration and development environment: processor: Intel (R) Core(TM) i7-4790 CPU @ 3.60 GHz; discrete graphics card: Ge Force GTX Titan X; memory (RAM): 32.0 GB; system type: Ubuntu 16.04; development language: Python; deep learning framework: PyTorch [16]; image reading software: ITK-SNAP [17].

Parameter settings: batch size is set to 16; the initial learning rate is set to 10^{-3}, and it is automatically set to 10^{-4} when 30 epochs are completed; the momentum is set to 0.95,

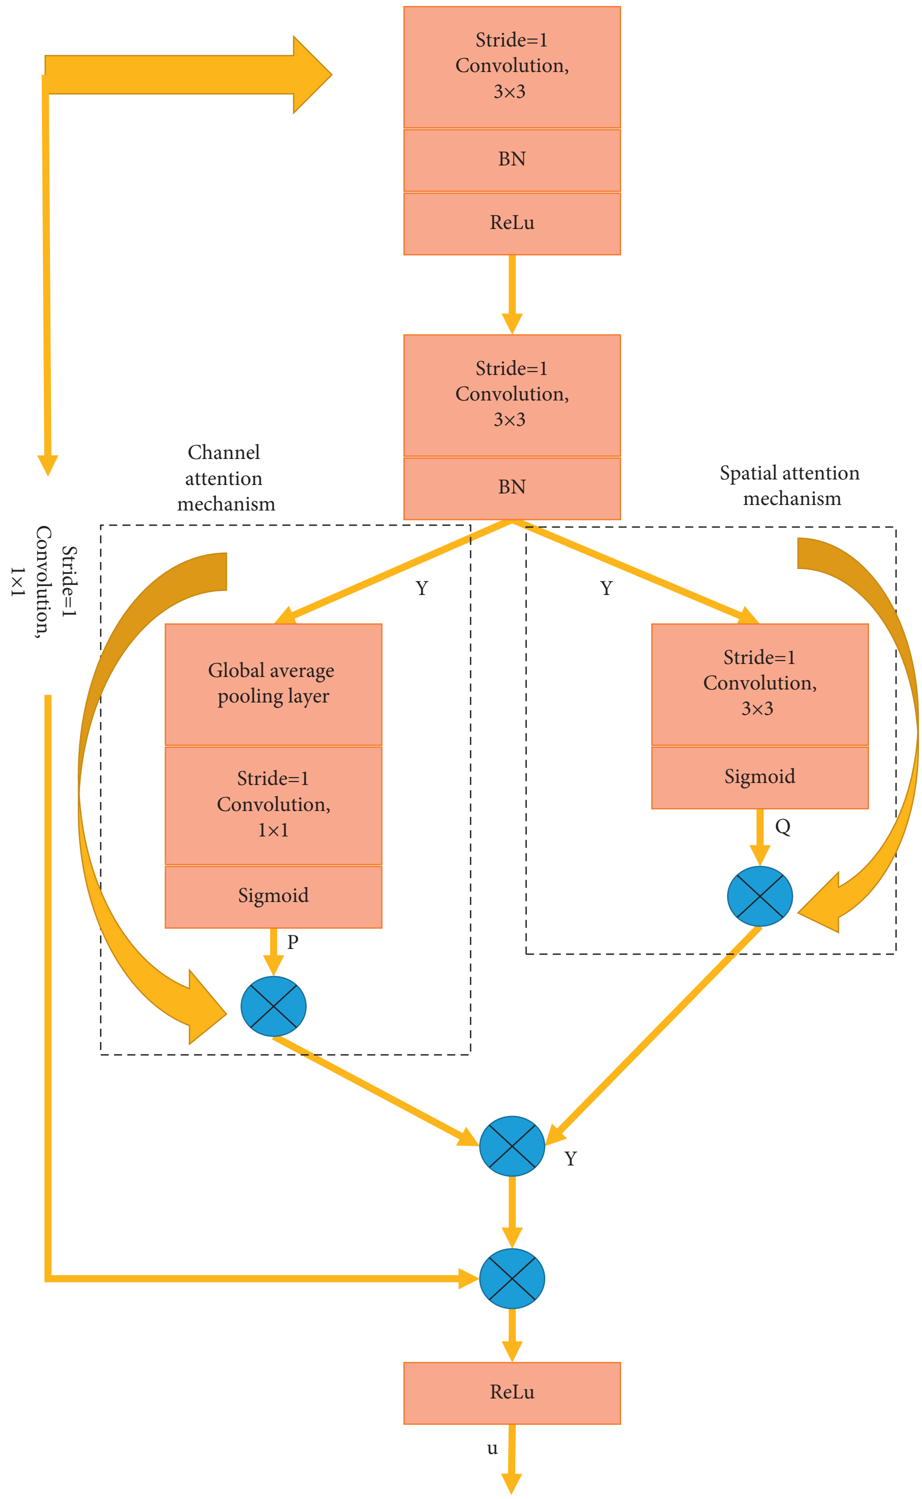

Figure 2: RDA module structure.

and the weight attenuation coefficient is constant 10^{-4}. The Adam optimizer is used for training, the training stops automatically after 50 epochs, and the test selects the parameter with the smallest loss value.

2.3. Evaluation Index. According to Figure 3, the kidneys are located on both sides of the spine. In this study, the spine was regarded as the dividing line, and the method of artificially annotating images and the method of network prediction

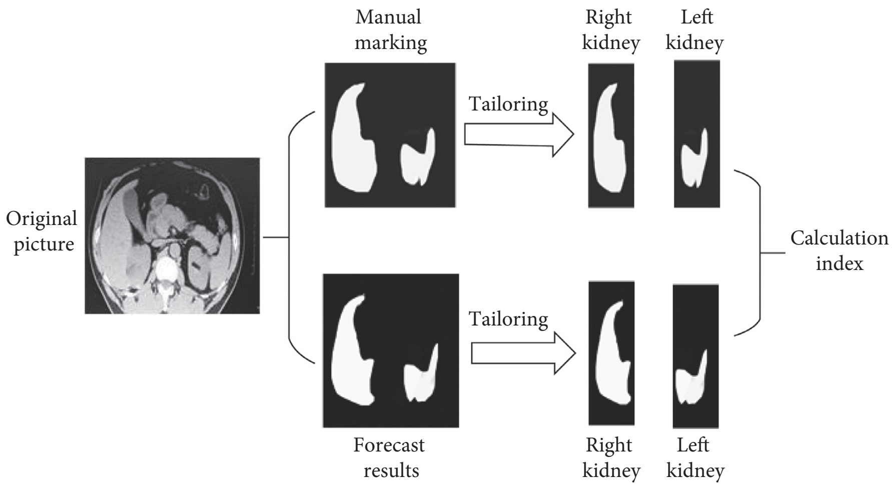

Figure 3: Evaluation method.

were used to segment the left and right kidneys. Since the left and right kidneys are not at the same height, the image will display other parts except the kidneys. The parts will be deleted during manual labeling and grid prediction. The segmentation accuracy was evaluated factoring into DSC, recall, and precision, defined as follows.

$$\mathrm{DSC} = \frac{2|E \cap F|}{|E| + |F|}, \tag{3}$$

$$\mathrm{precision} = \frac{SQ}{SQ + HQ}, \tag{4}$$

$$\mathrm{recall} = \frac{SQ}{SQ + HM}. \tag{5}$$

In equation (3), the model prediction result is E, F is the corresponding manual labeling result, and $E \cap F$ represents the foreground part in the segmentation image. In equations (4) and (5), SQ represents the part of the kidney that is correctly predicted, HQ represents that the background is predicted as the kidney, and HM represents that the kidney is predicted as the background.

2.4. User Interface. In order to facilitate operations, a simple user interface was designed using the Tkinter module based on the RDA-UNET model. This interface can accurately infer the edge contour, assisting users in segmentation.

2.5. Principles of 3D Reconstruction. CT imaging can reconstruct the three-dimensional image of the kidney. The three-dimensional image can accurately locate the area where the kidney is located to extract effective information. Doctors can preliminarily diagnose the type, the size, and the area of the renal cysts through the three-dimensional image. In addition, studies [18] have shown that the total kidney volume (TKV) is associated with the renal function to a certain extent. The TKV can be estimated by reconstructing the three-dimensional image of the kidney, and then the severity of the disease is evaluated. Therefore, the three-dimensional image of the kidney is reconstructed in the study.

3. Results

3.1. Comparison of Segmentation Effects. Figure 4 shows the relationship between the loss function of the network model in this study and the number of iterations in the training process. It was noted that the value of loss function can quickly decay and converge when the Adam optimizer was used.

Figure 5 shows the segmentation results of some images and their visualization during the training process. It was noted that the segmentation results of the algorithm proposed in this study were roughly similar to the results of manual labeling, and the spatial attention mechanism effectively and adaptively learned the spatial features. On the test set, the evaluation indicators of network models of different depths are shown in Table 1. The original models mainly included FCN-8S, FCN-16S, U-Net, and FCN-VGG10. On the basis of U-Net, U-Net (+BN) model was obtained, and UNet++ was further obtained on the basis of U-Net (+BN). In order to ensure the fairness of the experiment, no in-depth monitoring strategy was used throughout the process, and all models were trained from scratch and shared the same parameter value and Dice loss optimization. It was noted from Table 1 that the RDA-UNET model achieved 96.25% DSC, 96.34% precision, and 96.88% recall for the left kidney and 94.22% DSC, 95.34% precision, and 94.61% recall for the right kidney, which were better than other algorithms. The comparison between U-Net revealed that the use of BN greatly improved the segmentation performance.

The segmentation results of different models are shown in Figure 6. It was noted that compared with other algorithms, the RDA-UNET can segment the image more accurately and can effectively cope with changes in the shape of the kidney cysts.

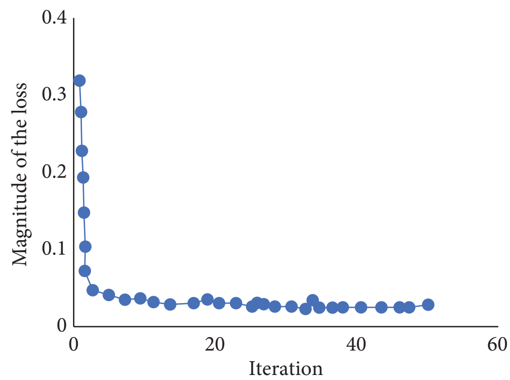

Figure 4: The decay curve of the loss function.

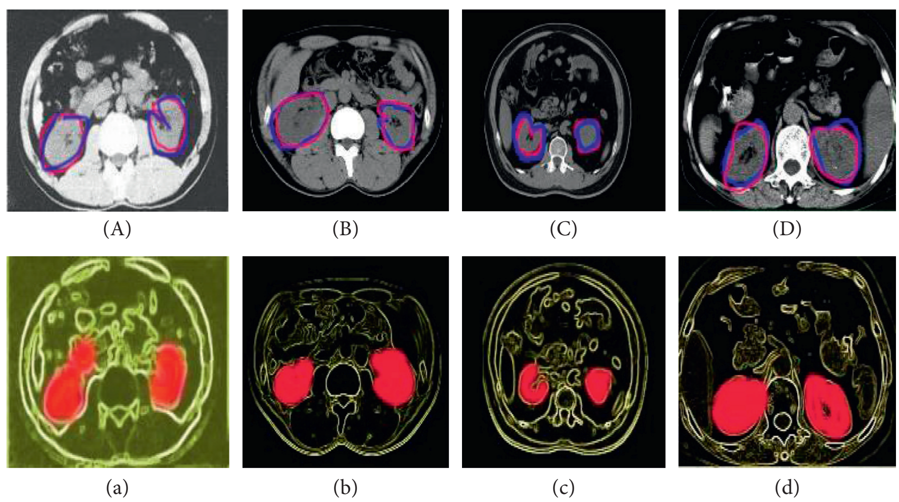

Figure 5: Segmentation effect and the visualization (the first line is the segmentation result, the red line is manual labeling, and the blue line is the network segmentation result. The second line is the spatial attention mask generated by the last RDA module).

Table 1: Average value of the evaluation index of different deep network models on the test set (%).

Model		FCN-8S[24]	FCN-16S[24]	FCN-VGG10[19]	U-Net[27]	U-Net (+BN)	UNet++[32]	RDA-UNET
Left kidney	DSC	88.12	87.53	95.23	92.65	95.09	94.88	96.25
	Precision	89.25	87.22	96.45	92.48	95.67	95.22	96.34
	Recall	89.88	87.43	95.55	93.66	96.45	95.88	96.88
Right kidney	DSC	85.34	84.13	92.23	90.44	93.79	93.32	94.22
	Precision	87.83	84.23	95.88	91.67	94.67	95.11	95.34
	Recall	87.03	88.46	91.19	92.57	94.65	94.45	94.61

3.2. Visualization of Results

3.2.1. The User Interface. Figure 7 shows the user operation interface. Figure 7(a) is the initial interface, which was mainly composed of three parts of the button for selecting the image, the button for segmenting, and the image display container. Clicking the button to select the image can load the image from the catalog to the interface. Figure 7(b) is the screen displayed on the interface after the original CT image was loaded. To click the segmentation button, the system would automatically start the image segmentation, and the segmentation results were then displayed and saved. Figure 7(c) shows the final segmentation results. When the segmentation was completed, the resulting image would be displayed. The red solid line is the contour of the kidney cyst depicted.

3.2.2. Three-Dimensional Reconstruction Results. As shown in Figure 8, the CT image of a patient was segmented first, and then the segmentation results were fused. ITK-SNAP software was used to construct a three-dimensional image.

4. Discussion

The constantly accelerated life rhythm resulting from the development of the economy results in constantly increasing pressure, so more and more diseases occur, threatening the health of people. The kidney disease is a representative one and attracts more and more attention. With the widespread application of artificial intelligence technology in medical imaging, image segmentation technology based on deep learning has become a focus. Intelligent algorithm can effectively segment images to obtain detailed image data, providing reference for the clinical diagnosis and treatment. In this study, a deep-learning-based segmentation model, RDA-UNET, was designed based on the residual dual-attention module, and its performance was compared with FCN-8S, FCN-16S, U-Net, FCN-VGG10, and U-Net (+BN). The results showed that the loss function value of the RDA-UNET model attenuated and tended to converge in a short time, in line with the research results of Zheng et al. [19], who combined deep learning with marginal space learning (MSL) to construct a renal segmentation algorithm and found that the segmentation accuracy of the RDA-UNET model was higher than that of other traditional algorithms.

Finally, RDA-UNET was compared with FCN-8S, FCN-16S, U-Net, FCN-VGG10, and U-Net (+BN) models, factoring into different evaluation indicators. The results showed that the RDA-UNET model achieved 96.25% DSC, 96.34% precision, and 96.88% recall for the left kidney and 94.22% DSC, 95.34% precision, and 94.61% recall for the right kidney, which were better than other algorithms. Thong et al. introduced two transformation methods and proposed a simple depth segmentation model, which can enhance the segmentation of renal CT images [20]. Xia et al. designed a semantic segmentation model based on the SCNN and ResNet combined with SIFT flow transform, which achieved a good segmentation effect with a small proportion of detailed information [21]. Sharma et al. proposed a neural network model for the segmentation of multiple renal cysts based on the structure of the VGG network. However, the morphology of renal cysts would change greatly with renal disease, so the edge contour of renal cysts could not be well located [22]. The results confirmed that the RDA-UNET model constructed in this study had good application feasibility in intelligent segmentation of renal organs and quantitative evaluation of nephropathy.

5. Conclusion

In this study, RDA-UNET, a new segmentation model based on deep learning, was proposed to segment CT images of renal cysts. Through comparison with other kidney segmentation models in terms of Dice, precision, and recall, it proved that this model had obvious advantages in the segmentation of CT slice images of renal cysts. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study. In conclusion, the RDA-UNET model has high accuracy in the segmentation of CT images of renal cysts, and the study provides a reference for the diagnosis and treatment of kidney diseases.

This study was to explore the application value of chest computed tomography (CT) images processed by artificial intelligence (AI) algorithms in the diagnosis of neonatal bronchial pneumonia (NBP). The AI adaptive statistical iterative reconstruction (ASiR) algorithm was adopted to reconstruct the chest CT image to compare and analyze the effect of the reconstruction of CT image under the ASiR algorithm under different preweight and postweight values based on the objective measurement and subjective evaluation. 85 neonates with pneumonia treated in hospital from September 1, 2015, to July 1, 2020, were selected as the research objects to analyze their CT imaging characteristics. Subsequently, the peripheral blood of healthy neonates during the same period was collected, and the levels of C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) were detected. The efficiency of CT examination, CRP, ESR, and combined examination in the diagnosis of NBP was analyzed. The results showed that the subjective quality score, lung window subjective score, and mediastinal window subjective score were the highest after CT image reconstruction when the preweight value of the ASiR algorithm was 50%. After treatment, 79 NBP cases (92.9%) showed ground-glass features in CT images. Compared with the healthy neonates, the levels of CRP and ESR in the peripheral blood of neonates with bronchial pneumonia were much lower ($P < 0.05$). The accuracy rates of CT examination, CRP examination, ESR examination, CRP + ESR examination, and CRP + ESR + CT examination for the diagnosis of NBP were 80.7%, 75.3%, 75.1%, 80.3%, and 98.6%, respectively. CT technology based on AI algorithm showed high clinical application value in the feature analysis of NBP.

1. Introduction

Neonatal bronchial pneumonia (NBP) is the most common pediatric pneumonia disease caused by mycoplasma infection, accounting for about 10% of neonatal pneumonia. Because of the anatomical and physiological characteristics of the neonatal respiratory tract and the immune characteristics of the body, the morbidity and mortality of bronchial pneumonia in children are significantly increased compared with adults, and its clinical symptoms are different. It is still one of the important diseases threatening the health of newborns [1]. According to the statistics of the causes of neonatal death of the World Health Organization (WHO) from 2000 to 2003, bronchopneumonia accounted for 19%, which is the first cause of neonatal death; the incidence of NBP in developed countries is 0.05 times/person/year. In developing countries, the incidence of NBP is 6 times that of developed countries, and the anatomical characteristics of children and the sensitivity of individuals to drugs are different. Approximately 2.4 million children die every year. NBP caused by multiple pathogens and physical and chemical factors is still threatening the health and life of newborns [2]. At present, pneumonia still ranks first in the neonatal prevalence and mortality in our country.

Therefore, it is necessary to explore the diagnosis and treatment methods of NBP, further improve the diagnosis and treatment of NBP, promote the early recovery of children, and reduce the pain of children. Most of the NBP treated with regular drugs have good results, but some children with pneumonia only rely on conventional drugs to treat the results poorly. Therefore, the diagnosis and treatment of neonatal pneumonia still need to be further explored [3]. There are many diagnostic methods for NBP, such as fiberoptic bronchoscopy and bronchography. CT imaging has also been used in the diagnosis of NBP and has a certain diagnostic value [4] with the rapid development of imaging technology. However, CT scan is highly radioactive. In order to reduce its impact on neonates' health, low-dose CT is often used clinically to diagnose pediatric diseases. Low-dose CT scanning reduces the radiation while increasing the noise in the image, which affects the diagnosis accuracy of the disease to a certain extent [5, 6].

The ASiR (an AI algorithm) has been introduced in recent years to balance the quality of CT image and radiation dose, and it has been proven to significantly improve the image quality and reduce the radiation dose of CT scans [7–9]. Compared with the filtered back projection (FBP) algorithm, the ASiR algorithm can reconstruct high-quality CT images with low noise and less artifacts [10], because the traditional iterative reconstruction algorithm runs slowly and the modified ASiR algorithm can effectively weight FBP data and ASiR data to fuse, while reducing the image noise and increasing the processing speed [11].

Based on this, the AI ASiR algorithm was introduced firstly in this study to reconstruct the low-dose chest CT images of neonates, and then the CT characteristics and clinical features of neonates with bronchial pneumonia were analyzed. In addition, the accuracy of different methods for the diagnosis of bronchial pneumonia was analyzed and compared. This study was intended to provide a reference for improving the clinical diagnosis rate of NBP.

2. Basic Theories of CT Reconstruction

2.1. Physical Basis of CT Reconstruction. The CT imaging process mainly used different energy waves as radiation sources to perform projection of the object after irradiation, so as to obtain the reconstructed object [12]. The radiation source of CT imaging was mostly X-ray or γ-ray. X-ray was selected as an example to explain the principle of CT image reconstruction. When X-rays passed through an object, they would gradually attenuate in the body of the object. The density of the constructed object was different, so the attenuation speed of X-ray was also different. For objects with a more homogeneous medium, the attenuation of X-rays obeyed the Lambert–Beer theorem [13]:

$$I = I_0 e^{-\mu x}, \tag{1}$$

where I refers to the intensity after the attenuation of the ray through the object, I_0 represents the intensity when the ray was incident, μ is the attenuation coefficient, and x refers to the transmission length.

For inhomogeneous object, the attenuation coefficient μ could be regarded as a function of x and y; that is, $\mu = \mu(x, y)$. Therefore, the total attenuation of the ray that can pass through the object along path L in a certain direction i could be expressed as follows:

$$\int_L \mu di = \ln\left(\frac{I_0}{I}\right). \tag{2}$$

2.2. Mathematical Basis of CT Reconstruction. The mathematical basis of CT image reconstruction was the Radon transformation (as shown in Figure 1) and the inverse transform theory proposed by the Austrian Mathematician Radon in 1917 [14].

As given in Figure 1, the calculation equation of straight line L in the plane xoy could be written as follows:

$$L: s = x\cos\varphi + y\sin\varphi, \tag{3}$$

where s represents the distance from origin O to straight line L, and φ represents the angle between the normal of straight line L and the x-axis (positive direction).

The mathematical expression of the line integral value of the attenuation function $f(x, y)$ along straight line L could be written as follows:

$$R_f(s, \varphi) = \int_L f(x, y)\mathrm{d}l, \tag{4}$$

where R refers to the Radon transformation of the attenuation function, which could be expressed as R_f.

The coordinate system xoy was rotated counterclockwise by φ degrees along origin O to obtain a new coordinate system $x'oy'$. Then, the parameter equations of x and y of straight line L in this coordinate system are given as follows:

$$\begin{cases} x = x'\cos\varphi - y'\sin\varphi, \\ y = x'\sin\varphi + y'\cos\varphi. \end{cases} \tag{5}$$

After equation (5) was incorporated into equation (4), the Radon transformation of the attenuation function could be performed in a rotating coordinate system, which could be written as follows:

$$R_f(s, \varphi) = \int_{-\infty}^{\infty} (x'\cos\varphi - y'\sin\varphi, x'\sin\varphi + y'\cos\varphi)dy'. \tag{6}$$

The process of Radon inverse transformation was the process of CT image reconstruction, which required to calculate the target object density based on projection data. The specific calculation equation of Radon inverse transformation is shown as follows:

$$f(r, \theta) = \frac{1}{2\pi^2}\int_0^{\pi}\int_{-\infty}^{\infty} \frac{1}{r\cos(\theta - \varphi) - s}\frac{\partial R_f(s, \varphi)}{\partial s}\mathrm{d}s\mathrm{d}\varphi. \tag{7}$$

where $f(r, \theta)$ is the polar coordinate representation of the attenuation function.

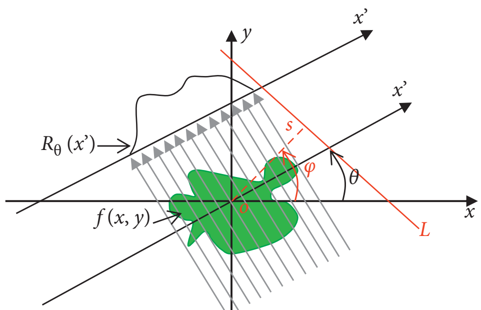

Figure 1: Radon transformation.

Equation (7) was conversed to obtain the convolution form. The polar coordinate representation of the converted attenuation function could be written as $f(r,\theta) = (1/2\pi)\int_0^\pi d\varphi\ (R_f'(s,\varphi) * (1/\pi x_r))_{x_r = r\cos(\theta-\varphi)}$, where $*$ is convolution and $(1/\pi x_r)$ refers to the convolution factor of Hilbert transform.

3. Methods

In this study, 85 NBP patients treated in our hospital from September 1, 2015, to July 1, 2020, were selected as the research objects. Firstly, all children underwent a CT imaging examination. After the examination, the CT images were processed using AI algorithms, and the quality of the processed CT images would be independently evaluated by two radiologists with at least 5 years of work experience. After that, 85 newborn children with pneumonia and 95 healthy children were checked for biochemical indicators, and the biochemical indicators of the two groups of children were compared. Finally, all research data were collected, and the biochemical indicators of the two groups of children were statistically analyzed. The sensitivity, specificity, and accuracy of CT diagnosis were analyzed and compared. The detailed research methods were as follows.

3.1. Research Objects. 85 cases of pneumonia neonates treated in hospital from September 1, 2015, to July 1, 2020, were selected as the research objects: 48 males and 37 females. 95 healthy children who underwent physical examination at the hospital during the same period served as the control group. The families of all had been clarified about the radioactivity of CT examination and the risks of enhanced examinations before the examination and had signed the informed consent forms. All examinations in this trial had been approved by the Medical Ethics Committee of the hospital.

3.2. Imaging Examination. The scan range of the image was strictly set. Brilliance 64-slice spiral CT (128 slices) was used to scan from the top to the bottom of the child's chest to the diaphragmatic level of the lung base. After the consent of neonates' family members, CT scan was performed in neonates' quiet state to remove the metal material on the chest to avoid the appearance of image artifacts. 0.5 mmBp lead clothing was adopted to cover the lower abdomen and pelvic cavity of the neonate, and the neonate was required to keep a supine position for chest CT scan. During the scanning, the specific parameters of the CT scan were set according to the requirements for chest low-dose scan of neonates. The tube voltage was 100~120 kV, the tube current was 50 mA, the speed was 0.8 s/rot, the pitch was 1.375 : 1.000, the noise index was 12, the layer thickness was 5 mm, and the spacing was 5 mm.

3.3. CT Images Process Based on AI Algorithm. The CT images obtained from low-dose scans were reconstructed using the AI ASiR and FBP algorithms. The preweight value of ASiR was set to 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100% to evaluate the reconstructed image with the ASiR algorithms. The preweight value was turned off to optimize the subjective scores of the mediastinal window and lung window so that they both could reach the highest preweight values, based on which the postweight value interval of the ASiR algorithm was set in turn. The percentage indicated the proportion of iterative reconstruction. When the proportion was 0%, it meant that the FBP algorithm was used for image reconstruction, and when the proportion was 100%, it meant that the ASiR algorithm was used for image reconstruction. The type of image reconstruction had to select a standard algorithm, and the reconstructed layer thickness was set to 1.25 mm.

3.4. Quality Evaluation of Reconstructed CT Image. The chest CT image was uploaded to the workstation for observation. The region of interest (ROI) was selected in the lung field, aorta, paraspinal soft tissue, and vertebral body in the upper (sternoclavicular joint layer), middle (pulmonary vein layer), and lower (near diaphragmatic muscle layer) parts of the axial CT image, and the ROI = 100 mm^2. The CT values (represented by ROIa and ROIm) and the density standard deviations (SD) of different ROI regions were recorded, and the average of the CT values of the 3 slices was calculated and adopted. The noise and contrast-to-noise ratio (CNR) in the reconstructed image were detected and calculated, respectively, of which CNR could be calculated with CNR = (ROIa/ROIm)/SD. When it was required to extract ROI regions in images of different levels, it was necessary to ensure that the position, size, and shape of the ROI were consistent.

2 radiologists with at least 5 years of work experience were selected for independent subjective evaluation of CT images. The mediastinal window and lung window were observed and scored. The scoring criteria were defined as follows. If the image reconstruction quality was very poor so that it could not be used for the clinical diagnosis of the disease, 1 point was scored; 2 points meant that the image reconstruction quality was relatively poor and could not meet the basic requirements of clinical disease diagnosis; 3 points indicated that image reconstruction quality was relatively average and basically could meet the requirements of clinical disease diagnosis; 4 points indicated that the image reconstruction quality was good and could meet the clinical requirements for the diagnosis requirements of the

above diseases; and 5 points were awarded for the good image reconstruction quality, which could fully meet the diagnosis requirements of the clinical diseases. When the total score of the image evaluation exceeded 3 points, the image could be used in the clinical diagnosis of the disease. If there were any different opinions between the 2 radiologists, this could be solved by negotiation.

3.5. Biochemical Indicators Examinations of Neonates. The venous blood had to be collected from all neonates. The neonate was required to fast with water 10 hours before blood collection. After 10 mL of venous blood was collected, the ESR level was detected according to Widman's method, and the CRP level was detected using an automatic biochemical analyzer. The normal level of ESR was 0~10 mm/h, and the normal level of CRP was >10 mg/L.

3.6. Statistical Analysis. The SPSS 22.0 statistical software package was adopted to process and analyze the test result data. The Kappa test was used to detect the consistency of the subjective scoring results of CT images. Kappa ≤0.4 was regarded as poor consistency, Kappa = 0.4–0.75 was regarded as good consistency, and Kappa ≥0.75 was regarded as excellent consistency. The single-factor ANOVA was applied to compare the image score results after reconstruction with different weights of the ASiR algorithm, and the LSD method was selected for pairwise comparison. The differences in the basic data and biochemical indicators of the two groups of neonates were compared using the independent-samples *t*-test, and the differences in the basic data and diagnosis accuracy of CT, biochemical indicators, and CT combined biochemical indicators of the two groups of neonates were compared using the chi-square test. When $P < 0.05$, the difference was statistically significant.

4. Results

4.1. Impacts of Preweight Value on Reconstructed Image Quality Based on ASiR Algorithm. The image noise and CNR changes after reconstruction of chest CT images using different preweight values (0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100%) of ASiR algorithm were analyzed firstly (as shown in Figure 2). With the gradual increase of the preweight value, the noise value in the CT image showed a gradually decreasing trend, while the CNR value showed a gradually increasing trend.

Secondly, the differences between the subjective noise and subjective quality score of the image were compared after the chest CT image was reconstructed with the ASiR algorithm with different preweight values (0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100%), and the results are illustrated in Figure 3. With the gradual increase of the preweight value of the ASiR algorithm, the subjective noise score in the reconstructed CT image showed a gradual decline, indicating that the noise in the reconstructed CT image was gradually reduced during the operation of the ASiR algorithm. With the gradual increase of the preweight value of the ASiR algorithm, the subjective quality score of the reconstructed CT image did not show a gradual upward trend. When the preweight value was 0%~50%, the subjective quality score increased gradually; the subjective quality score showed a gradual decline trend when the preweight value was 50%~100%. Among them, the subjective quality score of the CT image was the highest after reconstruction with the ASiR algorithm with 50% preweight value.

Then, the difference between the mediastinal window subjective score and lung window subjective score was compared when the chest CT image was reconstructed using the ASiR algorithm with different preweight values (0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, and 100%), and the analysis results are revealed in Figures 4 and 5, respectively. The changes in the mediastinal window and lung window subjective scores of the CT images after reconstruction were basically the same as the changes in the subjective quality score. When the preweight value was 40%~60%, the mediastinal window and lung window subjective scores of the CT images reconstructed by the ASiR algorithm were obviously higher. Among them, the mediastinal window and lung window subjective scores of the CT image after reconstruction by the ASiR algorithm with a preweight value of 50% were the highest.

4.2. Impacts of Postweight Value on Reconstructed Image Quality Based on ASiR Algorithm. The above results revealed that the reconstructed CT image quality was the best when the preweight value in the ASiR algorithm was 50%. Therefore, the preweight value in the ASiR algorithm was set to 0% and 50% to compare and analyze the impacts of different postweight values on the CT value of different positions after CT image reconstruction. As shown in Figure 6, the CT value of lung tissue after reconstruction using the ASiR algorithm under different preweight values showed a gradual downward trend with the increase of postweight value. The CT value of lung tissue under 50% of preweight value was obviously lower than that under the 0% of the preweight value when the postweight value was 50%~100%, as illustrated in Figure 6(a). With the increase of postweight value, the CT value of the vertebral body and aorta after reconstruction of the ASiR algorithm under different preweight values showed a gradual decrease, but the CT value of paraspine soft tissue was not changed greatly. The CT values of the vertebral body, aorta, and paraspine soft tissue under the preweight value of 50% were all less than those under the preweight value of 0% (as shown in Figures 6(b)–6(d)).

The impacts of ASiR algorithm on the SD value of the target position after reconstruction of the CT image under different postweight values were analyzed and compared, and the results are given in Figure 7. With the increase of postweight value, the SD value of lung tissue after reconstruction with ASiR algorithm at 0% preweight value was not obvious, while that after reconstruction with ASiR algorithm at 50% preweight value showed a trend of first increasing and then decreasing. Among them, the SD value of lung tissue under 70% postweight value was the largest (as disclosed in Figure 7(a)). As the postweight value increased, the SD values of the vertebral body, aorta, and paraspine soft tissue in CT images after reconstruction with

different preweight values of the ASiR algorithm showed gradual declines. The SD values of the vertebral body, aorta, and paraspine soft tissue after reconstruction with the ASiR algorithm under 0% preweight value were much lower than those under the 50% preweight value (as shown in Figures 7(b)–7(d)).

4.3. CT Characteristics of NBP. The CT images of 2 neonates were undertaken as examples to analyze the characteristics of CT images (Figure 8). In the CT image of neonate A, a large area of increased density shadow could be clearly observed in the lower right lobe of the lung, the internal density was not uniform, and the air shadow of the bronchus could be clearly observed. In the CT image of neonate B, patchy and ground-glass shadows could be clearly observed in the left lower lobe of the lung, and the characteristics of bronchial inflation could be seen.

The characteristics of CT images of 85 neonates with bronchial pneumonia were analyzed (as shown in Table 1). The ground-glass CT imaging characteristic accounted for the highest proportion, followed by nodular/small air cavity consolidation, and the vascular bundle thickening also accounted for more than 50%.

4.4. Characteristics of Biochemical Indicators of NBP. The differences between the levels of CRP and ESR in peripheral blood of healthy neonates and neonates with bronchial pneumonia were compared, and the results are illustrated in Figure 9. The levels of CRP and ESR in peripheral blood of neonates with bronchial pneumonia were 27.3 ± 3.5 mg/L and 19.1 ± 3.7 mm/h, respectively. The levels of CRP and ESR in peripheral blood of healthy neonates were 2.7 ± 2.4 mg/L and 6.1 ± 4.8 mm/h, respectively. After comparison, it was found that the CRP and ESR levels in peripheral blood of neonates with bronchial pneumonia were remarkably lower in contrast to the healthy neonates ($P < 0.05$).

4.5. Analysis of the CT Value and Biochemical Indicators in the Diagnosis of Bronchial Pneumonia. The specificity, sensitivity, and accuracy of CT examination, CRP examination, ESR examination, CRP + ESR examination, and CRP + ESR + CT examination in the diagnosis of NBP were analyzed and compared. As suggested in Figure 10, the accuracies of CT examination, CRP examination, ESR examination, CRP + ESR examination, and CRP + ESR + CT examination to diagnose the NBP were 80.7%, 75.3%, 75.1%, 80.3%, and 98.6%, respectively.

5. Discussion

Bronchial pneumonia is the most common infectious disease in infants and young children, caused by bacteria, viral infection, or colds [15]. Due to the gradual deepening of air pollution, there are more and more pathogenic bacteria that cause diseases, and the resistance of infants and young children is lower, so the younger neonates are more susceptible to bronchial pneumonia. The main clinical manifestations of the disease are mostly fever, chills, cough, headache and general malaise, fatigue, loss of appetite, nausea, vomiting, and diarrhea. The symptoms are not serious, but they are more common. However, as the symptoms worsen, there will be symptoms such as coughing, and, in infants and young children, there are symptoms such as wheezing or difficulty breathing. In severe cases, there will be extrapulmonary manifestations, such as the nervous system, digestive system, blood system, muscles, and bones. Such abnormalities are more common in mycoplasma pneumonia. The pathogenesis of *mycoplasma pneumonia* is not very clear, mainly including respiratory epithelial adsorption, direct invasion of *Mycoplasma pneumoniae*, and the theory of immunological disorders [16, 17].

At present, imaging methods such as X-ray, chest CT, and bronchography are clinically used in the diagnosis of bronchial pneumonia [18]. As a kind of invasive examination, bronchography is of little value in newborn children. Therefore, X-ray and chest CT are often used in newborns. In previous studies of *Mycoplasma pneumoniae* lung X-ray results, only the consolidation of lung lobes/pulmonary segments and diffusely infiltrated mesh nodules can be clearly distinguished. The current study found that the results of pathological slices showed changes in bronchial

Table 1: The characteristic distribution of CT images of neonates with bronchial pneumonia.

CT characteristics	Cases ($n = 85$)	Percentage
Ground-glass	79	92.9
Nodular/small air cavity consolidation	74	87.1
Vascular bundle thickening	56	65.9
Atelectasis	34	40.0
Pleural effusion	27	31.8
Swollen lymph nodes	22	25.9
Large sheet consolidation	21	24.7

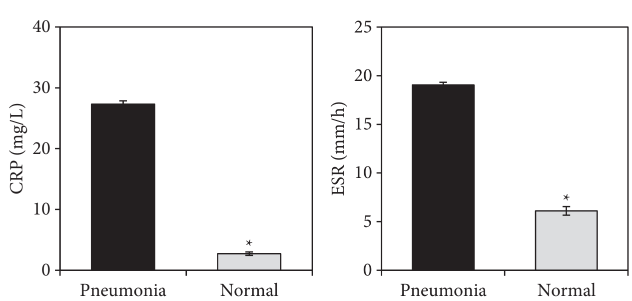

Figure 9: Comparison of (a) CRP and (b) ESR levels in peripheral blood between the two groups of neonates.

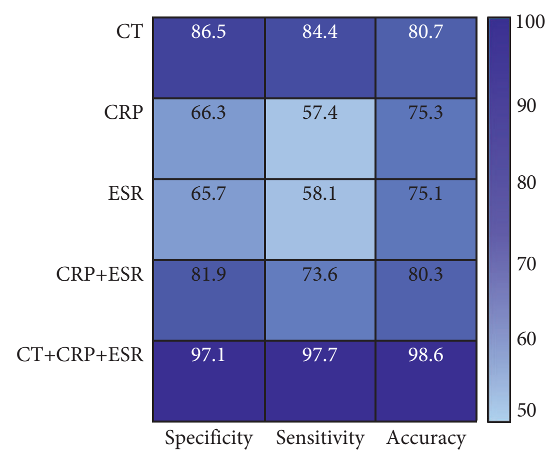

Figure 10: Comparison of the efficiency of different methods for diagnosing NBP.

inflammation and lobular consolidation, and chest X-rays could not show corresponding image changes. In the lung CT scan, the changes in bronchial inflammation such as the central nodules of the lobules can be clearly distinguished, and the patchy shadows and the pneumonia images with ground-glass changes can also be seen. Based on the lung CT thin-slice plain scan, it was known that more than two images presented in the above X-rays. At the same time, the “tree bud sign” and “tree fog sign” formed by the point and sheet infiltration formed in the early stage of the disease and the “double track sign” formed by the thickening and inflation of the bronchial wall formed by airway mucosal damage can also be affected. It can be clearly observed that uniform ground-glass changes can be clearly distributed in lung CT images. In summary, chest CT is the best examination method among neonatal pneumonia bronchial examinations. However, CT scan has high radiation. In order to reduce its impact on children’s health, low-dose CT is often used clinically to diagnose pediatric diseases. Low-dose CT scanning reduces the radiation but at the same time increases the noise in the image, which affects the diagnosis accuracy of the disease to a certain extent. With the continuous update and iteration of computer network technology, various image processing technologies have also been rapidly developed and penetrated into all walks of life. Various AI algorithms have also been applied and developed in the field of medical imaging. The iterative reconstruction algorithm under AI can achieve noise control through the description and expression of noise characteristics, so it has been widely used in the reconstruction of low-dose CT imaging, of which the ASiR algorithm is the most widely used [19–22]. Therefore, the effect of CT image reconstruction using the ASiR algorithm under AI was evaluated through subjective evaluation and objective measurement firstly. The results showed that, compared with the FBP algorithm, the noise of the CT image after reconstruction by the ASiR algorithm was dramatically reduced and the quality score was improved greatly. When the preweight value was 50%, the reconstruction of the CT image by the ASiR algorithm showed the best effect. When the preconditions of the ASiR algorithm are determined, the postweight value can affect the objective indicators of the image and the supervisor's score. It was found in this study that, with the increase of postweight value, the SD values of the vertebral body, aorta, and paraspine soft tissue decreased obviously, while the SD value of lung tissue did not change much. This may be due to the heterogeneity of the lung tissue itself.

Subsequently, the CT characteristics of neonates with bronchial pneumonia were analyzed, and the results showed that ground-glass features accounted for the largest proportion, followed by nodular/small patchy air cavity consolidation and vascular bundle thickening. Ground-glass can show increased lung density and blurred edges; part of it shows the distribution of full title pages; and the pathological basis is the appearance of a small amount of serous and inflammatory exudate in the alveoli [23]. The nodular/small patchy air cavity consolidation mainly shows small patches of increased density, occupying almost all acinars and lobules [24]. In addition, the changes in serum CRP and ESR levels of neonates were detected in this study. Serum CRP is a systemic inflammatory response protein, which can reflect the infection status of neonates [25]. ESR is a nonspecific marker for the evaluation of tissue inflammation and destruction, which can reflect the aggregation state of the fibrinogen and immunoglobulin of patients [26]. The results of this study revealed that neonates with bronchial pneumonia showed greatly increased CRP and ESR levels, indicating that they suffered from systemic inflammatory response. In addition, the diagnostic accuracy on neonates with bronchial pneumonia using only CRP or ESR levels was only about 75%, while that of CRP + ESR + CT examination could be as high as 98.6%.

6. Conclusion

In this study, the CT images of NBP patients were reconstructed based on the AI ASiR algorithm, and it was applied in combination with the detection of serum CRP and ESR levels in the diagnosis of NBP. It was found in this study that the AI ASiR algorithm can significantly improve the quality of CT images of NBP, and CT technology based on the AI ASiR algorithm can be used in the clinical diagnosis of bronchial pneumonia in children, but the efficiency of identifying bacterial and viral pneumonia was still low and had to be improved. The diagnostic method combining CT scan and serum CRP and ESR level detection had significantly improved the sensitivity, specificity, and accuracy of disease diagnosis. This study provided reference and basis for the early diagnosis and treatment of NBP in children. However, there were still some shortcomings in this study. For example, it only analyzed the influence of the preweight and postweight values on the reconstruction effect of the AI ASiR algorithm, and the influence of other parameters on the image quality needed to be considered in the follow-up. In addition, it only analyzed the CT characteristics of NBP in children. In the follow-up, the sample size needed to be further expanded to explore the differences and diagnostic efficiency in CT characteristics of bacterial and viral NBP.

Objective. This research aimed to explore the application of a mathematical model based on deep learning in hospital infection control of novel coronavirus (COVID-19) pneumonia. *Methods*. First, the epidemic data of Beijing, China, were utilized to make a definite susceptible-infected-removed (SIR) model fitting to determine the estimated value of the COVID-19 removal intensity β, which was then used to do a determined SIR model and a stochastic SIR model fitting for the hospital. In addition, the reasonable β and γ estimates of the hospital were determined, and the spread of the epidemic in hospital was simulated, to discuss the impact of basal reproductive number changes, isolation, vaccination, and so forth on COVID-19. *Results*. There was a certain gap between the fitting of SIR to the remover and the actual data. The fitting of the number of infections was accurate. The growth rate of the number of infections decreased after measures, such as isolation, were taken. The effect of herd immunity was achieved after the overall immunity reached 70.9%. *Conclusion*. The SIR model based on deep learning and the stochastic SIR fitting model were accurate in judging the development trend of the epidemic, which can provide basis and reference for hospital epidemic infection control.

1. Introduction

Novel coronavirus (COVID-19) is one of the current coronaviruses that can infect humans. On December 1, 2019, the first suspected case of COVID-19 was admitted to Jinyintan Hospital in Wuhan. After that, major hospitals in Wuhan received similar unidentified pneumonia patients one after another. The Wuhan Municipal Health Commission started an epidemiological investigation on December 29. On January 8, 2020, experts from the National Health Commission of China announced that the pathogen was a novel coronavirus [1]. According to the report of the Wuhan Health Commission on January 16, 41 new patients were reported in Wuhan, and 19 new cases were reported on January 19. Zhong Nanshan, head of the national expert team, said on January 20 that the disease was "human-to-human infectious" and that 217 new cases had been reported in Wuhan that day. The first cases were reported in Tianjin, Jiangxi, Zhejiang, and Henan provinces on January 21, marking the start of a full-scale outbreak of COVID-19 in China. As of March 1, the total number of confirmed cases in China has reached 80,000. Meanwhile, other countries have also reported the emergence of novel coronavirus infections. At present, the epidemic in China has been basically brought under control through continuous efforts. However, the epidemic continues to spread in other countries and the international situation is still grim. Against the background of global economic integration, the prevention and control of the epidemic must not be slackened. Currently, research on the COVID-19 model is mostly focused on the whole region [2]. There have been very few studies on hospitals. However, as the main battlefield of antiepidemic, it is very necessary to study the law of epidemic transmission and its control transmission. Specifically, health care workers are more likely to come into contact with patients and get sick. When health care workers get sick, it is not only a major blow to the health care system, but it also increases the risk to the general population. This is extremely detrimental to the prevention and control of the epidemic [3].

The use of models to study infection began as early as the 18th century. The concept of establishing a model to solve the spread of infectious diseases was first proposed by Bernoulli when he studied the smallpox virus. By the middle of the 20th century, scientists began systematic research on it. In 1926, Kermack and Mckendrick proposed the classic susceptible-infected-removed (SIR) warehouse model [4]. Various subsequent models were proposed based on that. Later, as the research on infectious disease models continues to deepen, scientists have further subdivided and characterized different infectious diseases, such as SIR and SIES models. In recent years, infectious disease models have developed rapidly with the development of computing power and big data. Many scientists modeled various infectious diseases. For example, some scientists established an SIR model with H1N1 as the research object and conducted a simulation study on it. There were many similar examples [5]. A large amount of research data showed that the establishment of infectious disease research models can effectively predict the development trend of infectious diseases, which was extremely important for the treatment and control of infectious diseases. The establishment of infectious disease models has occupied an irreplaceable and important position in modern infectious disease research.

Therefore, a SIR and stochastic model was established based on the data of the whole area of Beijing. Then, the data of the hospital was used as the research data to carry out empirical analysis on the model. It was expected to provide a basis for epidemic control and subsequent similar events.

2. Research Methods

2.1. Determination of SIR Model. Based on a set of ordinary differential equations, the population was divided into three types: susceptible, infected, and evacuated to establish the SIR model. Susceptible persons were represented by S_t, which meant the number of susceptible persons, and the susceptible persons were defined as healthy people who had not yet been infected with the disease. Infected people were expressed by I_t, which meant the number of people infected at time t, which was defined as a group that had been infected and could transmit from person to person. The migrants were represented by R_t, which meant the number of migrants at time t, which was defined as the people who had been isolated, passed away, or recovered from immunity. Assuming that an epidemic occurred in a closed environment, the effects of normal birth rate and death rate were excluded, while population dynamics were ignored, and the total population was counted as N. Then,

$$S_t + I_t + R_t = N. \tag{1}$$

In a unit of time at time t, if the infection intensity was β, the number of new infections was $\beta S_t l_t$. At time t, the number of people who were evacuated due to death and recovery was proportional to the number of infections. If the intensity of removal was calculated as r, the number of people who were evacuated was rI_t. The specific SIR model with different parameters is shown in Figure 1.

2.2. Stochastic SIR Model. For the stochastic SIR model, the stochastic process is as follows: for a given probability space $(\Omega, \wp, P)$ and a given parameter set T, each parameter satisfies $t \in T$. Then, $X_T = \{X(t, w), t \in T\}$ is the random variable defined in the probability space $(\Omega, \wp, P)$, and the corresponding random process $X_T = \{X(t, w), t \in T\}$ in the probability space $(\Omega, \wp, P)$ is denoted as $\{X(t), t \in T\}$ or $X(t)$. The discrete state continuous-time Markov process is as follows: in a random process $\{X(t), t \in T\}$, if there are any integer n and space states I, $0 \leq t_0 < t_1 < t_2 < \ldots < t_{n+1}$, $t_k \in T$, $k = 0, 1, 2, \ldots, n+1$, and their states meet the following conditions:

$$\begin{aligned} &P\{X(t_{n+1}) \leq i_{n+1} | X(t_n) = i_n, \ldots, X(t_0) = i_0\} \\ &= P\{X(t_{n+1}) \leq i_{n+1} | X(t_n) = i_n\}. \end{aligned} \tag{2}$$

Then, the stochastic process $\{X(t), t \in T\}$ is a discrete state continuous Markov process. Continuous-time Markov chain: for the random process $\{X(t), t \in T\}$, if there are any integers n and state space I, I, $0 \leq t_0 < t_1 < t_2 < \ldots < t_{n+1}$, $t_k \in T$, $k = 0, 1, 2, \ldots, n+1$, and the state satisfies the following conditions:

$$\begin{aligned} &P\{X(t_{n+1}) = i_{n+1} | X(t_n) = i_n, \ldots, X(t_0) = i_0\} \\ &= P\{X(t_{n+1}) = i_{n+1} | X(t_n) = i_n\}. \end{aligned} \tag{3}$$

Then, the stochastic process $\{X(t), t \in T\}$ is called the continuous-time Markov process, also known as the process $Q-$. The transition probability function: let $\{X(t), t \in T\}$ be a continuous countable Marko chain; then, for any i, the transition probability $j \in E$ is as follows:

$$pij(s, t) = P\{X(t) = j | X(S) = i\}, \quad s \leq t;\ i,\ j \in E. \tag{4}$$

The above Markov chain is called the time homogenous Markov chain, and its transition probability is only related to the time interval and has nothing to do with the time selection. Therefore, when only the time homogenous Markov chain was considered, the above formula can be rewritten as follows:

$$\begin{aligned} p_{\mathrm{ij}}(t-s) &= P\{X(t) = j | X(s) = i\} \\ &= P\{X(t-s) = j | X(0) = i\}, \quad s \leq t;\ i,\ j \in I. \end{aligned} \tag{5}$$

The transition probability matrix is defined as follows:

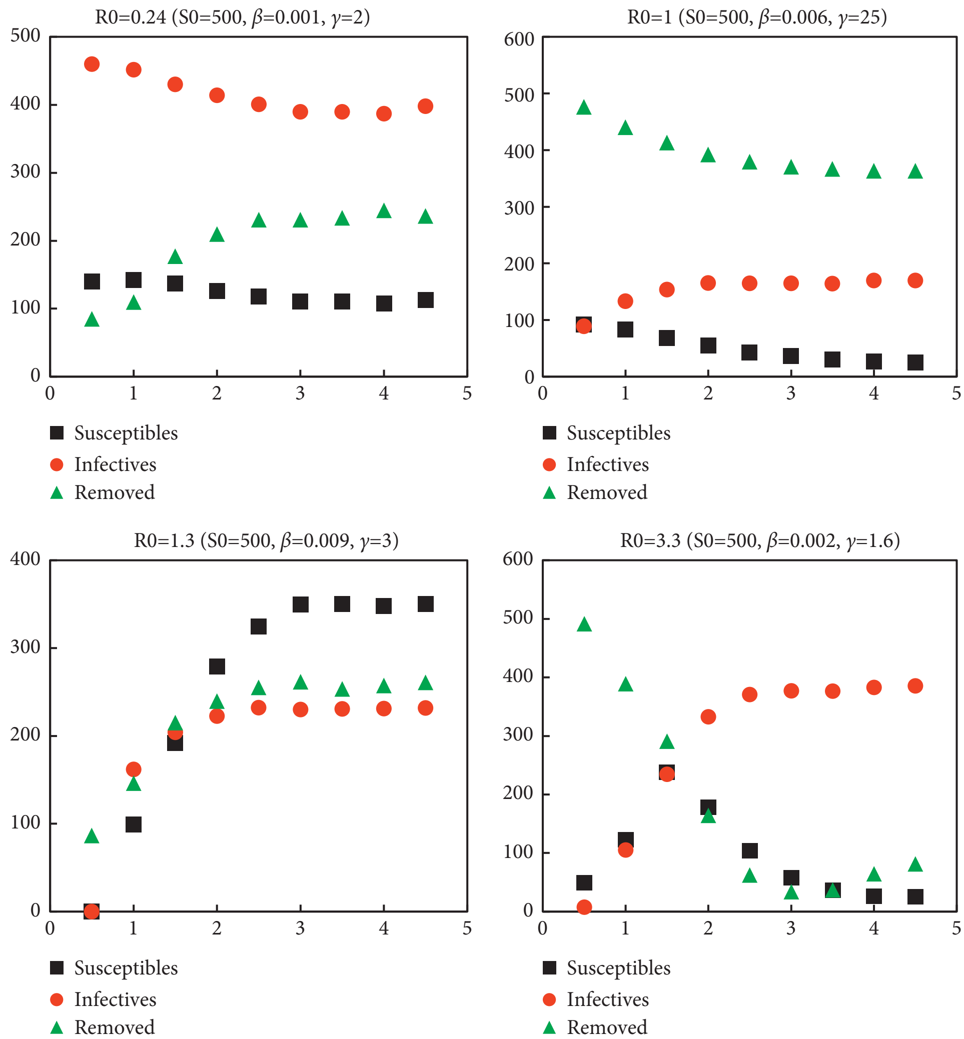

Figure 1: SIR epidemic model with different parameters.

$$P(t) = (pij(t))i, \quad j \in l. \tag{6}$$

Chapman–Kolmogorov equation: for any $s, t \geq 0$, i, $j \in I$, there is the following equation:

$$p_{ij}(s+t) = \sum_{k \in I} p_{ik}(s) p_{kj}(t). \tag{7}$$

Its matrix form is as follows:

$$P(s+t) = P(s)P(t), \quad \forall s, t \in [0, \infty). \tag{8}$$

The transition rate matrix is defined as follows:

$$A = \begin{pmatrix} a_{00} & a_{01} & a_{02} & \dots a_{0n} \\ a_{10} & a_{11} & a_{12} & \dots a_{1n} \\ a_{20} & a_{21} & a_{22} & \cdots a_{2n} \\ \vdots & \vdots & \vdots & \ddots \vdots \\ a_{n0} & a_{n1} & a_{n2} & \cdots a_{nn} \end{pmatrix},$$

$$a_{ij} = \lim_{\Delta t \longrightarrow 0^+} \frac{p_{ij}(\Delta t) - p_{ij}(0)}{\Delta t} = \left\{ \begin{matrix} \lim_{\Delta t \longrightarrow 0} \dfrac{p_{ij}(\Delta t)}{\Delta t}, & i \neq j \\ \lim_{\Delta t \longrightarrow 0} + \dfrac{p_{ij}(\Delta t)}{\Delta t}, & i = j \end{matrix} \right\}. \tag{9}$$

According to $\sum_{j=0}^{\infty} p_{ij}(\Delta t) = 1$, the following equation is acquired:

$$1 - p_{ij}(\Delta t) = \sum_{j=0, j \neq i}^{\infty} p_{ij}(\Delta t) = \sum_{j=0, j \neq i}^{\infty} \left[a_{ij} \Delta t + o(\Delta t) \right]. \tag{10}$$

Further, equation (11) is acquired:

$$a_{ii} = \lim_{\Delta t \longrightarrow 0^+} \frac{-\sum_{j=0, j \neq 1}^{\infty} \left[a_{ij} \Delta t + o(\Delta t) \right]}{\Delta t} = -\sum_{j=0, j \neq i}^{\infty} a_{ij}. \tag{11}$$

Then, the following equation is obtained:

$$\sum_{j=0}^{\infty} a_{ij} = a_{ii} + \sum_{j=0, j\neq i}^{\infty} a_{ij} = 0. \tag{12}$$

The pure generative process is defined as follows:

$$P\{X_{t+dt} = j|X_t = i\} = \begin{cases} \eta_i dt + o(dt), & j = i-1, \\ 1-\eta_i dt + o(dt), & j = i, \\ o(dt), & \text{others}. \end{cases} \tag{13}$$

The birth and death processes are shown as follows:

$$P\{Xt + dt = j|Xt = i\} = \begin{cases} \varsigma i dt + o(dt), & j = i+1, \\ \eta i dt + o(dt), & i = i-1, \\ 1-(\varsigma i + \eta i)dt + o(dt), & j = i, \\ o(dt), & \text{others}. \end{cases} \tag{14}$$

A susceptible person was likely to become infected with a probability of $\beta S_t I_t dt$. The probability that an infected person would recover or die and become a remover is $\gamma I_t dt$. The probability of the above two occurrences is $1-(\beta S_t + \gamma)I_t dt$. Therefore, the transition probability of a binary random process $\{S_t, I_t, t \geq 0\}$ is as follows:

$$P\{(S,I)_{t+dt} = (i,j)|(S,I)_t = (m,n)\}. \tag{15}$$

β and γ are removal coefficients. Specific infectious disease random models and least square cases under different coefficients are shown in Figures 2 and 3.

2.3. Parameter Estimation

Least square method: assuming unknown parameters $\theta = (\beta, \gamma)$, then the number of infected persons is $I = \{I_i, 1 \leq i \leq N\}$, the simulated value of the number of infected persons is $Y(\theta) = \{y_i(\theta), 1 \leq i \leq N\}$, and the residual is $V = Y(\theta) - 1$ and the sum of squares $\mathrm{SSE}(\theta)$ of the residual is as follows:

$$\begin{aligned} \mathrm{SSE}(\theta) &= \|V\|^2 \\ &= \sum_{i=1}^{N} [y_i(\theta) - I_i]^2, \end{aligned}$$

$$\begin{cases} \dfrac{\partial \mathrm{SSE}(\theta)}{\partial \beta} = 2\sum_{i=1}^{N} [y_i(\theta) - I_i] \dfrac{\partial y_i(\theta)}{\partial \beta}, \\ \dfrac{\partial \mathrm{SSE}(\theta)}{\partial \beta} = 2\sum_{i=1}^{N} [y_i(\theta) - I_i] \dfrac{\partial y_i(\theta)}{\partial \gamma}. \end{cases} \tag{16}$$

Weighted least square method: the recent data was given a large weight, while the long-term data was given a smaller weight, $w^{N-i}, 0 < w < 1$, so the sum of squares $\mathrm{SSE}(\theta)$ of the residual is as follows:

$$\mathrm{SSE}(\theta) = \|V\|^2 = \sum_{i=1}^{N} w^{N-i} [y_i(\theta) - I_i]^2 + \sum_{i=N+1}^{M} [y_i(\theta) - I_i]^2. \tag{17}$$

2.4. Empirical Study on COVID-19 in Hospital.

Firstly, the SIR model was used to fit the epidemic situation of the hospital. In the SIR model, the whole population was classified into susceptible persons (S_t), infected persons (I_t), and displaced persons (R_t). New diagnoses in hospital every day are shown in Figure 4. The number of newly diagnosed patients in hospital on a daily basis was consistent with the basic trend (I_t) in the SIR model, so the SIR model can be used for fitting.

The parameter estimation of the SIR model was determined. The number of communicators was taken as the number of confirmed cases on the day minus the number of deaths and ceases on the day, and the cumulative number of deaths and ceases R_t was obtained as follows:

I_t = number confirmed on a day − cumulative number of deaths and cures.

R_t = cumulative number of deaths and cures

The number of persons hospitalized with the virus per day and the cumulative number of deaths and discharges are the number of evacuees. Then, the differential equation of SIR model is determined as follows:

$$\begin{cases} \dfrac{\mathrm{d}s_t}{\mathrm{d}t} = -\beta S_t I_t, \\ \dfrac{\mathrm{d}I_t}{\mathrm{d}t} = \beta S_t I_t - \gamma I_t, \\ \dfrac{\mathrm{d}R_t}{\mathrm{d}t} = \gamma I_t. \end{cases} \tag{18}$$

The initial value was $I_0 = 241, R_0 = 5$, and the parameters to be evaluated were S_0, β, and γ. The least square method was used to estimate the unknown parameters. First, the following definition is made to estimate γ:

$$\gamma(t) = \frac{R(t) - R(t-1)}{I(t-1)}. \tag{19}$$

Thus, an estimate of 0.071 for γ is obtained, representing a recovery time of approximately 14 days per patient. Then, the least square estimation of S_0 and β is carried out by using the estimated value of the obtained γ. The parameter domain of unknown parameters is $[1.6 \times 10^{-4}, 1.8 \times 10^{-4}] \times [1600, 1800]$, and the minimum value SSE is found to obtain the 3D stereogram and contour map. The least square estimate of S_0 and β is as follows:

$$\widehat{\beta} = 1.68 \times 10^{-4} \widehat{S}_0 = 1672. \tag{20}$$

The sum of squares of the residuals is as follows:

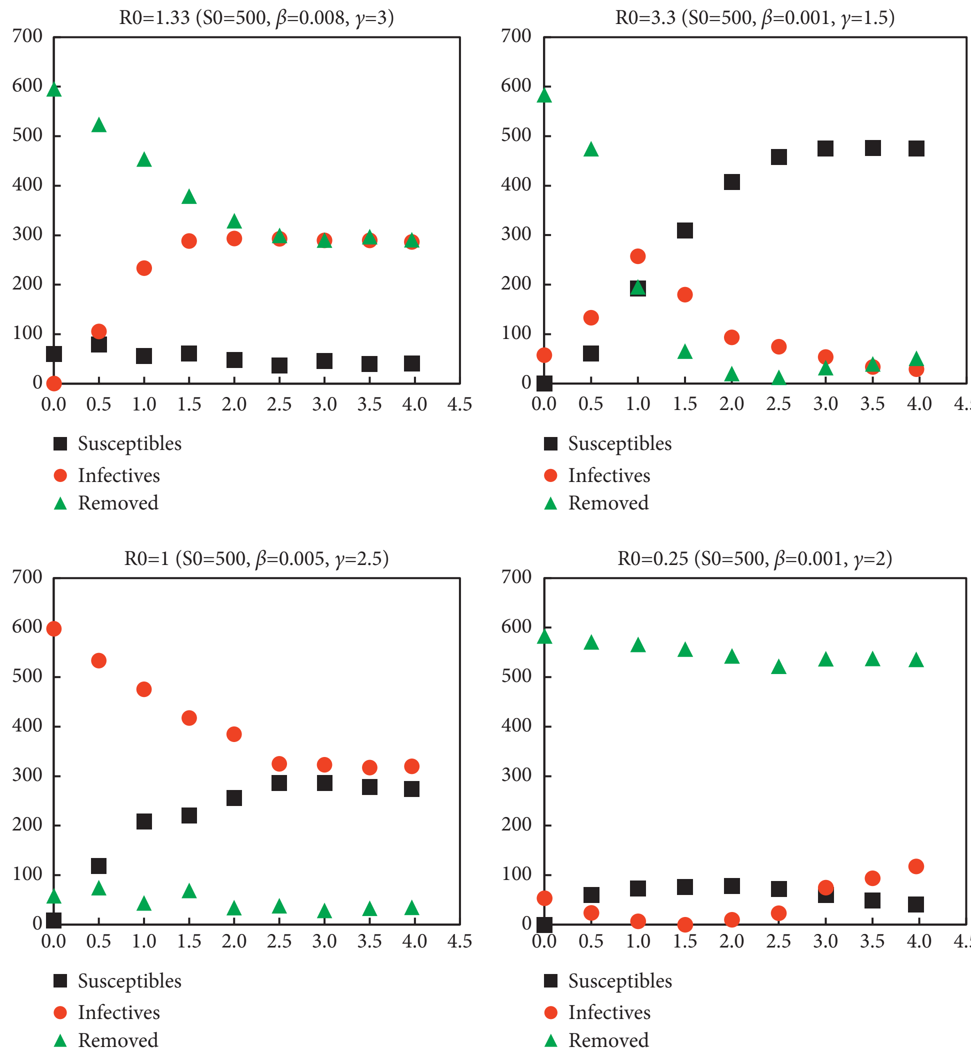

FIGURE 2: Random SIR epidemic model under different parameters.

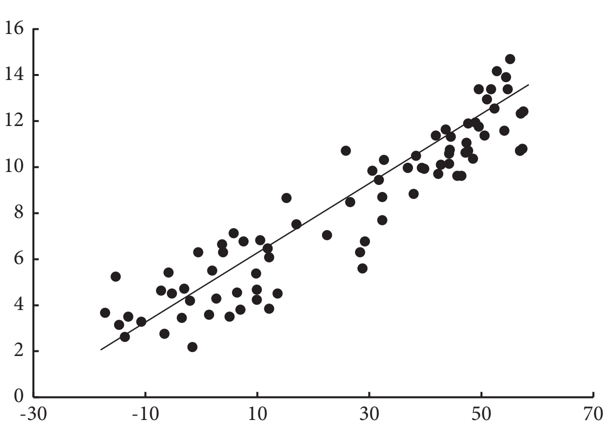

FIGURE 3: Least square case.

$$\mathrm{SSE} = 1.277 \times 10^{5}. \tag{21}$$

Then, the obtained $S_0 = 1672$ is used for the least square estimation of β and γ. The parameter domain of unknown parameters is $[1.6 \times 10^{-4}, 1.8 \times 10^{-4}] \times [0.068, 0.076]$, the minimum value SSE within the range is found, and the 3D stereogram and contour map are obtained. The least squares estimate is as follows:

$$\begin{aligned} \hat{\beta} &= 1.684 \times 10^{-4}, \\ \hat{\gamma} &= 0.072. \end{aligned} \tag{22}$$

The corresponding residual peace is as follows:

$$\mathrm{SSE} = 1.2633 \times 10^{5}. \tag{23}$$

Parameter estimation of stochastic SIR model was as follows. Simulation steps of the stochastic process are as follows: (i) when $t = 0$, the initial value is set as $(S_0, I_0), \beta, \gamma$. (ii) Random numbers with exponential distribution parameter $\beta S_t I_t + \gamma I_t$ are generated. (iii) Random number k that obeys uniform distribution $U(0, 1)$ is generated. Let $p = \beta S_t / \beta S_t + \gamma$, if $r \leq p$, then $(S_{t+dt}, I_{t+dt}) = (S_t - 1, I_t + 1)$. If $r > p$, then $(S_{t+dt}, I_{t+dt}) = (S_t, I_t - 1)$. (iv) The pretransfer state (S_t, I_t) is replaced with the posttransfer state (S_{t+dt}, I_{t+dt}); the previous process is repeated, and the process is terminated when $S_t = 0$ or when $I_t = 0$. The initial

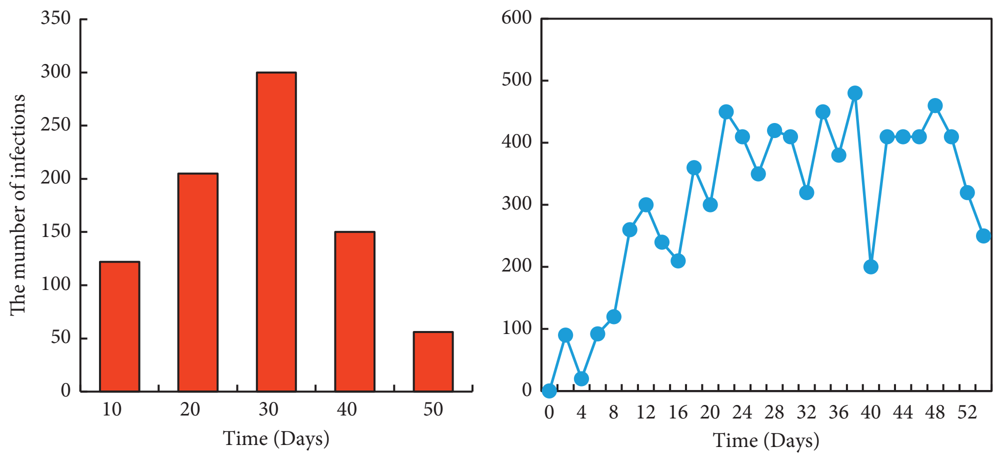

Figure 4: New diagnoses and statistics in hospital every day. (a) Newly diagnosed infections per day. (b) The number of new infections per day.

value is the same as that of the determined SIR model. The 25×25 grid is taken and the parameter domain is set as $[2.5 \times 10^{-6}, 2.7 \times 10^{-6}] \times [0.06, 0.08]$. The minimum value of SSE is obtained via MATLAB, to draw the 3D stereogram and contour diagram. The least square estimate of the position parameter is as follows:

$$\begin{aligned} \widehat{\beta} &= 2.588 \times 10^{-6}, \\ \widehat{\gamma} &= 0.073. \end{aligned} \tag{24}$$

For the determined SIR model, the parameter fitting is substituted to extract the I change image. For the stochastic SIR model, the $I1$ change image is also obtained by fitting its 10,000 orbits and averaging the values of the orbits on the whole point (Figure 5).

Although there is a certain gap in the image, considering the error that may occur in the operation is acceptable, the previous view is confirmed. The determined SIR model is regarded as the value of the whole point of the stochastic SIR model. When the stochastic SIR model has enough orbits to eliminate its random interference, the average value of the two is converged. The results of the two are similar, but the process is opposite. The determined SIR model is regarded as a macroscopic change. The stochastic SIR model is a microscopic action, which determines the change of a single person each time, which is more in line with objective changes. The changes in the three types of populations in the SIR model are not achieved overnight, so the stochastic SIR model is more convincing and more reasonable than the determined SIR model.

2.5. Statistical Methods. SPSS 22.0 data analysis software was used to analyze the data. The counting data were expressed as a percentage, and the measurement data were expressed as mean ± standard deviation. Analysis of variance was used to compare the data between groups, and $P < 0.05$ was considered statistically significant.

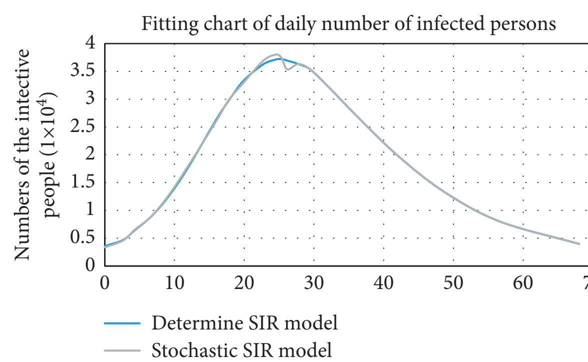

Figure 5: Fitting graph of the number of daily infected persons of determined SIR model and stochastic SIR model.

3. Results

3.1. Results Comparisons. The percentage error between the daily number of infected people and the actual number after February 12, the comparison between the fitting number of infected people and the real number, and the comparison of the number of displaced people are shown in Figure 6. For accurate data, the error control was better. There was not much difference between the fit number and the real number of infected people. There was a certain error in the fitting of the number of patients removed, which may be caused by a large number of patients during the epidemic and the failure of timely treatment and death of some patients or their self-healing.

3.2. Estimation of the Basic Regeneration Number. The variation of effective regenerative number and the relationship between basal regenerative number and herd immunity are shown in Figure 7. The effective number of regenerations in the first day was the basic number of regenerations, and the effective number of regenerations decreased as the susceptible person became infected. After the isolation of infected

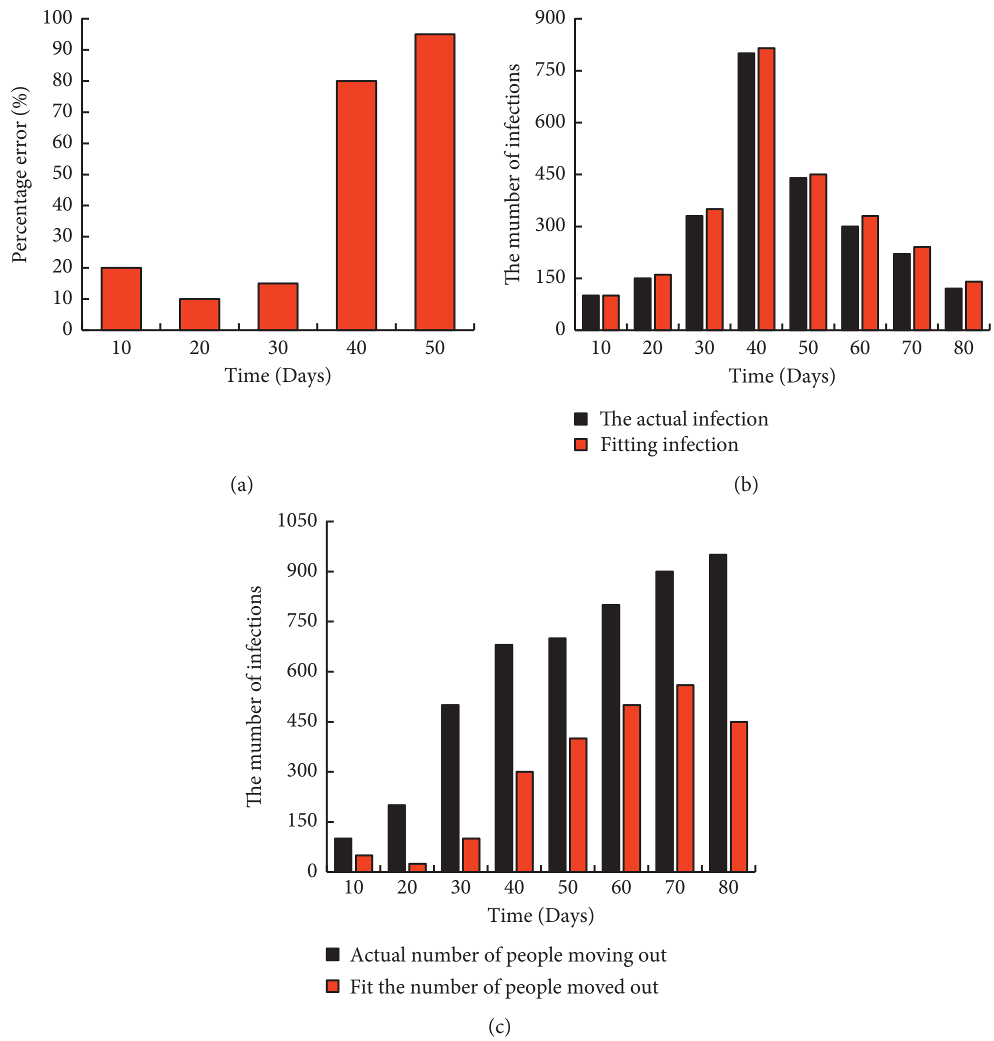

Figure 6: Comparison of fitting results. (a) Percentage of error between the daily infected number and the actual number. (b) Comparison between the actual number of people and the fitted number. (c) Comparison of the number of migrants.

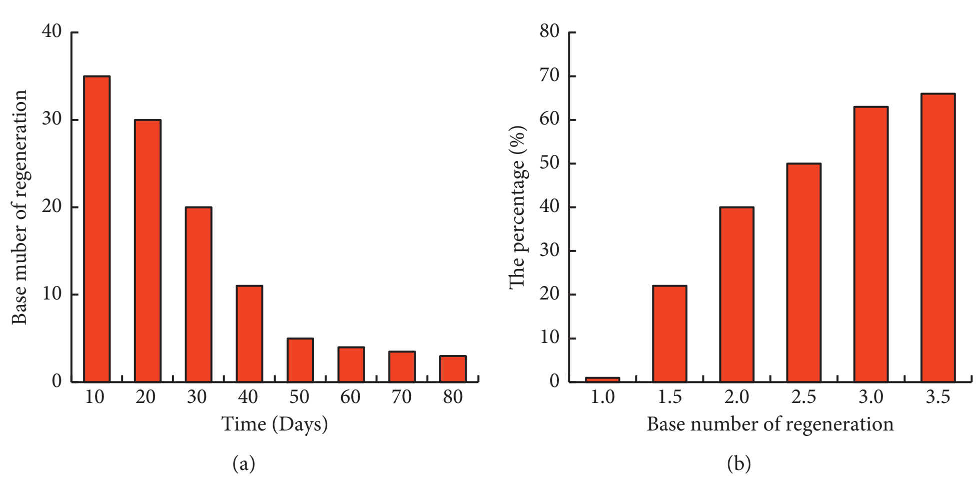

Figure 7: Analysis of basic regenerative number. (a) The variation of the base regeneration number. (b) Relationship between basal regenerative number and the proportion of herd immunity.

people and other measures, the susceptible group continued to shrink. The effect of herd immunity was achieved when the immune population reached 70.9% in the population, that is, when the basic regeneration number was less than or equal to 1. When the base regeneration number was less than or equal to 1, the outbreak would only occur in a small area and ended quickly.

3.3. Influences of Infection Intensity on the Development of the Epidemic. The number of people infected under different infection intensities is shown in Figure 8. When β decreased to 30%, the peak number of infections decreased significantly, and when β decreased to 50%, the peak number of infections decreased further. As β went down, the ability of the new coronet to infect went down, so did the peak number of infections. Although it had a small effect on the total number of people infected, it can slow the progression of the epidemic and reduce the pressure on medical care by delaying the peak.

3.4. The Impact of Vaccines and Other Measures on the Outbreak. Figures 9 and 10 show the comparison of 30% vaccine-covered and 30% vaccine-covered and quarantined with no measures of infection. When vaccine coverage reached 30 percent, both the peak daily patient count and the cumulative number of patients declined by 34 percent. When the vaccine was covered by 30% and the isolation measures were taken, the peak daily cumulative number of patients and the total cumulative number of patients decreased further, by 70%. Vaccine coverage and isolation control were proven effective.

4. Discussion

Infectious diseases have always been one of the common and dangerous factors threatening human life and health. Because of their tendency to spread on a large scale, they lead to not only the demise of individuals but also the demise of species, nations, and even civilizations. Civilizations have been wiped out by infectious diseases throughout human history. Early Spanish explorers to Latin America, for example, discovered that the Mayas and Incas who had lived there for generations were wiped out by smallpox [6]. In addition to that, there have been a number of similar epidemics in human history, such as the plague in the heartland of Mongolia in the east and the Black Death in the west. These have caused great disasters to human society. There were many similar cases. In ancient China, there were 261 plague cases recorded, and some scholars even found records of plague in oracle bones. To sum up, infectious diseases have a huge impact on human society [7]. Human beings have never stopped fighting against infectious diseases. As early as the pre-Qin period, China cut off the source of infection through isolation and other means. Modern western scholars performed smallpox virus research, and the smallpox virus has been eliminated. Another example is the outbreak of plague in Northeast China during the period of the Republic of China. Liande Wu, a medical doctor, was ordered to stop a deadly infectious disease [8].

With the continuous development of modern science and technology and medical treatment, the medical level has improved a lot. Human research on infectious diseases is deepening, but bacteria and viruses are also constantly mutating and evolving. All kinds of new pathogens emerge in an endless stream. For example, there was the outbreak of hepatitis C in China in 1989 and the middle east respiratory syndrome (MERS), which was prevalent in a small area in the Middle East a few years ago, and SARS which was prevalent in a large area in the world in 2003. In recent years, as the range of human activities continues to expand, the boundary between human beings and nature is getting lower and lower, which leads to the increasing probability of human being being infected with infectious diseases [9]. For example, the H1NI virus which emerged in 2009 originally appeared in birds. After continuous mutation, it eventually became parasitic on people. It took the lives of tens of thousands of people in the United States and caused a huge burden to the American society. There are more than 3,000 known viruses, and this is just the tip of the iceberg. Human beings have a long way to go in the prevention and treatment of infectious diseases [10].

Using models to study infection began as early as the 18th century. The concept of establishing a model to solve the spread of infectious diseases was first proposed by Bernoulli when he studied the smallpox virus. By the middle of the 20th century, scientists began systematic research on it. In 1926, Kermack and Mckendrick proposed the classic susceptible-infected-removed (SIR) warehouse model [11]. Various subsequent models were proposed based on that. Later, as the research on infectious disease models continues to deepen, scientists have further subdivided and characterized different infectious diseases, such as SIR and SIES models. In recent years, infectious disease models have developed rapidly with the development of computing power and big data. Many scientists modeled various infectious diseases [12]. For example, some scientists established an SIR model with H1N1 as the research object and conducted a simulation study on it [13]. There were many similar examples. A large amount of research data showed that the establishment of infectious disease research models can effectively predict the development trend of infectious diseases, which was extremely important for the treatment and control of infectious diseases. The establishment of infectious disease models has occupied an irreplaceable and important position in modern infectious disease research. Therefore, the SIR model and SIR stochastic model based on deep learning were established in this work to explore the development law of the COVID-19.

COVID-19 is one of the current coronaviruses that can infect humans. On December 1, 2019, the first suspected case of COVID-19 was admitted to Jinyintan Hospital in Wuhan. After that, major hospitals in Wuhan received similar unidentified pneumonia patients one after another. The Wuhan Municipal Health Commission started an epidemiological investigation on December 29. On January 8, 2020, experts from the National Health Commission of China announced that the pathogen was

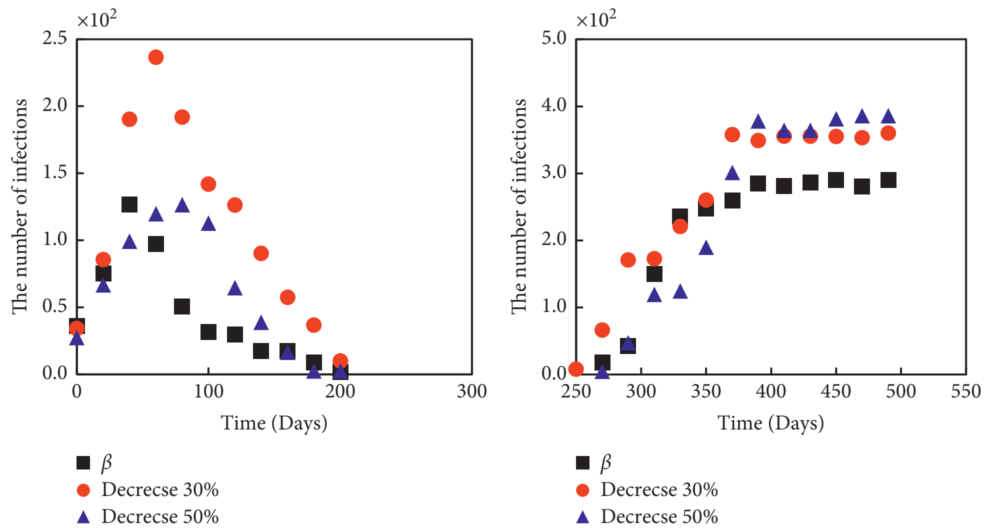

Figure 8: Number of infected persons under different infection intensities.

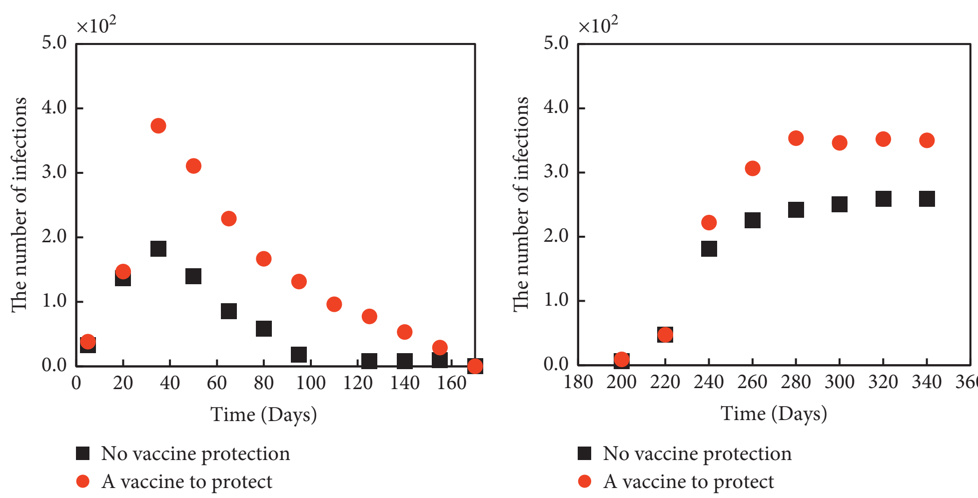

Figure 9: Comparison of the number of infected persons with vaccine coverage and those without vaccine coverage.

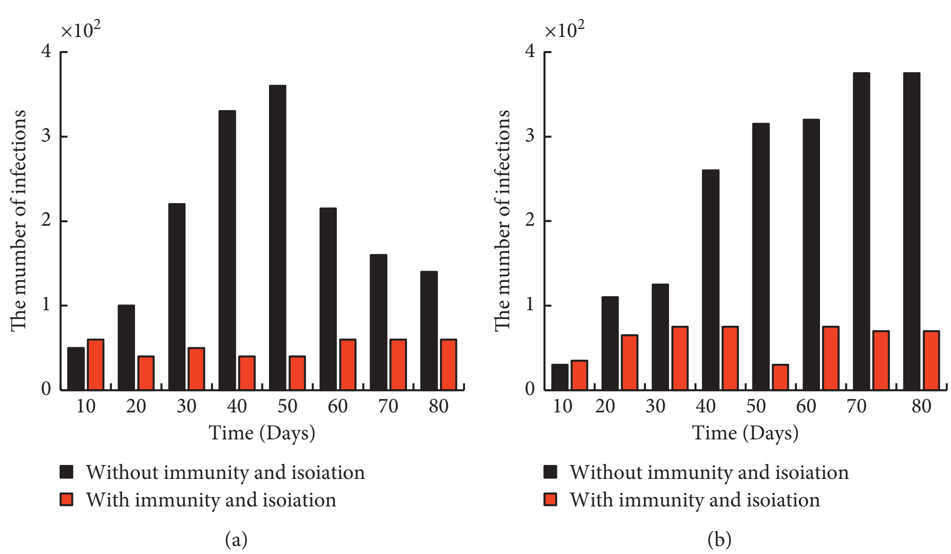

Figure 10: Comparison of 30% vaccine coverage plus isolation and no measures.

a novel coronavirus. According to the report of the Wuhan Health Commission on January 16, 41 new patients were reported in Wuhan, and 19 new cases were reported on January 19. Zhong Nanshan, head of the national expert team, said on January 20 that the disease was "human-to-human infectious" and that 217 new cases had been reported in Wuhan that day [14]. The first cases were reported in Tianjin, Jiangxi, Zhejiang, and Henan provinces on January 21, marking the start of a full-scale outbreak of COVID-19 in China. As of March 1, the total number of confirmed cases in China has reached 80,000. Meanwhile, other countries have also reported the emergence of novel coronavirus infection. At present, the epidemic in China has been basically brought under control through continuous efforts. However, the epidemic continues to spread in other countries and the international situation is still grim. Against the background of global economic integration, the prevention and control of the epidemic must not be slackened. Currently, research on the COVID-19 model is mostly focused on the whole region. There have been very few studies on hospitals. However, as the main battlefield of antiepidemic, it is very necessary to study the law of epidemic transmission and its control transmission. Specifically, health care workers are more likely to come into contact with patients and get sick. When health care workers get sick, it not only is a major blow to the health care system but also increases the risk to the general population this is extremely detrimental to the prevention and control of the epidemic [15].

Therefore, a retrospective analysis of the occurrence of COVID-19 in hospital was performed by using the SIR model based on deep learning and the SIR stochastic model. Based on the SIR model, the COVID-19 epidemic situation in Wuhan was studied, and the research time was from January 23, 2020, to March 31, 2020. The law of the spread of the epidemic was discovered through daily epidemic information and restoring of its development process. Finally, some valuable information was obtained through the model, which had positive significance for potential prevention and control work in the future. The determined SIR model and stochastic SIR model were taken as the core, and then the Wuhan area was modeled. First, S_0 was used as the parameter to be estimated, and its range was determined by MATLAB to find a better fitting effect. Then, the obtained o value was used to find β and Y suitable for the Wuhan area. In the stochastic SIR model, the continuous-time Markov Chain was used to fit S_0, B, and y again. The residual square SSE chart of the daily number of infected persons was plotted through the computer running 5,000 orbits, and the extreme points of the infection intensity B and the recovery intensity were found, which were compared with the determination of the SIR equation, and the error was within a reasonable range. Then, a simulation of 10,000 orbits was implemented to draw a simulation diagram of the three groups of people, which showed that the determined SIR model was the mean process of the stochastic SIR model without considering the covariance. Finally, the different results of changing the intensity of infection and the intensity of removal on the development of the epidemic were discussed. It was found that quarantine, vaccine, and other measures had an impact on the development of the epidemic. The intensity of infection was a key factor affecting the outbreak. It was also found that the SIR model and stochastic model based on deep learning had an ideal prediction effect on the development trend of the epidemic.

5. Conclusion

The deep learning SIR model and stochastic SIR model were used to retrospectively study the occurrence of COVID-19 in hospital. It was found that the above two models were accurate in predicting the development trend of the epidemic and had a high prospect in hospital epidemic control. In addition, vaccine, isolation, and infection intensity had a great impact on the development of the epidemic, and the epidemic can be controlled from these three aspects when similar situations occur in the future. However, due to the limited sample and space, the study on this issue is not comprehensive and in-depth enough. In future study and work, it will expand the sample for further study.

This work was developed based on the determined SIR model and stochastic SIR model. Although some effects were achieved in predictive analysis, there are many shortcomings. First, the variability of B and y is not fully considered, which are set as a constant. From the beginning to the end of the epidemic, B and y may change due to various reasons such as the government's control and the update of medical resources, so the patient's ability to get infected should go down, and the level of recovery should go up as various drugs are tested, In the future, we can consider its time-varying function to conform to objective facts. Secondly, the description index of the model is too single. For the most critical infection intensity and recovery intensity, population mobility, medical resource level, and aging rate in each region are different, which are all important parameters affecting the accuracy of the model. In the future, it can be considered as a breakthrough to continuously optimize model equations and parameters to achieve more accurate results.

The aim of this research was to explore the relationship between depression and brain nerve function in patients with end-stage renal disease (ESRD) and long-term maintenance hemodialysis (MHD) based on watershed segmentation algorithm using diffusion tensor imaging (DTI) technology. A total of 29 ESRD patients with depression who received MHD treatment in the hemodialysis center of hospital were included as the research subjects (case group). A total of 29 healthy volunteers were recruited as the control group, and a total of 29 ESRD patients with depression and brain lesions were recruited as the control group (HC group). Within 24 h after hemodialysis, the blood biochemical indexes were collected before this DTI examination. All participants completed the neuropsychological scale (MoCA, TMT A, DST, SAS, and SDS) test. The original DTI data of all subjects were collected and processed based on watershed segmentation algorithm, and the results of automatic segmentation according to the image were evaluated as DSC = 0.9446, MPA = 0.9352, and IOU = 0.8911. Finally, the average value of imaging brain neuropathy in patients with depression in the department of nephrology was obtained. The differences in neuropsychological scale scores (PSQI, MoCA, TMTA, DST, SAS, and SDS) between the two groups were statistically significant ($P < 0.05$). The differences of FA values in all the white matter partitions of Fu organs, except the cingulum of hippocampus (CgH) between the two groups, were statistically significant ($P < 0.05$). ESRD and DTI quantitative detection under the guidance of watershed segmentation algorithm in MHD patients showed that ESRD patients can be early identified, so as to carry out psychological nursing as soon as possible to reduce the occurrence of depression, and then protect the brain nerve to reduce brain neuropathy.

1. Introduction

End-stage renal disease (ESRD) [1] is a worldwide public health problem. It generally refers to the middle and late stages of various types of chronic kidney diseases and has a certain degree of similarity with the concept of uremia. However, there are still some differences in diagnostic criteria. Generally, ESRD can be diagnosed when the glomerular filtration rate is low to a certain standard. This standard is generally recognized as 15 mL (min.1.73 m^2) as the standard line. When the chronic kidney disease reaches the fifth stage, it enters the ESRD. At this stage, with the further decline of renal function, toxins continue to accumulate in the body, which may cause various symptoms of uremia. Generally, it relies on continuous maintenance dialysis or looking for appropriate renal sources for transplantation replacement therapy [2, 3]. In the ESRD for a long time, a large number of toxins accumulated in the body may cause damage to multiple important organs in the body. The central nervous system is the most likely to be affected. The central nervous system may cause many complications after injury, such as cerebrovascular injury, behavioral cognitive impairment, brain atrophy, cerebral infarction, and depression. According to relevant data, about 60% of ESRD patients have cognitive impairment, so it is of great significance to diagnose and intervene the brain structure changes of renal disease patients as soon as possible [4, 5]. However, the exact pathogenesis of cognitive impairment in ESRD patients is still unclear. Diffusion tensor imaging (DTI) can quantitatively display the abnormal pathological changes of white matter microstructure [6], and tract-based spatial statistics (TBSS) is a more ideal imaging method for automatic and efficient evaluation of white matter fiber integrity [7].

Watershed algorithm is a kind of algorithm technology derived from geodesy topology. It has many advantages, and the logical ideas in the algorithm are easy to understand. Therefore, it is widely used in various fields. Now, it is mainly used in image segmentation [8, 9]. The gradient map of the image to be segmented is regarded as the topology in geodesy [10, 11]. Watershed algorithm is a kind of applied morphology in general. Its main idea is to analogize the selected target image to topography. The gray value of the image represents the altitude of the terrain, and the gray pixels in the image represent the valleys and peaks in the terrain. It is assumed that a hole is placed on each extreme point of the gray pixel, and the analogy model is put into the water. At this moment, the terrain and area formed by the process of water rising from the extreme point are basins. Different catchment basins in the image are about to converge, and the junction of its convergence becomes a watershed [12]. The watershed algorithm is a mathematical morphological method, which belongs to a region segmentation technology, and is an effective image segmentation method. In addition, it is featured with fast calculation speed and more accurate positioning, so it has many applications in the field of image analysis. Marking extraction in an image is a method of controlling oversegmentation. The minimum value area of the original gradient image is forcibly modified by the previously mentioned marking, and irrelevant minimum values in the original gradient image are shielded, showing very good segmentation effect. DTI is currently the only noninvasive examination method that can track white matter fiber tracts in vivo and effectively observe it. It can directly show the spatial relationship between acute cerebral infarction lesions and fiber tract, so as to judge the severity of brain injury. At this stage, there are relatively few studies on the watershed algorithm in MRI DTT imaging on depression and brain nerve function in patients with ESRD. Therefore, in this study, the watershed algorithm was adopted to the image processing network, the DTI technology was applied to image the patient's CST, and the DTI images of brain injury were collected to understand the sleep, anxiety, and depression of patients in time and develop treatment plans for the patient as soon as possible to improve prognosis, so as to provide help for clinical diagnosis and treatment.

2. Methods

2.1. Research Objects. Twenty-nine ESRD patients who underwent hemodialysis in the hemodialysis center of the department of nephrology at a tertiary hospital from October 2018 to November 2019 were enrolled as the case group. Twenty-nine local healthy volunteers matched with the case group in age, gender, years of education, anxiety, depression, and sleep quality scores were enrolled. All subjects were educated for ≥6 years and were right-handed (Figure 1).

2.2. Inclusion and Exclusion Criteria. The inclusion criteria were as follows: (1) patients diagnosed with ESRD, according to K/DOQI chronic kidney disease classification criteria; (2) patients who underwent regular dialysis for three months; (3) patients with no history of renal transplantation or acute renal failure; (4) patients without previous headless trauma, intracranial occupation, stroke, mental and neurological diseases, metabolic diseases, and other diseases that may affect the nervous system; (5) patients with no history of smoking, drug addiction, or alcoholism; and (6) patients without MRI contraindications. This study was a prospective study and was approved by the hospital ethics committee. All subjects signed informed consent. The participants' general demographic information, conducted neuropsychological tests and MR scans, and relevant blood biochemical indexes were collected.

The exclusion criteria were as follows: (1) patients with lesions >1.0 cm in the brain confirmed by clinical history and conventional MRI examination, such as cerebral hemorrhage, cerebral infarction, and brain tumors; (2) patients who cannot complete the neuropsychological scale test; and (3) patients with MRI contraindications.

2.3. Watershed Segmentation Algorithm. Watershed algorithm is a kind of algorithm technology derived from geodesic topology. It has many advantages, and the logical ideas in the algorithm are easy to understand. Therefore, it is widely used in various fields. Now, it is mainly used in image segmentation [13, 14]. By applying this method to the field of image segmentation, it has made a significant contribution to optimizing the segmentation effect of the image. With further research on the watershed algorithm, the mathematical morphology technology was added to the segmentation field. Therefore, the complexity of the watershed algorithm is gradually improved, and the effect of the segmentation image is further improved. In different scenes and fields, the label and segmentation of the target image are realized at different levels, and the outline of the label parts after segmentation is clear.

The basic definition of watershed algorithm is as follows: the two-dimensional image N to be segmented is selected to set the discrete value in the interval of [0, M]. The image is defined as a gray image, where M is a positive number, and the following conditions need to be met:

$$D_N \varepsilon R^2 \longrightarrow \{0, 1, \ldots, M\}, \quad (1)$$

$$F \longrightarrow N(F). \quad (2)$$

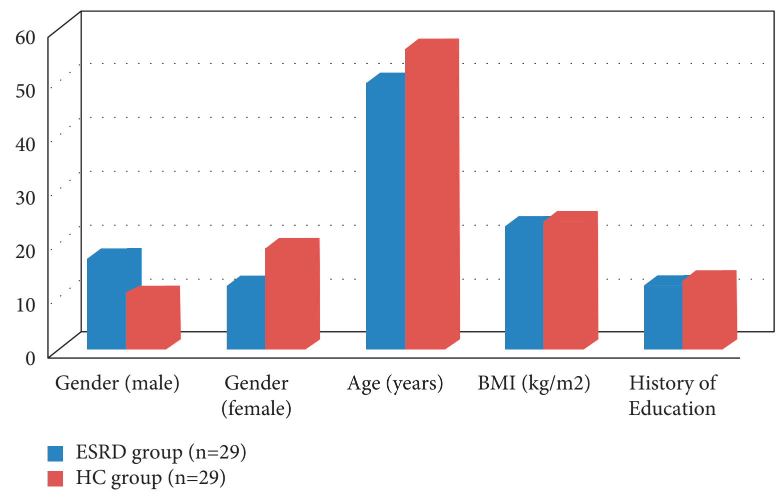

Figure 1: Comparison of differences in population data of subjects.

Let U be a grid, which represents a subset of the set $R^2 \times R^2$. Each grid has different names according to the number of grids contained in it.

Definition 1. Pixel set with height of H is selected from the selected image N.

$$T_H = \{F \in D \mid N(F) \leq H\}. \tag{3}$$

H represents the threshold, and n_A (α, B) geodesic distance is used to represent the distance between two points. The selection of these two points needs to satisfy a, $b \in A$. If $B \subseteq A$ appears, region B is divided into random G regions, and G regions are connected with each other, denoted as B_i, where $i = 1,\ldots,G$.

Definition 2. In set A, B_i divided into random regions is selected, and the solution equation of the influence region corresponding to this part is as follows:

$$\mathrm{NR}_A(B_i, B) = \left\{F \in A \mid (F, B_i) < N_A\left(F, \frac{B}{B_i}\right)\right\}. \tag{4}$$

Definition 3. Connect B and B_i to form a collection NR_A (B).

$$\mathrm{NR}_A(B) = \bigcup_{i=1}^{G} iR_A(B_i, B). \tag{5}$$

Definition 4. In set A, the absolute complement SKIZ of $\mathrm{NR}_A(B)$ is considered to be the skeleton affecting some regions.

$$\mathrm{SKIZ}_A(B) = \frac{A}{NR_A(B)}. \tag{6}$$

After the pixels in the foreground part are concentrated, the SKIZ is obtained, and the following equations are derived:

$$z_{h_{\min}} = \{F \in D \mid N(F) = h_{\min}\} = T_{h_{\min}}, \tag{7}$$

$$z_{G+1} = \mathrm{MIN}_{h+1} \cup NR_{T_{h+1}}(z_h), \quad h \in [h_{\min} - h_{\max}]. \tag{8}$$

Definition 5. In D, the watershed region Wshed (f) is the absolute complement set corresponding to $z_{h_{\max}}$.

$$\mathrm{Wshed}(\mathrm{f}) = \frac{D}{Z_{h_{\max}}}. \tag{9}$$

If there is a big difference in the gray value between the selected image and the target image background, then it is believed that the segmentation effect is better. If the difference between the both is not obvious, the phenomenon of "undersegmentation" easily appears. Therefore, the contrast of the image is enhanced to a certain extent, and the mathematical morphology technology is added into the segmentation field, so that the gray value between the selected image and the background of the target image is greatly different. Let ut (x, y) and $f(x, y)$ denote the denoised image and the gray image, respectively, and carry out the top-cap transformation on $f(x, y)$ to retain the region with large brightness in the original image. The top-hat transformation result is as follows:

$$h = f - (f \circ b). \tag{10}$$

b represents the structural element. $f \circ b$ represents the opening operation of b to f. The bottom-cap transformation is performed on $f(x, y)$ to save the dark details in the image. The bottom-cap transformation result is as follows:

$$j = (f \bullet b) - f. \tag{11}$$

$f{\cdot}b$ denotes closed operation b to f. $h(x, y)$ and $j(x, y)$ are added to get contrast enhanced gray image.

$$i(x, y) = h(x, y) + j(x, y). \tag{12}$$

$i \oplus b$ and $i \Theta b$ represent the expansion operation and corrosion operation of b to i, respectively, and the gradient of morphological image is as follows:

$$g = (i \oplus b) - (i \Theta b). \tag{13}$$

The flowchart of improved watershed segmentation algorithm is shown in Figure 2.

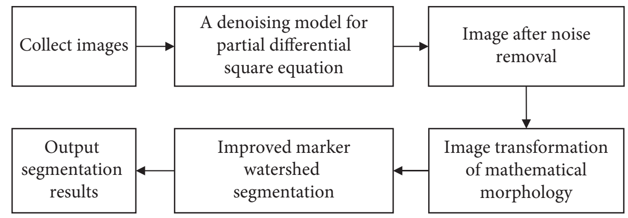

Figure 2: Image segmentation process based on improved watershed algorithm.

2.4. Assessment of Depression. Center for Epidemiological Survey, Depression (CES-D) was used to evaluate depression. One-way analysis of variance (ANOVA) was used to compare the differences among the three groups in terms of age, years of education, neuropsychological scale score, and DTI parameters (FA, MD, AD, and RD values) between the two groups. CES-D was designed to evaluate the frequency of current depressive symptoms, focusing on depression emotion or mood. CES-D, also known as the self-rating depression scale of stream invocation, was prepared by Sirodff at the National Institutes of Mental Health in 1997, known as the center for epidemiological studies depression scale. It is widely used in the field of depression diagnosis and is used in the clinical screening of patients with depressive symptoms in order to further check and diagnose them. Some also used an individual emotional examination to assess the severity of depressive symptoms. Compared with other self-rating depression scales, CES-D focuses more on the individual emotional experience and less on the somatic symptoms in depression. The minimum score of depression was 0, and the maximum score was 60. Psychologists set the 16 points as the dividing point. Those who scored above 16 points belonged to the depressed group, and those who scored below 16 points belonged to the nondepressed group. Sixteen to twenty points indicated mild depression, 21–25 points indicated moderate depression, and 26–60 points indicated severe depression. The degree of depression is easily affected by mood and mental state, so the measurement results may be different at different times, which is normal.

2.5. Inspection Equipment

2.5.1. DTI Examination. All subjects underwent examination and data acquisition using Siemens Verio 3.0T superconducting magnetic resonance imaging (Magnetom Verio 3.0T) and used 12-channel standard head coil. The specific process and DTI parameters were as follows. Single excitation white-spin plane echo sequence was used. Specific parameters are as follows: echo time (TE) = 86 ms, repeat time (TR) = 11908 ms, slice number (slice) = 65, slice thickness (ST) = 2 mm, matrix size (MS) = 128 x 128, field of view (FOV) = 244 mm × 244 mm, voxel size (VS) = 2 mm × 2 mm × 2 mm, diffusion weighted directions = 30, and b value = 0s/mm^2, 1000s/ram^2. The total examination time was 12 min and 56 s.

2.5.2. Blood Biochemical Examination Information. Before this MRI examination and within 24 h after hemodialysis, the patient group was tested for the following clinical biochemical indicators: serum creatinine (Scr), blood urea nitrogen (BUN), blood kalium (K), blood calcium (Ca), and blood phosphorus (P).

2.5.3. MRI Examination. The nuclear magnetic resonance (NMR) scanning equipment, 1.5 T HDC nuclear magnetic superconducting magnetic resonance scanner of the United States, with 8-channel head coil, was used. The patients were allowed to maintain supine posture on the check bed. The head and neck joint coil was used to fix the head of the patients. The quality of the head coil was tested before routine scanning to ensure that the 12 channels of the coil were all working properly. Subjects wore earplugs to avoid excessive noise affecting the tester' s state, and then, all the MRI scan lights were turned off to avoid unnecessary light interference.

2.6. Statistical Method. SPSS19.0 software was used for statistical analysis. Measurement data conforming to normal distribution were expressed as mean ± standard deviation, and the difference between groups was analyzed by independent sample t-test. The measurement data that did not conform to the normal distribution were represented by median and quarter position, and the difference between groups was analyzed by nonparametric rank sum test. Count data were expressed as n (%). Differences between groups were analyzed by chi-square test. Pearson correlation analysis was performed for DTI diffusion index, depression score, and clinical biochemical index. $P < 0.05$ was considered statistically significant.

3. Results

3.1. Correlation Analysis of DTI Diffusion Indexes with Depression Score and Clinical Biochemical Indexes Based on Segmentation Algorithm. The correlation analysis in this study showed that the FA value in the anterior part of the left corona was positively correlated with the DST score ($r = 0.586$, $P = 0.007$). The FA value of the right hook was positively correlated with MoCA score and negatively correlated with TMTA ($r = 0.545$, $P = 0.013$; $r = .0.464$, $P = 0.039$). Left Nd and subiculum MD values were negatively correlated with depression score ($r = -0.463$, $P = 0.040$). There was no correlation between the values of FA, MD, AD, and RD in all the different brain regions and PSQI scores ($P > 0.05$). In addition, there was no significant correlation between the results of DTI dispersion indexes and the blood biochemical indexes of the subjects ($P > 0.05$) (Figure 3).

The segmentation results of the target image based on the watershed algorithm model are shown in Figure 4. The results of automatic segmentation based on the image were evaluated as $DSC = 0.9152$, $MPA = 0.9229$, and $IOU = 0.8450$. In order to improve the segmentation accuracy of the watershed model, the watershed algorithm with fine-tuning weight was tested to segment the target image. The image was processed independently under the algorithm processing, but the processing results were continuous and stable in time. The results are shown in Figure 4. The evaluation of the automatic segmentation results based on the image was $DSC = 0.9446$, $MPA = 0.9352$, and $IOU = 0.8911$.

3.2. Comparison of Neuropsychological Cognitive Scores among Subjects. The differences in MoCA score and TMT_A score between the ESRD group and the HC group were statistically significant (Figure 5).

3.3. Comparison of Difference Values in DIC Measurement of Brain Volume by ESRD. Compared with the HC group, almost all white matter areas of ESRD maintenance hemodialysis patients had decreased FA value and increased MD value and RD value. Only in the right superior corona radiata, left superior corona radiata, right superior longitudinal bundle, the difference was statistically significant ($P < 0.05$) (Figure 6).

3.4. Comparison of General Condition between Depression Group and Nondepression Group. A total of 176 questionnaires were distributed to patients with regular hemodialysis for more than half a year in the hemodialysis room and were distributed and recovered by the competent nurses in the dialysis room. The recovery rate was 100%. There were 103 males and 73 females, with an average age of 61.24 ± 12.08 years. There were 58 cases in depression group and 29 cases in nondepression group. The number of depression accounts for 66% of the total. The general status of the two groups was significantly different in personal monthly income and working status ($P > 0.05$) (Figure 7).

3.5. Analysis of Brain Neuropathy Caused by Depression in Patients with ESRD. Depression often leads to the expansion of physical symptoms in patients with cerebral stroke, which generally causes double damage to the normal physical and social functions of patients, and at the same time seriously affects the self-psychological adjustment function of patients. The impact of psychological problems often leads to patients giving up or interrupting treatment, and then, they lose hope for subsequent life and recovery, which directly or indirectly affects the positive cooperation of patients in clinical treatment, thus affecting the best time for rehabilitation of patients and causing serious burdens on families and society (Figure 8). After stimulation of the vagus nerve, the brain activity of patients increased significantly. Patients with severe depression should communicate effectively with the attending physician timely and relieve anxiety and depression as much as possible after using certain antidepressant drugs. Then, further psychological treatment and psychological care were conducted. Figure 8 is a DWI image of the patient's skull. Both T2 and diffusion effects can cause DWI signal enhancement, and lesions with reduced or limited diffusion had higher signals on DWI images. In the imaging process, there was false positive performance with reduced dispersion due to the residual T2 component. Figures 8(a)–8(d) all show the characteristics of clear imaging and high resolution.

4. Discussion

ESRD is the end stage of chronic renal failure [15]. It generally refers to the middle and late stages of various types of chronic renal diseases, which is somewhat similar to the concept of uremia, but there are still some differences in the diagnostic criteria. When the chronic renal disease reaches the fifth stage, it enters the end stage of renal disease. At this time, with the further decline of renal function, the patients continue to accumulate toxins in the body, which may cause various symptoms of uremia. The patients generally maintain their normal life through hemodialysis. In addition, if the appropriate renal source can be found for transplantation and replacement, it can be treated. However, the psychological state of patients with such diseases often has various problems, among which depression is the most common [16, 17]. Studies showed that the incidence of depression in ESRD hemodialysis patients is much higher than that in the general population of 20%–30%. Depression is very harmful to hemodialysis patients. Studies indicated that depression in patients before dialysis treatment can produce a series of psychosomatic reactions, increasing the incidence and mortality of cardiovascular diseases [18]. The incidence of depression in ESRD hemodialysis patients was 42.2%, higher than foreign reports. The reasons may be related to the personality and mental stress of Chinese people and factors such as personal tolerance and economic level [19]. The study of Yoong et al. [20] showed that 49.9% of ESRD patients experienced increased depression, and 45.4% of ESRD patients experienced increased anxiety during treatment. The high proportion of anxiety and depression emphasizes the importance of testing and nursing care for ESRD patients during dialysis care. Mu et al. [21] segmented rough semantics in DTI images based on the feature extraction of deep learning, realized super pixel segmentation algorithm, used boundary optimization algorithm to optimize the segmentation accuracy of image edges, and improved the accuracy of image segmentation. In this study, the watershed algorithm was applied to the DWI imaging of patients with brain diseases, which had significant value for the early diagnosis of ESRD patients and psychological care. The correlation analysis of the DTI diffusion index of the segmentation algorithm in the image with the depression score and clinical biochemical indicators. The results showed that the FA value of the anterior left crown was positively correlated with the DST score

($r = 0.586$, $P = 0.007$). The FA value of right uppercut was positively correlated with MoCA score ($r = 0.545$, $P = 0.013$) and negatively correlated with TMTA ($r = 0.464$, $P = 0.039$). The correlation between the results of DTI dispersion index and the blood biochemical indexes of subjects was not significant. The left Nd and subiculum MD values were

negatively correlated with depression scores ($r = -0.463$, $P = 0.040$).

DTI technology is one of the most effective tools for noninvasively studying the structural and pathological changes of white matter (WM) at the microstructure level. It uses the diffusion anisotropy of water molecules in human tissues, uses various parameters to reflect the direction and degree of water molecule movement in fiber bundles, and visualizes the changes of WM microstructure. The main parameters include the following [22]: fractional anisotropy (FA), axial diffusion coefficient (AD), radial diffusion coefficient (RD), and mean diffusion rate (MD). Moreover, based on the imaging features of watershed segmentation algorithm, ESRD can be diagnosed early. Early treatment can reduce the medical costs, relieve economic pressure, and reduce depression complicated with brain lesions. Asman et al. [23] segmented the medical images and converted the TI-weighted DTI imaging data of the label information of the multiatlas segmentation into fully automated. The segmentation method constructed in the article showed a good effect on the FA of the measured image.

In this study, DTI technology is used to explore the correlation between depression and brain neuropathy in ESRD patients based on methods. The following conclusions are drawn: early diagnosis of ESRD based on watershed segmentation algorithm is conducive to early treatment and reduce depression and brain lesions in ESRD patients.

5. Conclusion

The purpose of this study is to use the watershed algorithm to segment the DTI image of the brain of ESRD patients and further analyze and explore the relationship between depression and brain nerve function of ESRD patients. The original DTI data of all subjects were collected and processed based on the watershed segmentation algorithm, and the results of automatic segmentation were evaluated as $DSC = 0.9446$, $MPA = 0.9352$, and $IOU = 0.8911$. The analysis of DTI images after watershed algorithm segmentation suggested that the WM microstructure of patients had undergone a certain degree of change and atrophy, and three main WM fibers had undergone lesions. However, the research content still has some limitations. This study only focuses on a single imaging diagnosis method, and the number of samples is not large enough. Therefore, it is necessary to increase the number of samples and deepen the further exploration of watershed algorithm. In conclusion, this study can analyze and judge the relationship between depression and brain nerve function in ESRD patients through watershed algorithm, which provides certain data support and theoretical basis for the diagnosis and treatment of depression in ESRD patients. The only shortcoming of this study was that the number of cases was not large and the number of subjects included in the experiment was limited. At a certain time, multiple centers can be used to conduct experiments, and the algorithm dataset training required a lot of data, so follow-up work needed to increase the training dataset and increase the accuracy.

Objective. The study focused on the separation effects of ultrasound blood flow signal detection, based on empirical mode decomposition (EMD) algorithm, and the clinical efficacy of Compound Danshen injection and magnesium sulfate in the treatment of pregnancy-induced hypertension (PIH) syndrome. *Methods*. The empirical mode decomposition (EMD) algorithm was optimized first and compared with other algorithms for the accuracy and stability in separation of blood flow signals. 80 patients with PIH syndrome undergoing ultrasound examination were selected as the research subjects and randomly divided into control group and observation group according to the actual treatment methods. 40 cases in the observation group were treated with Compound Danshen injection + magnesium sulfate, and 40 cases in the control group were treated with magnesium sulfate. After the treatment, the clinical indicators of the two groups of patients were analyzed. *Results*. The accuracy and stability in separating blood flow signal of the optimized EMD algorithm were better than those of other algorithms. After treatment, the total effective rate and blood pressure control of the observation group were significantly better than those of the control group, and the incidence of adverse maternal and infant outcomes was significantly lower than that of the control group. After treatment, the endothelin-1 (ET-1), C-reactive protein (CRP), and homocysteine (Hcy) indexes of the two groups of patients decreased significantly, and the decrease level of the observation group was significantly greater than that of the control group ($P < 0.05$). The prothrombin time (PT), fibrinogen (FIB), activated partial thromboplastin time (APTT), and plasma thrombin time (TT) levels of the two groups after treatment were better than those before treatment, and the observation group was better than the control group ($P < 0.05$). *Conclusion*. The optimized EMD algorithm is of great value for the separation of ultrasound blood flow signals. For patients with PIH syndrome, Compound Danshen injection combined with magnesium sulfate can be used as a treatment plan, which can improve maternal and infant outcomes; control blood pressure; reduce 24 h urine protein and serum ET-1, Hcy, and CRP levels; and improve coagulation function. It is worthy of promotion.

1. Introduction

Usually, pregnancy-induced hypertension (PIH) syndrome occurs in women with more than 20 weeks of pregnancy. Clinically, it mainly manifests itself as hypertension, proteinuria, and edema of limbs [1, 2]. PIH syndrome threatens maternal and infant health and can easily cause adverse events such as premature delivery, eclampsia, postpartum infection, or hemorrhage, which is not conducive to pregnancy outcome [3, 4]. Currently, the etiology of hypertension in pregnant women is mainly summarized as systemic small vasospasm [5]. Therefore, in practice, it is necessary to relieve systemic small vasospasm, and this strategy has been proved to have a significant effect [6]. Magnesium sulfate is a clinically effective drug for relieving systemic small vasospasm, and it is found to be effective in the treatment of hypertension in pregnancy [7]. However, the use of magnesium sulfate alone cannot achieve satisfactory results. Compound Danshen injection is a Chinese patent medicine mainly composed of Danshen (a traditional

Chinese medicine to promote blood circulation and dredge meridians) and Jiangxiang (a traditional Chinese medicine to remove stasis and stop bleeding) [8]. Compound Danshen injection has a variety of pharmacological effects, such as expanding blood vessels, improving microcirculation, scavenging oxygen free radical, protecting liver function, and sedating the mind [9], which can effectively lower blood pressure, thereby alleviating vascular endothelial injury [10]. Generally speaking, to treat small vasospasm in patients is to restore the secretion function of nitric oxide and vascular endothelin [11]. Research has found that Danshen has a good effect on improving this function [12].

Ultrasound Doppler technology has become an important method for the diagnosis and efficacy evaluation of diseases of the blood circulatory system, especially cardiovascular diseases, because of its ability to measure blood flow nondestructively. Due to the simplicity and noninvasiveness of ultrasound diagnosis technology, in recent years, ultrasound examination has gradually been used in the functional and morphological evaluation of PIH. Studies have shown that functional and morphological changes (such as endothelial diastolic function and vascular stiffness) are related to the occurrence and development of PIH. However, the blood flow signal detected by traditional ultrasound often contains the signal of the tube wall, which will interfere with the blood flow speed to a certain extent, leading to deviations in the diagnosis and evaluation of the disease. Empirical mode decomposition (EMD) has significant advantages in the processing of nonlinear and nonstationary signals. However, it adds the first few layers as the blood flow signal during the separation process, which leads to a certain deviation in the separation results. Hence, it needs to be further optimized.

In this study, the EMD algorithm was optimized to separate ultrasound Doppler blood flow and vessel wall signals. 80 patients with PIH syndrome were taken as the research subjects to explore the effect of the combined therapy of Compound Danshen injection and magnesium sulfate on PIH, expected to provide reference value for its clinical application.

2. Research Methods

2.1. Research Subjects and Grouping. 80 patients with PIH syndrome admitted to the hospital from July 2019 to August 2020 were selected as research subjects, and they were divided into a control group and an observation group according to different treatments. There were 40 cases in the control group, aged 23–40 years, with an average age of 29.34 ± 7.56 years. The gestational age was 31–41 weeks, with an average gestational age of 34.86 ± 3.95 weeks. There were 31 primiparous women and 9 postpartum women. There were also 40 cases in the observation group, aged 22–40 years, with an average age of 28.55 ± 6.94 years. The gestational age was between 32–41 weeks, with an average gestational age of 35.62 ± 3.80 weeks. There were 32 primiparous women and 8 postpartum women. The inclusion criteria of this study were as follows: (1) meeting the diagnosis criteria for the pregnancy-induced hypertension syndrome; (2) single pregnancy. Patients with other serious gynecological diseases were excluded. The experimental procedure of this study has been approved by the ethics committee of the hospital, and all the subjects included in the study have signed informed consent form. The two groups were compared for the age, gestational age, number of pregnancies, and other data. A P value greater than 0.05 was considered comparable.

2.2. The Separation Method of Blood Flow and Tube Wall Signals Based on EMD Algorithm. The blood flow is the integration of multiple moving blood cells, and the ultrasound Doppler signal scattered back by a single blood particle can be expressed as follows:

$$S_i(t) = A_i B_i \cos[\varphi(t) + \psi_i] C_i^t(t) C_i^r(t), \tag{1}$$

where i represents the number of the particle; A_i indicates the acoustic field characteristics of the particle's location; B_i is the scattering coefficient of the particle.

$C_i^t(t)$ and $C_i^r(t)$ represent the shapes of the ultrasound transmitting gate and receiving gate, respectively; and $\varphi(t)$ is the particle motion coefficient, $\varphi(t) = \omega_0 t + \varphi_d(t)$, where ω_0 is the angular frequency of ultrasonic emission and $\varphi_d(t)$ represents the phase change caused by the motion of the particle.

Assuming that the blood vessel is a straight round tube, the radial distribution of blood flow velocity can be expressed as follows.

$$s(y,t) = 2v_0\left(1 - y^2\right) + \sum_P v_p|\psi|_p \cos\left(\mathrm{pwt} + \varepsilon_p + \chi_p\right), \tag{2}$$

where

$$\psi = \alpha i^{3/2} \frac{J_0\left(\alpha i^{3/2}\right) - J_0\left(y\alpha i^{3/2}\right)}{\alpha i^{3/2} J_0\left(\alpha i^{3/2}\right) - 2J_1\left(\alpha i^{3/2}\right)}, \tag{3}$$

where y is the ratio of the distance from the center of the blood vessel to the radius of the blood vessel; J_0 and J_1 represent the Bessel function of the orders of 0 and 1, respectively; $v_p$represents the magnitude of the p-order Fourier coefficient of the average blood flow velocity curve; ε_p represents the phase of the p-order Fourier coefficient of the average blood flow velocity curve; w is the angular frequency of the heart beat; χ is the phase of ψ; and v_0 is the initial blood flow velocity.

The pulsation of the blood vessel wall can be analyzed by the curve of blood pressure over time. Assuming that the cross-sectional area of the blood vessel is S and the blood pressure is P, the characteristic function of the blood vessel wall can be expressed as follows:

$$S(t) = ae^{bP(t)} + c, \tag{4}$$

where a, b, e are constants related to the physiological characteristics of the blood vessel wall: $a = 3.6\,cm^2$, $b = -0.0119\,mmHg$, $c = 3.05\,cm^2$.

Then, the pulsation velocity curve of the blood vessel wall can be expressed as follows:

$$v(t) = \frac{dr(t)}{dt}, \tag{5}$$

where $r(t)$ is the radius of the blood vessel, $r(t) = \sqrt{S(t)/\pi}$.

According to the Doppler frequency shift formula, the ultrasonic Doppler tube wall signal is calculated as follows:

$$x_w = a_w \exp[i\phi_d(t)], \tag{6}$$

where a_w represents the constant of the signal amplitude of the tube wall.

The original signal is decomposed into the eigenmode function (IMF) of each layer through the EMD algorithm, and the original signal is finally $N-1$ decomposed into $N-1$ IMF and a residual component.

$$s(t) = \sum_{t=1}^{N-1} x_i(t) + r(t), \tag{7}$$

where $r(t)$ is the residual component.

For further time-frequency analysis of the original signal, the Hilbert transform needs to be performed on the IMF decomposed by the EMD algorithm. Then, the Hilbert transform of $x_i(t)$ can be expressed as follows:

$$y_i(t) = \frac{1}{\pi}\int_{-\infty}^{+\infty} \frac{x_i(\tau)}{t-\tau} d\tau. \tag{8}$$

The analytical signal $z_i(t)$ of $x_i(t)$ can be expressed as follows:

$$z_i(t) = x_i(t) + iy_i(t) = a_i(t)e^{\beta_i(t)}, \tag{9}$$

where $a_i(t)$ represents the amplitude of the analytical signal, $a_i(t) = \sqrt{x_i^2(t) - y_i^2(t)}$; and $\beta_i(t)$ represents the phase angle of the analytical signal, $\beta_i(t) = \arctan[y_i(t)/x_i(t)]$.

The instantaneous frequency is calculated as follows:

$$w_i(t) = \frac{d\beta_i(t)}{dt}. \tag{10}$$

Then, the original blood flow signal can be expressed as follows:

$$s(t) = \mathrm{Re}\left\{\sum_{i=1}^{n} a_i(t)\exp\left[i\int w_i(t)dt\right]\right\}. \tag{11}$$

In order to improve the accuracy of extracting pipe wall signals, an adaptive wavelet threshold algorithm is introduced to optimize the EMD algorithm. The i-th layer IMF component $x_i(t)$ can be expressed as follows:

$$x_i(t) = \begin{cases} b_i(t) & 1 \le i \le k-1 \\ b_i(t) + w_i(t) & k \le i \le M-1, \\ w_i(t) & M \le i \le N \end{cases} \tag{12}$$

where $b_i(t)$ is the blood flow signal; $w_i(t)$ is the wall signal; and k, M, and N are the numbers of different layers of the IMF component: k is the number of the blood flow signal layers, M is the number of layers of IMF component containing both the tube wall and the blood flow signal, and N is the number of IMF component layers of the tube wall signal.

According to the noise power estimation algorithm in wavelet decomposition and the characteristics of EMD decomposition, the power of the first layer blood flow signal IMF is expressed as follows:

$$\sigma_1 = \frac{\mathrm{median}\{|x_1(t) - \mathrm{median}\, x_1(t)|\}}{0.6745}. \tag{13}$$

The power of the blood flow signal IMF in the i-th layer can be expressed as follows.

$$\sigma_i = \frac{\sigma_1}{\sqrt{2}^{i-1}}. \tag{14}$$

The threshold denoising method is used to remove the blood flow signal in the tube wall signal, and the tube wall signal can be expressed as follows:

$$w_i = \begin{cases} \mathrm{sgn}[x_i(t)]\left\{|x_i(t)| - \dfrac{2\sigma_i}{1+\exp\{L[x_i^2(t) - \sigma_i^2]\}}\right\} & |x_i(t)| > \sigma_i \\ 0 & |x_i(t)| \le \sigma_i. \end{cases} \tag{15}$$

Finally, the signal is reconstructed, and the signal calculation method of the original pipe wall is as follows:

$$w(t) = \sum_{i=k}^{M-1} w_i(t) + \sum_{i=M}^{n} x_i(t). \tag{16}$$

Then, the extreme values of the original ultrasonic blood flow signal are solved, then the upper and lower envelopes are obtained, and the average value of the upper and lower envelopes is subtracted from the initial signal to obtain the optimized signal, which is regarded as the first layer of the IMF. Next, the remaining signals are calculated and used as a new signal. After the signal decomposition termination condition is met, the separation of the blood flow signal is completed. The specific flow to separate the blood flow signal by the optimized EMD algorithm is shown in Figure 1.

2.3. Separation Effect of Blood Flow and Tube Wall Signals by Doppler Ultrasound. In this study, the separation effects of blood flow and vessel wall signals by Doppler ultrasound are evaluated factored into the relative error of the average frequency curve of the blood flow signal (E_f) and the mean relative error (MRE) of the power spectrum of the blood flow signal. They are commonly used blood flow evaluation parameters, expressed as follows:

$$E_f = \sqrt{\frac{\sum_t [F(t) - F_s(t)]^2}{\sum_t F_s(t)^2}}, \tag{17}$$

where $F_s(t)$ is the average frequency of the standard pure blood flow signal and $F(t)$ is the average frequency of the blood flow signal extracted by the separation algorithm.

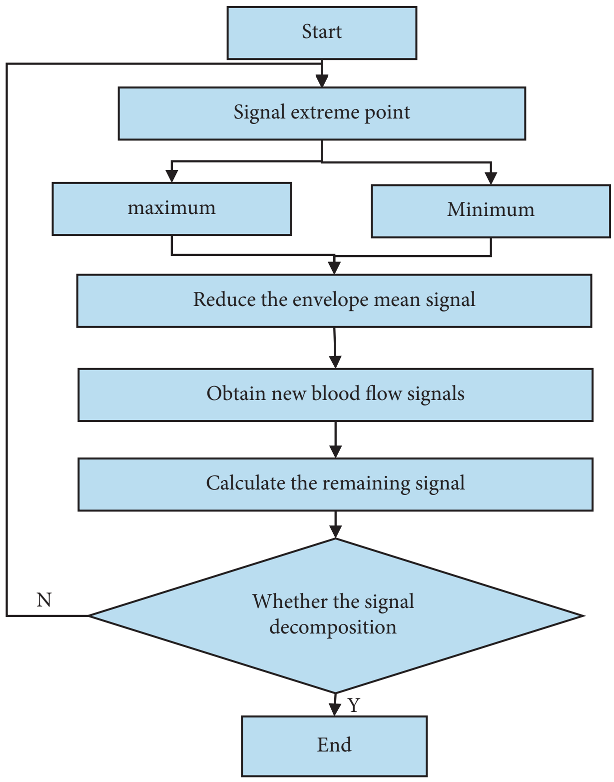

Figure 1: Flow chart of blood flow signal separation by the optimized EMD algorithm.

$$\text{MRE} = \frac{1}{M}\sum_{i=1}^{M}\frac{\sum_f \left|P_1(f,i) - P_2(f,i)\right|}{\sum_f P_2(f,i)}, \tag{18}$$

where f represents the frequency; M is the total number of blood flow signal segments; and P_1 and P_2, respectively, represent the power spectral density of the initial blood flow signal and the separated blood flow signal in the i-th time period.

2.4. Treatment Plans and Observation Indicators for Different Groups. Patients in both groups were examined by the ultrasonic diagnostic instrument produced by Philips, and the probe frequency was adjusted to 2.0–5.0 mhz. At the beginning of the examination, the position of the umbilical cord was first determined, and the placental umbilical artery was sampled with a volume of 2 mL to ensure that the arterial vasculature angle and pulse Doppler sampling should be below 30°. Then, the blood flow spectrum was determined.

The control group was treated with magnesium sulfate alone, and the observation group was treated with Compound Danshen injection and magnesium sulfate. The specific scheme was as follows.

Control group used magnesium sulfate alone. The dosage of the drug was 4~10 mL/time, mixed and diluted with 5% glucose injection and then intravenously infused, once a day on average, for a total of 10 days.

Observation group used Compound Danshen injection and magnesium sulfate. The dosage and method of magnesium sulfate were the same as the control group. The dosage of Compound Danshen injection was 10–20 mL/time, and it was diluted with 100–500 mL glucose injection with a concentration of 5%. Intravenous infusion was carried out once a day on average. The treatment also lasted 10 days.

The two groups were compared for the blood pressure and 24 h urine protein before and after treatment; the levels of serum endothelin-1 (ET-1), homocysteine (Hcy), and C-reactive protein (CRP) before and after treatment; the changes of blood coagulation function indexes, such as plasma prothrombin time (PT), fibrinogen (FIB), activated partial thromboplastin time (APTT), and plasma thrombin time (TT) before and after treatment; and the outcome of pregnancy.

2.5. Efficacy Evaluation. After the treatment, if the relevant clinical symptoms (such as edema, urine protein) basically disappear and the fetus is delivered smoothly, it is considered markedly effective; if the relevant clinical symptoms have been greatly reduced and, although the fetus can be delivered naturally, there are different degrees of suffocation, it is considered effective; if the relevant clinical symptoms of the patient are not significantly reduced and the pregnancy is forced to terminate, it is considered ineffective. Total effective rate = (markedly effective + effective)/number of cases × 100%.

2.6. Statistical Analysis. In this study, SPSS 22.0 was used for data processing and analysis, measurement data was expressed in the form of "$\bar{x} \pm s$," and t-test was used for comparison between groups. Count data were expressed by "n" (%), and chi-square test was used for comparison between groups. $P < 0.05$ indicated that the difference was statistically significant.

3. Results

3.1. Separation Results of Blood Flow Signal Based on Optimized EMD Algorithm. The ultrasound Doppler blood flow signal was separated using the optimized EMD algorithm, and the result is shown in Figure 2. It was noted that the optimized EMD algorithm can separate the blood flow signal and the tube wall signal.

The optimized EMD algorithm was used to decompose the ultrasound Doppler blood flow signal into multiple instantaneous frequencies. Here, the instantaneous frequencies of the 1st to 6th layers were analyzed (Figure 3). With the continuous increase of the number of layers, the instantaneous frequency corresponding to the IMF lowered continuously.

Then, the changes of instantaneous frequency over the amplitude were further analyzed (Figure 4). It was found that as the instantaneous frequency continued to increase, its corresponding amplitude gradually decreased.

The traditional EMD algorithm, the optimized EMD algorithm, and the high-pass filter method (HPF) were compared for the power spectral density after the ultrasound Doppler blood flow signal was separated (Figure 5). The

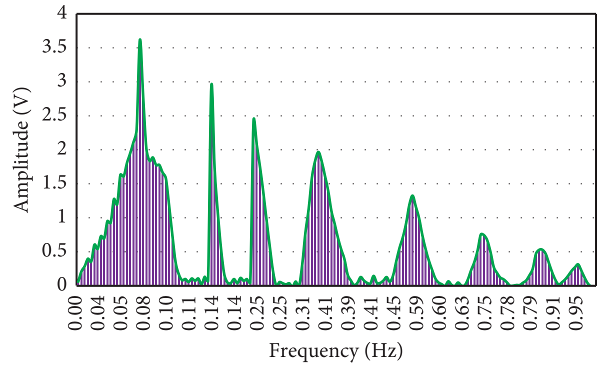

Figure 4: Changes of blood flow signal amplitude at different frequencies.

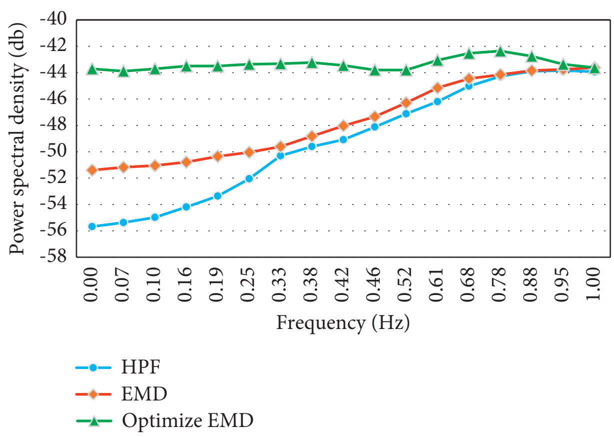

Figure 5: The power spectral density curves of blood flow signals separated by different algorithms.

power spectral density of blood signals separated by the optimized EMD algorithm was greater than those of the other two algorithms under different frequencies.

3.2. Separation Effects of Blood Flow and Tube Wall Signal by Optimized EMD Algorithm. Different algorithms were compared for the Ef and MRE values (Figures 6 and 7). It was found that the Ef and MRE values of the optimized EMD algorithm at different frequencies were significantly higher than those of the other two algorithms, and the optimized EMD algorithm showed statistically significant differences from the traditional EMD algorithm in Ef and MRE values ($P < 0.05$).

3.3. Clinical Efficacy. As for the total effective rate of the two groups of patients in this study, the total effective rate of the observation group was significantly better, and the difference compared with the control group was statistically significant ($P < 0.05$) (Table 1).

3.4. Blood Pressure. In this study, there was no significant difference in various indicators between the two groups of patients before treatment ($P > 0.05$). After treatment, from the perspective of blood pressure control, the observation group's SBP, DBP, and 24 h urine protein indexes were significantly better, and the difference was statistically

Table 1: Comparison of the total effective rate of the two groups of patients after treatment.

Index	Observation group	Control group	P value
Markedly effective (n)	23	18	0.031*
Effective (n)	14	11	0.048*
Ineffective (n)	3	11	0.003**
Total effective rate (%)	92.50	72.50	0.016*

*represents a statistical difference compared with the control group, $P < 0.05$; **represents a significant difference compared with the control group, $P < 0.01$.

Table 2: Comparison of blood pressure control between the two groups of patients after treatment.

Index	Time	Observation group	Control group	P value
SBP (mmHg)	Before treatment	158.32 ± 11.86	159.33 ± 11.90	0.913
	After treatment	127.85 ± 9.34	138.49 ± 9.11	0.021^*
DBP (mmHg)	Before treatment	117.09 ± 11.56	119.13 ± 10.97	0.861
	After treatment	78.35 ± 9.77	85.84 ± 8.71	0.032^*
24 h urine protein (g)	Before treatment	4.19 ± 1.36	4.17 ± 1.29	0.953
	After treatment	1.36 ± 0.24	2.25 ± 0.26	0.016^*

*represents a statistical difference compared with the control group, $P < 0.05$.

significant compared with the control group ($P < 0.05$) (Table 2).

3.5. Expression of ET-1, CRP, and Hcy. In this study, there was no significant difference in the expression of ET-1, CRP, and Hcy between the two groups of patients before treatment ($P > 0.05$). After treatment, the ET-1, CRP, and Hcy indexes of the two groups of patients decreased significantly, and the decrease in the observation group was more obvious than that in the control group ($P < 0.05$) (Table 3).

3.6. Coagulation Function. Before treatment, there was no significant difference in the levels of PT, APTT, TT, and FIB between the two groups ($P > 0.05$); after treatment, the levels of PT, APTT, TT, and FIB in the two groups were better than those before treatment, and the observation group was better than the control group. The difference was statistically significant ($P < 0.05$) (Table 4).

3.7. Maternal and Infant Outcome. As shown in Table 5, the incidence of adverse maternal and infant outcomes in the observation group was significantly lower than that in the control group ($P < 0.05$).

4. Discussion

Compound Danshen injection can prevent coagulation dysfunction, cerebrovascular accidents, and other complications. Combined with magnesium sulfate, it can not only effectively alleviate PIH syndrome, but also improve blood circulation and immunity [13, 14]. In this study, it was found that the blood pressure and 24 h urine protein of the observation group after treatment were significantly better than those in the control group ($P < 0.05$). It can be inferred that the treatment plan of Compound Danshen injection combined with magnesium sulfate is helpful to optimize the blood pressure control of patients with PIH syndrome. In addition, the total effective rate in the observation group was significantly higher than that of the control group ($P < 0.05$). It can be inferred that the treatment plan of Compound Danshen injection combined with magnesium sulfate can improve the maternal and infant outcomes.

Hcy is an important intermediate product in the process of methionine metabolism. The increase of serum Hcy level in pregnant women is closely related to the occurrence and development of HDP [15]. CRP is one of the important indicators that reflect the body's inflammatory response. The increase in serum CRP concentration in HDP patients has a certain correlation with vascular endothelial damage [16]. The results of this study showed that, after treatment, the serum Hcy and CRP levels of the observation group were significantly lower than those of the control group, suggesting that the combination of Compound Danshen injection and magnesium sulfate can significantly reduce the serum Hcy and CRP levels of HDP patients.

From the perspective of traditional Chinese medicine, hypertension during pregnancy belongs to the category of "blood stasis," and its occurrence is related to the blood stasis, deficiency of qi and blood, and obstruction of blood circulation. Therefore, the treatment aims to promote blood circulation, remove blood stasis, and dredge the meridians. Compound Danshen injection is a Chinese patent medicine composed of traditional Chinese medicine Danshen and Jiangxiang. Danshen is slightly cold and bitter, and it has the effects of calming the mind, removing blood stasis, and promoting blood circulation [17, 18]. Jiangxiang is known for nourishing the heart, dredging the meridians, relieving pain, stopping bleeding, and removing blood stasis [19]. The combination of the two has the effect of calming the mind, promoting blood circulation, and removing blood stasis [20]. It has been found that the polyphenols in Danshen can inhibit the release of a variety of coagulation factors [21]. By inhibiting the release of the α receptor, the aggregation of platelets is greatly reduced, so as to relax the capillaries and increase the secretion of nitric oxide (NO) in endothelial cells, to reduce the oxygen consumption of the myocardium, improve microcirculation, and effectively control the blood pressure [22]. At the same time, Danshen can positively affect the blood rheology and increase the perfusion flow of the placenta, so that the placenta can get sufficient blood supply and the occurrence of adverse pregnancy outcomes is greatly reduced [23]. Dalbergin and volatile oil in Jiangxiang can regulate the balance between ET and NO and antagonize thrombosis [24, 25], thereby improving the patient's oxidative stress and blood hypercoagulability and reducing the incidence of adverse pregnancy outcomes.

In conclusion, the treatment of PIH syndrome patients with Compound Danshen injection combined with magnesium sulfate proved to be effective and can improve maternal and infant outcomes; control blood pressure; and reduce 24 h urine protein and serum ET-1, Hcy, and CRP. Additionally, it can improve the blood coagulation function, and thus the treatment plan can be widely promoted in the clinic.

5. Conclusion

Based on the EMD algorithm, this study established a separation method of ultrasound blood flow signal, which was then applied to the diagnosis of patients with pregnancy-induced hypertension syndrome. Compound Danshen injection combined with magnesium sulfate was used to treat patients with pregnancy-induced hypertension syndrome. EMD algorithm can improve the accuracy of blood flow signal separation in ultrasonic images. Treatment of pregnancy-induced hypertension syndrome by Compound Danshen injection combined with magnesium sulfate can improve maternal and infant outcomes; control blood pressure; reduce 24 h urinary protein and serum ET-1, Hcy, and CRP levels; and improve coagulation function. However, the study still has the following disadvantages. It only analyzes the strain curve of the ultrasonic imaging blood flow signal. In future work, on the basis of ultrasonic imaging blood flow signal strain curve, the peak strain, negative peak strain, and positive peak strain rate should be evaluated, to evaluate the value of blood flow signal decomposition based on EMD algorithm in the diagnosis of pregnancy-induced hypertension syndrome. In conclusion, the EMD algorithm optimized in this study is of great significance for the diagnosis based on ultrasonic blood flow signals. Compound Danshen injection combined with magnesium sulfate can improve clinical indicators of pregnancy-induced hypertension syndrome, providing a reference basis for the clinical diagnosis and treatment of pregnancy-induced hypertension syndrome.

The objective of this study was to perform segmentation and extraction of CT images of pulmonary nodules based on convolutional neural networks (CNNs). The Mask-RCNN algorithm model is a typical end-to-end image segmentation model, which uses the R-FCN structure for nodule detection. The effect of applying the two algorithm models to the computed tomography (CT) diagnosis of pulmonary nodules was analyzed, and different indexes of pulmonary nodule CT images in lung function examination after algorithm optimization were compared. A total of 56 patients diagnosed with pulmonary nodules by surgery or puncture were taken as the research objects. Based on the Mask-RCNN algorithm, a model for CT image segmentation processing of pulmonary nodules was proposed. Subsequently, the 3D Faster-RCNN model was used to label the nodules in the pulmonary nodules. The experimental results showed that the trained Mask-RCNN algorithm model can effectively complete the segmentation task of lung CT images, but there was a little jitter at the boundary. The speed of R-FCN algorithm for nodular detection was 0.172 seconds/picture, and the accuracy was 88.9%. CT scans were performed on the 56 patients based on a deep learning algorithm. The results showed that 30 cases of malignant pulmonary nodules were confirmed, and the diagnostic accuracy was 93.75%. There were 22 benign lesions, the diagnostic accuracy was 91.67%, and the overall diagnostic accuracy was 92.85%. This study effectively improved the diagnostic efficiency of CT images of pulmonary nodules, and the accuracy of CT images in the diagnosis of pulmonary nodules was analyzed and evaluated. It provided theoretical support for the follow-up diagnosis of pulmonary nodules and the treatment of lung cancer. It also significantly improved the diagnostic effect and detection efficiency of pulmonary nodules.

1. Introduction

Pulmonary nodules are considered to be a multi-system and multi-organ granulomatous disease with unknown etiology at present, which often occurs in the lungs, bilateral hilar lymph nodes, eyes, skin, and other organs, and the incidence in the chest is as high as 80%–90% [1]. At present, there have been many studies on the pathogenic causes of pulmonary nodules, including observation and study on bacteria, viruses, mycoplasma, fungi, and other infectious factors, but the exact pathogenic causes have not been obtained. According to relevant studies, most people currently believe that the important pathogenesis of pulmonary sarcoidosis is the disorder of cellular immune function and humoral immune function, which is the result of the interaction between cellular immunity and humoral function of the body caused by unknown antigens [2, 3]. In recent years, with the development of society and changes of environment, the incidence of various lung diseases in China has been on the rise, among which lung cancer has become the cancer with the highest incidence in China. According to relevant data [4], in 2015 alone, the number of deaths due to lung cancer in China reached more than 700,000. Lung cancer was the leading cause of cancer deaths in 2018, accounting for 20 percent of all cancer deaths. By the end of 2017, the number of lung cancer patients and deaths in China had reached 800,000 and 700,000. The incidence of lung cancer is increasing at an annual rate of 27%, based on which the mortality rate of lung cancer patients in China will increase to 40% in the next 20 years [5].

The manifestations of early lung cancer are mainly pulmonary nodules, and there are generally no other specific symptoms in clinical practice. Lung cancer usually goes undetected by patients until they have obvious symptoms. Such symptoms include fever caused by repeated infection, inflammation of the lungs, chest tightness and shortness of breath, persistent coughing and hemoptysis, and excessive fatigue. At that time, lung cancer has generally entered the middle and late stages, and the best treatment period has been missed. At this time, the optimal treatment period has been missed, so the early diagnosis of lung cancer is extremely important. One of the key factors determining the survival rate of patients with lung cancer is the early accurate diagnosis of pulmonary nodules [6, 7]. If early pulmonary nodules are diagnosed and treated in advance and its early symptoms and related indicators are studied, it can effectively improve the early diagnosis rate and survival rate of lung cancer patients.

Currently, the main detection methods for lung cancer include computed tomography (CT) [1, 8]. CT is based on X-ray technology. The X-ray is sent out by the scanner in a fan-shaped wire bundle of a certain thickness to illuminate the patient at different angles. Then, the collected data are converted into current intensity signals in and out of the computer through the scanner and finally converted into three-dimensional images through the algorithm. CT detection is very important in the examination of lung function, but the analysis and diagnosis of lung CT images are often affected by doctors' experience and other subjective reasons. The diagnosis of the same CT image varies greatly among doctors of different skills, and a large number of CT images also produce excessive burden on radiologists. Therefore, algorithm-assisted processing of CT images based on convolutional neural network (CNN) is extremely important. Generally, there are two important methods for the algorithm-assisted CT diagnosis of pulmonary nodules [9, 10]. The first is the segmentation of lung CT images. To ensure that doctors can observe the nodules in the three-dimensional images carefully, the lung parenchyma needs to be segmented to remove the irrelevant data in the CT images. The second is adopting the algorithm to automate the detection of pulmonary nodules in CT images, which can not only effectively improve the diagnostic efficiency of radiologists but also improve the poor diagnostic effect caused by subjective differences.

Therefore, a model for CT image analysis of pulmonary nodules was proposed based on CNN deep learning technology, and then a comparison of different indexes of lung function examination of pulmonary nodules CT images was conducted after the optimization of the algorithm. The results of this study were intended to provide reference for the improvement of clinical diagnosis and treatment of patients with pulmonary nodules.

2. Methods

2.1. Research Objects. Fifty-six patients with pulmonary nodules confirmed by surgery or puncture in the hospital from May 2018 to May 2020 were selected as the research subjects. All patients received CT and MRI examination at admission and had complete clinical diagnosis records and imaging data. Among the 56 patients, 34 were males and 22 were females. Patients ranged in age from 30 to 77 years, with a mean age of (56.8 ± 4.7) years. The diameter of nodules in all patients ranged from 1.1 cm to 2.8 cm, with an average diameter of (2.0 ± 0.4) cm. There were 28 cases of right pulmonary nodules and 27 cases of left pulmonary nodules. All patients had signed informed consent, and this study had been approved by the Ethics Committee of the hospital.

Inclusion criteria were as follows: (i) those who met the diagnostic criteria of pulmonary nodules; (ii) patients who did not receive any radiotherapy, chemotherapy, or other treatment before treatment; (iii) patients who had no other serious heart, liver, kidney, and brain diseases or malignant tumors; (iv) patients who agreed and accepted the research; and (v) patients who were not allergic to contrast agents.

Exclusion criteria were as follows: (i) patients with imperfect imaging data; (ii) patients who were unable to cooperate with the completion of imaging examination; (iii) patients who were allergic to contrast agents; and (iv) patients with other serious heart, liver, kidney, and brain diseases or malignant tumors.

2.2. CT Examination. Whole-body low-dose CT was performed using a Siemens Somatom Emotion 16-slice spiral CT scanner. Patients were trained to hold their breath before the scan, and the whole lung scan was performed. Voltage and current were set as 120 kV and 100 mAs, respectively. The layer thickness was 8.0 mm, layer spacing was 1 mm, reconstruction interval was 8.0 mm, pitch was 0.811, and collimation was 16×0.75. For a CT scan, the patient was supine with arms crossed and placed in the lower abdomen. During scanning, the maximum layer of pulmonary nodules was selected for dynamic enhanced scanning. After the scanning range was reduced, the nonionic contrast agent ioversol (320 mgl/mL) was injected through cubital vein with high pressure, the dose was 90 mL, and the rate was 4.0 mL/s.

2.3. CT Image Segmentation Based on Mask-RCNN Algorithm Model. The Mask-RCNN algorithm model is a type of algorithm that combines detection and classification based on the Faster-RCNN algorithm. It is a convolutional neural network model that combines object detection and image segmentation [11]. Under the interaction of the target detection algorithm and the segmentation algorithm, the pixel-level segmentation effect is achieved, and the segmentation of the CT image is completed efficiently and quickly. Unlike the Faster-RCNN algorithm, the Mask-RCNN algorithm replaces the ROI pooling layer in the original algorithm with a better ROI alignment layer, which effectively improves the accuracy of the image segmentation boundary [12]. Based on the new network model, a fully convolutional network is used for image segmentation. The structure diagram is shown in Figure 1.

The change of the ROI alignment layer is the most important update implemented on the Mask-RCNN algorithm repooling layer, which realizes the mutual correspondence between output pixels and input pixels and effectively retains the spatial data contained in the image. The target pixel position in the original CT image in the image processing process is calculated by the following equations.

$$\begin{aligned} \mathrm{Src}M &= \mathrm{dst}\,M\left(\frac{\mathrm{src\ Width}}{\mathrm{dst\ Width}}\right),\\ \mathrm{Src}N &= \mathrm{dst}\,N\left(\frac{\mathrm{src\ Height}}{\mathrm{dst\ Height}}\right), \end{aligned} \tag{1}$$

where dstM and dstN represent the pixel coordinates in the area suggestion box, srcM and srcN represent the coordinates of the target pixel in the original CT image, srcWidth and srcHeight represent the width and height of the original image, respectively, and dstWidth and dstHeight are the width and height of the regional suggestion box, respectively. The following equation is used to calculate the pixel value of the sampling point of each unit through the bilinear interpolation method, and then the maximum pooling operation is implemented.

$$t(e+f, g+h) = (1-f)(1-h)t(e,g) + (1-f)ht(e,g+1) + f(1-h) + (e+1,g) + fht(e+1,g+1). \tag{2}$$

In the equation, there are four coordinate points to interpolate the M and N directions.

The loss function is used to train the model, which includes the bounding box regression loss and the target classification loss. The overall loss function expression equation is as follows.

$$k = k_{clS} + k_{\mathrm{box}} + k_{\mathrm{mask}}, \tag{3}$$

where k_{mask} refers to the average binary cross-entropy loss, and its expression is as follows.

$$\mathrm{Crossentropy}(t,0) = -(t,\ \log(v) + (1-t)\log(1-v)), \tag{4}$$

where t represents the target and v represents the output of the network model. The processing of the loss function generates labels of different category attributes for objects of different categories so that the interaction between the same categories will not occur.

2.4. Pulmonary Nodule Detection Algorithm Based on R-FCN. The CT image of the lungs segmented by the Mask-RCNN algorithm was used as the input of CNN for feature extraction. Subsequently, the fully convolutional network R-FCN was used as the detection algorithm model for pulmonary nodules, which is an end-to-end network model [13]. Similar to Faster-RCNN, R-FCN also performs network extraction of ROI, but Faster-RCNN loses certain characteristics after the extraction process. To retain some of the missing features, Faster-RCNN uses a deeper network model, but it undoubtedly sacrifices the training and testing efficiency of the model. The R-FCN used encodes location information by creating a location-sensitive feature map to retain the relevant features of the data, and there is no convolutional layer behind the pooling layer. The model's structure and location-sensitive features are shown in Figures 2 and 3.

For the grid of the mth row and nth column of the target object F, the expression of the position-sensitive pooling layer is as follows.

$$r_F(m,n\,|\,\theta) = \sum_{(x,y)\varepsilon\mathrm{bin}(m,n)} \frac{z_{m,n,F}(x+x_0, y+y_0\,|_{\theta})}{n}, \tag{5}$$

where $r_F(m,n)$ represents the average score of the (m, n) th network in the F target after passing through the pooling layer, $z_{m,n,F}$ is an output of the sensitive feature map at the $k^2(F{+}1)$th position, (x_0, y_0) represents the coordinates of the ROI, n means the number of all pixels in the model, and θ represents the parameters in the network; the score expression of the target F object is as follows.

$$r_F(\theta) = \sum_{m,n} r_F(m,n\,|\,\theta). \tag{6}$$

Then, the loss function of each target object consisting of cross-entropy loss and boundary regression loss is calculated.

$$k\left(r, v_{x,y,w,h}\right) = K_{c_l s}(r_{c^*}) + \phi[c^* > 0]k_{\mathrm{reg}}(v, v^*), \tag{7}$$

where c^* represents the true calibration value of ROI, $K_{c_l s}(r_{c^*})$ represents the cross-entropy loss function, $k_{\mathrm{reg}}(v, v^*)$ represents the boundary loss function, and v^* represents the real border of the ROI.

2.5. Statistical Mathematical Processing. SPSS 19.0 was used for statistical analysis. The measurement data conforming to normal distribution were expressed as mean ± standard deviation, and the difference between groups was analyzed

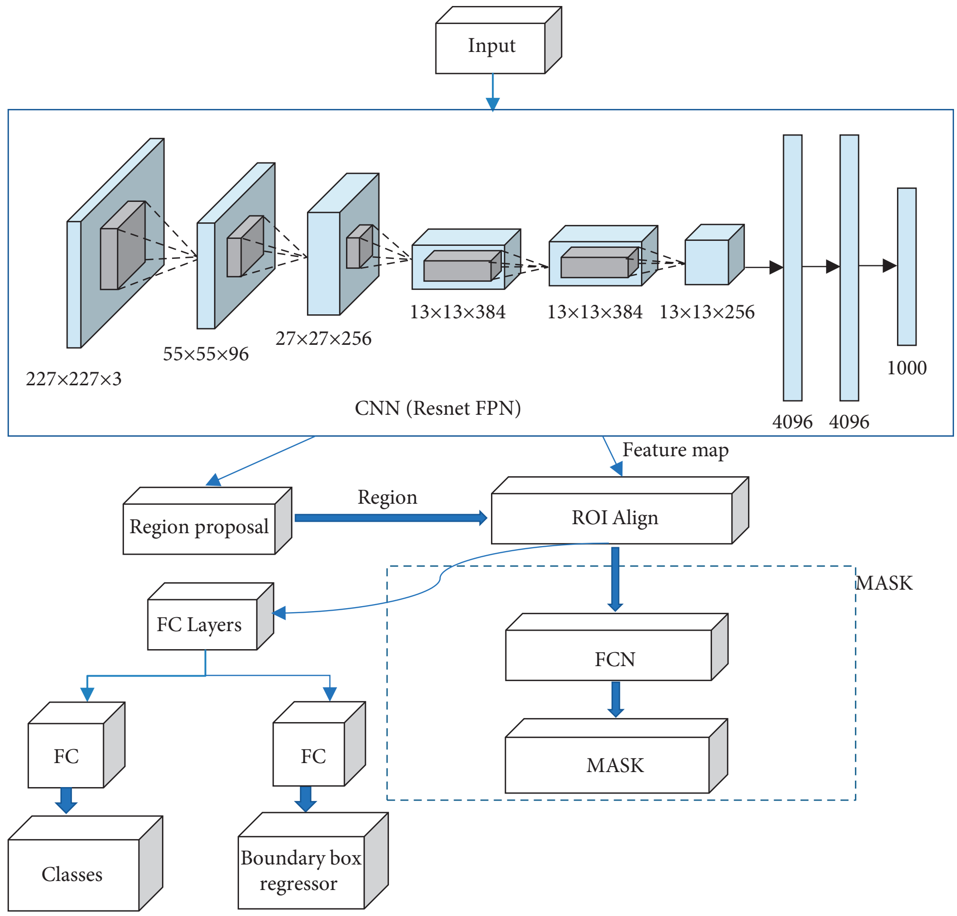

Figure 1: Schematic diagram of Mask-RCNN algorithm segmentation.

by independent sample t-test. The measurement data that did not conform to normal distribution were represented by median value and quad position, and the comparison between groups was analyzed by nonparametric rank sum test. N (%) was used to represent the count data, and chi-square test was used to analyze the difference between groups. The p value was calculated according to the variance value, and $p < 0.05$ was considered statistically significant.

3. Results

3.1. Image Segmentation Results Based on Mask-RCNN Algorithm Model. The deep learning framework for algorithm models was TensorFlow. This learning framework has a high degree of flexibility and strong portability, which supports multi-language and automatic differentiation. Regarding the training of the algorithm model, the CT image data used in this study were all the medical image data of the observation objects selected.

The training of the Mask-RCNN algorithm model used a stochastic gradient descent training network (SGD), the number of iterations (epoch) was 500, the momentum was 0.8, the learning rate was 0.0001, the batch size was 4, and the weight attenuation was 0.0001. After 400 iterations of the network model, the loss started to converge. Therefore, it was decided to use the training model after 450 iterations to segment the lung CT image. The comparison chart of the effect before and after segmentation is shown in Figure 4.

From the before and after comparison of the segmentation effect of the Mask-RCNN algorithm model on the lung CT image, the trained Mask-RCNN algorithm model can effectively complete the segmentation task of the lung CT image, but there was a slight jitter at the boundary. Therefore, the Mask-RCNN algorithm model cannot fully learn the boundary features of the image, but the segmentation of the lung parenchyma fully met the requirements.

3.2. Comparison of Results of Pulmonary Nodule Detection Algorithms Based on R-FCN. The CT image data used in this section were all the medical image data of the observed objects selected in this study. Each lung CT image contained pulmonary nodules with a diameter range of approximately 1.1 cm–2.8 cm, with an average diameter of (2.0 ± 0.4) cm. The position and shape of nodules in all CT images were not fixed. Randomly assigned according to a 2 : 1 ratio, the datasets were divided into training set and verification set. Nodules on all CT images contained both benign and malignant lesions. Malignant lesions were characterized by irregular and burr-like edges and exponential growth rate. Benign lesions were characterized by nodules with relatively smooth edges and slow growth.

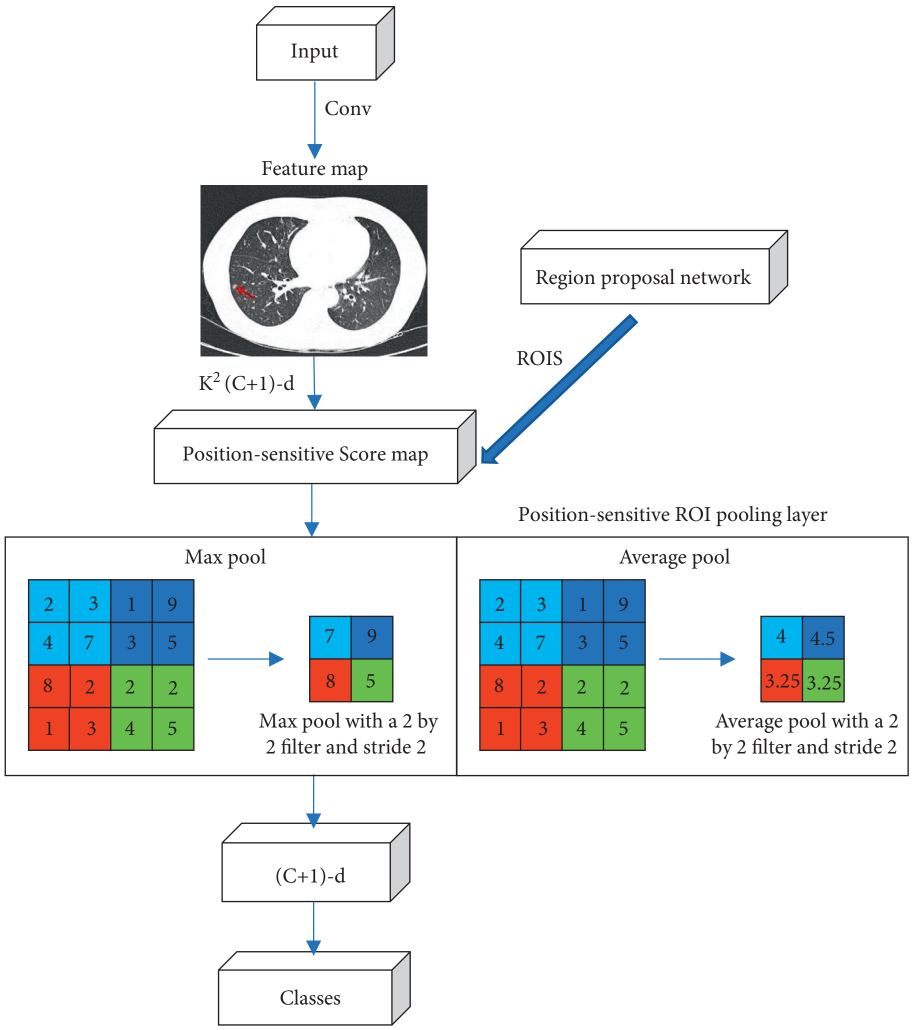

Figure 2: Schematic diagram of R-FCN model structure.

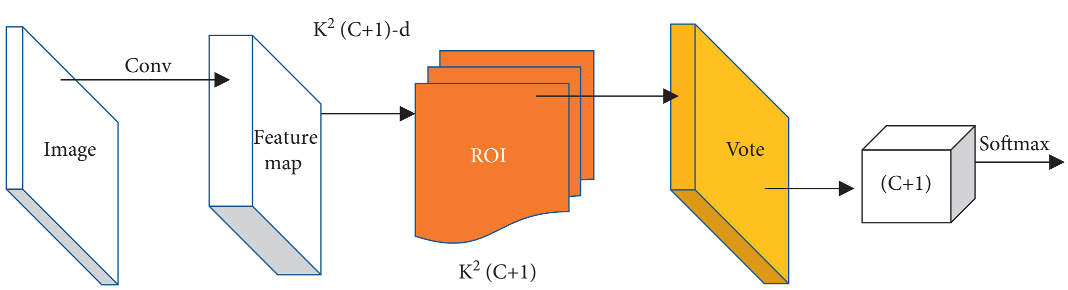

Figure 3: Location-sensitive feature map of R-FCN.

The training of the R-FCN algorithm model used a stochastic gradient descent training network (SGD), the number of iterations (epoch) was 500, the momentum was 0.8, the learning rate was 0.0001, the batch size was 4, and the weight decay was 0.0001. According to the experimental results, the speed of R-FCN algorithm for nodule detection was 0.172 seconds/frame, and the accuracy was 88.9%. The results before and after the test are shown in Figure 5.

3.3. CT Image Performance of Different Pulmonary Nodules Based on Deep Learning. Fifty-six patients who were diagnosed with pulmonary nodules by surgery or puncture in the hospital in a certain area were the research objects. Among 56 cases of pulmonary nodules diagnosed after surgery or pathological examination, 32 cases were malignant lesions and 24 cases were benign lesions. CT scans based on deep learning algorithms were performed on

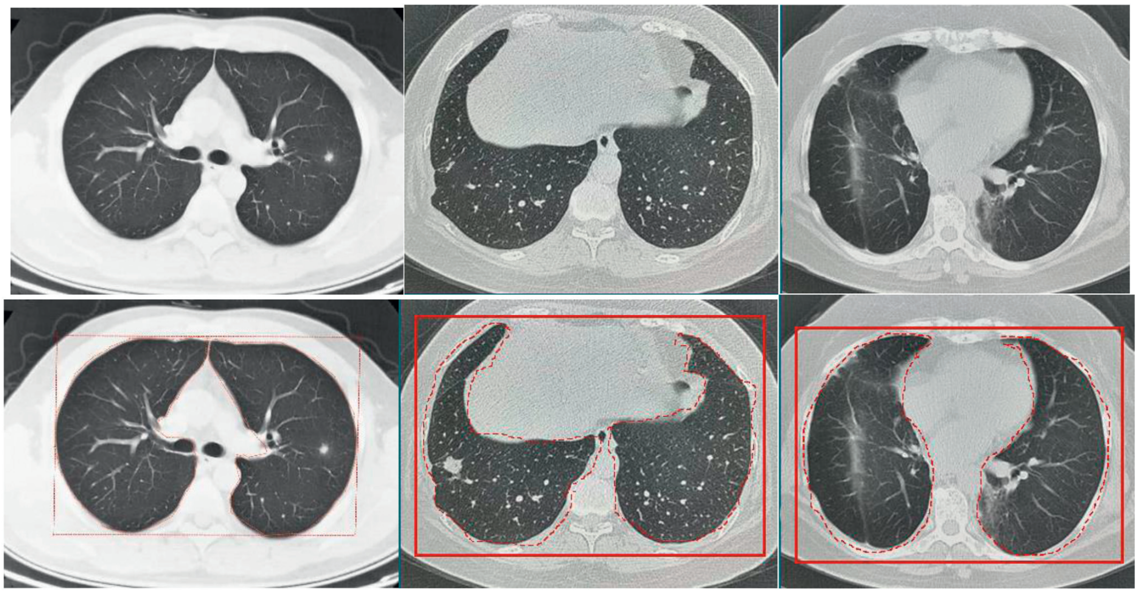

Figure 4: Comparison of the segmentation effect of Mask-RCNN algorithm on lung CT images (the box represents the automatic selection and labeling of lung parenchyma by Mask-RCNN algorithm, and the dotted line represents the further automatic segmentation of lung parenchyma).

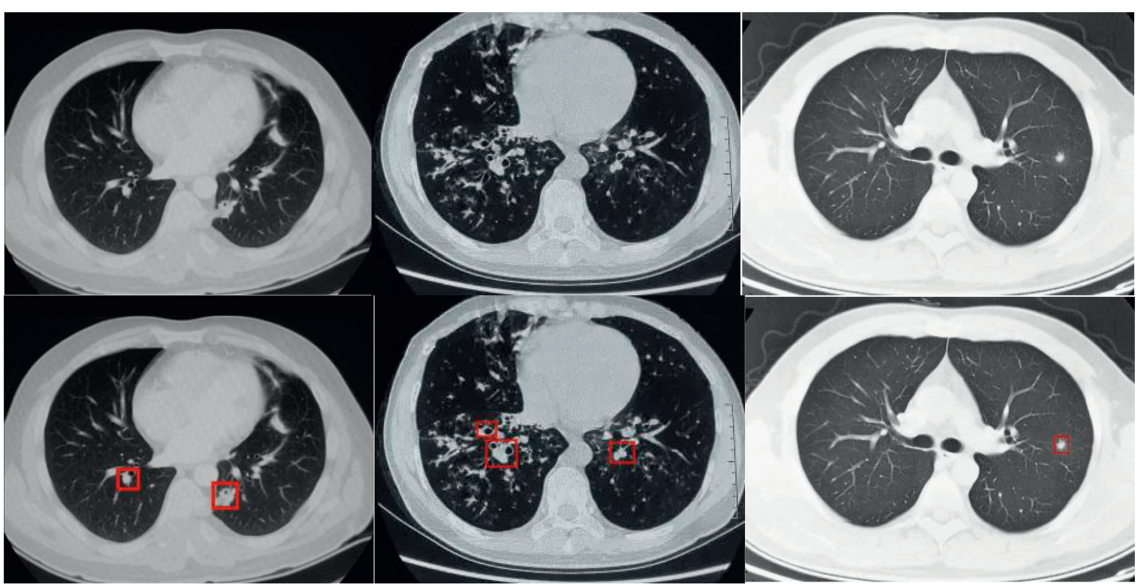

Figure 5: Comparison of the detection effect of R-FCN algorithm on CT images of pulmonary nodules (the box represents the automatic segmentation labeling of pulmonary nodules by R-FCN algorithm).

these 56 patients, 30 cases of malignant lesions of pulmonary nodules were confirmed, and the diagnosis accuracy was 93.75%. There were 22 cases of benign lesions, the diagnostic accuracy was 91.67%, and the overall diagnostic accuracy was 92.85%. At the same time, MRI scan diagnosis was performed, 27 cases of malignant lesions were detected, and the diagnosis accuracy was 84.38%. 16 cases of benign lesions were detected, the diagnostic accuracy was 66.66%, and the overall diagnostic accuracy was 76.78%. In Figure 6, the accuracy of CT scan based on deep learning for the diagnosis of pulmonary nodules was higher than that of MRI.

The CT scan parameters of different pulmonary nodules were recorded. The peak enhancement (PH) and the ratio of aortic enhancement (SPH/PPH) of malignant nodules and inflammatory nodules were higher than those of benign nodules. The detailed values are shown in Figures 7–8.

4. Discussion

The incidence of lung diseases has been increasing year by year, and lung cancer has become the number one enemy affecting the health of Chinese people in recent years. As an important feature of early lung cancer, pulmonary nodules are of great significance for the medical diagnosis and observation analysis of lung cancer. Rapid and effective diagnosis of pulmonary nodules can effectively improve the survival rate of patients with pulmonary diseases.

In the current clinical diagnosis of pulmonary nodules, it is generally believed that benign pulmonary nodules mainly occur in the posterior part of the upper lobe and the dorsal part of the lower lobe of the lung [14–16]. Most of the inflammatory nodules were found in the dorsal and inferior lobes of the lungs. The common sites of malignant nodules are mainly the upper lobe, lingual lobe, and middle lobe of the lung. The morphology of pulmonary nodules is classified into lobular, quasi-circular, and irregular shapes. The quasi-round shape is mainly manifested by the accumulation of nodular masses, usually with expansible growth, and malignant and benign can occur. The irregularity is usually seen in inflammatory nodules. The lobulated nodules are characterized by oval or round mass with uneven surface. According to relevant data, lobulated nodules are present in more than 70% of lung cancer patients [17]. Malicious nodules often have lobulated contours or irregular nodular edges. Almost 90% of lobulated nodules are malignant lesions. Malignant nodules also have features other than lobulated nodules, such as burr-like features, pleural depression, and obvious fibrous tissue proliferation in and around the nodules.

At the present stage of clinical treatment, fiberoptic bronchoscopy, CT, MRI, and needle biopsy are all conventional methods for the diagnosis of pulmonary nodules. However, due to the low sensitivity and limited value of chest radiograph, fiberoptic bronchoscopy has been gradually phased out in the diagnosis of early lung cancer [18]. In addition, puncture biopsy is an invasive operation for tumor detection, which will cause certain physical and mental damage to patients and has poor tolerance. The spatial resolution of MRI imaging examination is low [19], and the morphological characteristics of small and medium-sized pulmonary nodules are not obvious. Moreover, the price is relatively high. CT is currently a research hotspot in the examination of pulmonary nodules, with its remarkable advantages of fast and efficient scanning, small noninvasive radiation, and high tissue resolution. It can not only provide the morphological information of pulmonary nodules but also have a good display rate of the subtle signs of pulmonary nodules.

At present, CT images have become one of the procedures of routine clinical examination, and the number of CT images has increased greatly in recent years, which has certain requirements on the diagnostic accuracy and efficiency of radiologists. Therefore, it is of great significance to help radiologists effectively improve the diagnostic efficiency. Nowadays, CT scanning equipment has high spatial resolution [20, 21]. With the gradual development of computer and artificial intelligence algorithms, the automation engineering in the field of medical imaging has become increasingly important. Deep learning algorithms have been widely used in image processing, such as image segmentation, target selection, and image enhancement [22, 23]. In today's environment of significantly enhanced server computing capacity, richer datasets, and perfect network training technology, many algorithm models have been proposed. The recognition ability and precision of medical images are also gradually improving. When applied to the processing of medical images, it can completely replace doctors' preliminary subjective diagnosis of diseases in some cases.

5. Conclusion

This study aimed to use deep learning technology to segment and extract the CT images of pulmonary nodules, so as to further improve the clinical diagnosis effect of pulmonary nodules. The results showed that the speed of R-FCN algorithm for nodule detection was 0.172 seconds/piece, and the accuracy was 88.9%. By comparing the CT image effects after segmentation detection, the diagnostic accuracy of CT scan based on deep learning for pulmonary nodules was 91.67%, and the overall diagnostic accuracy was 92.85%. CT scan parameters of pulmonary nodules with different properties were recorded. The enhancement peak value (PH) and aortic enhancement value ratio (SPH/PPH) of malignant and inflammatory nodules were higher than those of benign nodules, and the data showed good consistency with the results of surgical examination. Moreover, the data showed a good agreement with the results of surgical examination. These results indicated that CT images based on deep learning were efficient and accurate in the diagnosis of pulmonary nodules. However, the research content of this work still has some limitations. Only a single imaging diagnosis method was studied, and the sample size was not large enough. At present, only automatic detection and labeling of pulmonary nodules can be achieved, but the nature of nodules cannot be distinguished, and artificial diagnosis is still needed. Therefore, it is necessary to increase the number of samples and further explore the deep learning algorithm in the future. In conclusion, this study can effectively improve the diagnostic efficiency of CT images for pulmonary nodules, and analyze and evaluate the accuracy of CT images for pulmonary nodules. In addition, it provides theoretical support for the follow-up diagnosis of pulmonary nodules and the treatment of lung cancer and also significantly improves the diagnostic effect and detection efficiency of pulmonary nodules.

Academic Editor: Enas Abdulhay

This study aimed to explore the application value of emission computed tomography (ECT) imaging technology based on filtered back projection reconstruction algorithm (FBP) in cardiac function examination after percutaneous coronary intervention (PCI) in patients with acute myocardial infarction (AMI). Eighty patients with myocardial infarction diagnosed by medical history, electrocardiograph (ECG), and myocardial enzyme admitted to hospital from February 2018 to February 2019 were selected as the research objects. All patients underwent PCI seven days after the onset of myocardial infarction. ECT was performed for all patients before and after surgery. In addition, all ECT images were processed by the FBP reconstruction algorithm. On this basis, preoperative and postoperative cardiac surgery function and ischemia of the patients were diagnosed. Then, the diagnostic results were compared with the results of coronary angiography and echocardiogram. The results showed that all patients had a total of 541 segments before PCI surgery. ECT examination revealed 294 abnormal segments of the ventricular wall, with a total score of 585 points. A total of 100 segments were scored with 1 point, a total of 194 segments were scored with 2 points, and a total of 50 segments were scored with 3 points. After PCI, the number of abnormal segments was reduced to 58, with a total score of 193. There were 6 segments with a score of 1, 44 segments with a score of 2, and 5 segments with a score of 3. The left ventricular diastolic volume (EDV), left ventricular systolic volume (ESV), stroke volume (CO), and ejection fraction (EF) of the patients before the operation were 148 ± 16 mL, 77 ± 14.5 mL, 4.29 ± 0.37 L/min, and $41.9 \pm 8\%$, respectively. The EDV, ESV, CO, and EF of the patients after surgery were 132 ± 16 mL, 62 ± 13 mL, 4.89 ± 0.71, and $53 \pm 6\%$, respectively. Significant changes occurred in various systolic function parameters before and after surgery, $P < 0.05$. The standardized regression coefficients of the three groups were 0.32, 0.41, and 0.47, respectively, $P < 0.05$, which indicated that the greater the coronary artery stenosis rate, the higher the diagnostic coincidence rate of left anterior descending limb (LAD), left circumflex branch (LCX), and left coronary artery (RCA). The conformity of ECT imaging in the LCX group for diagnosis of myocardial ischemia was higher than that of UCG, $P < 0.05$. To sum up, the ECT technology based on the FBP reconstruction algorithm had a good application prospect in the diagnosis of cardiac function recovery in AMI patients after PCI.

1. Introduction

In recent years, with the aggravation of the aging of the population in China and the increasing pressure on people's life, the prevalence and mortality of cardiovascular diseases are rising. Among them, coronary atherosclerotic heart disease (CAD) has become one of the primary cardiovascular diseases threatening the life and health of Chinese people [1]. Coronary heart disease (CHD) is defined as a narrowing or obstruction of the lumen caused by atherosclerosis of the coronary artery, or a functional change in the coronary artery that leads to myocardial ischemia, hypoxia, or necrosis that further leads to heart disease. Clinically, CHD is generally classified into five types: (i) asymptomatic myocardial ischemia, (ii) angina pectoris, (iii) acute myocardial infarction (AMI), (iv) ischemic cardiomyopathy, and (v) sudden death. Among them, AMI is the most common and serious [2]. AMI is defined as the rapid reduction or interruption of the blood supply of the coronary artery based on coronary artery disease, resulting in severe and persistent acute ischemia of the corresponding myocardium leading to myocardial necrosis. Once myocardial infarction occurs, ventricular remodeling will occur, which will further lead to complications such as left ventricular dysfunction and congestive heart failure. They will seriously affect the long-term prognosis of patients and reduce the quality of life of patients [3]. Effective and timely reperfusion is the key to the early treatment of AMI. Clinical data showed that percutaneous coronary intervention (PCI) has a good therapeutic effect on AMI. However, recent studies pointed out that PCI has time compliance in the treatment of AMI. Direct PCI within twelve hours of acute myocardial infarction can effectively save the myocardium, reduce the size of myocardial infarction, and improve left ventricular remodeling. However, PCI was less effective in saving dying cardiomyocytes after seven days of acute myocardial infarction. Its effects on improving the blood flow of the left ventricular remodeling, resting or hibernating myocardium, and preventing the expansion and extension of the infarct area remain controversial. In addition, many studies revealed that about 30%~40% of AMI patients will have no-reflow after PCI, which seriously affects the therapeutic effect and leads to the prognosis of patients. Therefore, there is an urgent need for an effective method to examine and evaluate the cardiac function recovery of AMI patients after PCI [4–6].

Radionuclide emission computed tomography (ECT) is a computer aided technique, which uses isotopes to label drugs, thereby measuring the concentration intensity of isotopes in various organs in the body and its change with time based on the principle of human body synthesis. In this way, the visual shape of the organs is displayed, and the functional image information of their physiological process and metabolism is reflected [7]. ECT technology develops rapidly and has become one of the markers of nuclear medicine modernization at present [8]. It has been widely used in the diagnosis of tumors, bone diseases, and cerebrovascular diseases because it can well combine functional images with anatomical images. It is also the main means of heart disease diagnosis, especially in the diagnosis of coronary heart disease, which shows a good diagnostic efficiency and has become one of the recognized methods to detect coronary heart disease. When radiopharmaceuticals enter the coronary arteries, they are selectively ingested by normal cardiomyocytes, and the amount ingested is proportional to the coronary blood flow. When a coronary artery is narrowed or blocked, blood flow in the coronary arteries is reduced, and heart muscle cells are damaged. At that point, the ability of the heart muscle to absorb radioactive drugs is reduced or even unable to absorb them. Therefore, ECT can accurately display the metabolism and blood flow of the myocardium, so as to further determine whether the myocardium is ischemic, ischemic site, and ischemic area. Compared with coronary angiography, exercise plate, and other examination methods, it has the advantages of noninvasive and no exercise load, so it is a relatively safe and effective examination method in clinical practice [9]. Patients with negative ECT examinations can basically exclude coronary heart disease. For patients with positive ECT examination, the specific coronary artery lesions are further inferred according to the abnormal blood flow distribution and perfusion volume.

ECT examination is mainly classified into functional image examination and anatomical structure image examination, but the image resolution collected by functional image examination is very low and lacks anatomical information. To solve this problem, image fusion is proposed. At present, CET and CT can be organically combined to provide high-quality images with anatomical localization. To a certain extent, the quality of ECT images is provided [10]. However, there are still many problems such as image quality distortion caused by attenuation factors such as the Compton effect and scattering on image fusion. Image reconstruction technology has developed rapidly in recent years. According to the collected data, the image is reconstructed by computing the pixels in the image matrix. FBP is the most widely used algorithm in image reconstruction at present. At present, it mainly exists in the X-ray CT system, but there are few studies on its application in CET [11].

In this study, patients with acute heart infarction were taken as the research objects. ECT examination was performed before and after PCI. FBP algorithm was used to process the obtained images, and on this basis, the efficacy of PCI in MAI was evaluated, to provide reference and basis for clinical use of ECT, PCI, and FBP algorithm in treatment and diagnosis of AMI.

2. Materials and Methods

2.1. Research Objects. A total of 80 patients admitted to the hospital from February 2018 to February 2019 who were diagnosed with AMI by medical history, ECG, and myocardial enzyme were selected. There were 55 male patients and 25 female patients, with an average age of 61.6 ± 11.2 years. Exclusion criteria are as follows: patients with onset less than twelve hours or longer than one month; patients suffering from cerebrovascular diseases or severe liver and kidney dysfunction or hyperthyroidism; patients suffering from malignant arrhythmia, congenital heart disease, cardiac hypertrophy, and myocarditis resulting in cardiac insufficiency; patients with a history of respiratory dysfunction, malignant tumor, or active bleeding; and patients who were long-term bedridden and unable to perform ECT examination. All studies had obtained patients' informed consent and met the requirements of medical ethics.

2.2. Overview of Research Methods. All the subjects underwent percutaneous coronary intervention (PCI) seven days after myocardial infarction. All patients were examined with radionuclide emission computed tomography (ECT) before and after surgery. All ECT images are processed by filtering back projection reconstruction algorithm. On this basis, the preoperative and postoperative cardiac operation function and ischemia were diagnosed. The diagnostic results were compared with coronary angiography and ultrasound ECG.

2.3. ECT Inspection Method. The inspection instrument was Siemens symbia-1, the imaging agent was 9mTc-MIBI, and the radiochemical purity was >95%. All patients were routinely given antiplatelet aggregation, anticoagulants, beta-blockers, nitrates, ACEI drugs, and statins after admission. 99mTc-MIBI was intravenously injected on the morning of the 7th day of admission, in the fasting and resting state, with a dose of 925~1110 MBq (25~30 mCi). Half an hour later, the patient was fed a fried egg or 250 mL of pure milk. Resting-gated myocardial perfusion imaging was performed 1.5 to 2 hours later. ECT was equipped with a parallel hole low energy and high-resolution collimator. The R wave of ECG was the trigger wave. The patient lied on the examination bed with his head outwards. ECG gating device was opened, and the ECG electrodes were connected correctly. The starting angle of probe 1 was −45°, and the starting angle of probe 2 was 56°. The angle between probes was 101°, one position per 3D, running 1050 in total, and 36 individual positions were collected. Eight frames were collected per cardiac cycle, and the acceptable heart rate range was ±20% of the mean heart rate. The matrix was 64 × 64, and the acquisition time was 30 seconds/section. The energy peak was 140, and the magnification (ZOOM) was 1.33.

ECT results were classified into four grades: normal (grade 0), decreased perfusion (grade 1), substantially decreased perfusion (grade 2), and perfusion defect (grade 3). The calculation of wall thickening rate was automatically graded into normal wall thickening rate (>25%, grade 0), reduced (10~24%, grade 1), substantially reduced (10% to 9%, grade 2), and substantially reduced or no exercise (<9%, grade 3).

2.4. Image Processing Method. The back projection reconstruction algorithm usually introduces star artifacts, which will lead to image distortion after reconstruction. This problem can be solved by rate-wave processing of the image before reconstruction.

The projection theorem is the basis of image reconstruction. The specific content is as follows. A slice of the 2D Fourier transform $F(w_1, w_2) = \widehat{F}(\rho, \phi)$ of $f(x, y)$ is given by the 1D Fourier transform of an image $p_\phi(x_r)$ projected at the angle ϕ of view $f(x, y)$. The slice and the axis w_1 intersect at an angle ϕ and pass through the origin of the coordinate. The specific schematic diagram is shown in Figure 1. It is further explained that the 1D Fourier transform of the projection of the image $f(x, y)$ in the direction ϕ gives a slice of the 2D Fourier transform of $f(x, y)$, and the position of the slice passes through the origin and forms an angle ϕ with w_1.

$$\zeta_1\left[p_\phi(x_r)\right] = \widehat{F}(\rho, \phi)|_{\phi=arctg w_2/w_1}. \tag{1}$$

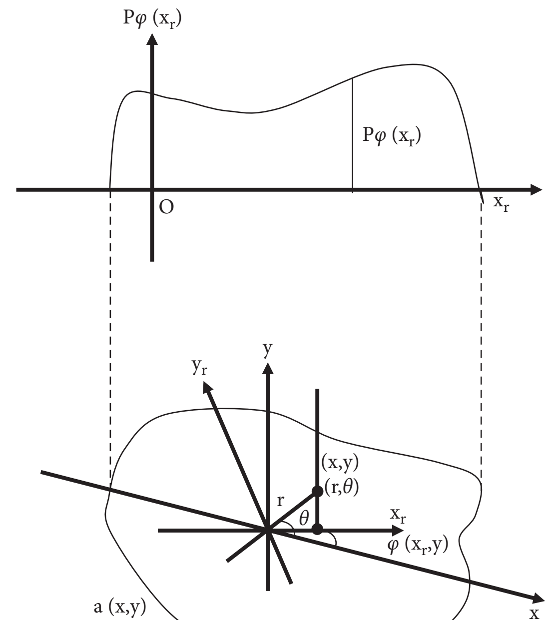

Figure 1: Coordinate system used for FBP.

The relationship between the projection angle ϕ of view and the rotation coordinates (x_r, y_r) and (x, y) is as follows.

$$\begin{cases} x_r = x \cos \phi + y \sin \phi, \\ y_r = -x \sin \phi + y \cos \phi. \end{cases} \tag{2}$$

w_1, w_2 are not independent but bound by

$$\begin{cases} w_1 = 2\pi\rho \cos \phi, \\ w_2 = 2\pi\rho \sin \phi. \end{cases} \tag{3}$$

FBP reconstruction is as follows. The image to be built is $a(x, y)$; then, its 2D Fourier transform is $A(w_1, w_2) = \widehat{A}(\rho, \theta)$. According to the central slice theorem, $\widehat{A}(\rho, \theta)$ is obtained by 1D Fourier transform of $p_\phi(x_r)$ of the projection of $a(x, y)$ under different viewing angles, which is expressed as follows.

$$A(w_1, w_2) = \widehat{A}(\rho, \theta) = \xi_1\left[p_\phi(x_r)\right] = P_\phi(\rho) = P(\rho, \phi). \tag{4}$$

The image to be built is as follows.

$$\overset{\Delta}{a}(r, \theta) = a(x, y) = \xi_2^{-1}\left[A(w_1, w_2)\right]. \tag{5}$$

Then, there is

$$\overset{\Delta}{a}(r, \theta) = \int_0^X d\phi \int_{-\infty}^{\infty} |\rho| P(\rho, \phi) e^{J\pi\rho r \cos(\theta-\phi)} d\rho. \tag{6}$$

The second integral of equation (6) is as follows.

$$\int_{-\infty}^{\infty} |\rho| P(\rho, \phi) e^{J2\pi\rho r \cos(\theta-\phi)} d\rho. \tag{7}$$

The above equation is rewritten as the inverse Fourier variant with the spatial variable x_r as follows.

$$\int_{-\infty}^{\infty} |\rho| P(\rho,\phi) e^{J2\pi \rho r \cos(\theta-\phi)} d\rho = \int_{-\infty}^{\infty} |\rho| P(\rho,\phi) e^{J2\pi \rho r \cos(\theta-\phi)} |_{xr=r\cos(\theta-\phi)}, \\ = g(x_r,\phi)|_{x_r=r\cos(\theta-\phi)} \\ = g[r\cos(\theta-\phi),\phi] \tag{8}$$

$$g(x_r,\phi) = p(x,\phi) * h(x_r). \tag{9}$$

Equation (9) is substituted in equation (5), and then, equation (10) is obtained.

$$\overset{\Delta}{a}(r,\theta) = \int_0^X g[r\cos(\theta-\phi),\phi]\mathrm{d}\phi. \tag{10}$$

Equation (10) is the filter back projection equation, which can reflect the various steps of the filter back projection algorithm. The schematic block diagram of the specific filtering back projection reconstruction process is shown in Figure 2. Generally speaking, it has three major steps:

(I) The projection $p(x_r,\phi_i)$ measured under the fixed viewing angle ϕ_1 is filtered to obtain the filtered projection $g(x_r,\phi_i)$

(II) For each ϕ_i, $g(x_r,\phi_i)$ is projected back on all points (r,θ) on the ray satisfying $x_r = r\cos(\theta-\phi_i)$

(III) All the back projection values $(0<\phi<\pi)$ in the second step are integrated to get the reconstructed image

2.5. Image Reconstruction Effect Evaluation. The required calculation is used to evaluate the reconstruction effect of the algorithm proposed in this study and the traditional algorithm. The lower the amount of calculation, the better the reconstruction effect. The specific calculation process is as follows. It is supposed that the one-dimensional calculation of N points in the algorithm proposed in this study is a function of the transformation length IV, denoted by $A(N)$, and $A(N) = O(N\log_2 N)$. The calculation amount of the first step of filtering is real number multiplication and addition of $A(2N)$ times. The calculation amount of the second step is real number multiplication of $2N$ times. The calculation amount of the third step is the same as that of the first step. Therefore, to complete the filtering of azimuth projection data, the amount of calculation required is expressed as follows.

$$\begin{cases} \text{Real number multiplication}: 2A(2N) + 2N, \\ \text{Real number addition}: 2A(2N). \end{cases} \tag{11}$$

The calculation steps required by the traditional algorithm are the same as those of the new method as follows.

$$\begin{cases} \text{Real number multiplication}: 5A(2N) + 4N, \\ \text{Real number addition}: 5A(2N). \end{cases} \tag{12}$$

2.6. Treatment Methods. All patients underwent PCI seven days after AMI. 6F guiding catheter was placed at the opening of the diseased vessel. The guidewire was inserted to the distal end of the stenosis and the occlusion. Balloon angioplasty was performed on the lesion site through balloon insertion along the guidewire. Then, according to the diameter and length of the lesion, the appropriate stent was selected for intracoronary stent implantation, and the balloon pressure of the stent was preexpanded and the balloon pressure of the stent was released regarding the characteristics of the lesion. All patients received 9mTc-MIBI resting-gated myocardial perfusion two days after PCI, using the same method as before. The myocardial perfusion and cardiac function improvement were evaluated. The imaging method was the same as before. To ensure the comparability of myocardial images, the activity of the imaging agent, the instrument, and the position of the patient were as consistent as possible before and after stent implantation in the same patient.

2.7. Statistical Methods. SPSS 11.0 was employed for data statistics and analysis. Mean ± standard deviation ($\square x \pm s$) was how measurement data were expressed, and the t-test was used to test the significance of patients' data before and after the operation. Percentage (%) was how count data were expressed, and the χ^2 test was used to test the significance. The pairwise comparison was performed by analysis of variance. The difference was statistically considerable with $P < 0.05$.

3. Results

3.1. General Patient Information. General information of the patient's age and sex, smoking history, number of diseased blood vessels, coronary artery branches, and ECG are shown in Tables 1 and 2. The average age of the patients was 59.1 ± 12.33. There were 55 male patients, accounting for 68.7%. The number of patients with diseased blood vessels of 1 and 2 was 37 and 38, respectively. The numbers of patients with the three types of coronary artery branch lesions were basically the same, which were 36, 27, and 31, respectively. Most of the patients showed AMI and myocardial ischemia.

3.2. Patient ECT Examination Results. The ECT examination results before and after the operation and the comparison of ECT before and after processing by the FBP reconstruction algorithm are shown in Figures 3 and 4. The results of ECT examination before PCI operation indicated that the left ventricular apex, anterior wall, and septal segment were almost defective in resting state, and the inferior wall partial septal segment was obviously sparse or defective. Cardiac perfusion and filling gradually recovered over time after PCI

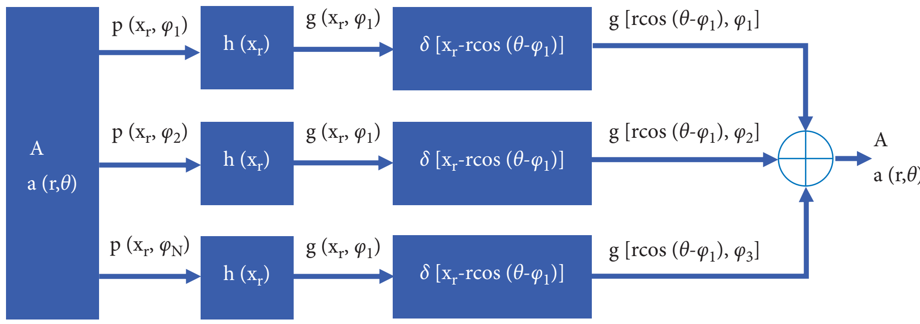

Figure 2: Schematic diagram of FBP reconstruction.

Table 1: Patient age and underlying disease data.

Index	$N = 80$
Age (years)	59.1 ± 12.33
Gender (male, n (%))	55 (68.7%)
Smoking history (n (%))	53 (66%)
Hypertension (n (%))	44 (55%)
Diabetes mellitus (n (%))	77 (96.2%)
Dyslipidemia (n (%))	61 (76.25%)

Table 2: UCG examination and coronary artery lesions of patients.

Item		Case number
Number of diseased vessels	0	9
	1	37
	2	38
	3	11
Types of coronary artery branch lesions	LAD	37 (46%)
	LCX	26 (32.5%)
	RCA	31 (38.7%)
Echocardiographic test results	Normal	2 (2.5%)
	Myocardial ischemia	39 (48.75%)
	Myocardial infarction	39 (48.75%)

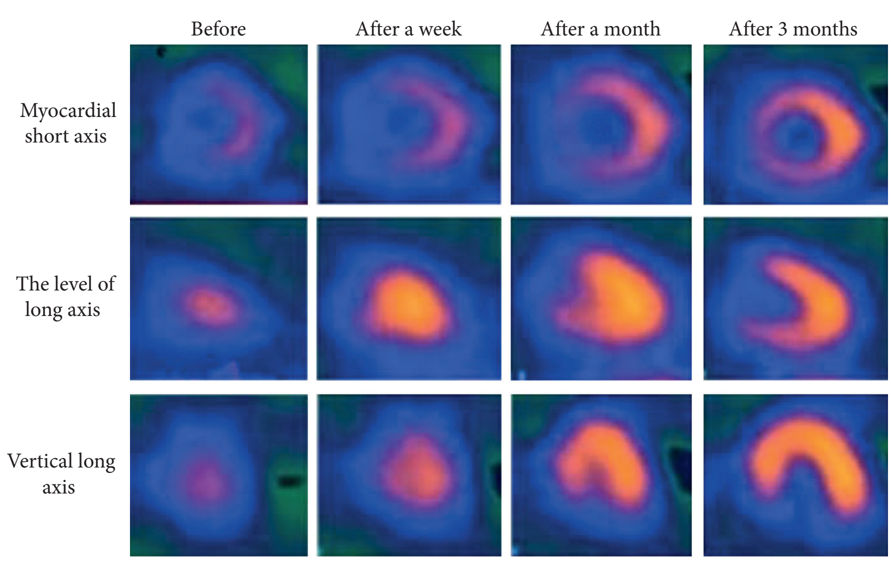

Figure 3: ECT images of patients at various stages before processing by the FBP reconstruction algorithm.

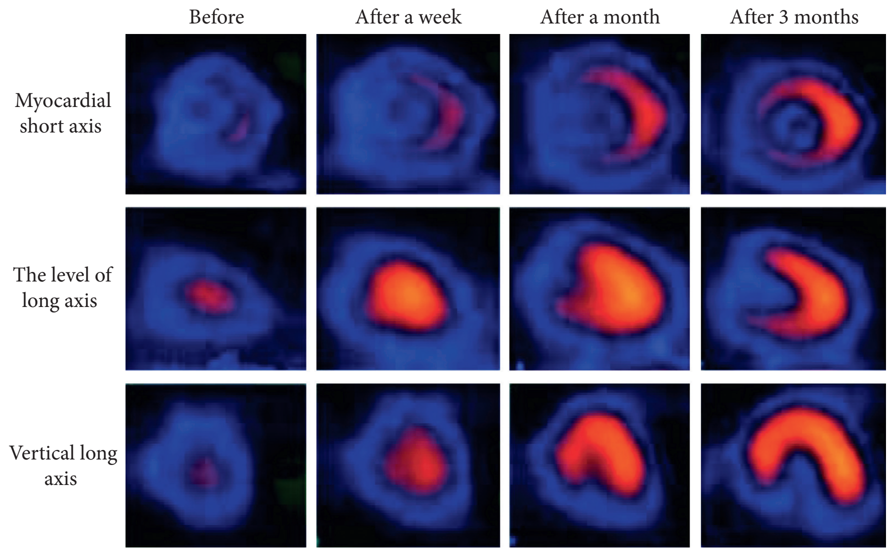

Figure 4: ECT images of patients at various stages after processing by the FBP reconstruction algorithm.

surgery. Figures 3 and 4 were compared, the quality of the ECT image processed by the unfiltered back projection reconstruction algorithm was poor, and the image was blurry. After being processed by the FBP reconstruction algorithm, the image quality was substantially improved, and the contour and edge of the target observation part became clearer.

3.3. Comparison of the Amount of Calculation Required for Image Reconstruction of the Two Algorithms. Table 3 shows the comparison results of the calculation amount required for image reconstruction under different algorithms. In the new method, since only $[M/4]$ back projection calculations of azimuths require positioning operations $[X]$ (representing the smallest integer greater than X), and in each direction, only the pixels in the positioning part need positioning operations, the calculation amount of multiplication in the new method operation is $3N[M/4]/2$ approximately, and the calculation amount of other operations can be deduced by analogy. Therefore, the required calculation of the new method is only 1/8 of the traditional method.

3.4. Comparison of Myocardial Perfusion before and after PCI. The comparison of myocardial perfusion in patients before and after PCI operation is shown in Figure 5. All patients had a total of 541 segments before PCI. ECT examination revealed 294 abnormal segments of the ventricular wall, with a total score of 585 points. A total of 100 segments were scored with 1 point, a total of 194 segments were scored with 2 points, and a total of 50 segments were scored with 3 points. After PCI, the number of abnormal segments was reduced to 58, with a total score of 193. There were 6 segments with a score of 1, 44 segments with a score of 2, and 5 segments with a score of 3. The decrease in blood perfusion of patients after PCI surgery was considerable.

Table 3: The amount of calculation required for reconstruction under different algorithms.

Operation Algorithm	Multiplication	Addition	Rounding
Traditional algorithm	$3MN$	$2MN^2$	MN^2
New method	$3N[M/4]/2$	$N^2[M/4]$	$N^2[M/4]/2$

3.5. Comparison of Systolic Function Parameters of Patients before and after PCI. The comparison of the cardiac function parameters of the patients before and after PCI is shown in Figure 6. The EDV, ESV, CO, and EF of the patients before the operation were 148 ± 16 mL, 77 ± 14.5 mL, 4.29 ± 0.37 L/min, and $41.9 \pm 8\%$, respectively. The EDV, ESV, CO, and EF of the patients after surgery were 132 ± 16 mL, 62 ± 13 mL, 4.89 ± 0.71, and $53 \pm 6\%$, respectively. Various parameters of cardiac systolic function changed substantially before and after the operation, and the difference was considerable, $P < 0.05$.

3.6. Comparison of ECT Imaging and CAG Results Based on FBP Reconstruction Algorithm. According to the classification of coronary artery disease, the patients were rolled into three groups of left anterior descending limb (LAD), left circumflex artery (LCX), and left coronary artery (RCA), to perform regression analysis of ECT diagnosis coincidence rate and coronary artery stenosis rate. From Figure 7, in the LAD group, $F = 4.39$, $P < 0.05$, which was statistically considerable. In the LCX group, $F = 8.21$, $P < 0.05$, which was statistically considerable. In the RCA group, $F = 11.36$, $P < 0.05$, which was statistically considerable. The standardized regression coefficients of the three groups were 0.29, 0.42, and 0.48, respectively, and the significance of the three groups was $P < 0.05$, which indicated that the greater the coronary artery stenosis rate, the higher the diagnostic coincidence rate of the three groups of LAD, LAD, and RCA.

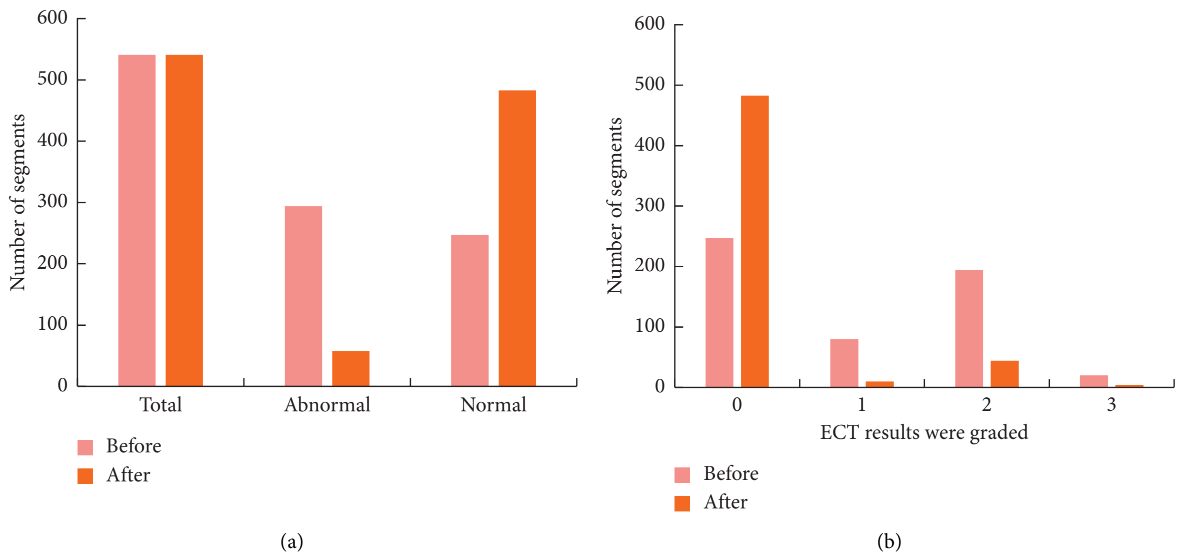

Figure 5: Classification of ECT examination results before and after surgery.

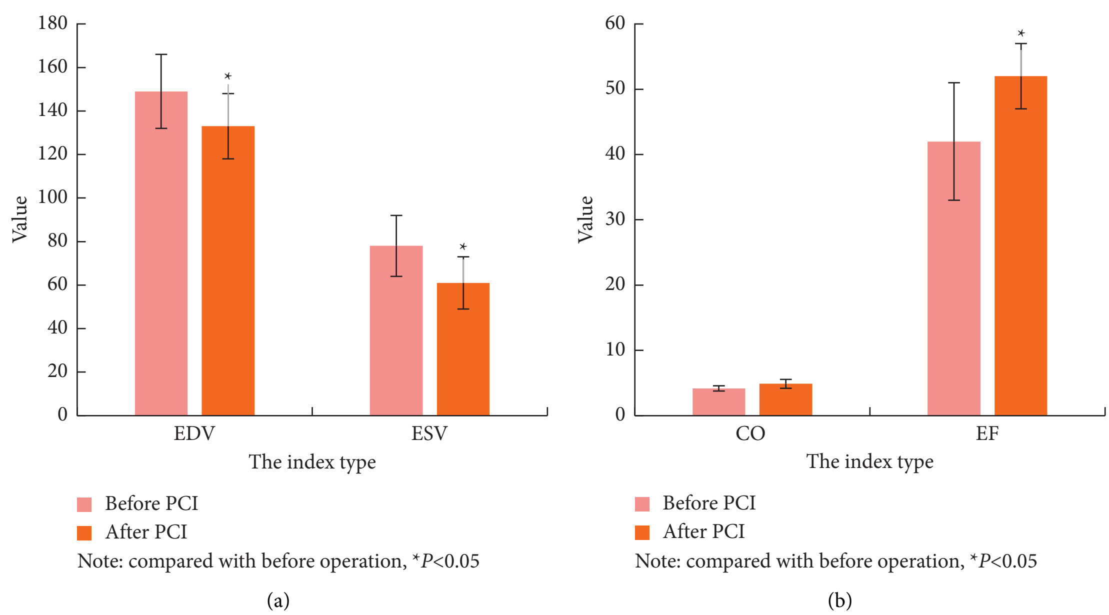

Figure 6: Comparison of patient's systolic function before and after surgery, compared with before operation, $^*P < 0.05$.

3.7. Comparison of Diagnosis Coincidence between Myocardial ECT Imaging and UCG. The comparison results of myocardial ECT imaging and UCG diagnosis are shown in Figure 8. There was no difference between the LAD group's myocardial ECT imaging in the diagnosis of myocardial ischemia and UCG, $P = 1$. The conformity of ECT imaging in the LCX group for diagnosis of myocardial ischemia was higher than that of UCG, and the difference was considerable, $P < 0.05$. The conformity of ECT imaging in the RCA group for diagnosis of myocardial ischemia was higher than that of UCG, but the difference was not considerable, $P > 0.05$.

4. Discussion

AMI refers to the rapid reduction and interruption of the blood supply of the coronary artery when the coronary artery disease occurs, and then, the relevant myocardium presents continuous ischemia and then leads to myocardial necrosis [12]. As the most serious coronary heart disease, acute attack infarction seriously threatens people's life and health. In addition, the aging of our population is becoming more and more serious. AMI has become one of the major causes of death in China. Currently, the most effective treatment for AMI is PCI [13]. All the patients in this study

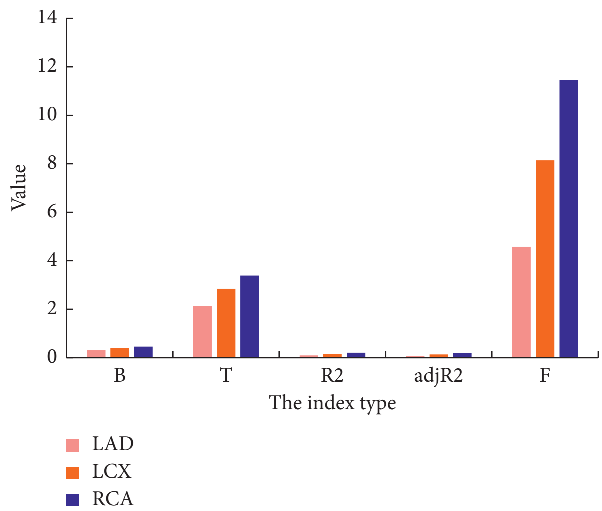

Figure 7: Regression analysis of ECT diagnosis coincidence rate and coronary artery stenosis rate.

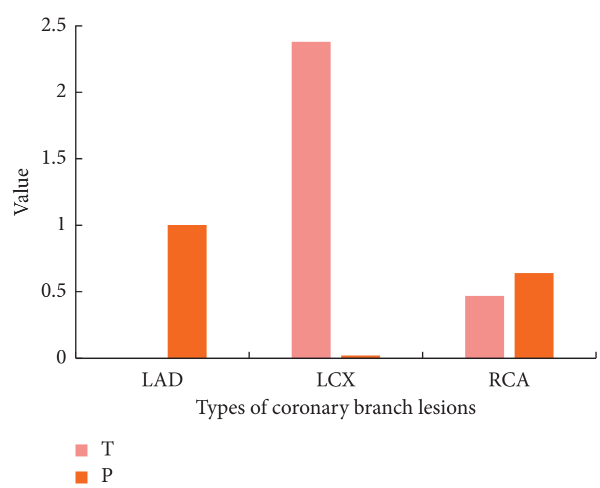

Figure 8: Comparison of the diagnosis coincidence between myocardial ECT imaging and UCG.

underwent PCI seven days after the occurrence of AMI, and the cardiac perfusion function of most patients was improved after the operation. Then, the parameters of cardiac systolic function all changed greatly compared with those before the operation, which suggested that PCI had a good effect on cardiac perfusion and systolic function in patients with AMI.

At present, coronary angiography is still the gold standard for the diagnosis of AMI. With the continuous development of nuclear medicine and imaging technology, radionuclide ECT has also been applied in the diagnosis of heart diseases [14]. ECT is defined as a computer aided technology that uses isotopes to label drugs. Using the principle of human body synthesis, it measures the concentration intensity of isotopes in various organs of the body and its change with time. In this way, the visual shape of the organs is displayed and the functional image information of their physiological process and metabolism is reflected [15]. Clinical data showed that ECT can well reflect myocardial metabolism and blood flow. ECT can also judge the bleeding site, whether bleeding or not, and bleeding area. Compared with coronary angiography, exercise plate, and other examination methods, it has the advantages of noninvasive and no exercise load, which is a noninvasive examination method with good clinical application prospects at present. However, there is currently no consensus on the accuracy, sensitivity, and specificity of ECT in the diagnosis of AMI [16].

Image reconstruction is an important research branch in image processing. It refers to the reconstruction of images based on the data obtained from object detection. Its significance lies in obtaining the image of the internal structure of the detected object without causing any physical damage to the object. Due to its considerable advantages, it has shown unique importance in various application fields [17–19]. For example, it has many applications in medical radiology, nuclear medicine, electron microscopy, radio radar astronomy, light microscopy, holographic imaging, and theoretical vision. FBP algorithm is one of the most widely used algorithms in medical image reconstruction. At present, it is widely used in the generation X-ray CT system [20–22]. CT examination is an important part of the ECT examination. In addition, the images obtained by CT examination are generally of poor quality and low resolution, which seriously affects the quality of the final ECT image fusion. In addition, the images obtained by ECT examination are all the images obtained by the fusion of CT examination and radiological examination, which is also one of the reasons that affect the image quality of ECT examination. At present, the application research of the FBP reconstruction algorithm is basically focused on CT and X-ray image processing, while the application research of ECT image processing is almost absent [23–26].

In this study, the diagnostic effect of ECT image features based on the FBP reconstruction algorithm on the recovery of cardiac function in patients with AMI after PCI surgery was explored. The results showed that all patients had a total of 541 segments before PCI. ECT examination showed 294 abnormal segments of the ventricular wall, with a total score of 585. A total of 100 segments were scored as 1 point, a total of 194 segments were scored as 2 points, and a total of 50 segments were scored as 3 points. After PCI, the abnormal segments were reduced to 58 segments, with a total score of 193. Six segments scored 1 point, 44 segments scored 2 points, and 5 segments scored 3 points. The preoperative EDV, ESV, CO, and EF were 148 ± 16 mL, 77 ± 14.5 mL, 4.29 ± 0.37 L/min, and $41.9 \pm 8\%$, respectively. The EDV, ESV, CO, and EF of the postoperative patients were 132 ± 16 mL, 62 ± 13 mL, 4.89 ± 0.71, and $53 \pm 6\%$, respectively. All systolic function parameters changed significantly after the operation, $P < 0.05$. The standardized regression coefficients of the three groups were 0.32, 0.41, and 0.47, respectively, $P = 0.05$, indicating that the greater the coronary stenosis rate, the higher the diagnostic coincidence rate of LAD, LAD, and RCA. The diagnostic conformity of ECT images in the LCX group for myocardial ischemia was higher than that of UCG, $P < 0.05$, which showed that the results of

ECT examination after PCI showed that the patient's cardiac perfusion and cardiac systolic function were greatly improved. The coincidence rate of the ECT examination based on the filtered back projection reconstruction algorithm for the cardiac function examination results and the coronary angiography examination results increased with the increase of the coronary artery stenosis rate. Compared with cardiac ultrasound, the ECT examination based on the filtered back projection reconstruction algorithm had a higher degree of agreement between the results of the cardiac function examination and the results of coronary angiography. In summary, the ECT technology based on the filtered back projection reconstruction algorithm had a good application prospect in the examination of cardiac function after PCI in AMI patients. However, due to the limited sample size and space, the study was not comprehensive and in-depth enough. In future studies and work, the sample will be further expanded and further studied.

5. Conclusion

This study investigated the diagnostic effect of ECT image features based on the FBP reconstruction algorithm on cardiac recovery after PCI in AMI patients. The results showed that the patients' visceral function recovered significantly after PCI, and ECT based on the FBP reconstruction algorithm had better performance in cardiac function examination than cardiac ultrasound. This study provides a reference and basis for the application of PCI, FBP reconstruction algorithm, and ECT in the diagnosis and treatment of AMI patients. However, due to the limited sample size and space, this study still has some limitations and deficiencies. In future studies and work, we will expand the sample size to further study this problem.

CT image information data under deep learning algorithms was adopted to evaluate small airway function and analyze the clinical efficacy of different glucocorticoid administration ways in asthmatic children with small airway obstruction. The Res-NET in the deep learning algorithm was used to perform feature extraction, summary classification, and other reconstruction of CT images. A deep learning network model Mask-R-CNN was constructed to enhance the ability of image reconstruction. A total of 118 children hospitalized with acute exacerbation of asthma in the hospital were recruited. After acute exacerbation treatment, 96 children with asthma were screened out for small airway obstruction, which were divided into glucocorticoid aerosol inhalation group (group A, 32 cases), glucocorticoid combined with bronchodilator aerosol inhalation group (group B, 32 cases), and oral hormone therapy group (group C, 32 cases). Asthmatic children with small airway obstruction were screened after acute exacerbation treatment and were rolled into glucocorticoid aerosol inhalation group (group A), glucocorticoid combined with bronchodilators aerosol inhalation group (group B), and oral hormone therapy group (group C). Lung function indicators (maximal mid-expiratory flow (MMEF75 and 25), 50% forced expiratory flow (FEF50), and 75% forced expiratory flow (FEF75)), FeNO level, and airway inflammation indicators (IL-6, IL-35, and eosinophilic (EOS)) were compared before and one month after treatment. The ratio of airway wall thickness to outer diameter (T/D) and the percentage of airway wall area to total airway area (WA%) were measured by e-Health high-resolution CT (HRCT). The constructed network model was used to measure the patient's coronary artery plaque and blood vessel volume, and the image was reconstructed on the Res-Net network. It was found that the MSE value of the Res-Net network was the lowest, and the efficiency was very high during the training process. T/D and WA (%) of asthmatic children with small airway obstruction after treatment were significantly lower than those before treatment ($P < 0.01$). After treatment, MMEF75/25 and FEF75 were significantly higher than those before treatment ($P < 0.05$). Lung function-related indicator FEF50 was significantly higher than that before treatment ($P < 0.01$). FeNO level after treatment was remarkably lower than that before treatment ($P < 0.01$). In addition, lung function-related indicators, airway inflammation indicators, and FeNO level improved the most in group C, followed by group B, and those improvements in group A were the least obvious, with great differences among groups ($P < 0.05$). In summary, the Res-Net model proposed was of certain feasibility and effectiveness for CT image segmentation and can effectively improve the clinical evaluation of patient CT image information. Glucocorticoids could improve small airway function and airway inflammation in asthmatic children with small airway obstruction, and oral corticosteroids were more effective than aerosol inhalation therapy.

1. Introduction

Bronchial asthma, referred to as asthma, is a relatively common small airway disease, which is the chronic inflammation of the airway involving a variety of cells such as eosinophils and lymphocytes [1]. The incidence of asthma occurs in all ages, especially in children [2]. Studies have shown that children under the age of 14 suffer the most severe damage from asthma [3]. With the acceleration of urbanization and the increase of air pollution, the prevalence of childhood asthma in China is increasing year by year, which poses a serious threat to children's physical and mental health [4]. Glucocorticoids are the basic drugs for clinical treatment of asthma, which can not only participate in the multiple processes of airway inflammation, but also affect the permeability of capillaries. Moreover, it has a significant effect on alleviating bronchospasm and preventing pulmonary edema. As a result, the lung function is improved, and finally the onset of asthma is inhibited [5, 6]. There are many ways of drug treatment; systemic administration takes effect quickly, yet there are many adverse reactions; thus, it is restricted in clinical use. Local treatments are usually susceptible to drug particle size restrictions. However, the drug directly acts on the target organs, which is safe and effective. Studies have shown that glucocorticoid combined with bronchodilators can improve the clinical symptoms and pulmonary airway function of asthma patients, and the clinical efficacy is better than single administration. Whether the combination of drugs has the same effect on asthmatic children with small airway obstruction is still not clear. Therefore, exploring the different ways of administration of glucocorticoids is of great significance for the clinical treatment of asthmatic children with small airway obstruction.

The small airway is the most important part of asthma and chronic obstructive pulmonary disease. The onset of asthma is characterized by irreversible obstruction of the patient's airway. Therefore, small airways play a key role in the control and management of asthma diseases [7].

Medical image analysis is greatly influenced by subjective experience. The use of CT for auxiliary diagnosis of diseases can quickly and accurately judge diseases and reduce the rate of missed diagnosis and misdiagnosis in clinical diagnosis. It can improve the diagnosis rate of clinical lung cancer, thereby improving the quality of life of patients after surgery. The application of deep learning methods in images can assist physicians to make early disease diagnosis, positive treatment plans, and effective clinical decisions through measurement, evaluation, classification, diagnosis, and assisting preoperative design, which can effectively improve the efficiency of medical imaging for disease detection, recognition, and diagnosis and then promote and realize computer assisted treatment in the field of medical and health. Deep learning can realize image translation and other operations through weight sharing and other methods, optimize complex operations of image preprocessing, and achieve target detection and image classification [8]. With the rapid development of the e-health field, a variety of medical electronic products such as lung function instruments [9], spiral CT [10], and high-resolution CT (HRCT) [11] can be adopted in the detection of small airway diseases. Among them, high-resolution CT is the preferred method for evaluating small airway function, and it is also a hot spot in the field of imaging [12]. Dual-source computed tomography is a new device based on mature 64-slice CT technology. It has a great breakthrough in time resolution. The system imaging time resolution reaches 83 ms, which is 0.1 s less than the time required for cardiac imaging. The speed of each heartbeat is fast, which effectively improves the time resolution and has become the main method for noninvasive diagnosis of coronary heart disease. Dual-source CT has the characteristics of thin layer thickness, small pitch, small collimation, etc. The whole heart cycle exposure scanning method has a large radiation dose to the patient's blood vessels.

HRCT is of high sensitivity and specificity for the detection of small airway diseases, which can quickly collect the information of the lesion area and accurately identify the small structural changes of the airway. It is a safe, noninvasive, and easy-to-operate inspection method, which is widely used in clinical practice. Deep learning networks are often used in medicine to learn original images and are widely used in image segmentation, image classification, and target image positioning. Some scholars have proposed in research that combining pixel information of different scales can extract the best size information; some researchers believe that reducing the size of the convolution kernel can increase the running speed of the neural network. At present, there are few reports on the diagnosis of glucocorticoid in the treatment of children with asthma with small airway function obstruction by high-resolution CT image information data, and the study of deep learning method in this aspect is still insufficient. On the basis of the above research, this research further optimizes the convolutional neural network. The Res-Net network is used to reconstruct CT images, and a deep learning network model is constructed to enhance the ability of image reconstruction. By measuring lung function, airway inflammation indicator, and FeNO level, the clinical efficacy of glucocorticoid therapy was explored, to provide a theoretical basis for the assessment of asthma and the exploration of treatments.

2. Materials and Methods

2.1. Research Subjects. A total of 118 children who were hospitalized with acute exacerbation of asthma from October 2017 to October 2019 were selected, including 72 males and 46 females (6.86 ± 2.31 years). Inclusion criteria: I, patients aged 1–14 years; II, patients who met the diagnostic criteria for childhood asthma [13]; III, patients who could receive FeNO and lung function tests. Exclusion criteria: I, patients received glucocorticoid therapy in the past month; II, patients with antihistamine treatment history; III, patients with lung tissue fibrosis; IV, patients with pneumonia, chronic obstructive pulmonary disease, or malignant tumor; V, patients with poor compliance. This experiment had been approved by the ethics committee of the hospital, and the children and their families included in the study had signed an informed consent.

2.2. Grouping and Treatments. All patients received treatments of anti-inflammatory, anti-asthma, and phlegm, and the course of treatment was 7–12 days. Lung function indicators and FeNO levels were measured after symptom improvement. During this period, 2 children with respiratory failure were excluded. Then, according to the lung function test results, 8 patients with normal small airway function and 12 patients with obstructed atmospheric airway function were excluded. A total of 96 patients with small airway obstruction were screened, and the basic data of patients with mild obstruction (MMEF75/25 ≥ 50%) and patients with severe obstruction (MMEF75/25 < 50%) were compared.

Exclusion criteria for normal small airway function: FEV1/FVC > 70%, FEV1, FVC, and PEF were all greater than 80% of predicted values; there were no more than 2 indicators lower than 65% of predicted values among FEF50%, FEF75%, and MMEF75/25.

Exclusion criteria for atmospheric channel functional obstruction: FEV1/FVC < 70%, FEV1, FVC, and PEF were all less than 80% of predicted values.

Inclusion criteria for small airway obstruction: FEV1/FVC > 70%, FEV1, FVC, and PEF were all greater than 80% of predicted values; there were no less than 2 indicators lower than 65% of predicted values among FEF50%, FEF75%, and MMEF75/25.

A total of 96 small airway obstruction children were randomly divided into group A, group B, and group C. Patients in group A were treated with glucocorticoid aerosol inhalation (local administration), namely, budesonide suspension, twice per day. The children in group B were treated with glucocorticoid combined with bronchodilator aerosol inhalation (local administration), namely, budesonide suspension combined with terbutaline sulfate atomization solution, twice per day. Group C were treated with systemic drug administration, namely, oral methylprednisolone at 8 mg/day.

2.3. HRCT Detection. Patients were examined using Siemens Somatom Definition DSCT, Germany. The e-health equipment HRCT was adopted to examine asthmatic children with small airway obstruction. Target scanning technology was adopted, and scanning was performed when patients were peacefully breathing. The scanning range included the aortic arch, tracheal bifurcation and 2 cm below the bifurcation, 2 cm above the top of the pulmonary diaphragm, and the inferior pulmonary vein trunk, with a total of 5 layers. Scanning parameters: 120 kV, 200 mA; reconstruction parameters: 1200–1500 Hu window width, −500 window level, 3 mm layer thickness, and 2 mm layer spacing. Two or more experienced pediatric imaging physicians selected all levels of airway on the cross-sectional image for measurement. The measurement diagram of the airway wall inner diameter L and the airway wall outer diameter D is shown in Figure 1, and the average value was taken.

The ratio of airway wall thickness to outer diameter (T/D) was calculated according to the following equation, and the percentage of airway wall area accounting for airway cross-sectional area (WA%) was calculated via equation (2).

$$\frac{T}{D} = \frac{D - L}{2D}, \tag{1}$$

$$\text{WA\%} = \frac{\pi (D/2)^2 - \pi (L/2)^2}{\pi (D/2)^2} \times 100\%. \tag{2}$$

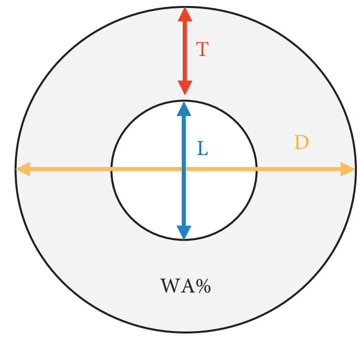

Figure 1: Schematic diagram of measurement of the inner and outer diameter of airway wall.

2.4. Deep Learning Reconstruction Algorithm. There are many algorithms for CT image reconstruction using deep learning, and the filtered backprojection algorithm can reconstruct CT images with better quality. The research on the network structure of deep learning is getting more and more in-depth, and the deep abstract semantic information of the image can also be extracted. As the number of layers increases, different neural networks have different trends in the classification of accuracy in the model. Networks such as AlexNet, GoogLeNet, and Res-Net are gradually decreasing in classification accuracy. The network depth keeps increasing, and the accuracy will increase to a certain extent, but beyond this level, there will be a gradient explosion problem, so the accuracy of the model training will decrease. In the NesNet network, there are residual errors and the results of the remaining modules, and its accuracy is better than that of networks such as AlexNet and GoogLeNet. As shown in Figure 2, the module connects the output to the input through skip connect. In the convolution calculation, a lot of image information corresponding to the input feature mapping of the residual module can be retained. This realizes that the NesNet network effectively improves the model when it is added in-depth.

2.5. Design of the Network Model. The R-CNN in the deep learning model follows the traditional target detection idea, first extracting candidate frames, and then extracting features for each frame. In the Fast-R-CNN network structure, classification, feature extraction, proposal extraction, and border regression are integrated into one network, which is conducive to the deep learning network to complete multiple tasks at the same time, and the detection speed is significantly improved. As shown in Figure 3, Mask-R-CNN adds a branch to Fast-R-CNN to obtain a new network framework. This new mask branch is applied to each RoI (Region of Interest). The small-scale fully convolutional neural network predicts the segmentation mask in a pixel-to-pixel manner, and a variety of flexible architecture designs are also added to the training. Mask-R-CNN uses bilinear interpolation to obtain the key coordinates of the small unit and performs the maximum pooling operation internally.

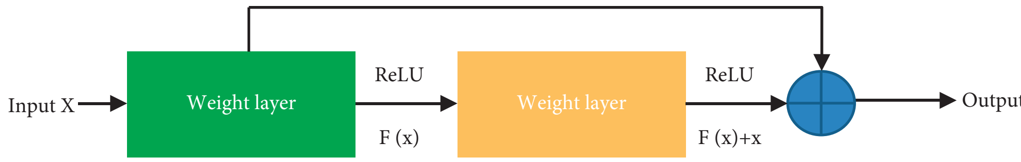

Figure 2: ResNet.

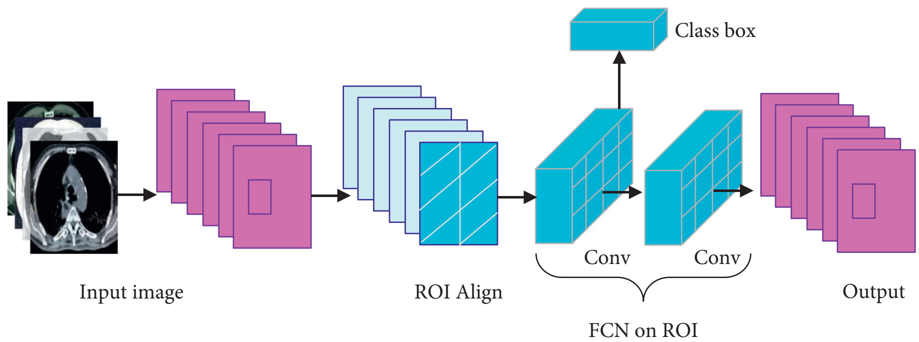

Figure 3: Structure of mask-R-CNN.

2.6. Model Improvement. The neural network trains the initial weight file on the MSCOCO data set in advance and trains it in the subsequent training process. The neural network of the multilayer residual block constitutes a semantic feature extraction module. The information after the module convolution operation and the input information are connected by the residual block through Skip connect to ensure the integrity of the information flow. The residual equation is as follows:

$$H(x) = F(x) + X. \tag{3}$$

In equation (3), $F(x)$ is the result of the convolution operation of the current residual block of the input information X. The upsampling function enables the input image to obtain deep abstract semantic information and restore feature maps of different sizes. When predicting the candidate frame, the feature map generated in the first step needs to have anchor boxes with different aspect ratios. If the size of the i-layer image is (H, W), and n is the number of candidate frame aspect ratios, then the aspect ratio $R = [R1, R2, R3, \ldots, Rn]$, H means height, and W means width; then, the equation for the total number of anchor boxes in this layer is expressed as

$$N = H \times W \times n. \tag{4}$$

Anchor boxes of different specifications slide on the feature map, and the target area is not necessarily within the frame selection area. The selection of the candidate frame in the algorithm is based on the degree of overlap (IOU) between the content of the candidate frame and the gold standard. If C is the candidate frame area, and D is the gold standard area, then equation (4) indicates that the coincidence degree of the two areas is

$$\mathrm{IOU} = \frac{(C \cap D)}{(C \cup D)}. \tag{5}$$

Let β be the threshold; if IOU $<\beta$, the candidate region is considered as a positive sample; if IOU $>\beta$, the candidate region is considered as a negative sample. After the Anchor box detection is valid, the offset between the candidate box and the gold standard is calculated. Let the height and width of the candidate box be (H, W), the center coordinates of the Anchor box (a, b), the height and width of the image (H_1, W_1), and the target coordinates (a_1, b_1), and then the offset is

$$\begin{aligned}
\Delta a &= \frac{a_1 - a}{W},\\
\Delta b &= \frac{b_1 - b}{h},\\
\Delta w &= \log \frac{w_1}{W},\\
\Delta h &= \frac{h_1}{h}.
\end{aligned} \tag{6}$$

After the prediction of the candidate box, enter the Anchor box in the RPN network example for classification and regression. First, the gold standard corresponding to the positive sample and the screening are performed to obtain the score of the Anchor box. Calculate the cross entropy function. The cross entropy function can adjust the backpropagation and classification. The function equation is as follows:

$$\mathrm{LOSS}_C = \sum_{j=1}^{T} y_j \log \frac{e^{aj}}{\sum_{K=1}^{T} e^{ak}}. \tag{7}$$

In the equation, y_j represents the probability value of the gold standard corresponding to the positive sample, and a_j represents the predicted probability of the sample before normalization. The loss function calculation is performed according to the offset calculated when the anchor box is generated and the offset between the positive sample and the gold standard. The equation is as follows:

$$\text{smooth}\,L(x) = \begin{cases} 0.5\,(x)^2, & if\ |x| < 1, \\ |x| - 0.5, & \text{otherwise}, \end{cases} \qquad (8)$$
$$L = \sum \text{smooth}_L\,(t - t^*).$$

The target area scores are obtained for sorting, and the candidate frames with high scores are normalized by bilinear interpolation.

2.7. Detection Indicators

2.7.1. FeNO. FeNO levels of children in each group were measured before and 1 month after treatment. Preparation before the test was as follows. Fasting food with high nitrogen content was conducted 10 hours before the test, and the consumption of stimulants drinks such as caffeine was prohibited. The strenuous activities were avoided, and the child was kept calm. Specific detection method: the nose clip was used to gently clip the patient's nose, and the filter was held by the mouth. Children breathed the air in lung out, then breathed normally, and kept the uniform speed of breath about 5 s.

2.7.2. Pulmonary function. Pulmonary ventilatory function was measured before and 1 month after treatment in each group with the Jaeger Master Screen. Children should not take hormones, bronchodilators, and other drugs one day before the test. Two hours before the test, children should fast for solids and liquids, avoid strenuous exercise, and remain calm. Specific test method: children should sit and then close the nasal cavity and mouth with a nasal clip to completely contain the filter. After breathing normally several times, children should try their best to exhale the air in the lungs quickly. The test was repeated for several times, the three test values conforming to the quality control standard were taken, and the maximum value was taken as the final test result. The indicators of small airway were as follows: MMEF75/25, FEF50%, FEF75%, FEV1, PEF, and FVC. The improvement rate = (Posttreatment − pretreatment)/pretreatment × 100%.

Serum airway inflammation indicators: IL-35 and IL-6 levels were detected by ELISA, and EOS was determined by automatic blood count.

2.8. Statistical Analysis. SPSS22.0 statistical software was used for analysis. Normally distributed measurement data were expressed as mean plus or minus standard deviation ($\overline{x} \pm s$), and differences between groups were analyzed by variance analysis. If $P < 0.05$, the difference was statistically significant.

3. Results

3.1. Comparison of Clinical Data. A total of 118 children with bronchial asthma were treated in the acute exacerbation period, after which 12 cases of children with large airway injury were excluded, 8 cases of small airway function were normal, and 2 cases of respiratory failure were also excluded. Table 1 shows comparison of basic data of children with different degrees of small airway obstruction. There was no significant difference in age, gender, and BMI between children with mild obstruction and children with severe obstruction ($P > 0.05$). The course of children with mild obstruction was 18.56 ± 8.69 (months), and the interval of medication was 7.36 ± 5.47 (h). The course of the children with severe obstruction was 20.26 ± 5.38 (months), and the interval of medication was 9.76 ± 6.59 (h). The duration of the disease in children with severe obstruction was longer than that in children with mild obstruction, and the time interval from onset to regular medication was longer than that of children with mild obstruction ($P < 0.05$).

Table 2 shows the comparison of baseline data of the three groups of asthmatic children with small airway obstruction. There were no statistically significant differences in age, gender, BMI, lung function-related indicators (MMEF75/25, FEF50, and FEF75), and FeNO levels between group A, group B, and group C ($P > 0.05$). However, the three groups had statistically significant differences in the course of disease and interval between medications ($P < 0.05$).

3.2. Imaging Characteristics of Asthmatic Children with Small Airway Obstruction. The HRCT of e-health equipment was adopted to examine the characteristics of small airway lesions in asthmatic children with small airway obstruction, as shown in Figure 4. In some patients, the wall of the bronchioles had thickened, with small nodules, branch shadows, or ring shadows (Figure 4(a)). About 3–5 mm below the pleura, there were multiple small nodules and branch-like dense shadows distributed in the center of the leaflets, which looked like branch buds (Figure 4(b)). The lungs had limited low-density shadows and clear edges (Figure 4(c)). Irregular patterns or patches appeared in areas with increased lung density and areas with decreased lung density, but the edges were very clear (Figure 4(d)). The red box in the images indicated the location of the lesion.

3.3. Comparison of HRCT Test Results and Small Airway Function before and after Treatment. HRCT was used to detect changes in T/D and WA (%) in asthmatic children with small airway obstruction in asthma before and after treatment. In Figure 5, before treatment, T/D and WA (%) were 34.65 ± 3.86 (%) and 85.29 ± 12.54 (%), respectively. After one month of treatment, the T/D and WA (%) of asthmatic children with small airway obstruction were 23.38 ± 3.27 (%) and 78.65 ± 13.45 (%), respectively. The T/D and WA (%) of asthmatic children with small airway obstruction after treatment were significantly lower than those before treatment ($P < 0.01$).

Before treatment, the MMEF75/25, FEF50, and FEF75 of asthmatic children with small airway obstruction were 2.08 ± 0.52, 2.38 ± 0.48, and 1.25 ± 0.32, respectively. After one month of treatment, the MMEF75/25, FEF50, and

Table 1: Basic conditions of children with different degrees small airway obstruction.

Figure 4: HRCT images of asthmatic children with small airway obstruction. (a) Bronchiolar wall thickening; (b) tree-in-bud; (c) air trapping; (d) mosaic sign.

FEF75 of asthmatic children with small airway obstruction were 2.88 ± 0.84, 3.24 ± 0.79, and 1.68 ± 0.39, respectively. After treatment, the pulmonary function-related indicators MMEF75/25 and FEF75 were significantly higher than those before treatment ($P < 0.05$). After treatment, FEF50, a related indicator of lung function, was extremely significantly higher than that before treatment ($P < 0.01$) (Figure 6(a)). The FeNO level of asthmatic children with small airway obstruction was 35.00 ± 2.11 (ppb) before treatment and 34.12 ± 2.16 (ppb) after treatment. The FeNO level after treatment was lower than that before treatment ($P < 0.01$), as shown in Figure 6(b).

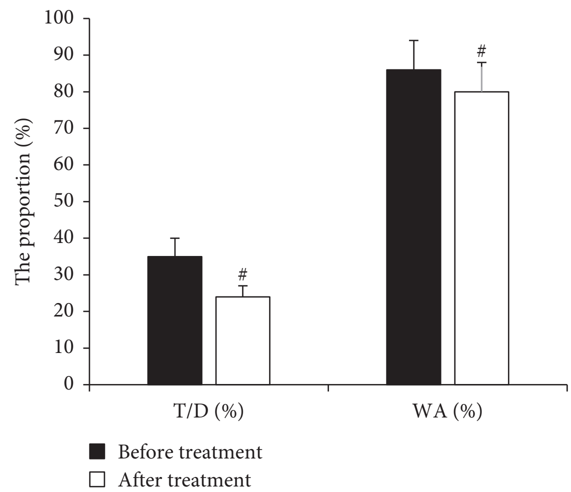

Figure 5: Comparison of T/D and WA (%) before and after treatment ($^{\#}P < 0.01$ as compared to that before treatment).

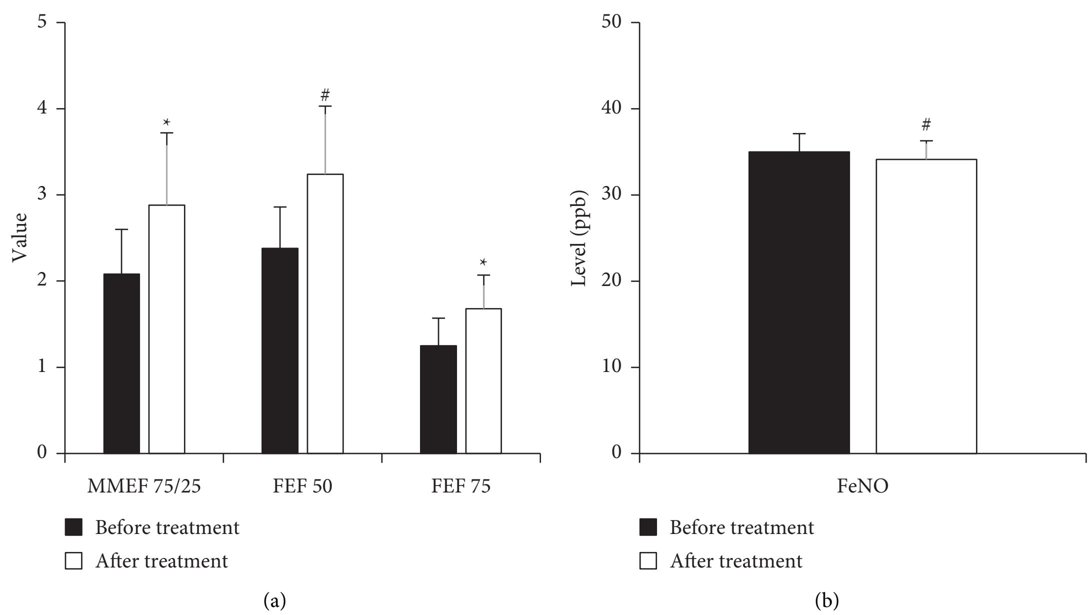

Figure 6: Comparison of lung function-related indicator and FeNO level before and after treatment. (a) Lung function-related indicator; (b) FeNO; $^{*}P < 0.05$ as compared to that before treatment; $^{\#}P < 0.01$ as compared to that before treatment.

3.4. Comparison of Improvement of Small Airway Function in Each Group. Figure 7 shows the changes in lung function of children in each group after treatment. The MMEF75/25 values of group A, group B, and group C were 2.55 ± 0.68, 2.92 ± 0.76, and 3.13 ± 0.92, respectively; FEF50 values were 2.82 ± 0.68, 3.03 ± 0.70, and 3.78 ± 0.74, respectively; FEF75 values were 1.50 ± 0.21, 1.71 ± 0.39, and 1.76 ± 0.46, respectively. The improvement rates were 17.32 ± 5.87 (%), 34.36 ± 4.98 (%), and 56.12 ± 9.54 (%), respectively. The MMEF75/25, FEF50, and FEF75 values and improvement rate of children in group B were significantly higher than those in group A ($P < 0.05$). The values of MMEF75/25, FEF50, FEF75, and improvement rate of children in group C were significantly higher than those in groups A and B ($P < 0.05$).

Figure 8 shows the comparison of FeNO levels of children in each group after treatment. FeNO levels of group A, group B, and group C were 34.76 ± 2.07 (ppb), 34.12 ± 2.18 (ppb), and 33.28 ± 2.16 (ppb), respectively. The FeNO level of children in group B was lower than that of group A ($P < 0.05$), and the level of FeNO of children in group C was lower than that of groups A and B ($P < 0.05$).

3.5. Comparison of Airway Inflammation Indicators in Each Group. The comparison of IL-6 and IL-35 levels of children in each group before and after treatment is shown in Figure 9. In Figure 9(a), the IL-6 levels (ng/mL) before treatment in group A, group B, and group C were 6.24 ± 1.54,

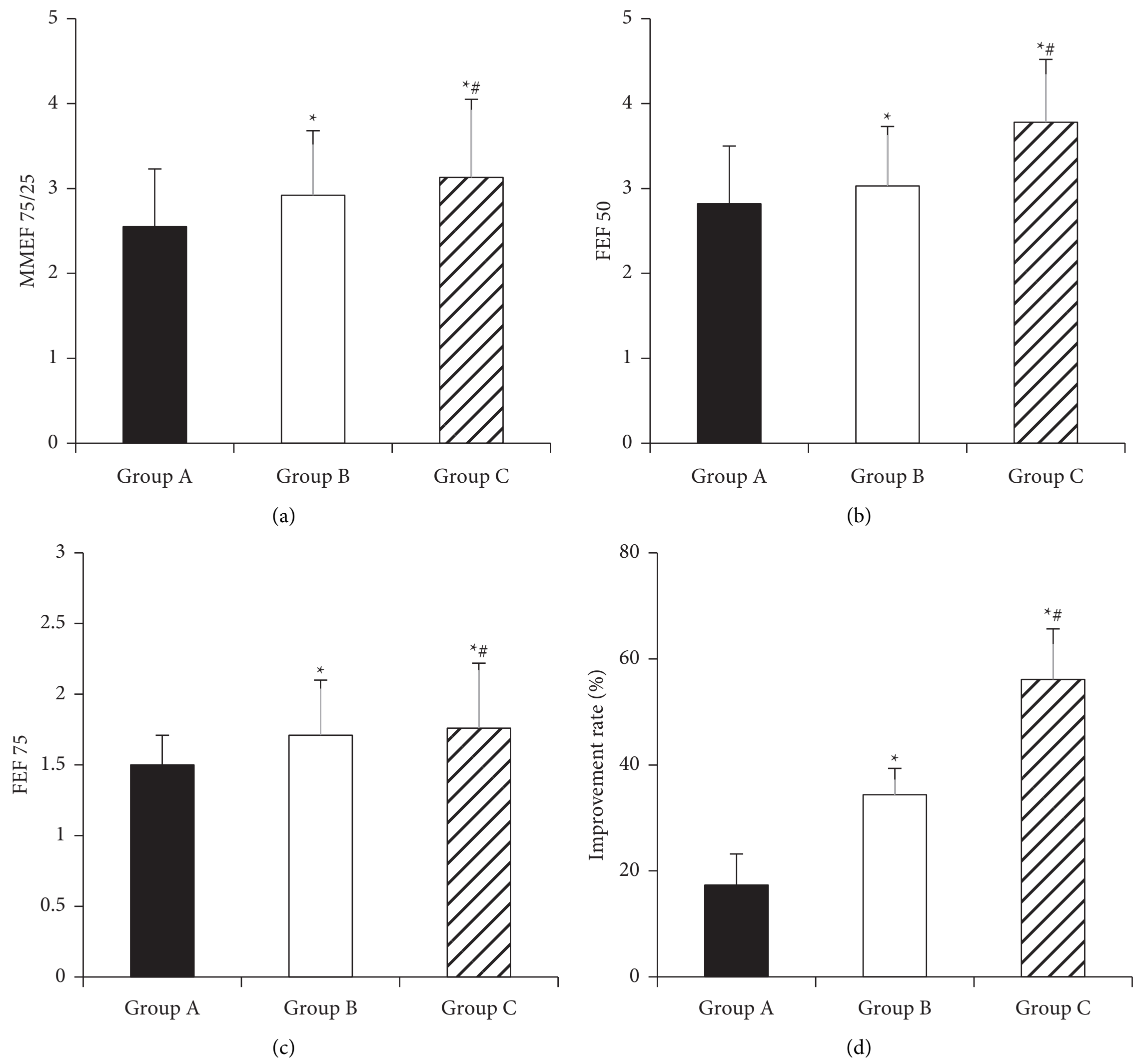

Figure 7: Comparison of lung function-related indicator after treatment in each group. (a) MMEF75/25; (b) FEF50; (c) FEF75; (d) improvement rate; *compared with group A $P < 0.05$; #compared with group B $P < 0.05$).

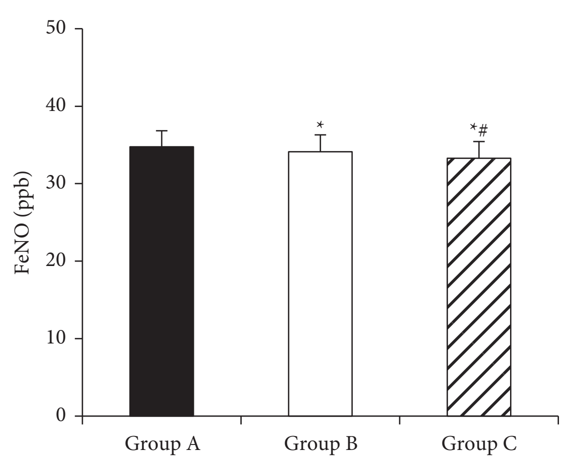

Figure 8: Comparison of FeNO levels after treatment in each group (*compared to group A ($P < 0.05$; #compared to group B $P < 0.05$).

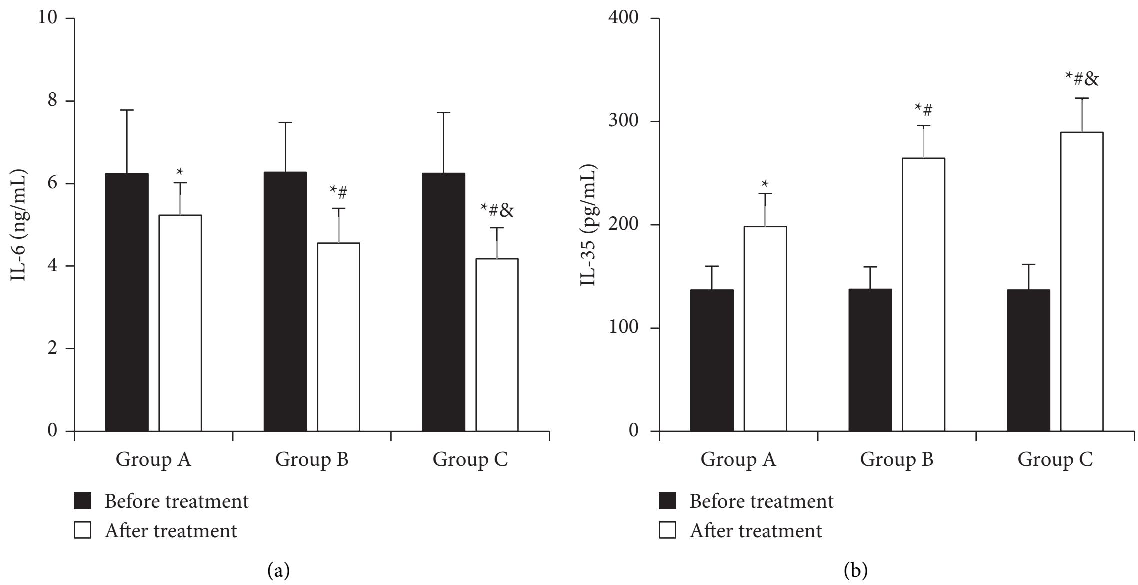

Figure 9: Comparison of IL-6 and IL-35 levels before and after treatment in each group. (a) IL-6; (b) IL-35; $^*P < 0.05$, compared to that before treatment; $^\#P < 0.05$, compared to that in group A; $^\&P < 0.05$, compared to that in group B.

6.27 ± 1.21, and 6.25 ± 1.47, respectively. The levels of IL-6 (ng/mL) after treatment were 5.23 ± 0.79, 4.56 ± 0.84, and 4.18 ± 0.75, respectively. After treatment, the IL-6 level of children in each group was significantly lower than that before treatment ($P < 0.05$), that of children in group B was lower than that of group A ($P < 0.05$), and that of children in group C was lower than that in group A and group B ($P < 0.05$). In Figure 7(b), the IL-35 levels (Pg/mL) of group A, group B, and group C before treatment were 136.67 ± 23.26, 137.56 ± 21.67, and 136.96 ± 24.72, respectively. The levels of IL-35 (Pg/mL) after treatment were 198.25 ± 32.02, 264.59 ± 31.64, and 289.65 ± 33.12, respectively. The levels of IL-35 in children in each group were significantly higher than those before treatment ($P < 0.05$), those in group B were higher than those in group A ($P < 0.05$), and those in group C were higher than those in group A and group B ($P < 0.05$).

The comparison of EOS values before and after treatment in each group is shown in Figure 10. The EOS ($\times 10^6$/L) before treatment in group A, group B, and group C was 685.28 ± 86.26, 692.54 ± 76.78, and 689.62 ± 79.94, respectively. EOS ($\times 10^6$/L) after treatment was 264.27 ± 42.65, 225.62 ± 40.37, and 201.35 ± 42.19, respectively. After treatment, the EOS of children in each group was significantly lower than that before treatment ($P < 0.05$), that of group B was lower than that of group A ($P < 0.05$), and that of group C was lower than that of group A and group B ($P < 0.05$).

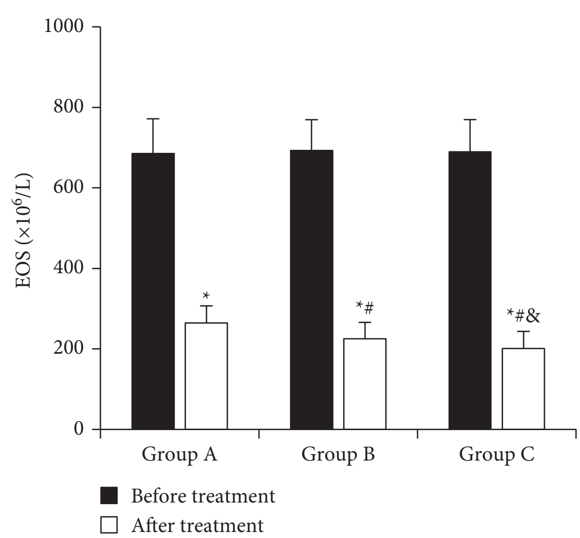

Figure 10: Comparison of EOS values before and after treatment in each group. $^*P < 0.05$, compared to that before treatment; # $P < 0.05$, compared to that in group A; & $P < 0.05$, compared to that in group B.

3.6. MSE Curve. The smaller the MSE, the better the accuracy of the prediction model to describe the experimental data. In Figure 11, the Res-Net network has a smaller MSE than the other two networks, and the effect is extremely fast during the training process, indicating the improvement. The network effect is remarkable.

3.7. CT Image. Figure 12(b) shows a CT image of the lungs. The patient was a male 52-year-old patient. Compared with the right lung, the left lung is obviously branched. In Figure 12(a), the patient's lungs show that the bronchial tubes are not thinned but widened, which is a typical branch expansion. The red box in the figure shows the characteristics of the lesion CT.

4. Discussion

Asthma is a heterogeneous disease of the airways, whose attacks usually involve the air passages and can also cause

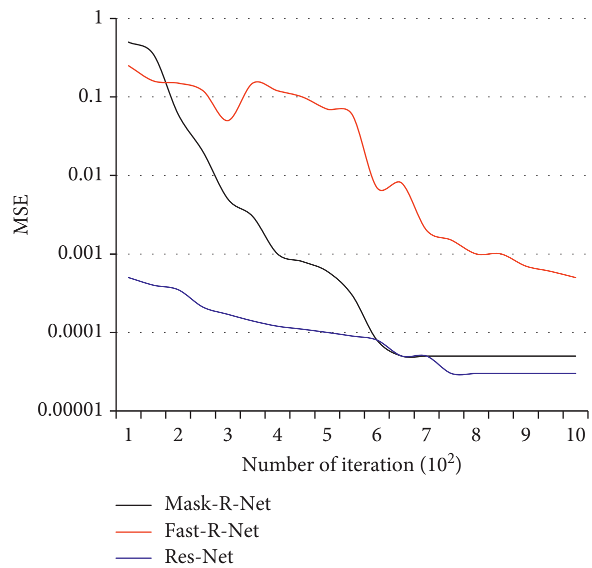

Figure 11: MSE curve diagram.

Figure 12: CT image of the patient's lungs.

obstruction or airflow limitation of small airways. e-health HRCT is an effective method to detect changes in airway structure. e-health HRCT was used to evaluate imaging changes in asthmatic children with small airway obstruction, and features such as thickening of bronchial wall, tree-in-bud, air trapping, and mosaic sign were found. It was almost consistent with the findings of Garcia-Clemente et al. [14]. In the research of Jiang et al. [15], 9 patients with small airway asthma and 20 healthy controls underwent HRCT with e-Health equipment, and the results showed that WA% in patients with small airway asthma was higher than that in healthy controls. In this research, T/D and WA (%) after glucocorticoid treatment were significantly lower than those before treatment ($P < 0.01$), which demonstrated the effectiveness of glucocorticoids in the treatment of asthma with small airway obstruction from the perspective of imaging.

FEEF50%, FEF75%, and MMEF75/25 are important clinical indicators for the evaluation of small airway function [16], and glucocorticoid is an effective method in preventing and treating asthma. FEEF50%, FEF75%, and MMEF75/25 were measured to evaluate the pulmonary function of asthmatic children with small airway obstruction before and after treatment. It was found that MMEF75/25 and FEF75 were significantly higher than those before treatment ($P < 0.05$), and FEF50 was significantly higher than that before treatment ($P < 0.01$). It suggested that, after glucocorticoid treatment, the pulmonary function of asthmatic children with small airway obstruction was effectively improved, which was consistent with the research results of Licari et al. [17]. FeNO is a marker of airway inflammation, and the greater the value, the more serious the airway obstruction [13]. It was found that FeNO level after treatment was lower than that before treatment ($P < 0.01$), indicating that glucocorticoid had alleviative effect on airway inflammation. Inflammatory cells in asthmatic children were activated, and there were more EOS in the airway epithelium, secreting a large amount of eosinophil basic protein, thus inducing the inflammatory damage of airway epithelium. The results showed that IL-6 and IL-35 played an important role in inflammatory response and airway hyper-responsiveness. It was found that IL-6, IL-35, and EOS of the children in each group were significantly improved after treatment compared with those before treatment, and the improvement was more obvious in group C compared with the other two groups. It suggested that glucocorticoids could relieve airway inflammation, and systemic administration was superior to local treatment. The results showed that aerosol therapy was superior to oral therapy. The atomizing device can disperse drugs into tiny droplets or particles, so that they are suspended in the gas, enter the respiratory tract or lung, and directly affect the drug on the lesion site, which can then wet the airway, clean the airway, and realize treatment effect.

Deep learning continues to develop rapidly. Researchers use repetitive programming of related programs to achieve effective deep learning algorithms. In deep learning, only the appropriate model needs to be selected, and the weight parameters of the model area are optimized after training. Chen et al. [18] simulated the evacuation design of buildings in the network model based on deep learning, introduced auxiliary image data prediction training algorithm, tracking sequence prediction training algorithm, and verified that the convolutional neural network model can predict data accuracy of the set. After the image is classified by deep learning, the location of the lesion can be displayed more clearly, and the characteristics of the lesion can be clearly classified. The image segmentation for deep learning in medicine includes convolutional neural network image segmentation and full convolutional neural network image segmentation. Frikel et al. [19] used microburst analysis to illustrate the appearance of artifacts in CT reconstruction images, which proved that deep learning algorithms can reconstruct the structure information of the scan target, and deep learning algorithms can achieve the effect of noise reduction.

5. Conclusion

The e-health equipment HRCT was adopted to diagnose childhood asthma with small airway obstruction. In this study, it was found that, after one month of treatment for children with asthma with small airway obstruction, the indexes related to lung function were significantly higher than those before treatment ($P < 0.05$), and the FeNO level of children with asthma with small airway obstruction was 35.00 ± 2.11 (ppb) before treatment and 34.12 ± 2.16 (ppb) after treatment. One month after treatment, T/D and WA were 23.38 ± 3.27 (%) and 78.65 ± 13.45 (%), respectively. Overall results showed that oral treatment was superior to aerosol inhalation. However, there are still some shortcomings in this research. For example, the number of samples is limited, and the clinic time and hospital are limited. Only the small airway function in one month after treatment is analyzed, but the long-term efficacy and possible side effects of the drug are not discussed. In the future, it needs to increase the diversity of sample regions and time, and further research on the effect of improving small airway function will be conducted. In short, the results of this study can provide a theoretical basis for the diagnosis and clinical treatment of asthma patients with small airway obstruction.

The study aimed to explore the accuracy and stability of Deep metric learning (DML) algorithm in Magnetic Resonance Imaging (MRI) examination of Alzheimer's Disease (AD) patients. In this study, MRI data of patients obtained were from Alzheimer's Disease Neuroimaging Initiative (ADNI) database (A total of 180 AD cases, 88 women, 92 men; 188 samples in healthy conditions (HC), including 90 females and 98 males. 210 samples of mild cognitive impairment (MCI), 104 females and 106 males). On the basis of deep learning, an early AD diagnosis system was constructed using CNN (Convolutional Neural Network) and DML algorithms. Then, the system was used to classify AD, HC, and MCI, and the two algorithms were compared for the accuracy and stability of in classification of MRI images. It was found that in the classification of AD and HC, the classification accuracy and sensitivity of the deep measurement learning model are both 0.83, superior to the CNN model; in terms of specificity, the classification specificity of the DML model was 0.82, slightly lower than that of the CNN model; and that in the classification of MCI and HC, the classification accuracy and sensitivity of the DML model was 0.65, superior to the CNN model; and in terms of specificity, the classification specificity of the DML model was 0.66, slightly lower than that of the CNN model. It suggested that the DML model demonstrated better classification effects on early AD patients. The loss curve analysis results showed that, for classification of AD and HC or MCI and HC, the DML algorithm can improve the convergence speed of the AD early prediction model. Therefore, the DML algorithm can significantly improve the clarity and quality of MRI images, elevate the classification accuracy and stability of early AD patients, and accelerate the convergence of the model, providing a new way for early prediction of AD.

1. Introduction

Alzheimer's Disease (AD) is a chronic neurodegenerative cognitive disease. At the onset of the disease, patients will suffer from cognitive dysfunction such as memory loss and language function loss [1]. Nowadays, with the aging of the population, the AD population is increasing rapidly, and it has become a major disease threatening the health of the elderly, which seriously affects the quality of life of the elderly, and the need for nursing and care brings about heavy burdens to the patient's family and society [2]. Clinically, the cause of Alzheimer's disease is still unclear, and the condition is irreversible, and a thorough treatment of the disease has not yet been developed [3]. Only when AD is diagnosed in the early stage can it be possible to slow down or inhibit the progression. Thus, early prediction and diagnosis of AD is very important and meaningful in clinical treatment. Mild Cognitive Impairment (MCI) is a cognitive dysfunction between Alzheimer's disease (AD) and Healthy Controls (HC) [4]. Studies have found that, most patients with MCI have developed AD [5].

At present, Magnetic Resonance Imaging (MRI) technology is a main method to diagnose AD. Studies have discovered that, there are prominent biological signs in the brains of AD patients, which is conducive to the early prediction and diagnosis of AD [6]. In-depth clinical research on AD has revealed that, family inheritance is an important cause of AD [7].

Artificial intelligence (AI) has developed rapidly in recent years, and AI technology has been widely used in the medical field [8]. Nowadays, machine learning (ML) or Deep Learning (DL) algorithms are always incorporated into MRI imaging [9], but the above methods all have limitations [10]. The machine learning algorithm analyzes the MRI image only after manually determining the area, but subjective factors will affect the subjectivity of the results [11]. Deep learning algorithms can automatically extract features of MRI images, but fails to interpret these features. As a result, it is difficult to identify biological features of AD [3]. Convolutional Neural Networks (CNN) is a kind of Feedforward Neural Networks with deep structure and convolution computation, which is one of the representative algorithms of deep learning and has the ability of representation learning. It can effectively reduce the dimension of a large amount of data into a small amount of data, while retaining image features, in line with the principle of image processing. Deep metric learning (DML) is a metric learning method. It is to learn a mapping from the original feature to the low-dimensional and dense vector space, so that the distance between objects of the same class is relatively close by using the commonly used distance function in the embedding space, while the distance between objects of different classes is relatively far.

In the study, the MRI data (There were 180 cases of AD, including 88 women and 92 men. There were 188 HC samples, including 90 females and 98 males. There were 210 samples of mild MCI, 104 females and 106 males) of patients were from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database. The traditional machine learning algorithms and Convolutional Neural Networks (CNNs) were optimized by deep learning to construct an early diagnosis system of AD based on Depth metric learning (DML) algorithm. The system was used to classify AD, MCI, and HC, and different algorithms were compared for the clarity and specificity of MRI images.

2. Materials and methods

2.1. Experimental data. The experimental data of this study were from the ADNI database [12]. The MRI image data used in this article were divided into 3 categories, namely: 180 cases of AD, including 88 cases of females, and 92 cases of males; 188 samples of HC, including 90 cases of females and 98 cases of males; and 210 samples of MCI, including 104 females and 106 males. There was no significant difference in age and gender of the three types of subjects, and the average age was approximately 74 years old.

2.2. Pre-processing of MRI images. Figure 1 showed the preprocessing of the MRI image, including correction, segmentation, template formation, and skull removal. The MRI images were obtained at various angles due to the head movement during MRI scan. Generally, the brain MRI image includes the skull and neck bones, and the skulls and neck bones are different in size, thickness, and length between individuals. The classification of AD is mainly to analyze the internal tissue structure of the brain, and thus the skull and neck bones in the MRI image are all noise signals.

2.3. CNN model and parameters. CNN is extensively used in the field of image recognition for its unique structure [13]. To use deep learning technology to automatically segment MRI images can greatly reduce the dependence on the subjective judgment of doctors. The traditional CNN structure mainly includes the convolutional layer, the pooling layer, and the fully connected layer. The neural unit layers of various functions are stacked to form a deep CNN, as shown in Figure 2. There are a total of 8 convolutional layers, and the size of the convolution kernel used by each convolutional layer is 3×3×3, and the step size is 1×1×1. There are 5 pooling layers, all pooling layers use Maximum pooling, and the core size and step size of the first pooling layer are 1×2×2, that is, the time dimension is not pooled, and the core size and step size of the remaining pooling layers are 2×2×2. There are two fully connected layers, and the length of the output column vector is 4096. There is a softmax layer. The convolutional pooling layer aims to reduce the size of the feature map by half and double the number of channels.

2.4. DML loss function. The classification data used in this study contained data of AD, HC, and MCI. They were classified into two categories, namely AD and HC, MCI and HC. In the classification of AD and HC, the category label of AD is 0 and the category label of HC is 1. In MCI and HC, the category label of MCI is 0 and the category label of HC is 1.

2.4.1. Cross entropy loss function. This study uses the cross-entropy loss function, and the two-category cross-entropy loss function is adjusted to the following equation (1).

$$\text{cross\_entropy} = \frac{1}{N}\sum_{k=1}^{N} -\left[w_k \ln x_k + (1-w_k)\ln(1-x_k)\right], \tag{1}$$

Where N refers to the batch size, w_k represents the category of the Kth subject, and x_k refers to the probability that the Kth category label predicted by the detection system is 1, calculated as follows.

$$x_k = \text{Softmax}(w_k) = \frac{\exp(w_k^1)}{\exp(w_k^0) + \exp(w_k^1)}, \tag{2}$$

Where w_k refers to Kth classification vector, w_k^0 represents the first w_k value, and w_k^1 refers to the second w_k value.

2.4.2. Loss function based on metric learning. The loss function of metric learning is expressed as equation (3).

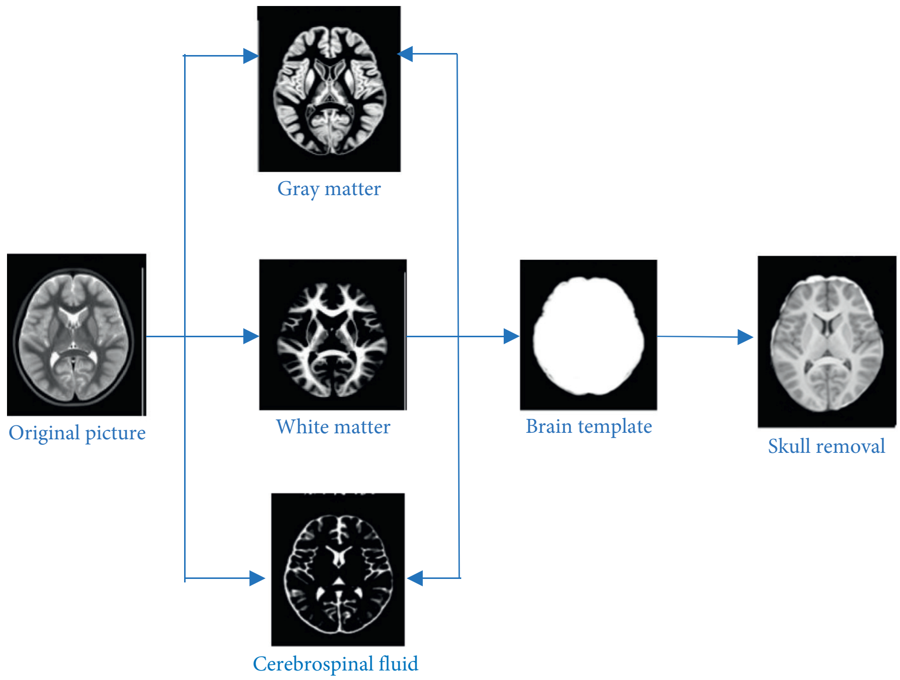

Figure 1: Preprocessing of MRI images.

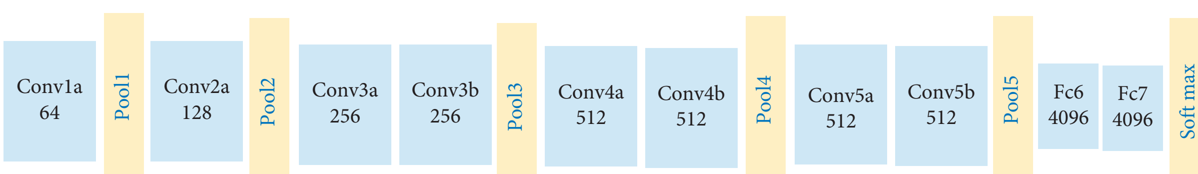

Figure 2: CNN structure.

$$\text{loss}_{\text{contrastive}} = \frac{2}{N(N+1)} \sum_{h=1} \sum_{g=h} \left[w_{hg} m\left(x_h, x_g\right) + \left(1 - w_{hg} \max\left(a - D\left(x_h, x_g\right), 0\right)\right) \right], \tag{3}$$

Where N refers to the batch size, a refers to the interval, x_h is the hth sample and x_g is the g th sample. When x_h and x_g belong to different categories, w_{hg} is 0; and when x_h and x_g belong to the same category, w_{hg} is 1. $D(x_h, x_g)$ is calculated as equation (4), and $f(x)$ represents the output vector.

$$D(x, y) = f(x) - f(y)_2. \tag{4}$$

2.4.3. Overall loss function. This research combines AD classification and DML to construct a DML loss function, expressed as follows.

$$\text{loss} = \text{cross}_{\text{entropy}} + q\,\text{loss}_{\text{conrastive}}, \tag{5}$$

Where $\text{cross}_{\text{entropy}}$ is calculated by equation (1); and $\text{loss}_{\text{conrastive}}$ is calculated by equation (3). The value of q is greater than 0, and it refers to the adjustment coefficient of classification and measurement loss.

2.5. Evaluation Index. The performance of predictive classification algorithms of early AD was evaluated factoring into Accuracy (Acc), Sensitivity (Sens), and Specificity (Spec). The number of patients accurately diagnosed is represented by the letter A, the number of normal subjects diagnosed as normal is represented by the letter B, the number of normal subjects who are incorrectly diagnosed as patients is represented by the letter C, and the number of patients who are mistakenly diagnosed as normal people is represented by the letter D. The involved indexes are calculated as follows.

Acc refers to the proportion of the number of people who can be correctly predicted and classified, calculated as equation (6).

$$Acc = \frac{A + B}{A + B + C + D}. \tag{6}$$

Sens refers to the ratio of the patients who are correctly detected to the total number of patients, calculated as equation (7).

$$\text{Sens} = \frac{A}{A + D}. \tag{7}$$

Spec refers to the ratio of the correctly detected normal samples to the total number of normal people, calculated as equation (8).

$$\text{Spec} = \frac{B}{B + C}. \tag{8}$$

2.6. Statistical analysis. Statistical analysis was performed using SPSS 24.0 software, expressed as mean ± standard deviation ($\bar{x} \pm s$). The count data were analyzed by t test, and α=0.05. $P < 0.05$ was the threshold for significance.

3. Results

3.1. Brain MRI features of AD patients. Figure 3 below showed MRI images of the brain of AD patients and normal people. In the MRI images of the brain of AD patients, brain atrophy was observed, which mainly occurred in the hippocampus, parahippocampal gyrus, and medial temporal lobes. At the same time, ventricles were dilated.

3.2. MRI images of AD patients based on CNN and DML algorithms. Figure 4 showed the MRI images of AD patients after processed by CNN and DML algorithms. Compared with MRI images processed by the CNN algorithm, MRI images processed by DML algorithm had clearer texture and better imaging effects on cerebral blood vessels. Further, the sharpness was higher, so DML can greatly improve the visual sharpness of MRI images.

3.3. Comparison of classification results. CNN and DML models classified the patients separately, and they were compared for the classification accuracy, sensitivity, and specificity. The specific classification effects of AD and HC, MCI and HC were shown as below.

3.3.1. Classification of AD and HC. Figure 5 below showed the classification results of AD and HC. It was noted that the classification accuracy and sensitivity of the deep measurement learning model are both 0.83, superior to the CNN model. In terms of specificity, the classification specificity of the DML model was 0.82, slightly lower than that of the CNN model.

3.3.2. Classification results of MCI and HC. Figure 6 showed the classification effects of MCI and HC. It was noted that in terms of accuracy and sensitivity, the classification accuracy and sensitivity of the DML model was 0.65, superior to the CNN model; and in terms of specificity, the classification specificity of the DML model was 0.66, slightly lower than that of the CNN model.

3.4. Loss curve analysis. The convergence curves of the CNN model and the MDL model were analyzed, and the loss curves of AD and HC, MCI and HC were shown below.

3.4.1. Classification of AD and HC. Figure 7 showed the loss curves of the classification of AD and HC when the CNN model and the DML model were used for training. It was noted that when the CNN model was used for training, as the number of iterations increased, the training loss decreased. At the beginning, the training loss decreased rapidly, but after 3000 iterations, the training loss decreased slowly, and the training loss tended to be stable and the model fully converged after 6000 iterations. When the DML model was used for training, the training loss decreased as the number of iterations increased. At the beginning, the training loss dropped quickly. After 2000 iterations, the training loss decreased slowly. The training loss tended to be stable and the model fully converged after 4500 iterations. Taken together, the DML model can improve the convergence speed of the model.

3.4.2. Classification results of MCI and HC. Figure 8 showed the loss curves of the classification of MCI and HC when the CNN model and the DML model were used for training. It was noted that when the CNN model was used for training, as the number of iterations increased, the training loss decreased. At the beginning, the training loss decreased rapidly, but after 4000 iterations, the training loss decreased slowly, and the training loss tended to be stable and the model fully converged after 7000 iterations. When the DML model was used for training, the training loss decreased as the number of iterations increased. At the beginning, the training loss dropped quickly. After 3000 iterations, the training loss decreased slowly. The training loss tended to be stable and the model fully converged after 4500 iterations. Taken together, the DML model can improve the convergence speed of the model.

4. Discussion

AD is a chronic degenerative cognitive disease of the nervous system. At the onset of the disease, patients will suffer from cognitive dysfunction such as memory loss and language function loss. The disease has a long incubation period and will worsen with time [14]. The pathogenesis of AD still remains unclear, and it cannot be cured once diagnosed. Therefore, early diagnosis and prediction become particularly important. Only when AD is diagnosed in the early stage can it be possible to slow down or inhibit the progression [15]. In recent years, there is a large amount of research on the classification and prediction of early AD using traditional machine learning methods [16], and the classification and prediction of early AD using deep learning technology is a common occurrence [17]. For example, Folego et al. (2020) [18] used CNNs to process MRI images, and the classification accuracy of AD and HC reached 0.97. Perezn et al. (2019) [19] connected multiple image blocks to classify the MRI samples in the ADNI database, and the

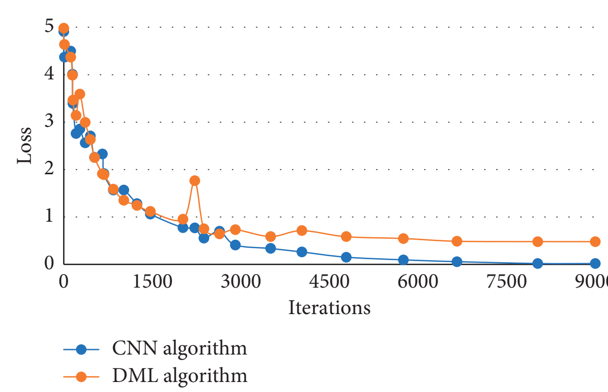

Figure 7: Loss curves of classification of AD and HC.

accuracy rate can reach 0.95. Therefore, to construct a simple, stable, and accurate early diagnosis system for AD is important for early intervention and treatment of AD. In order to explore the role of artificial intelligence in the prediction of early AD from MRI images, the CNN model and the DML model were used to classify AD, HC, and MCI.

Takenoshita et al. (2019) [20] extracted features of MRI samples in the ADNI database to classify AD, MCI, and HC, and the effect was very good. MRI of healthy persons and AD patients were compared, and it was found that brain atrophy occurred in AD patients, mainly in the hippocampus, parahippocampal gyrus, medial temporal lobe, and other

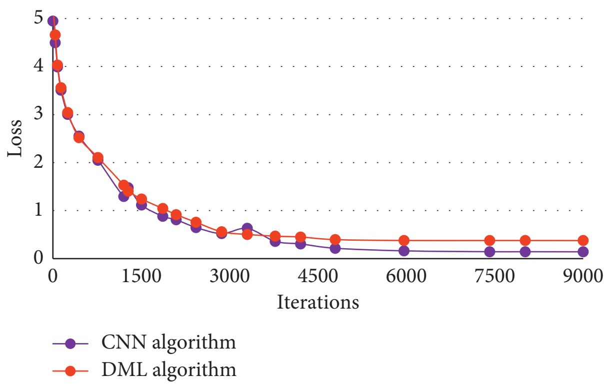

Figure 8: Loss curves of classification of MCI and HC.

brain regions, and ventricular dilation was also observed, which indicated that MRI images could clearly show the lesions in the brain domain of patients, and had diagnostic value. The classification accuracy and sensitivity of DML model were both 0.83, higher than those of CNN model. The classification specificity of DML model was 0.82, slightly lower than that of CNN model. Usually, sensitivity refers to the proportion of patients who are correctly diagnosed. If an AD patient is mistakenly diagnosed as a normal person, the opportunity for treatment will be missed and it will lead to serious consequences; if a normal person is mistakenly diagnosed as an AD patient, usually, he will be diagnosed again. Therefore, in clinical practice, specificity can be appropriately reduced to improve the sensitivity of prediction. Above, the DML model demonstrated better classification effects on early AD patients.

The training loss of CNN model decreased with the increase of iterations. After 3000 iterations, the decline rate of training loss tended to be gentle, and converged completely after 6000 iterations. The DML model also saw a decline in training loss with the increase of iterations. After 2000 iterations, the decline rate of training loss tended to be stable, and it completely converged after 4500 iterations. This showed that compared with the CNN model, the DML model in this study had a faster convergence speed and better computing performance. Figure 8 showed the loss curves of the classification of MCI and HC when the CNN model and the DML model were used for training. It was noted that when the CNN model was used for training, as the number of iterations increased, the training loss decreased. At the beginning, the training loss decreased rapidly, but after 4000 iterations, the training loss decreased slowly, and the training loss tended to be stable and the model fully converged after 7000 iterations. When the DML model was used for training, the training loss decreased as the number of iterations increased. At the beginning, the training loss dropped quickly. After 3000 iterations Whitwell, the training loss decreased slowly. The training loss tended to be stable and the model fully converged after 4500 iterations. Taken together, the DML model can improve the convergence speed of the model. Hence, the DML model can speed up the convergence for the classification of the both categories, which was in line with the research results of Vaithinathan et al. (2019) [21].

5. Conclusion

In the study, the MRI data used were from the ADNI database. On the basis of deep learning, an early diagnosis system for AD was constructed using CNN and DML algorithms. Then, the system was used to classify AD, HC, and MCI, and the two algorithms were compared for the accuracy and stability of in classification of MRI images. It was found that the DML algorithm can significantly improve the clarity and quality of MRI images, elevate the classification accuracy and stability of early AD patients, and accelerate the convergence of the model, providing a new way for early prediction of AD. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study.

Objective. The study aimed to explore the risk factors of infections after enterostomy through the information data analysis method based on a mathematical model. *Methods*. 156 cases of enterostomy patients admitted to the hospital were retrospectively selected as the study subjects and were divided into the infection group (17 cases) and normal group (139 cases) according to whether they were complicated with infections. Then, the factors of infection and related indexes before and after surgery were analyzed, and the data of the whole hospital were estimated by mathematical modelling. *Results*. The length of hospital stay in the infection group was 21 ± 11.2 days, which is longer than 10.1 ± 7.1 days in the normal group ($P < 0.05$). The incidence of anastomotic fistula in the infection group was 14%, which is higher than 2% in the normal group. The mortality rate of infection group (44%) was higher than that of normal group (5%). In the infection group, the incidence of single-cavity stoma (69%) was higher than that of double-cavity stoma (31%), the nosocomial infection rate (11%) was significantly higher compared with out of hospital (2%), and there were significant differences ($P < 0.05$). *Conclusions*. Patients with malnutrition and hypoproteinemia before enterostomy, the use of gastric tube and ventilator in the treatment, single lumen stomy in the operation, and the occurrence of anastomotic fistula were more likely to have concurrent infections.

1. Introduction

Enterostomy is a common surgical treatment for certain gastrointestinal diseases, which can effectively improve the quality of life of patients [1]. The specific operations of this method are to make an artificial wound in the abdomen of the human body and then suture the opening of the digestive tract so that the patient can excrete waste from the human body through this opening [2]. Patients who undergo the enterostomy often need to have their original diseases treated before permanent or temporary enterostomy, which will change the fecal excretion mode [3]. However, the waste discharged from the stoma cannot be controlled and often flows out involuntarily, soaking the abdominal skin around the stoma. Moreover, the excrement contains many bacteria, which often infect the stoma and surrounding tissues to cause complications, so that the quality of life of patients will be affected [4]. According to reports, the number of patients undergoing ostomy in Taiwan has increased by about 100,000 each year and the number of patients with early complications is about 6.3%–53.8% [5].

Among the many complications, the incidence of stoma infection is higher [6]. The common complications of ostomy include wound infections near the stoma, infections caused by sutures, detachment of the stoma mucosa, and complications caused by the patient's own factors. The above complications will have a serious impact on the patient's postoperative physiology and psychology, which also indirectly lead to unsatisfactory postoperative recovery [7]. In addition, the body's immunity will decrease after surgery and the integrity of the skin and mucous membranes will be destroyed, resulting in open wounds, especially the excretion of feces. Worse still, the stoma and surrounding tissues are prone to bacterial infections, and severe cases may even cause systemic acute infections due to local infections [8].

As its name suggests, mathematical modelling is the process to establish a mathematical model based on actual data information to deal with the problems in reality [9]. Specifically, information data are transformed from basic to in-depth and from rough adjustment to high precision so that more meaningful and usable information can be obtained from simple numbers to solve practical problems in life. It is also a process of integrating theory with practice [10, 11]. The establishment of mathematical models is diverse, and it has been extensively used in various industries, such as medicine and education [12, 13].

In this study, mathematical modelling was introduced to analyse the possible risk factors of bacterial infections after enterostomy, and the obtained data information was adopted in medical practice, which is expected to provide a certain theoretical basis for the prevention of complications caused by enterostomy.

2. Experimental Methods

2.1. Research Objects. 156 patients admitted to hospital for acute enterostomy from September 2018 to January 2021 were taken as the research subjects, including 89 male patients and 67 female patients, aged 54–89 years, with an average age of 56 ± 9 years, and they were rolled into the infection group ($n = 17$) and the normal group ($n = 139$) based on whether they had complicated infections. The criteria for infection were the white blood cell (WBC) count greater than 10×10^9/L, neutrophils greater than 80%, or were accompanied by cough, chest tightness, dyspnea, and other symptoms. One patient with 4 or more of the above could be diagnosed. The study had been approved by the ethics committee of hospital, and the patients and their family members understood the content and methods of this study and agreed to sign the corresponding informed consent.

Inclusion criteria: (1) all patients were between 50 and 90 years old, (2) patients and their families signed the informed consent, (3) patients were conscious during the study, and (4) the general clinical data of the patients were complete.

Exclusion criteria: (1) patients with heart, liver, and kidney dysfunction and (2) women in pregnancy.

2.2. Research Methods. In this study, a retrospective analysis was conducted on the postoperative development of the enterostomy in hospital, and the general data and clinical treatment data of the research subjects were sorted out for comparative analysis. Besides, the conditions of all patients in the hospital were explored on the basis of mathematical modelling.

2.3. Observation Indicators. The etiology of enterostomy in patients was analyzed, and the probability of infections in patients with different variables was compared. Different variables included factors such as stoma intestinal segment, anastomosis method, age, stoma-reduction interval, surgical time, postoperative hospital stay, postoperative anastomotic fistula, postoperative intestinal obstruction, and other factors.

The general information status of patients was compared for statistical significance, including gender, age, and etiology of the stoma.

According to the infection of enterostomy, the patients were divided into groups and compared for hypoproteinemia, the use history of gastric tube and ventilator, the postoperative malnutrition, and the stoma method. Besides, the mortality rate of the infected patients was also counted.

2.4. Analysis Method Based on Mathematical Modelling. The mathematical modelling was constructed based on randomly selected patients undergoing enterostomy, so as to estimate the conditions of all patients in the entire hospital.

In order to estimate the number of enterostomy patients with concurrent infection in the whole hospital, the number of enterostomy patients with concurrent infection in the hospital was set as $f(x)$, the number of randomly selected patients who underwent enterostomy was set as y, the number of infected cases was set as x, and the total number of patients undergoing enterostomy in the whole hospital was set as $f(y)$. Then, equation (1) could be obtained:

$$f(x) = f(y) \times \frac{x}{y}. \tag{1}$$

Thus, the number of patients without concurrent infection in the whole hospital $f(x')$ could be expressed in equations (2) and (3):

$$f(x') = f(y) - f(x), \tag{2}$$

$$f(x') = f(y) - \left(f(y) \times \frac{x}{y} \right). \tag{3}$$

The number of patients with concurrent infections caused by this factor in the whole hospital could be set as M to understand the proportion of concurrent infections after surgery caused by different factors in the whole hospital, and the number of cases with this cause in the randomly selected patients was set as M'. The calculation is shown in equations (4) and (5):

$$\frac{M}{f(x)} = \frac{M'}{x}, \tag{4}$$

$$M = \frac{M'}{x} \times \left(f(y) \times \frac{x}{y} \right). \tag{5}$$

Among them, the number of randomly selected patients who underwent enterostomy (y), the number of the infected patients (x), and the total number of patients who received enterostomy in the hospital ($f(y)$) were all the known quantity.

2.5. Statistical Methods. SPSS19.0 software was used for statistical analysis of the data, and the measurement data were expressed as mean ± standard deviation. One-way analysis was adopted for analysis. The Wilcoxon rank-sum test or *t*-test was used for measurement data, and count data were detected by the chi-square test or Fisher's exact test. In addition, $P < 0.05$ meant that the difference was statistically substantial.

3. Results

3.1. Comparison on the Incidence of Infection Caused by Different Factors. Table 1 shows the relationship between the occurrence of incision infection and gender and age. In the infection group, there were 11 males and 6 females. In the normal group, there were 78 males and 61 females. The average age of infected patients was 54 ± 7 years, and the average age of the uninfected was 57 ± 6 years, with no statistical significance ($P > 0.05$). Table 2 shows the relationship of the ostomy-reduction interval, operation time, and postoperative hospital stay with the incidence of infection. The length of stay in the infection group was 21 ± 11.2 days, which is longer than 10.1 ± 7.1 days in the normal group ($P < 0.05$). Figure 1 shows different intestinal sites for ostomy. It was found that there was no significant relationship between the intestinal site of ostomy and the incidence of infection ($P > 0.05$). Figure 2 shows the relationship between anastomotic fistula and the incision infection. The analysis showed that the incidence of anastomotic fistula in the infection group (14%) was higher than that in the normal group (2%) ($P < 0.05$). It can be concluded that there is a certain relationship between the postoperative hospital stay and postoperative anastomotic fistula with the incidence of infection.

There were a total of 350 patients undergoing enterostomy between September 2020 and March 2021 in this hospital. The etiology was then statistically analyzed, and the etiology distribution of patients with enterostomy in the whole hospital was estimated using the analytical method based on mathematical modelling, as shown in Figure 3. Among them, 122 cases were caused by colorectal cancer and obstruction, accounting for 34.8% of the number of enterostomy cases; 88 cases with colorectal trauma accounted for 25%; 35 cases with anastomotic fistula after colorectal cancer surgery accounted for 10%; 21 cases with colorectal perforation accounted for 6%; 17 cases suffered from intestinal obstruction (5%); 21 cases (6%) suffered from surgery/colonoscopy side injury; 12 patients had intestinal strangulation due to volvulus, accounting for 3.4%; and 13 cases had congenital megacolon, accounting for 3.7%. In addition, there were 21 patients with other etiologies, accounting for 6%.

3.2. Age and Gender Distribution of the Two Groups of Patients. After grouping, the general data of patients from the two groups were compared and evaluated (Table 3). It was found that there were no significant differences between the basic information of the two groups of patients ($P > 0.05$).

Table 1: The relationship of the incidence of incision infection with gender and age.

	Male	Female	Age (years)
The total number of cases	89	67	56 ± 9
The number of infected cases	11	6	54 ± 7
The number of noninfected cases	78	61	57 ± 6

3.3. Comparison on the Typical Stoma Status between the Normal Group and the Infection Group

3.3.1. Comparison on the Dermatitis around the Stoma. Figure 4(a) indicates that the patient's intestinal stoma was in a good state. There was no atrophy of the stoma, and there was no separation between the stoma and the surrounding skin tissue. Besides, the skin tissue around the stoma showed a normal state, without obvious redness, depression, and other symptoms. Figure 4(b) presents the stoma with poor healing after complicated infection. It was found that the stoma was in a shrinking state, and it was separated from the surrounding skin tissue. Moreover, the skin around the stoma had obvious redness, swelling, and depression symptoms.

3.3.2. Comparison on the Separation of the Stoma Mucosa. The intestinal stoma of one patient was in a good state after the surgery (Figure 5(a)), showing that there was no separation of the skin and mucosal tissue around the stoma. In Figure 5(b), the separation of the intestinal stoma and mucosal tissue could be clearly observed, and the surrounding skin had slight redness. Furthermore, it mainly occurred in the early stage after the surgery.

3.4. Comparison on Relevant Indicators of Patients from the Two Groups. The two groups were compared for relevant indexes, such as the history of gastric tube application, history of ventilator application, malnutrition, and hypoproteinemia. It was found that the proportion of these cases in the normal group was lower than that of the infection group. The mortality rate of the infection group was as high as 44%, while the mortality rate of patients in the normal group was only 5%, with obvious statistical significance ($P < 0.05$), as shown in Figure 6. In terms of the stoma methods, 69% of patients in the infection group had single-cavity stoma and 31% of patients had double-cavity stoma. Besides, 40% of patients had single-cavity stoma and 60% had double-cavity stoma in the normal group, suggesting that the single-cavity stoma would increase the chance of infection (Figure 7).

3.5. Comparison on the Conditions of Infection between In-Hospital and Out-of-Hospital Patients. Based on the results in Section 3.1, the infection rate of the hospitalized patients and out-of-hospital patients was further compared. It was found that the incidence of concurrent infections in hospitalized patients (11%) was higher than that of discharged patients at home (5%), with significant statistical differences ($P < 0.05$), as shown in Figure 8.

Table 2: The relationship of the stoma-reduction interval, the surgical time, and the number of days of hospitalization after surgery with the incidence of infection.

	Stoma-reduction interval (M)	Surgical time (min)	Number of days in hospital after surgery (D)
Total average time	7.9 ± 17.9	166.2 ± 80.5	13.2 ± 6.9
Time of infection	15.5 ± 43.9	140.9 ± 56.8	21 ± 11.2
Time of noninfection	7.1 ± 10.9	169.1 ± 83.0	10.1 ± 7.1

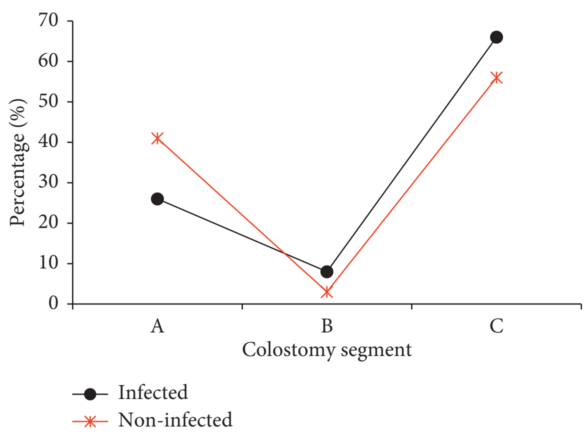

Figure 1: Comparison on infection rates of different stoma intestinal segments (*Note.* A: transverse colon; B: ascending colon; C: sigmoid colon).

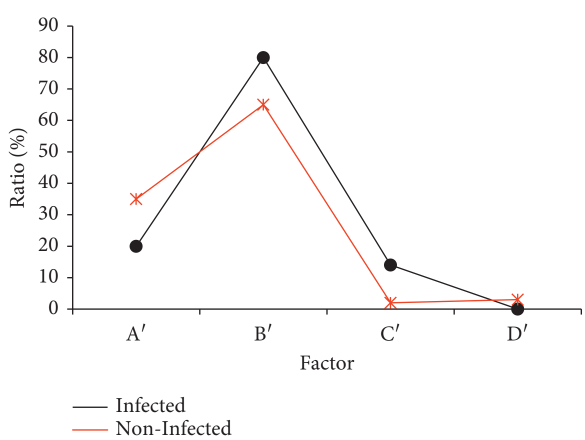

Figure 2: Data results of the anastomotic method, the occurrence of anastomotic fistula, and intestinal obstruction after infection (*Note.* A′: manual suture; B′: instrument anastomosis; C′: anastomotic fistula; D′: intestinal obstruction).

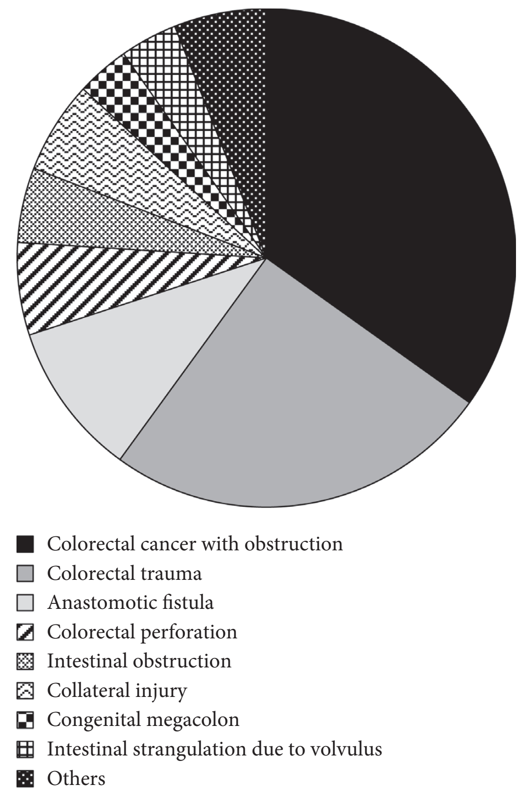

Figure 3: Prediction of the distribution of causes of enterostomy in the hospital based on data analysis of mathematical modelling.

4. Discussion

According to statistics, postoperative infection types mainly includes infections at the surgical site, lung, and urinary system, and about 3%–44% of colorectal cancer patients develop surgical site infection after surgery [14]. Moreover, postoperative infection seriously affects the prognosis of patients after surgical treatment. The study showed that the number of patients with colorectal cancer complicated with obstruction was the largest, accounting for 34.8% of the total number of colorectal cancer cases, indicating that most patients with colorectal cancer required enterostomy, but there were differences between patients in different countries. Carlsson et al. [15] concluded that colonic diverticulitis was the second cause of colorectostomy in that region, which was different from colorectal trauma ranking second in this study. Roque-castellano et al. [16] found that most of the patients requiring this operation suffered from nontumor diseases. The study results of Desay et al. [17] showed that the probability of tumor patients requiring ostomy and reductive surgery was only 13%, and the effective rate of this method reached 70%. The above study results clearly show the individual differences between patients in China and those in Western countries.

Some studies have suggested that old age seems to be a risk factor [18]. However, the results of this study showed that the incidence of postoperative complications after enterostomy was not significantly related to age ($P > 0.05$). It was found that postoperative coinfection was significantly related to postoperative hospital stay and whether postoperative anastomotic fistula occurred ($P < 0.05$). A longer postoperative hospital stay will lead to a higher infection rate. Based on this, the infection rate of hospitalized patients

Table 3: Comparison on general clinical data of patients from the two groups.

	The number of males	The number of females	Age (years)
Infection group	11	6	54 ± 7
Normal group	78	61	57 ± 6

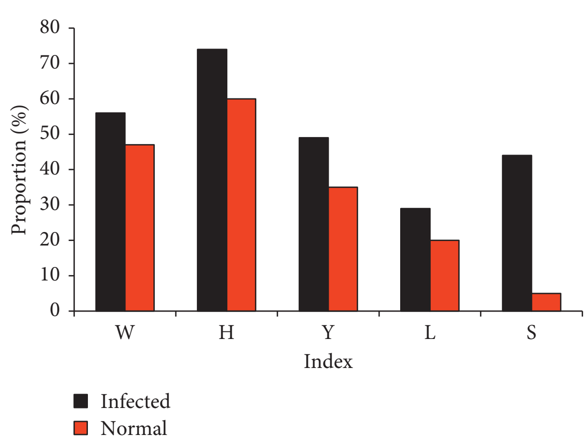

Figure 6: Comparison on relevant indicators between the two groups of patients (*Note*. W: history of gastric tube application; H: history of ventilator application; Y: preoperative malnutrition; L: hypoproteinemia; S: mortality rate).

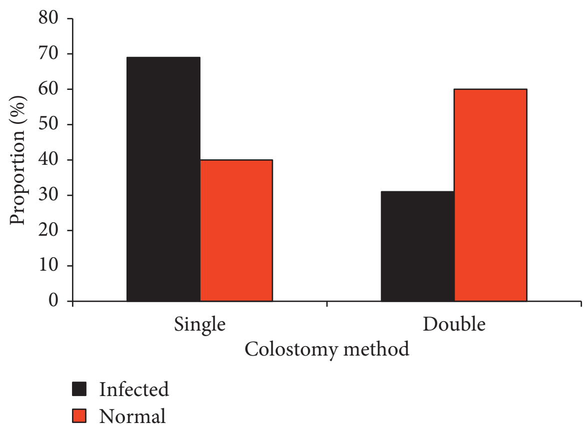

Figure 7: Comparison on the relationship between two groups of ostomy methods and concurrent infections.

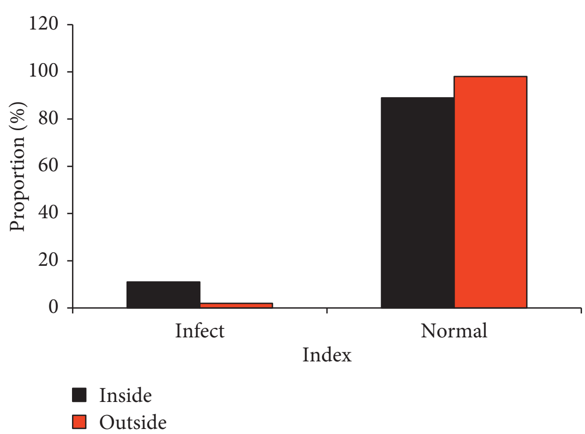

Figure 8: Comparison on the conditions of hospital infection and out-of-hospital infection.

and out-of-hospital patients was analyzed, and it was found that the nosocomial infection rate was higher compared with the out of hospital. Hospitalized patients have to have tests for postoperative efficacy and physical indicators of detection, which to a certain extent can reduce the body resistance and immune suppression and increase the vulnerability to infection. Moreover, there are so many people in hospital, including the patients, ward staff, the patient's family and friends, and health care workers, and they can all be regarded as carriers of the bacteria [19]. At home, although the nursing is not so professional as that in hospital, but there are few people around, so the probability of infection is lower in a certain extent.

In this study, the patients in the hospital were sampled randomly. The mathematical model established in Section 2.4 was employed to calculate, and then, the concurrent infections of all the patients in the hospital could be estimated. If a nationwide sampling survey is conducted, the mathematical modelling algorithm can also be adopted to estimate the postoperative infections after enterostomy in Taiwan. Mathematical modelling is to solve and optimize actual problems by calculations in the computer. After the data and information are processed, variables are introduced through abstract hypotheses and actual problems are expressed through mathematical theoretical knowledge to deal with actual problems. Wang et al. [20] applied mathematical modelling to analyse the data of traditional Chinese medicine and concluded that the modelling had good data analysis capabilities. Thus, it had certain guiding significance for the synthesis of Chinese patent medicines.

5. Conclusion

In the study, 156 cases of enterostomy patients were retrospectively selected as the study subjects and were divided into the infection group (17 cases) and normal group (139 cases) according to whether they were complicated with infections. The factors of infection and related indexes before and after surgery were analyzed, and the data of the whole hospital were estimated by mathematical modelling. In conclusion, patients with malnutrition and hypoproteinemia before enterostomy, the use of gastric tube and ventilator in the treatment, single lumen ostomy in the operation, and the occurrence of anastomotic fistula were more likely to have concurrent infections. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study. It is hoped that this study can provide a reasonable theoretical basis for the prevention and treatment of postoperative infection after enterostomy to reduce the postoperative pain of patients and improve the quality of life of patients to a certain extent.

This work aimed to study the diagnostic value of dynamic electrocardiogram (ECG) based on P wave detection algorithm for arrhythmia after hepatectomy in patients with primary liver cancer, and to compare the therapeutic effect of different doses of Betaloc. P wave detection algorithm was introduced for ECG automatic detection and analysis, which can be used for early diagnosis of arrhythmia. Sixty patients with arrhythmia after hepatectomy for primary liver cancer were selected as the research objects. They were randomly divided into control group, SD group, MD group, and HD group, with 15 cases in each group. No Betaloc, low-dose (≤47.5 mg), medium-dose (47.5–95 mg), and high-dose (142.5–190 mg) Betaloc were used for treatment. As a result, P wave detection algorithms can mark P waves that may be submerged in strong interference. P waves from arrhythmia database were used to verify the performance of the proposed algorithm. The prediction precision (Pp) of ventricular arrhythmia and atrial arrhythmia was 98.53% and 98.76%, respectively. Systolic blood pressure (117.35 ± 7.33, 126.44 ± 9.38, and 116.02 ± 8.2) mmHg in SD group, MD group, and HD group was significantly lower than that in control group (140.3 ± 7.21) mmHg after two weeks of treatment. Moreover, those of SD group and HD group were significantly lower than MD group ($P < 0.05$). The effective rate of cardiac function improvement in SD group ($72.35 \pm 1.21\%$) was significantly higher than that in control group, MD group, and HD group ($38.2 \pm 0.98\%$, $65.12 \pm 1.33\%$, and $60.43 \pm 1.25\%$; $P < 0.05$). In short, dynamic ECG based on P wave detection algorithm had high diagnostic value for arrhythmia after hepatectomy in patients with primary liver cancer. It was safe and effective for patients to choose small dose of Betaloc.

1. Introduction

Liver cancer is a malignant tumor that occurs in the liver, the largest organ of the human body. It is generally classified into PHC and secondary liver cancer according to its etiology and other factors [1, 2]. PHC mainly includes hepatocellular carcinoma, intrahepatic cholangiocarcinoma, cholangiocarcinoma, angiosarcoma, hemangioendothelioma, and hepatoblastoma [3, 4]. At present, the preferred clinical treatment for liver cancer is hepatectomy, which is the traditional radical treatment for liver cancer, and the five-year survival rate of patients after surgery is greater than 50% [5, 6]. However, this surgery has certain limitations and is only suitable for patients with good liver function and complete tumor resection. In addition, it can lead to serious complications, such as liver failure and bleeding [7, 8]. Arrhythmia refers to when the origin of heartbeat excitement is abnormal or the conduction pathway is abnormal, and the sequence of excitement is disordered, which changes the heartbeat rate or rhythm [9, 10]. Arrhythmia is caused by a variety of triggers, and different clinical symptoms can occur due to different causes and types. In severe cases, syncope and sudden death can occur [11, 12]. In addition, a variety of treatments or antiarrhythmic drugs will have different degrees of side effects on patients. Therefore, when a drug is choosing for treatment, it is necessary to have a certain understanding of the pharmacokinetics and pharmacodynamics of the drug to prevent it from causing adverse reactions and complications to patients [13–15].

The ECG of arrhythmia shows that P wave appears in advance, and the shape is different from that of sinus P wave. PR interval is greater than 0.12 s. The QRS pattern is the same as that of sinus rhythm. In addition to accompanied by ventricle difference, conduction can appear inconsistent. There are usually incomplete compensatory intervals after pre-phase contraction of room type [16–18]. Detection of P wave is of great significance to ECG analysis of arrhythmia and analysis of characteristic points of ECG signal. Therefore, a P wave detection algorithm was proposed in this study to perform automatic detection and analysis of ECG and locate the P wave starting point, so as to achieve accurate and effective prediction and diagnosis of arrhythmia [19, 20]. At present, β-blocker drugs are gradually widely used in arrhythmia, especially in patients with primary liver cancer after hepatectomy, such as β-blocker metoprolol succinate sustained-release tablets (Betaloc) [21, 22]. However, because β-blockers have a certain blocking effect on β-receptors, there are certain limitations in clinical application [23, 24]. In addition, there is still a lack of relevant studies on the effect of dosage of β-blocker metoprolol succinate sustained-release tablets (Betaloc) on arrhythmia and its therapeutic effect [25, 26].

Therefore, in this study, patients with arrhythmia after hepatectomy for primary liver cancer were selected as the research objects, and no Betaloc, low-dose Betaloc, medium-dose Betaloc, and high-dose Betaloc were used for patients. By studying the cardiac function indexes, blood lipid indexes, and liver function indexes of different patients in different treatment periods, the therapeutic effect of low-dose Betaloc on arrhythmia after hepatectomy in patients with primary liver cancer was analyzed.

2. Materials and Methods

2.1. Basic Information. In this study, 60 patients with arrhythmia after hepatectomy for primary liver cancer who were hospitalized in hospital from September 2018 to October 2020 were selected as the research objects. Among them, 30 were male and 30 were female. They were randomly divided into control group, SD group, MD group, and HD group, with 15 cases in each group. No Betaloc, low-dose (≤47.5 mg), medium-dose (47.5–95 mg), and high-dose (142.5–190 mg) Betaloc were used for treatment. This study had been approved by the Ethics Committee of hospital, and patients and their families understood the study content and methods and agreed to sign corresponding informed consent forms.

Inclusion criteria were as follows: (i) patients aged between 40 and 65 years old; (ii) patients who were emotionally stable and can cooperate with treatment and sample collection; (iii) patients with arrhythmia after hepatectomy; (iv) patients with complete clinical data and information; (v) patients who had no history of mental illness and were emotionally stable; (vi) the left ventricular ejection fraction (LVEF) was less than 45%, and the left ventricular short axis fractional shortening (FS) was less than 25%; and (vii) patients with cardiac function grades III and IIII.

Exclusion criteria were as follows: (i) patients who withdrew and transferred for treatment due to personal reasons; (ii) patients with other serious diseases or infectious diseases; (iii) patients with diseases, such as hypertension and coronary heart disease, or similar surgical treatment experience; (iv) patients whose tumors had metastasized; and (v) patients who had not undergone cooperative treatment due to personal or other factors.

2.2. Required Sample Size Calculation. The required sample size is calculated as follows:

$$N = \frac{Z^2 \times (P \times (1 - P))}{E^2}, \tag{1}$$

$$n = \frac{Z^2 \sigma^2}{d^2}. \tag{2}$$

In equation (1), N is the total number of samples required in the experiment and Z is the statistic. When the confidence level is 95%, $Z = 1.96$. When the confidence is 90%, $Z = 1.64\%$. E represents the error and P is the probability. In equation (2), n represents the required sample size for each group, d represents the sampling error range, and σ represents the standard deviation, which is generally 0.5. Through the above equations, it is calculated that n is 10, and the total number of samples required is 40 cases. In this study, 60 cases were selected, and there were 15 cases in each group.

2.3. ECG P Wave Detection Algorithm. The patient was placed in horizontal supine position with chest, wrist, and ankle exposed. The skin was cleaned with alcohol, and lead electrodes were placed to collect the electrocardiogram. Normal ECG signals are composed of P wave (from the point change of atrial depolarization before atrial contraction), QRS wave (from the change of ventricular depolarization before ventricular contraction), T wave (potential change during ventricular repolarization), PR segment, PR interval, ST segment, QT interval, and U wave with certain sequence (Figure 1).

The characteristic parameters related to P wave in ECG include P wave amplitude, PR interval, P wave duration, P wave dispersion, and atrial rate. P wave represents atrial depolarization, QRS wave represents ventricular depolarization, and T wave represents ventricular repolarization. In the actual ECG computer automatic analysis, the detected ECG signals are preprocessed first. The P wave amplitude is taken by the amplitude of the P-value. The PR interval refers to the beginning of the P wave to the beginning of the QRS wave, representing the time that the heart excited from the atria to the ventricles. The PR interval is divided into PA interval, AH interval, and HV interval, which is normally in the range of 120~200 ms. PR interval is obtained according to the following equation:

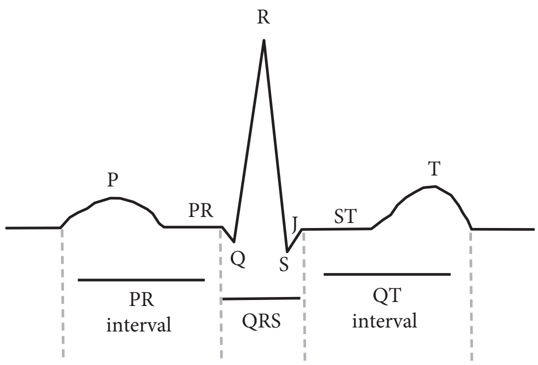

Figure 1: Waveform diagram of ECG signal.

$$\overline{PR} = \frac{(S_Q - S_P)}{t}. \tag{3}$$

In equation (3), S_Q represents the starting point of QRS wave, S_P represents the starting point of P wave, and t represents the sampling rate. The P wave time limit refers to the process of left and right atrium depolarization and repolarization, with the general time (width) less than 0.12 s and the voltage (amplitude) less than 0.25 mV. In the analysis of electrical signals, the P wave time limit is calculated by the following equation:

$$\text{P wave duration} = \frac{(S_P - E_P)}{t}. \tag{4}$$

In equation (4), S_P represents the starting point of P wave, E_P represents the end point of P wave, and T represents the sampling rate. P wave dispersion (PWD) refers to the difference between the maximum time (*Pm*) and the minimum time (*Pn*) measured in different leads of a 12-lead ECG recorded synchronically. The P wave dispersion of normal subjects is less than 40 ms, and the BBB 0 50 ms suggests the presence of heterogeneous electrical activity in different parts of the atrium P wave dispersion is a new index of body surface ECG in predicting atrial tachycardia and paroxysmal atrial fibrillation. The calculation method is shown in the following equation:

$$\text{P wave dispersion} = Pm - Pn. \tag{5}$$

In equation (5), *Pm* represents the maximum time limit of P wave, and *Pn* represents the minimum time limit of P wave. The calculation method of heart rate is shown in the following equation:

$$\text{HR} = \frac{60\,(s)}{\overline{\text{PP}} or \overline{\text{RR}}\,(s)}. \tag{6}$$

In equation (6), $\overline{\text{PP}}$ represents the average P-P interval and $\overline{\text{RR}}$ represents the average R-R interval. Figure 2 shows the flow of P wave detection algorithm.

After the QRS is detected, the P wave search segment is determined, and the zero crossing between the mode extremum pairs in this segment is the P wave. The method to determine the mode extremum pair is shown in the following equations:

$$P_x = \frac{2}{5} \times \left(\frac{1}{10} \sum_{i=1}^{10} X_i \right), \tag{7}$$

$$P_y = \frac{1}{3} \times \left(\frac{1}{10} \sum_{i=1}^{10} Y_i \right). \tag{8}$$

In equations (7) and (8), P represents the amplitude, X_i represents the positive maximum value of the P wave search segment, and Y_i represents the negative maximum value of the P wave search segment. The local modulus maximum pairs are determined by screening the modulus extreme value pairs whose amplitude of point A was greater than P_x and that of point B less than P_y, and the time interval was less than 100 ms. The detection of modulus extremum against slope is shown in the following equation:

$$K = \left| \frac{P_A - P_B}{P_A - P_B} \right|. \tag{9}$$

In this study, the search criteria for P wave were as follows. The maximum value of the scale coefficient in the window was the modulus maximum point, the minimum value of the scale coefficient was the modulus minimum point, and the zero crossing between them was the P wave.

2.4. Drug Therapy for Patients. The patients in the control group, SD group, MD group, and HD group were guided and managed in the course of medication and diet after surgery. In addition, the real-time monitoring was performed on the heart and lung function indexes, blood gas analysis indexes, and psychological status of each group of patients. The four groups of patients were treated with different doses of beta-blocker metoprolol succinate sustained-release tablets (Betaloc) after surgery.

No Betaloc was adopted by patients in control group. SD group: initial dose of Betaloc was 12 to 24 mg once a day, and the patient's tolerance was observed the next day. If the patient could tolerate the previous daily dose, the dose was doubled three weeks later and increased to the target dose of 47.5 mg in SD group. If the patient had adverse reactions or drug intolerance, it was necessary to reduce the drug dose and stop using it in severe cases. In addition, other agents were used or the Betaloc dosage was gradually restored after the patient's condition became stable. MD group: the initial dose of Betaloc was 12 to 24 mg once a day, and the patient tolerance was observed the next day. If the patient could tolerate the previous daily dose, the dose was doubled three weeks later and increased to the target dose of 47.5–95 mg in the MD group. If the patient had adverse reactions or drug intolerance, it was necessary to reduce the drug dose and stop using it in severe cases. In addition, other agents were used or Betaloc dosage was gradually restored after the patient's condition became stable. In the HD group, the initial dose of Betaloc was 12 to 24 mg once a day, and the patient's tolerance was observed the next day. If the patient could tolerate the previous daily dose, the dose was doubled three weeks later, and the target dose was successively

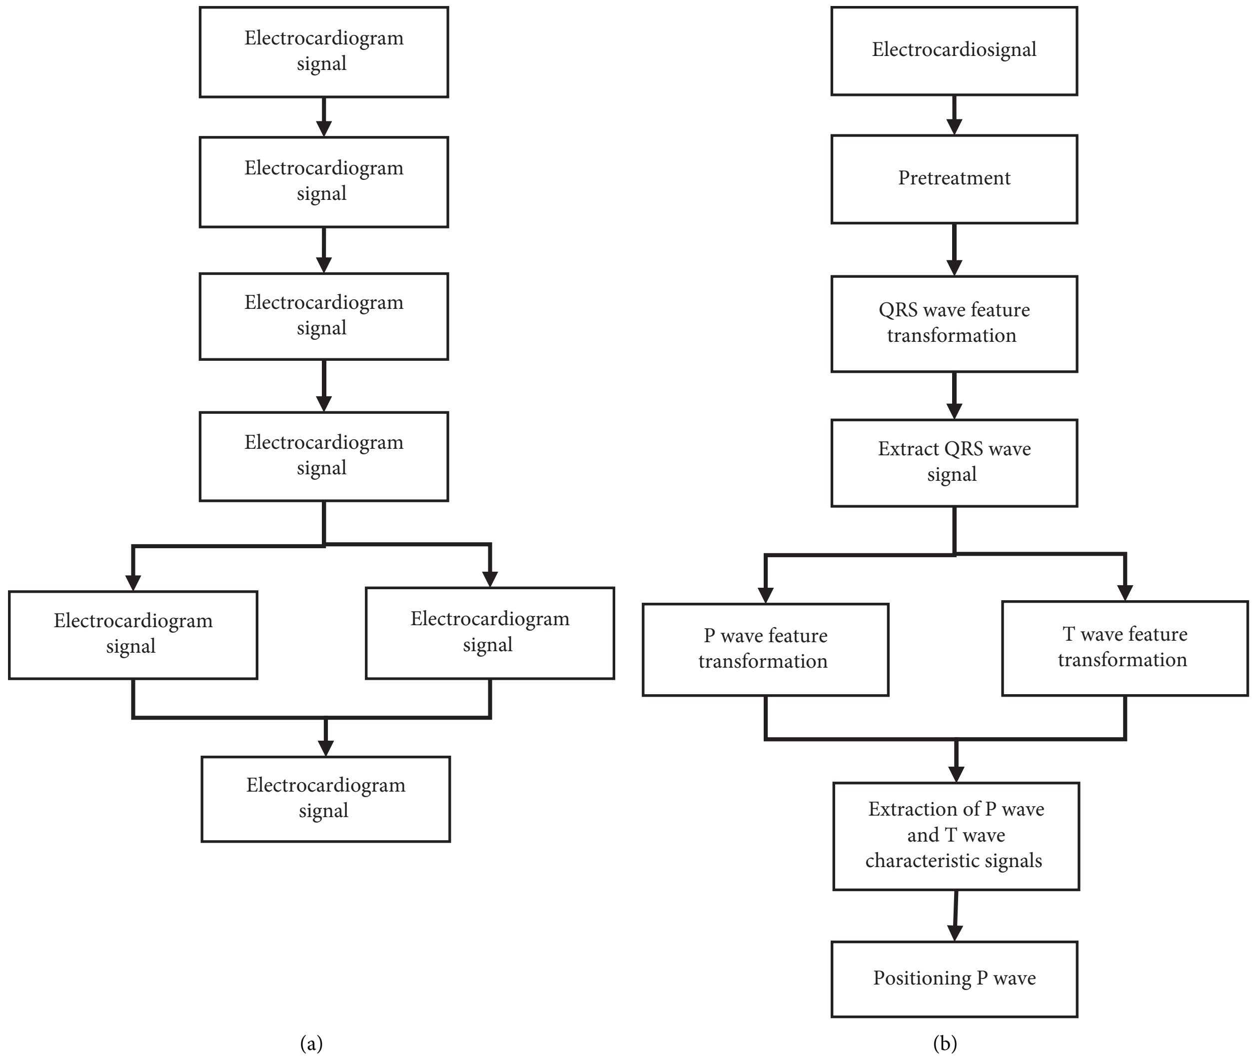

Figure 2: ECG detection process (a) and P wave detection process (b).

increased to 142.5–190 mg as that of the HD group. In the case of adverse reactions or drug intolerance in patients, the drug dose should be reduced and discontinued in severe cases, and the dosage of Betaloc should be gradually resumed after the patient's condition became stable.

2.5. Evaluation Indexes. The four groups of patients were treated with different treatment methods and doses. In addition, the patients' heart function indexes, blood lipid indexes, liver function indexes, and ECG signal were detected before and at different periods after treatment, including diastolic blood pressure, systolic blood pressure, heart rate, B-type natriuretic peptide precursor (pre-proBNP), blood sugar (GLU), cholesterol (TC), triglycerides (TG), alanine aminotransferase (ALT), aspartate aminotransferase (AST), and types and incidence of complications.

2.6. Statistical Methods. SPSS 19.0 was employed for data statistics and analysis. Mean ± standard deviation ($\overline{x} \pm s$) was how measurement data were expressed, and percentage (%) was how count data were expressed. Pairwise comparison adopted analysis of variance. The difference was statistically considerable with $P < 0.05$.

3. Results

3.1. ECG Signal Monitoring in Patients with Arrhythmia. Figure 3 shows the ECG signal monitoring record of patients with arrhythmia. In Figure 3(a), there was no relationship between the central atrial wave and the ventricular wave, showing a complete disconnection. The atrial rate was 88 bpm, the ventricular rate was 30 bpm, the atrial rate was greater than the ventricular rate, and the Q-T interval was 0.68 s. In Figure 3(b), the P wave appeared regularly, with a frequency of 62 bpm. After the first, third, and fourth P waves, there were downstream QRS-T complexes. QRS-T complexes without downcoming after the 5th wave were type I atrioventricular block.

Figure 4 shows the detection results of ECG signal. It was found that the P wave detection algorithm can mark the P wave, which may be submerged in strong interference,

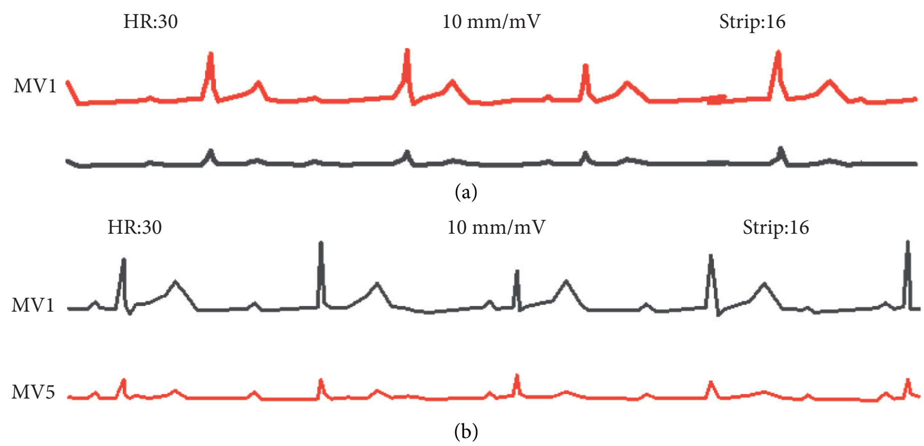

Figure 3: Patient's ECG signal monitoring chart. (a) ECG signal monitoring chart of a patient with arrhythmia. (b) ECG signal monitoring chart of patient with arrhythmia combined with atrioventricular block.

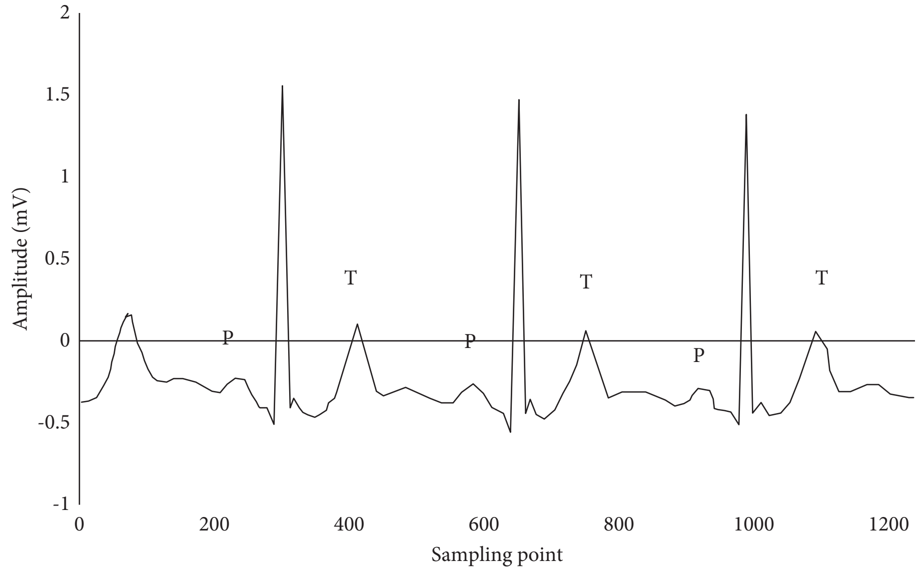
accurately locate the P wave and T wave peaks of ECG signal, and detect the P wave and T wave singularity. The diagnostic error rate (Er), sensitivity (Se), and prediction precision (Pp) of P wave detection algorithm for ventricular arrhythmia were 0.24%, 99.23%, and 98.53%, respectively. Er, Se, and Pp of atrial arrhythmia were 0.28%, 99.45%, and 98.76%, respectively.

3.2. Basic Patient Information. Figure 5 shows the comparison results of the basic information of the four groups of patients before treatment. Figure 5(c) shows the number of patients with cardiac function grades of grade III and IIII. Figure 5(d) shows the number of patients with mild heart failure, moderate heart failure, and no heart failure. There was no considerable difference in the proportion of patients with different ages, genders, heart function grades, and combined heart failure in each group ($P > 0.05$).

3.3. Changes of Diastolic Blood Pressure, Systolic Blood Pressure, and Heart Rate before and after Treatment. Figure 6(a) shows the changes in systolic blood pressure of the four groups of patients before treatment, one week after treatment, and two weeks after treatment. With the treatment time, the systolic blood pressure of the four groups of patients gradually decreased. After one week of treatment, patients in the SD group and HD group had lower systolic blood pressure, while the control group had higher systolic blood pressure. The systolic blood pressure of the SD group, MD group, and HD group after two weeks of treatment (117.35 ± 7.33 mmHg, 126.44 ± 9.38 mmHg, and 116.02 ± 8.2 mmHg) were significantly lower versus that of control group (140.3 ± 7.21 mmHg), and that of SD group and HD group was greatly inferior to the MD group ($P < 0.05$). Figure 6(b) shows the changes in diastolic blood pressure of the four groups of patients before treatment, one week after treatment, and two weeks after treatment. The diastolic blood pressure of the SD group was considerably inferior to that of the control group one week after treatment ($P < 0.05$). After two weeks of treatment, the diastolic blood pressure (74.12 ± 9.38 mmHg, 88.15 ± 8.2 mmHg, and 84.33 ± 7.21 mmHg) of the SD group, MD group, and HD group was substantially lower relative to that of control group (95.38 ± 7.33 mmHg), and that of SD group was evidently lower versus that of MD group and HD group ($P < 0.05$). Figure 6(c) shows the heart rate changes of the four groups of patients before treatment, one week after treatment, and two weeks after treatment. The heart rate of the SD group after two weeks of treatment was obviously inferior to that of the control group and the HD group ($P < 0.05$). Figure 6(d) shows the comparison results of the pre-proBNP content of type B natriuretic peptide of the four groups of patients. The pre-proBNP of SD group was notably lower versus that of control group, MD group, and HD group, and MD group was lower than HD group ($P < 0.05$).

3.4. Comparison on the Effective Rate of the Improvement of the Heart Function. Figure 7 shows the comparison results of the changes in the effective rate of cardiac function improvement after the four groups of patients were treated with different doses of Betaloc for 1, 2, and 3 weeks. After one week of treatment, patients in the MD and HD groups had a relatively higher effective rate of improvement in heart function. With the treatment time, the effective rate of cardiac function improvement of the four groups of patients gradually increased. After three weeks of treatment, the effective rate of cardiac function improvement ($72.35 \pm 1.21\%$) in the SD group was notably superior to that of the control, MD, and HD groups ($38.2 \pm 0.98\%$, $65.12 \pm 1.33\%$, and $60.43 \pm 1.25\%$) ($P < 0.05$).

3.5. Analysis of Blood Lipid Indexes before and after Treatment. Figure 8(a) shows the comparison results of the GLU content of the four groups of patients before and after treatment. There was no remarkable difference in the GLU content among the control group, SD group, MD group, and HD group before treatment ($P > 0.05$). After treatment, the GLU content of the SD group (5.84 ± 0.62 mmol/L) was greatly higher than that of the control group, MD group, and HD



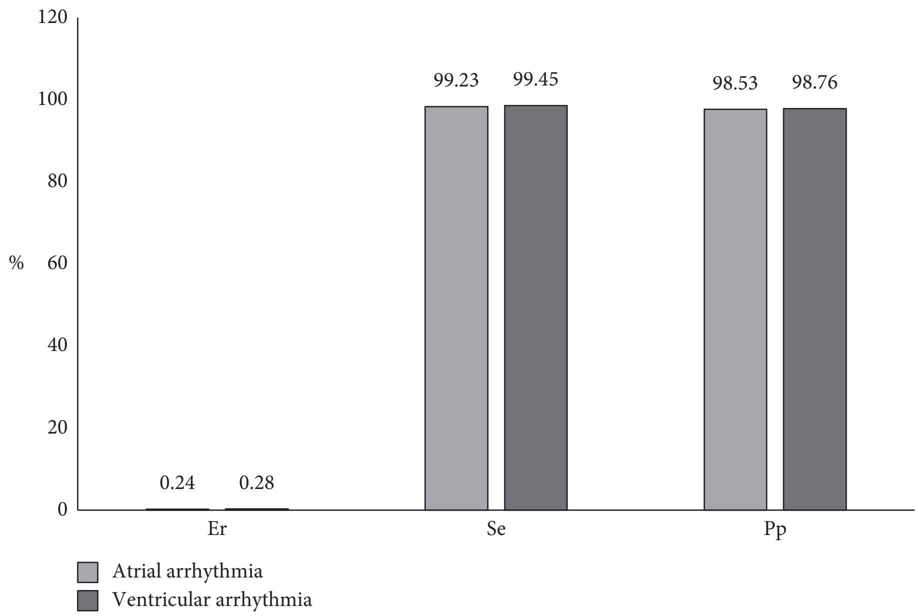


FIGURE 4: ECG signal detection results. (a) P and T wave detection results (P means P wave and T means T wave). (b) Arrhythmia diagnosis results.

group (4.56 ± 0.58 mmol/L, 4.97 ± 0.49 mmol/L, and 5.09 ± 0.54 mmol/L) ($P < 0.05$). Figures 8(b) and 8(c) present the comparison results of the TC content and TG content of the four groups of patients before and after treatment, respectively. There was no considerable difference in TC content and TG content among the control group, SD group, MD group, and HD group before treatment ($P > 0.05$). After treatment, the TC content and TG content of the SD group were dramatically superior to those of the control group, MD group, and HD group ($P < 0.05$).

Figure 9 shows the comparison results of the changes in liver function indexes ALT and AST content of the four groups of patients. From Figure 9(a), there was no substantial difference in ALT content among the four groups of patients after one week of treatment ($P > 0.05$). After two weeks and three weeks of treatment, the ALT content of the SD group was remarkably inferior to that of the control group, MD group, and HD group, and that of MD group and HD group was greatly lower versus control group ($P < 0.05$). From Figure 9(b), the AST content of the SD group and the HD group was notably lower than that of the control group and the MD group after two weeks of treatment, and that of MD group was dramatically lower relative to control group ($P < 0.05$). After three weeks of treatment, the content of SD group was substantially lower than that of control group, MD group, and HD group ($P < 0.05$).

(b)

Figure 5: Continued.

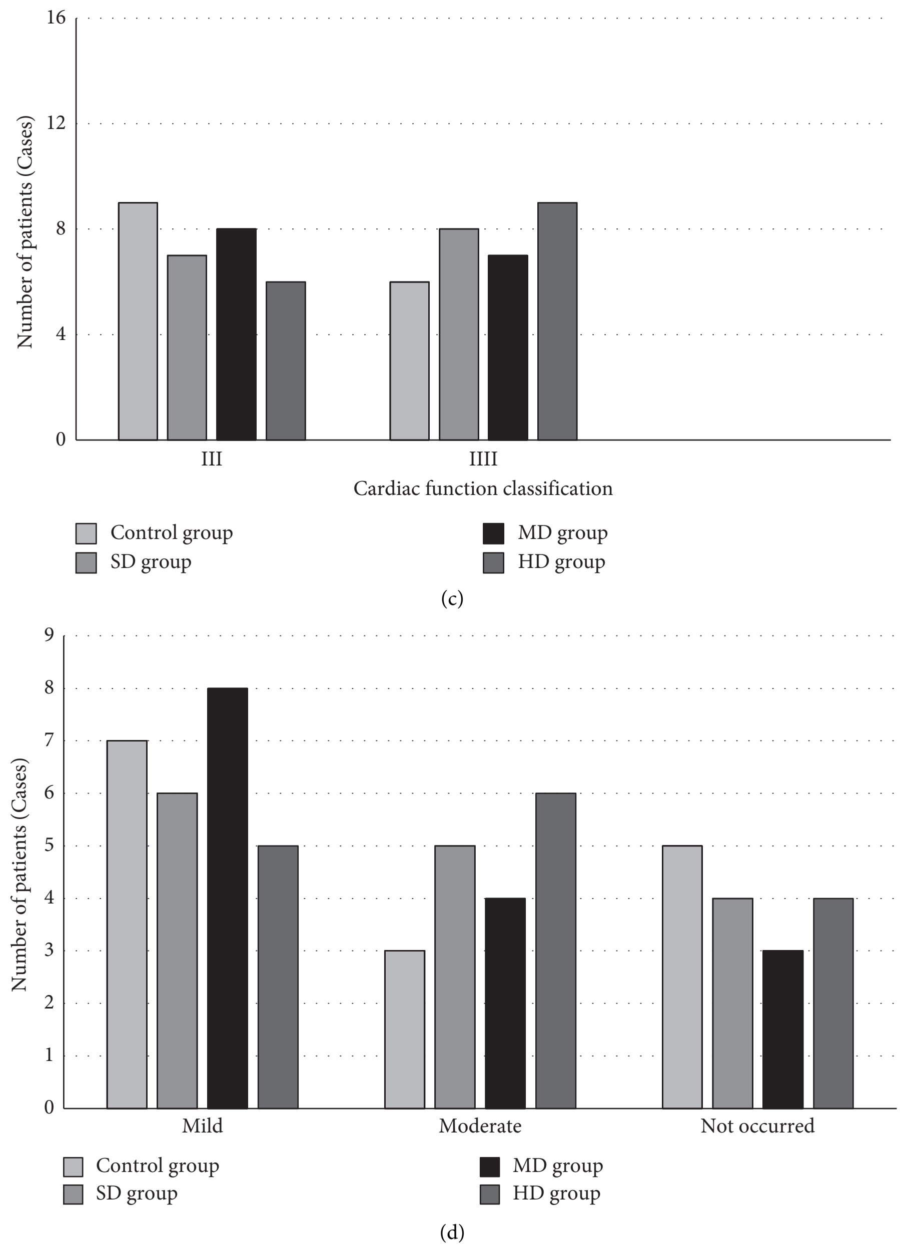

Figure 5: Comparison of the basic information of the four groups of patients. (a) Age. (b) Gender ratio. (c) Heart function level before treatment. (d) Patients complicated with heart failure.

3.6. Complications in the Four Groups. Figure 10 shows the types and incidence of complications in the four groups of patients before and during treatment. From Figures 10(a) and 10(b), patients with PHC undergoing hepatectomy for arrhythmia were prone to hypertension, diabetes, atrial fibrillation, postoperative arrhythmia, atrioventricular block, sinus bradycardia, hypotension, nausea and vomiting, headache, dizziness, etc. From Figure 10(c), the incidence of the above complications in the control group, SD group, MD group, and HD group was 34.6%, 12.4%, 20.5%, and 32.5%, respectively. The incidence of the above complications was the lowest in the SD group, followed by the MD group and the HD group.

4. Discussion

ECG records at the onset of arrhythmias are important evidence for the diagnosis of arrhythmias. During diagnosis, emphasis should be placed on checking whether the patient has organic heart disease such as hypertension, coronary heart disease, and myocarditis, and some physiological and pathological factors can cause arrhythmias [27, 28]. Physiological factors include exercise and emotional excitement, while pathological factors include cardiovascular diseases and endocrine diseases [29, 30]. Studies found that Betaloc is the drug with the lowest side effects among all drugs for the treatment of arrhythmia, and the only drug that can reduce

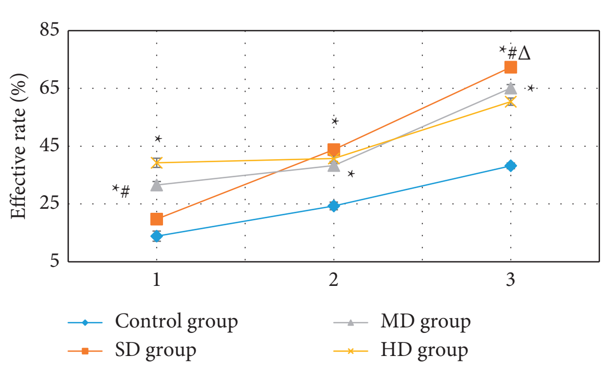

Figure 7: Comparison of the effective rate of cardiac function improvement in the four groups of patients. * indicates considerable differences versus control group ($P < 0.05$); # indicates considerable differences versus HD group ($P < 0.05$); Δ indicates considerable differences versus MD group ($P < 0.05$).

the mortality rate of the disease. It can not only be applied to angina pectoris and myocardial infarction, but also can effectively reduce myocardial oxygen consumption, slows heart rate, reduces angina pectoris, and effectively prevents arrhythmia after myocardial infarction [31–33]. Kotecha et al. [34] found that due to differences in physique and drug response of different patients, whether it is angina pectoris, arrhythmia, or heart failure, if Betaloc is selected as a therapeutic drug, it is necessary to start taking a small dose. If adverse reactions such as drug intolerance occur, it is necessary to stop taking it. The study of Blessberger et al. [35] found that Betaloc, as a beta-blocker, can slow down heart rate, reduce myocardial contractility, and thereby lower blood pressure. It mainly acts on the heart and has certain effects on bronchial smooth muscle. Although drugs such as Betaloc can reduce the heart rate and protect the heart, if the condition is unstable (when the condition is severe or acute left heart failure) for patients with arrhythmia or heart failure, they should avoid taking such drugs without authorization [36]. When heart failure worsens, fast heart rate is also a kind of self-protection. It is necessary to control the heart failure to a stable state before using Betaloc to lower the heart rate. Forcibly suppressing the heart rate when heart failure worsens will have a greater impact on the patient, and even life-threatening [37–39].

The P wave detection algorithm was introduced to detect and analyze the ECG automatically, and it was used in the early diagnosis of arrhythmia. Patients with arrhythmias after hepatectomy for PHC were selected as subjects and treated with different doses of Betaloc. The cardiac function indexes,

(c) The complication rate.

blood lipid indexes, and liver function indexes of patients at different stages of treatment were analyzed; the therapeutic effect of low-dose Betaloc on arrhythmia after hepatectomy in patients with PHC was analyzed. As a result, the P wave detection algorithm can accurately locate the P wave and T wave peaks of the ECG signal. The diagnostic error rate, sensitivity, and correct prediction of ventricular arrhythmia were 0.24%, 99.23%, and 98.53%, respectively. The diagnostic error rate, sensitivity, and correct prediction of atrial arrhythmia were 0.28%, 99.45%, and 98.76%, respectively. Therefore, the proposed P wave detection algorithm had high application value for the diagnosis and early prediction of arrhythmia. The heart rate of the SD group after two weeks of treatment was obviously lower versus control group and the HD group ($P < 0.05$), which suggested that Betaloc can reduce the heart rate of patients with arrhythmia, and the effect of low-dose Betaloc in reducing the heart rate was the most obvious. The effective rate of cardiac function improvement in SD group (72.35 ± 1.21 mmHg) was remarkably superior to that of control group, MD group, and HD group (38.2 ± 0.98 mmHg, 65.12 ± 1.33 mmHg, and 60.43 ± 1.25 mmHg) ($P < 0.05$), which suggested that a small dose of Betaloc can significantly improve the cardiac function of patients with arrhythmia. After two weeks and three weeks of treatment, the ALT content of the SD group was substantially inferior to that of the control group, MD group, and HD group, and that of MD group and HD group was greatly lower versus control group ($P < 0.05$). After two weeks of treatment, the AST content of the SD group and the HD group was considerably lower versus control group and the MD group, and that of MD group was notably lower versus control group ($P < 0.05$). After three weeks of treatment, the content of SD group was evidently lower than that of control group, MD group, and HD group ($P < 0.05$), which was consistent with the results of Irizarry-Alvarado [40], indicating that patients with arrhythmia after PHC hepatectomy were safer to choose low-dose Betaloc, which had a good curative effect, can effectively reduce the heart rate, reduced the occurrence of complications, and improved heart function.

5. Conclusion

In this study, the automatic detection and analysis of ECG was carried out by introducing the P wave detection algorithm, and it was used for the early diagnosis of arrhythmia. Different doses of Betaloc were used to treat arrhythmia, so as to study the therapeutic effect of low-dose Betaloc on the complications of arrhythmia after hepatectomy in patients with primary liver cancer. The results suggested that dynamic ECG based on P wave detection algorithm had high diagnostic value for arrhythmia after hepatectomy in patients with primary liver cancer. The low-dose Betaloc used by patients was safer and had relatively better curative effect. However, the sample size selected in this study is small, which may have a certain impact on the experimental results, and the representativeness is low. Therefore, in the follow-up experiments, the sample size will be increased, and the application of Holter based on P wave detection algorithm combined with low-dose Betaloc in the diagnosis and treatment of arrhythmia after liver cancer resection will be further studied.

To evaluate the effect of specific nursing intervention in children with mycoplasma pneumonia (MP), a feature extraction algorithm based on gray level co-occurrence matrix (GLCM) was proposed and combined with computed tomography (CT) image texture features. Then, 98 children with MP were rolled into the observation group with 49 cases (specific nursing) and the control group with 49 cases (routine nursing). CT images based on feature extraction algorithm of optimized GLCM were used to examine the children before and after nursing intervention, and the recovery of the two groups of children was discussed. The results showed that the proportion of lung texture increase, rope shadow, ground glass shadow, atelectasis, and pleural effusion in the observation group (24.11%, 3.86%, 8.53%, 15.03%, and 3.74%) was significantly lower than that in the control group (28.53%, 10.23%, 13.34%, 21.15%, and 8.13%) after nursing ($P < 0.05$). There were no significant differences in the proportion of small patchy shadows, large patchy consolidation shadows, and bronchiectasis between the observation group and the control group ($P > 0.05$). In the course of nursing intervention, in the observation group, the disappearance time of cough, normal temperature, disappearance time of lung rales, and absorption time of lung shadow (2.15 ± 0.86 days, 4.81 ± 1.14 days, 3.64 ± 0.55 days, and 5.96 ± 0.62 days) were significantly shorter than those in the control group (2.87 ± 0.95 days, 3.95 ± 1.06 days, 4.51 ± 1.02 days, and 8.14 ± 1.35 days) ($P < 0.05$). After nursing intervention, the proportion of satisfaction and total satisfaction in the experimental group (67.08% and 28.66%) was significantly higher than that in the control group (40.21% and 47.39%), while the proportion of dissatisfaction (4.26%) was significantly lower than that in the control group (12.4%) ($P < 0.05$). To sum up, specific nursing intervention was more beneficial to improve the progress of characterization recovery and the overall recovery effect of children with MP relative to conventional nursing. CT image based on feature extraction algorithm of optimized GLCM was of good adoption value in the diagnosis and treatment of MP in children.

1. Introduction

Mycoplasma pneumonia (MP) is a common respiratory disease in children. It is caused by mycoplasma pneumoniae infection and is often associated with atelectasis and large lung infiltration. It can cause extrapulmonary multisystem complications [1, 2]. Mycoplasma pneumonia in children is mainly transmitted by respiratory droplets, which then invades the respiratory mucosa. Through its special structure, it is closely adsorbed on the receptor of the cell membrane. It can then multiply and release toxic substances, which can trigger a cascade of symptoms. The prevalence rate of this disease is very high throughout the year, especially in winter. Mycoplasma pneumonia in children generally presents a subacute onset, and the clinical symptoms are usually dry cough, sore throat, headache, and unsteady fever. Sometimes, a severe cough with normal body temperature may be present [3]. If not treated in time, it will bring multisystem and organ damage to the children, and the skin will appear measles-like changes [4]. Specific nursing is a targeted approach to quality care, whose core is people-oriented. It embodies the humanistic spirit and respects the life value, personal dignity, and personal privacy of patients. Patients are greatly helped in rehabilitation treatment by advocating humanized service concept, paying attention to humanized nursing management, and creating humanized service environment [5, 6].

Relevant studies showed that MP is often manifested as the separation of clinical symptoms, signs, and imaging features, and the abnormal rate of pulmonary imaging is substantially higher than the positive rate of pulmonary signs [7]. Clinical examination of MP mainly adopts imaging methods, among which chest X-ray has a high spatial resolution for patient scan. It can reflect the overall condition of the lung, showing interstitial infiltration, lobular, lobular consolidation, and hilar lymph node enlargement. However, due to the overlapping relationship between the front and the rear, the resolution of pulmonary fine lesions is limited to a certain extent, so it is relatively difficult to detect early or ultraearly lesions [8, 9]. High-resolution CT scan can display patients' pulmonary lesions on multiple levels, which is conducive to accurate positioning and clear extent and range of lesions [10, 11]. Feature information extraction is an important work in medical image processing. Different image data need to be processed by different methods, such as the texture feature extraction method based on statistics, the feature extraction method based on frequency, and the feature extraction method based on model [12, 13]. Gray level co-occurrence matrix (GLCM) is the data used to describe the texture related information among image pixels. It can calculate the similarity of gray levels between different pixel points in a specific distance and direction to describe the overall texture information of the image [14] and effectively reduce the time of texture feature calculation and improve the efficiency of the algorithm. Therefore, a novel feature extraction algorithm based on GLCM was proposed and applied to the CT image evaluation of MP in children.

To sum up, the analysis of image texture features is an important work in clinical diagnosis and treatment. Therefore, 98 children with MP were rolled into the observation group with 49 cases (specific nursing) and the control group with 49 cases (routine nursing). CT images based on feature extraction algorithm of optimized GLCM were used to examine the children before and after nursing intervention, and the recovery of the two groups of children was discussed. This research was developed to comprehensively analyze the adoption of CT image texture feature based on GLCM feature extraction algorithm in evaluating the effect of specific nursing intervention in children with MP.

2. Materials and Methods

2.1. Research Objects. A total of 98 children with MP who were hospitalized in the hospital from June 15, 2019, to April 3, 2021, were selected as the study subjects, including 42 males and 56 females. All the children were divided into the experimental group (49 cases) and the control group (49 cases) according to different nursing plans. This study had been approved by the medical ethics committee of the hospital. The patients and their family members knew about this study and signed the informed consent.

Inclusion criteria: (I) school-age children, (II) children with acute onset, (III) children with fever and respiratory symptoms, (IV) chest X-ray showed patchy infiltrating opacity, (V) children with complete clinical data, and (VI) the family members signed the informed consent.

Exclusion criteria: (I) children unwilling to cooperate with the examination, (II) children with autoimmune diseases, (III) children who had received medical treatment, (IV) children with mixed pulmonary and extrapulmonary infections found by virus examination, and (V) children who quitted the experiment.

2.2. Imaging Examination. Philips Brilliance iCT 256-slice spiral extremely fast CT was used to perform high-resolution CT examination of the patient's lungs. The scan range was from the tip of the lung to the diaphragm. The scanning parameters were tube voltage of 120 kV, tube current of 30 mA, and fault of 1-2 mm.

Results judgment was as follows. The distribution, morphological characteristics, and the condition of lung, pleura, and mediastinum were evaluated by professional imaging physicians. The lesion involved sites were left (upper, middle, and lower) and right (upper, middle, and lower) lung field. A mediastinal window scan was also performed to evaluate lymph nodes and pleural cavities, such as pleural effusion. The lung features of HRCT mainly included increased lung texture, cord-like shadow, ground glass shadow, small patchy shadow, large patchy consolidation shadow, atelectasis, bronchiole dilatation, pleural effusion, and hilar mediastinal lymph node enlargement.

2.3. Feature Extraction Algorithm Based on Optimized GLCM. The GLCM can calculate the similarity between different pixels at a specific distance and gray level in a specific direction to describe the overall texture information of the image [15]. It is supposed that an image is Q and the gray level is z; then, the GLCM of the image is $z * z$. From a pixel point C with a gray level of c to a pixel point D that is e pixels away, the corresponding pixel points generated by the two points C and D are (c, d). Then, the number of all pixels appearing in the image can constitute the elements of the GLCM. In different directions (0°, 45°, 90°, 135°), the GLCM calculation equation is as follows:

$$
\begin{aligned}
F_0(c,d) &= [u-i=e, v-j=0, f(i,j)=c, f(u,v)=d \mid [(i,j),(u,v)\in Q]],\\
F_{45}(c,d) &= [u-i=e, v-j=e, f(i,j)=c, f(u,v)=d \mid [(i,j),(u,v)\in Q]],\\
F_{90}(c,d) &= [u-i=0, v-j=e, f(i,j)=c, f(u,v)=d \mid [(i,j),(u,v)\in Q]],\\
F_{135}(c,d) &= [u-i=-e, v-j=e, f(i,j)=c, f(u,v)=d \mid [(i,j),(u,v)\in Q]],
\end{aligned}
\tag{1}
$$

where $f(i,j)=c$ represents the pixel point with the coordinate (i,j) in the image and the gray value of c, $f(u,v)=d$ represents the pixel point with the coordinate (u,v) in the figure and the gray value of d, and $F_0(c,d)$, $F_{45}(c,d)$, $F_{90}(c,d)$, and $F_{135}(c,d)$ represent the number of pixel pairs appearing in the image at a distance of e and in the direction of 0°, 45°, 90°, and 135°, respectively.

Figure 1 graphically shows the specific definitions in the directions of 0°, 45°, 90°, and 135°.

To better understand the calculation method of the GLCM, a binary image with a gray level of 8 and a size of 5×4 (Figure 2(a)) is taken as an example. Figure 2(b) shows that the number of occurrences of the element $(1,1)$ in the 0° direction is 1, the number of occurrences of the element $(1,2)$ is 0, and the number of $(1,3)$ occurrences is 1. By analogy, the GLCM in the 0° direction is finally obtained. Figure 2(c) shows that the number of occurrences of element $(1,1)$ in the 90° direction is 0, the number of occurrences of element $(1,2)$ is 1, and the number of occurrences of $(1,3)$ is 1. Then, the final GLCM in the 90° direction is obtained.

However, the GLCM has a large amount of data, which is not conducive to the extraction of image features and the classification and recognition of images. Therefore, four statistical indicators of energy (Energy), moment of inertia (Contrast), correlation (Correlation), and entropy (Entropy) were redefined to summarize the characteristic information in the GLCM [16, 17].

Energy reflects the correlation between the distribution of image grayscale and image texture, and the size of the energy is directly proportional to the size of the texture. The larger the value of the moment of inertia, the clearer the image texture. Correlation reflects the correlation of the local pixel distribution of the image. Entropy reflects the texture complexity of the target image. The higher the texture complexity, the higher the entropy value, and vice versa, the lower the entropy.

The equations are as follows:

$$
\begin{aligned}
\text{Energy} &= \sum_i \sum_j F(i,j)^2,\\
\text{Contrast} &= \sum_{v=0}^{V_{g1}} v^2 \sum_{i=1}^{V_g} \sum_{j=1}^{V_g} F(i,j),\\
v &= |i-j|,\\
\text{Correlation} &= \frac{\left[\sum_i \sum_j (i,j)F(i,j) - \alpha_x \alpha_y\right]}{\beta_x \beta_y},\\
\text{Entropy} &= \sum_{i=2}^{2V_g} \log(F(i,j)) * F(i,j).
\end{aligned}
\tag{2}
$$

Among them, $P(i,j)$ represents the element value at the coordinate (i,j) in the GLCM, $i,j\in[0,z]$. z represents the gray level of the image. Then, the average value of the four directions of the special parameter is used as the final parameter value:

$$
\begin{aligned}
\text{Energy} &= \frac{(\text{Energy}_0 + \text{Energy}_{45} + \text{Energy}_{90} + \text{Energy}_{135})}{4},\\
\text{Contrast} &= \frac{(\text{Contrast}_0 + \text{Contrast}_{45} + \text{Contrast}_{90} + \text{Contrast}_{135})}{4},\\
\text{Correlation} &= \frac{(\text{Correlation}_0 + \text{Correlation}_{45} + \text{Correlation}_{90} + \text{Correlation}_{135})}{4},\\
\text{Entropy} &= \frac{(\text{Entropy}_0 + \text{Entropy}_{45} + \text{Entropy}_{90} + \text{Entropy}_{135})}{4}.
\end{aligned}
\tag{3}
$$

Eight lung cancer CT images, eight lung benign lesion CT images, and eight healthy adult lung CT images were selected, and the energy, moment of inertia, correlation, and entropy parameters of different types of CT images were calculated. The results were shown in Figure 3. When the feature parameters of the image were calculated by energy, entropy, correlation, and moment of inertia, the features of different types of samples were not obvious. Therefore, although the four parameters can describe the texture information of the image, there was no clear distinction between the feature information of different categories, which misled the image classification work.

To solve these problems, vector fitting [18] is proposed to optimize the GLCM, and the four directions of each feature

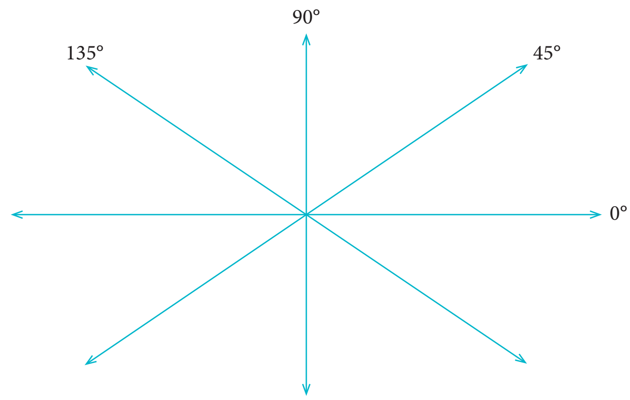

Figure 1: Calculation direction of GLCM.

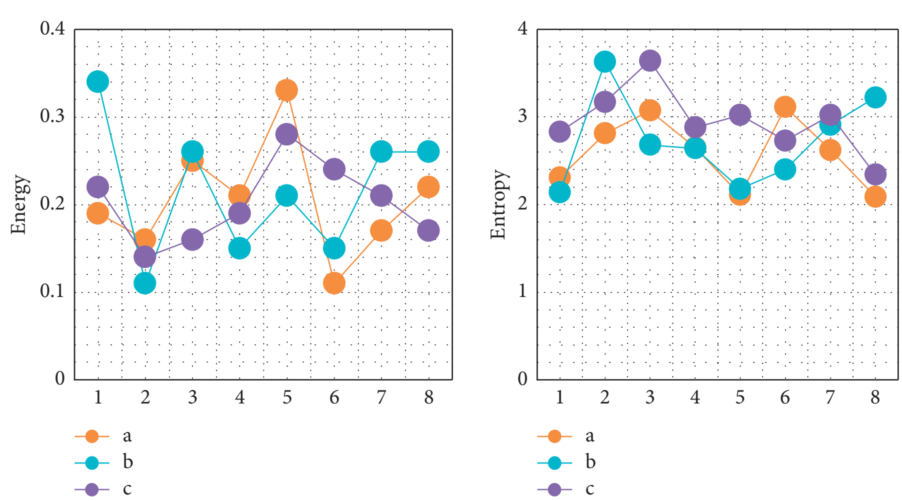
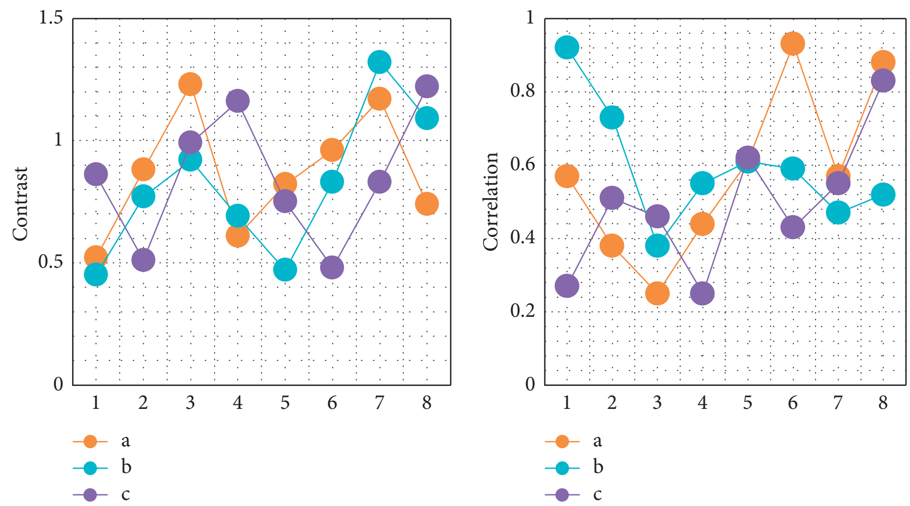
Figure 2: Calculation of GLCM: (a) a binary image; (b) a GLCM in the 0° direction; (c) a GLCM in the 90° direction.



(a) (b)

Figure 3: Continued.



(c) (d)

FIGURE 3: Energy, moment of inertia, correlation, and entropy parameters of different types of CT images (a–c were CT images of lung cancer, CT of benign lung lesions, and CT of healthy adult lungs, respectively): (a) energy; (b) entropy; (c) moment of inertia; (d) correlation.

parameter are vectorized. The vector and modulus of these four vectors are regarded as new feature parameters, and they are expressed as follows:

$$\begin{aligned}
\text{Energy} &= \overrightarrow{\text{Energy}_0} + \overrightarrow{\text{Energy}_{45}} + \overrightarrow{\text{Energy}_{90}} + \overrightarrow{\text{Energy}_{135}},\\
\text{Contrast} &= \overrightarrow{\text{Contrast}_0} + \overrightarrow{\text{Contrast}_{45}} + \overrightarrow{\text{Contrast}_{90}} + \overrightarrow{\text{Contrast}_{135}},\\
\text{Correlation} &= \overrightarrow{\text{Correlation}_0} + \overrightarrow{\text{Correlation}_{45}} + \overrightarrow{\text{Correlation}_{90}} + \overrightarrow{\text{Correlation}_{135}},\\
\text{Entropy} &= \overrightarrow{\text{Entropy}_0} + \overrightarrow{\text{Entropy}_{45}} + \overrightarrow{\text{Entropy}_{90}} + \overrightarrow{\text{Entropy}_{135}}.
\end{aligned} \tag{4}$$

The optimized GLCM is applied to the above different categories of CT images (Figure 4). After the characteristic parameter vector fitting, the information difference of energy value, correlation, moment of inertia, and similarity of different categories of CT images are greatly improved. In general, the improved GLCM parameters based on vector fitting solve the problem that the difference of feature information is not obvious.

2.4. Nursing Methods. For the control group, routine treatment of anti-infection, physical cooling, antiasthmatic, sedation, oxygen inhalation, and other nursing treatment was performed. Nursing staff should understand the basic situation of children and the history of allergy through asking the children's parents. Appropriate psychological comfort was made to reduce children's fear of emotion.

Observation group nursing was as follows. (I) Physical sign nursing: the heart rate, respiration, pulse, and so on were observed during admission. If the child's temperature was unstable, it should be measured every two hours, and every five hours when the temperature was stable. For children with high fever, physical cooling and drug intervention can be used, while keeping their skin clean. (II) Psychological care: whether children had negative emotions such as irritability and anxiety were timely observed, and children's treatment compliance should be enhanced through language communication and interaction. At the same time, communicate was made with the families of the children, so did the targeted guidance. (III) Nutrition care: high-protein food was added in the diet of children to ensure adequate nutrition of children. (IV) Environmental care: nurse should pay attention to keep the ward clean and hygienic, fresh air, regular cleaning, and disinfection. (V) Propaganda and nursing: nurse should educate family members about disease prevention and control and conduct propaganda brochures, verbal education, and other methods to popularize knowledge about the disease. Nursing staff should closely observe the vital indicators and clinical signs of the children during treatment to avoid the occurrence of acute sudden symptoms.

2.5. Curative Effect Indexes. The improvement of clinical symptoms (the cough disappearance time, the time for returning to normal temperature, the disappearance time of

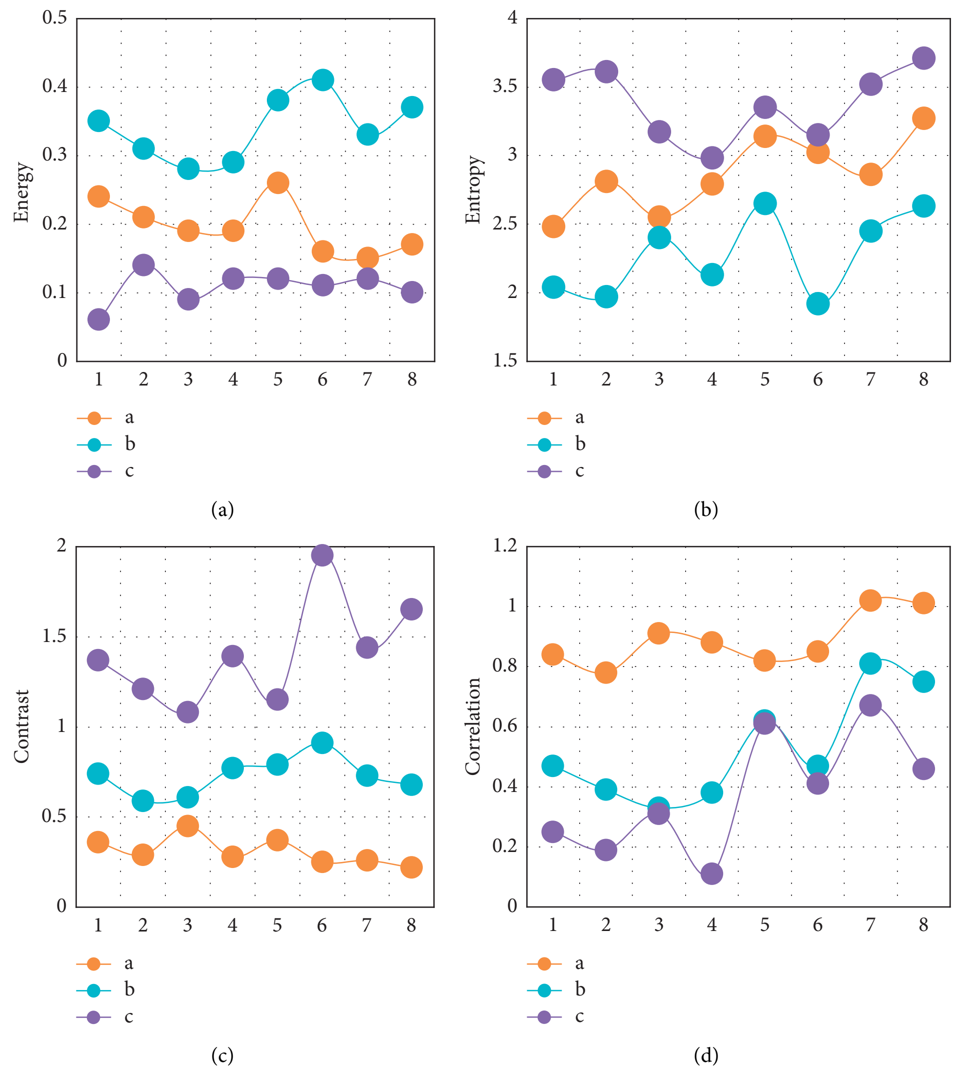


Figure 4: Energy, moment of inertia, correlation, and entropy parameters of different types of CT images after optimization (a–c were CT images of lung cancer, CT of benign lung lesions, and CT of healthy adult lungs, respectively): (a) energy; (b) entropy; (c) moment of inertia; (d) correlation.

lung rales, and the lung shadow absorption time) was recorded during treatment. The recovery of the two groups of children after half a month of treatment was compared and analyzed. The effects of different nursing interventions are shown in Table 1.

2.6. Statistical Analysis. SPSS 19.0 was employed for data statistics and analysis. Mean ± standard deviation ($\overline{x} \pm s$) was how measurement data were expressed, and percentage (%) was how count data were expressed. The pairwise comparison was performed by analysis of variance. The difference was statistically considerable with $P < 0.05$.

3. Results

3.1. Summary of Clinical Manifestations of Children. In Figure 5, the clinical symptoms of 98 children included fever, cough, sore throat, headache, fatigue, wheezing, and kicking sound. The cases of fever, cough, and sore throat were 86, 72, and 59, respectively. The onset time of fever was the earliest (1.24 ± 0.66 days), followed by cough (1.86 ± 1.13 days) and sore throat (1.94 ± 0.58 days). Cough lasted the longest (14.12 ± 3.02 days), followed by fever (8.27 ± 2.85 days).

3.2. CT Image of MP. Figure 6 shows chest CT images of a 6-year-old female child with no previous history of hypertension, diabetes, infectious disease, or family history (parents were healthy). Physical examination showed that the child was clear with no deformity of the chest, clear sound on percussion of both lungs, clear breath sound on auscultation of both lungs, no rales were heard, the heart rhythm was uniform, no deformity of the limbs and spine, and the movement was free. CT images showed consolidation of the right upper lobe with air bronchial sign. The lesion distribution was wedge-shaped, ground glass shadow around consolidation, interstitial change, and interlobular interstitial thickening was obvious.

Table 1: Curative effect indexes of nursing intervention.

Nursing effect	Standard
Satisfied	The child's symptoms improved substantially, and the clinical symptoms were relieved
Generally satisfied	The child's symptoms were slightly improved, and other clinical symptoms were partially relieved
Dissatisfied	The child's symptoms did not improve or worsen

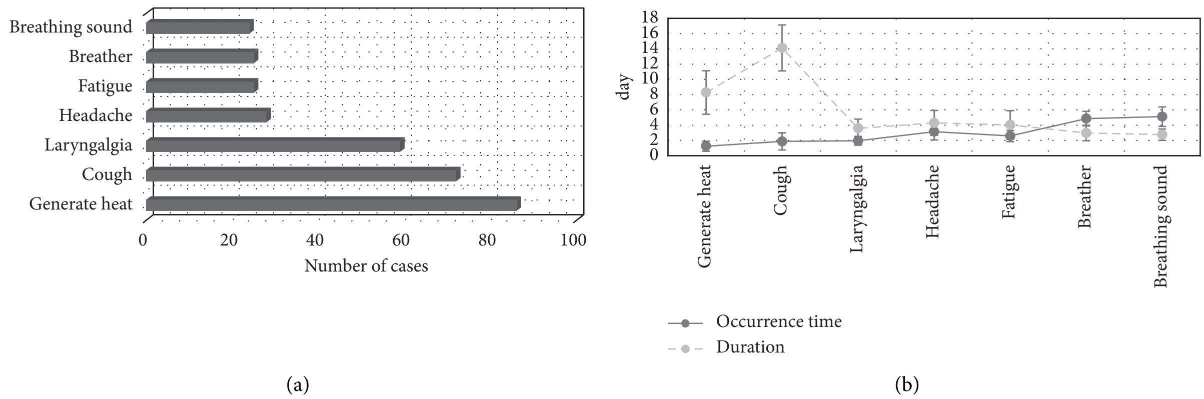

Figure 5: Summary of clinical manifestations of children: (a) the number of patients; (b) the time and duration of symptoms.

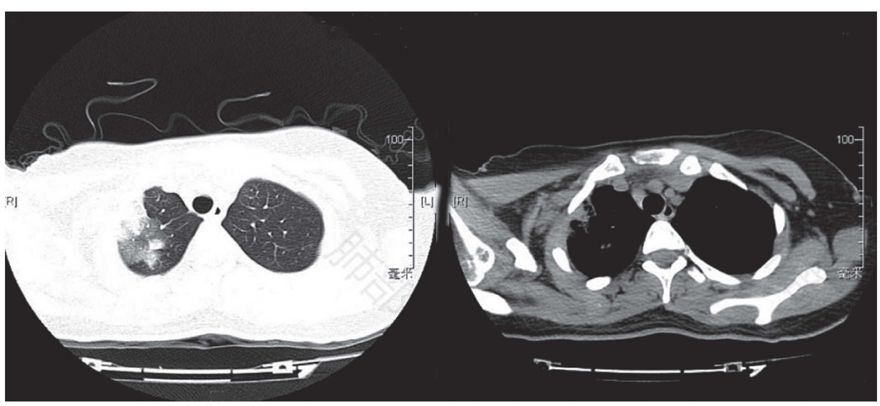

Figure 6: A 6-year-old female child's lung CT image.

3.3. CT Image Characteristics of Two Groups of Children after Nursing Intervention. Figure 7 shows the comparison of CT image features between the two groups after nursing intervention. After nursing, the proportion of increased lung texture, stripe shadow, ground glass shadow, atelectasis, and pleural effusion in the observation group was substantially lower than that in the control group ($P < 0.05$). There was no considerable difference in the proportion of small patchy shadow, large patchy consolidation shadow, and bronchiole dilation between the observation group and the control group ($P > 0.05$).

Figure 8 shows CT images of a 7-year-old male child in the experimental group before and after treatment. Contrast-enhanced CT scan before treatment revealed a distinctly unenhanced low-density area with compartments in the right lung consolidation, marked pleural thickening, and enlarged and uniformly marked lymph nodes behind the anterior tracheal vena cava. After three months of treatment, the review found that the general condition was good, with enlarged anterior mediastinum.

3.4. Comparison of Symptom Improvement of Two Groups of Children during Nursing. In Figure 9, the cough disappearance time, the time for returning to normal temperature, the disappearance time of lung rales, and the lung shadow absorption time of the observation group were substantially shorter than those of the control group, and the differences were great ($P < 0.05$).

3.5. Comparison of Satisfaction after Nursing Intervention between the Two Groups. Figure 10 shows that the proportion of satisfaction and total satisfaction of children in the experimental group after nursing intervention was substantially higher than that in the control group, and the difference was notable ($P < 0.05$). The proportion of

unsatisfied children in the experimental group after nursing intervention was substantially lower than that in the control group, and the difference was great ($P < 0.05$).

4. Discussion

Mycoplasma pneumonia is one of the common diseases in children, with a high incidence, which is extremely detrimental to children's physical and mental health development. In addition, due to the particularity of the body structure of children, treatment will bring some difficulties, so it is critical to choose reasonable and effective nursing treatment in clinical practice [19, 20]. Moreover, the infection of mycoplasma pneumoniae has a common antigen with the tissues in the body, so the infection will have a chain reaction with the corresponding tissues. Therefore, it is very necessary to clinically treat the disease and provide care for the disease [21]. According to this particularity, 98 children with MP were divided into 49 cases of the observation group (specific nursing) and 49 cases of the control group (routine nursing). Then, CT images based on the optimized GLCM feature extraction algorithm were used to examine the children before and after nursing intervention, and the recovery of the two groups of children was discussed. The clinical manifestations of the children were summarized, and it was found that the clinical manifestations of the 98 children included fever, cough, sore throat, headache, fatigue, and wheezing. The cases of fever, cough, and sore throat were 86, 72, and 59, respectively. The onset time of fever was the earliest (1.24 ± 0.66 days), and the duration of cough was the longest (14.12 ± 3.02 days).

The CT image characteristics of the two groups of children after nursing intervention were analyzed. It was found that the proportion of increased lung texture, stripe shadow, ground glass shadow, atelectasis, and pleural effusion in the observation group was substantially lower than that in the control group after nursing, and the difference was great ($P < 0.05$). This was similar to the findings of Hata et al. [22], indicating that specific nursing intervention can more effectively promote the recovery of children with MP compared with routine nursing. In addition, there was no considerable difference between the observation group and the control group in the proportion of small patchy shadow, large patchy consolidation shadow, and bronchiole dilation ($P > 0.05$), which was different from the research of Branco et al. [23]. The reason may be that the time of review in this study was relatively short and there was not a considerable difference in long-term outcomes in children. In the process of nursing intervention, the cough disappearance time, the time for returning to normal temperature, the disappearance time of lung rales, and the lung shadow absorption time in the observation group were substantially shorter than those in the control group ($P < 0.05$). It was proved that specific nursing measures for children with MP were conducive to improving the progress of children's characterization recovery [24]. After nursing intervention, the proportion of satisfaction and total satisfaction in the experimental group was substantially higher than that in the control group, while the proportion of dissatisfaction was substantially lower than that in the control group ($P < 0.05$), which indicated that the total nursing effect of specific nursing measures on children was substantially better than that of conventional nursing, which improved the satisfaction of children and their families [25].

5. Conclusion

In this study, CT images based on optimized co-occurrence matrix feature extraction algorithm were used to examine 98 children with mycoplasma pneumonia before and after nursing intervention and to explore the rehabilitation of the two groups of children. The results showed that, compared with conventional nursing, specific nursing intervention was beneficial to improve the progress of characterization recovery and the overall recovery effect of children with MP. Therefore, CT image based on feature extraction algorithm of optimized GLCM was of good adoption value in the diagnosis and treatment of MP in children. However, the optimized GLCM feature extraction algorithm designed was not trained and learned enough samples, so it is necessary to do further research on its image processing performance in the future. In conclusion, this study provides data support for clinical nursing intervention in children with MP.

In order to explore the application of artificial neural network in rehabilitation evaluation, a kind of ANN stable and reliable artificial intelligence algorithm is proposed. By learning the existing clinical gait data, this method extracted the gait characteristic parameters of patients with different ages, disease types and course of disease, and repeated data iteration and finally simulated the corresponding gait parameters of patients. Experiments showed that the trained ANN had the same score as the human for most of the data (82.2%, Cohen's kappa = 0.743). There was a strong correlation between ANN and improved Ashworth scores as assessed by human raters ($r = 0.825$, $P < 0.01$). As a stable and reliable artificial intelligence algorithm, ANN can provide new ideas and methods for clinical rehabilitation evaluation.

1. Introduction

Artificial intelligence (AI) has become a neighborhood with many practical applications and active research topics. Artificial neural network (ANN), as an important branch of modern artificial intelligence technology, has been widely and deeply applied to modern medical activities due to its powerful learning ability and stable feature recognition and prediction functions [1]. Rehabilitation assessment is mainly a quantitative or qualitative description of patients' functional status, including physical motor function assessment, balance assessment, and other dimensions. However, at present, many rehabilitation assessment methods are time-consuming and laborious and difficult to accurately quantify [2]. Therefore, in recent years, artificial intelligence experts have designed and developed a variety of ANN algorithms, and in the real clinical environment to evaluate the rehabilitation of patients, they have achieved satisfactory results. As an artificial intelligence tool, the artificial neural network has been widely used in the clinical diagnosis of diseases such as tumor and pulmonary embolism since the 1990s. Dr. Robert H. Nielsen, the inventor of the neural computer, defined the neural network as a computing system composed of many simple and highly interconnected processing elements, which can deal with real problems by dynamically reacting to external input information [3]. Stroke has become a common disease in clinical practice due to its high morbidity and disability rate. It is often accompanied by a variety of functional disorders, among which the upper limb motor dysfunction is the most widely affecting limb dysfunction. Recently, rehabilitation medicine is gradually developing towards the direction of precision, long-distance, intelligence, and individuation, among which precise evaluation is an important direction. Based on the fusion of sensor technology and artificial intelligence theory, the automatic evaluation of upper limb motor function is deeply studied, and the motion measurement system is designed from the motor dysfunction of arm, hand, and upper limb activity function. Three different depth learning methods based on sensor data are proposed to realize the feature extraction of clinical scale [4].

Pryor et al. proposed a body evaluation model based on the mixed density neural network. The movement sequences of patients were collected by the Microsoft Kinect sensor as the input of the neural network. The neural network consists of two layers: self-coding layer and mixed density layer. The former is used to reduce the dimension of the motion sequence and extract the features, while the latter is used to express the patient's motion sequence as a Gaussian density function and compare it with the preset motion to evaluate the patient's body function. This model can be applied to the rehabilitation evaluation and training guidance of stroke rehabilitation patients in the family environment [5]. Wilkinson et al. used clustering analysis and artificial neural network to analyze the gait data of 74 stroke patients obtained by the three-dimensional motion analysis system. First, they performed clustering analysis on the gait patterns of patients through K-means algorithm, the characteristics used included 14 parameters such as the landing position of the patient's foot, and three patient clusters were obtained. The first touching position of the foot was found to correspond to the forefoot, foot base, and heel, respectively; then, the angle change of the knee joint was used as the input of the multilayer perceptron to classify the first touching position of the patient's foot, with a classification accuracy of 100% [6]. Based on the research results of this paper, it can be found that using sensor sensing technology and deep learning artificial intelligence analysis method can realize the accurate measurement and quantitative evaluation of the motor function of stroke patients, make up for the lack of traditional evaluation methods, and facilitate the development of rehabilitation evaluation in the family and community environment.

Building a virtual mechanical model or learning and forecasting existing data through neural network algorithm can better reflect the balance ability of the target population. However, the main problem at present is the lack of large sample and multidisease clinical evaluation model and its clinical feasibility needs further study.

2. Materials and Methods

Artificial intelligence is an important branch of computer science, which includes many application fields such as machine learning, machine vision, and intelligent search. Machine learning (ML) is the fundamental way to make computers intelligent, to put it simply. ML can be understood as enabling the computer to discover and mine deep rules from massive data and then carry out data classification and prediction, which is similar to the functional model in mathematics. The data sample is taken as the input variable, and the output is the expected result of simulation. ML can be further divided into supervised and unsupervised learning modes [7]. Unsupervised learning is to directly model the data without providing the data samples for training in advance. The ANN to be discussed is a supervised machine learning category requiring data training. See Figure 1 for the specific machine learning classification. Figure 2 provides a visual explanation of these two concepts through the function image.

2.1. Evaluation of Rehabilitation. Rehabilitation assessment is a process of collecting patient history and related data; putting forward hypotheses; carrying out inspection and measurement; comparing, synthesizing, analyzing, and interpreting the results; and finally forming a conclusion and diagnosis of obstacles. Rehabilitation assessment includes all functional or ability disabilities requiring rehabilitation treatment. Through rehabilitation assessment, the location, scope, type, nature, characteristics, degree, causes, and prognosis of obstacles can be found and determined, so as to provide the basis for the formulation of clear rehabilitation goals and rehabilitation treatment plans. Correct and accurate evaluation of rehabilitation is the premise and basis for formulating correct principles, plans, and specific implementation programs of rehabilitation treatment. In addition, the effect of patients' rehabilitation treatment also needs to be reflected by the change of rehabilitation evaluation results [8–10].

The whole process of rehabilitation treatment must rely on rehabilitation assessment. Generally speaking, rehabilitation assessment mainly has the following functions: (1) seek and determine the type, degree, and cause of obstacles; (2) guide the formulation of rehabilitation treatment plan; (3) determine rehabilitation treatment programs; (4) judge the rehabilitation effect; (5) prognostic analysis; and (6) prevent the occurrence and development of obstacles. In the process of assessing various functional disorders, the commonly used rehabilitation evaluation methods include observation method, investigation method, scale method, and instrument measurement method; among them, scale method is the most commonly used evaluation method in clinical practice at present, and it is a method to use standardized scale to classify the severity of dysfunction of patients or to summarize the score.

2.2. Circulating Neural Network. Recurring neural network (RNN), also known as automatic association network or feedback network, is one of the most popular deep learning algorithms at present. RNN units are connected to each other in turn to form a directed cycle, and the internal state of the units makes the network show dynamic temporal behavior. They are particularly powerful in tasks where context is crucial for predicting results and are often applied to solve problems in areas such as speech recognition and natural language processing. The RNN can use its internal memory to process any input sequence. In RNN, signals propagate forward and backward by introducing a loop in the network.

The forward propagation formula of RNN is shown as follows:

$$z_h^t = \sum_{i=1}^{I} wihx_i^t + \sum_{h'}^{H} wh'h^{a_{h'}{}^{t-1}}, \tag{1}$$

$$a_h^t = f_h\left(z_h^t\right), \tag{2}$$

$$y_k^t = \sum_{h=1}^{H} w_{hk}a_h^t, \tag{3}$$

where lining is the input vector of neuron I in the input layer at time t, a_h^{t-1} is 1 moment h' neurons' hidden state vectors,

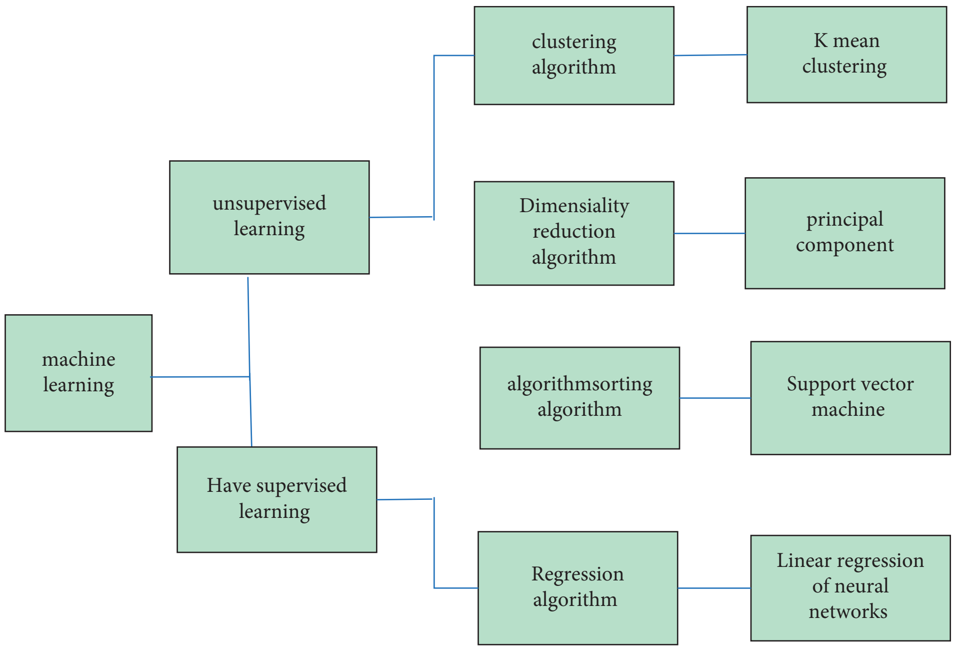

Figure 1: Machine learning classification.The ANN to be discussed is a supervised machine learning category requiring data training.

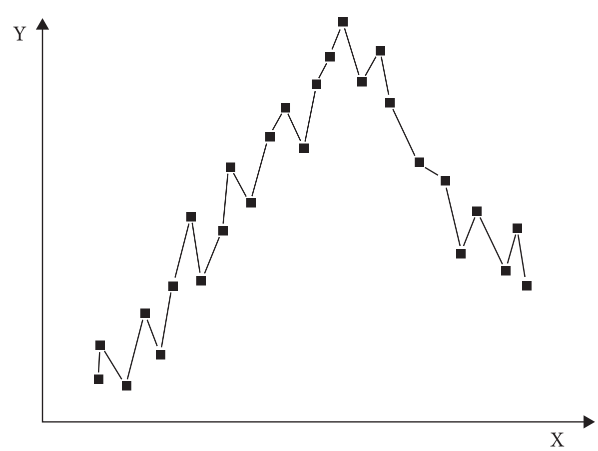

Figure 2: Fitting function simulation provides a visual explanation of these two concepts through the function image.

which are information from memory units at the previous moment, z_h^t is the input information at time t and the memory unit information at the previous time obtained by weighted product and sum, after nonlinear transformation of the activation function $f_h(\cdot)$. It becomes the information spit of the memory unit at the current moment. Common activation functions include Softmax, ReLU, and Tanh. y_h^t is the output vector of K neuron in the output layer at time t. $w_{ih}, w_{h'h}$, and w_{hk} are, respectively, the connection weights between the input layer and hidden layer, hidden layer and hidden layer, and hidden layer and output layer.

Accuracy: accurate rate can be used to represent the ability of the classifier to correctly classify samples in the whole sample set, that is, the ratio of all correctly classified samples to the total number of samples, including true positive and true negative samples, and their calculation is shown as follows:

$$\text{accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FN} + \text{FP} + \text{TN}}. \tag{4}$$

Precision: accuracy is the percentage of samples that are predicted to be positive where the true value is also positive. It is the degree to which the predicted sample is close to the true value, and its calculation is shown in the following formula:

$$\text{precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \tag{5}$$

False positive rate (FPR) represents how many negative samples were wrongly classified as positive, calculated as follows.

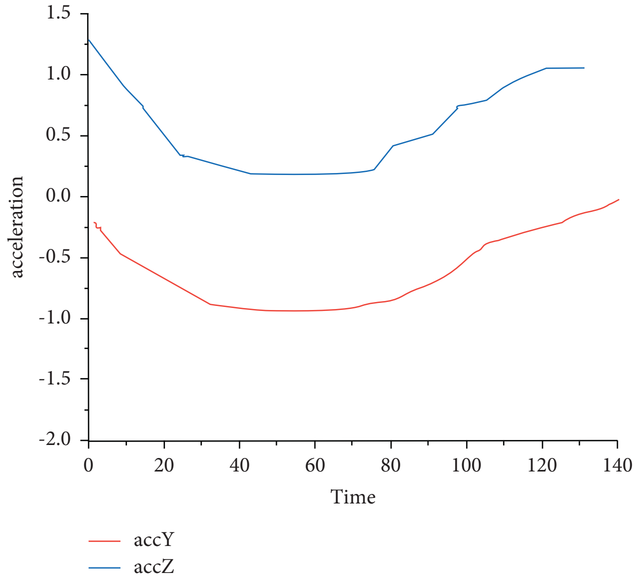

FIGURE 3: Sample IMU acceleration data of subjects at different stages. Due to the different severity, the patient's arm presents different distribution rules in the process of performing the same activity.

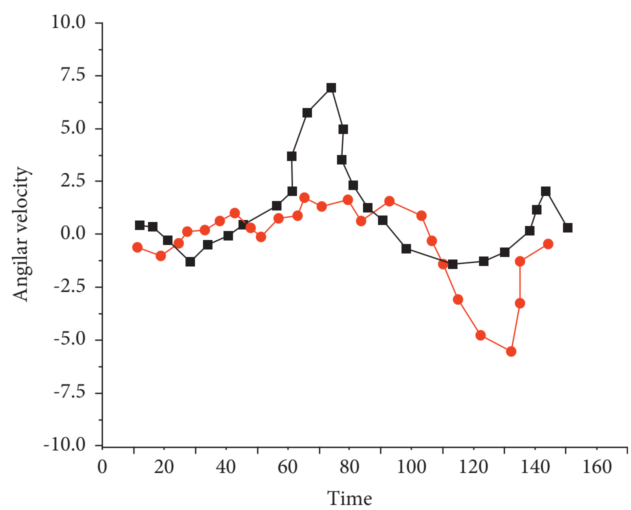

FIGURE 4: Sample data of subject's forearm IMU sensor. As for the logistic regression model, its average accuracy in 5 categories was 27.80%, with an average AUROC of 0.53 and AUPRC of 0.35.

TABLE 1: Brunnstrom staging confusion matrix (TARM).

		Ground truth					Classified sum
Prediction	Stage II	Stage II	Stage III	Stage IV	Stage V	Stage VI	
	Stage III	7	0	0	0	0	7
	Stage IV	0	9	0	0	0	9
	Stage V	0	3	0	0	0	9
	Stage VI	0	0	0	0	6	6
No. of samples		7	9	9	6	5	5
Accuracy		100%	100%	100%	100%	100%	

$$\mathrm{FRP} = \frac{\mathrm{FP}}{\mathrm{FP} + \mathrm{TN}}. \tag{6}$$

The mean square error can be understood as the Euclidean distance between the true value of the sample and the predicted value as follows:

$$\mathrm{MSE} = \frac{1}{N}\sum_{i=1}^{N}\left(y_i - \hat{y}_i\right)^2. \tag{7}$$

Since MSE contains square operation, the value of the calculated result is very large, which is not conducive to comparative analysis. Therefore, RMSE is born, that is, the square sign of MSE is taken to make the order of magnitude of the error result consistent with the order of magnitude of the sample data as follows:

$$\mathrm{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(y_i - \hat{y}_i\right)^2}. \tag{8}$$

3. Results and Discussion

This data collection experiment was carried out in the Chinese Medicine Knowledge and Data Engineering Experiment of University of Electronic Science and Technology of China. The actions of the experiment were conducted under the guidance of clinical professionals, and all of them came from rehabilitation doctors with rich experience in the rehabilitation research of stroke patients and stroke rehabilitation treatment. According to the results of existing studies, at least 20 subjects (5 in each group) are required to achieve a statistical power of 0.95 in the test to detect differences in limb mobility among patients with different degrees of impairment. Therefore, a total of 36 healthy subjects (20 males, 16 females, mean age 23 ± 1.5 years) were enrolled in this study, and each participant was subjected to a Brunnstrom II–VI simulation of upper limb motor dysfunction in stroke patients.

The shoulder touch exercise was used as arm activity assessment, and the motor ability of the subjects' upper limbs was observed. Under normal circumstances, a complete movement process includes the following four steps:

(1) Starting position: the subject is comfortably seated on the chair, with the torso straight, head straight, neck straight, upper limbs hanging naturally on both sides of the body (neutral position), lower limbs naturally relaxed, and knees bent 90°

(2) Lift the hemiplegic arm on the sagittal plane to horizontal height (shoulder flexion 90°)

(3) Bend the elbow and touch the opposite shoulder with the palm of your hand (elbow flexion and forearm pronation)

(4) The upper limbs naturally return to the starting position (shoulder extension, elbow extension, and forearm pronation); therefore, the number of data samples in each period is equal to 36; a total of 180 samples were identified

In the simulation data collection stage, Figure 3 shows the sample triaxial acceleration data collected by two IMU of forearm and upper arm during the Brunnstrom II–VI simulation of movement disorders of the same subject. The solid line is the triaxial acceleration data collected by the IMU at the forearm position, while the dashed line is the triaxial acceleration data of the IMU at the forearm position. As can be seen from Figure 3, due to the different severity, the patient's arm presents different distribution rules in the process of performing the same activity. Stage II patients have higher severity, and the upper limb joints cannot realize a full range of activities.

From Figure 4, we first observe that the deep learning model based on the cyclic neural network has better performance than the linear model in all indicators. As for the logistic regression model, its average accuracy in 5 categories was 27.80%, with an average AUROC of 0.53 and AUPRC of 0.35, which was the worst performance among all models. This is consistent with previous research results that compared the neural network with linear model of time series data. Deep learning method has more and more complex parameters than the traditional learning method and can extract richer and more accurate features by itself.

In order to further prove the performance effect of the proposed method, we analyze the confusion matrix on the test set of all the methods. Table 1 denotes the confusion matrix of TARM and LR classification results on the test set. The TARM was consistent in classifying data for each Brunnstrom stage, and patients with stage III and IV injuries, depending on the location of the injury. The upper limb movements are more complex than those of other stage patients, leading to unstable data classification of these stages in the LR model.

4. Conclusions

Evaluation of rehabilitation is an important link in the process of rehabilitation treatment, which is the basis for the establishment of rehabilitation program and the evaluation of rehabilitation effect. In view of the upper limb motor dysfunction that often occurs after stroke, based on the objectivity and performance defects of the existing clinical rehabilitation evaluation methods and automatic evaluation research, deep learning technology was first applied to the automatic evaluation research of stroke rehabilitation. Firstly, the commonly used clinical scales are analyzed, and the motion measurement system is designed according to the evaluation project content and scoring requirements. Then, different depth learning algorithm models are output according to the data characteristics and expected output. Finally, this automatic evaluation research is compared with relevant depth learning algorithms to verify that the proposed method is a better method for realizing the automatic evaluation task of upper limb motor function. Experiments showed that the trained ANN had the same score as human for most of the data (82.2%, Cohen's kappa = 0.743). There was a strong correlation between ANN and improved Ashworth scores as assessed by human raters ($r = 0.825$, $p < 0.01$). These characteristics of ANN can help it to learn a large number of clinical data and then generate a stable clinical evaluation model, improve the accuracy and efficiency of rehabilitation evaluation, reduce the work intensity of rehabilitation physicians and therapists, and alleviate the current shortage of rehabilitation resources. Using measurement methods, although the degree of interference is low, it is easy to produce measurement error, affect the quality of the data, missing values, and other problems. In terms of data analysis, the data collected by neural network lack missing processing.

In order to discuss the clinical characteristics of patients with scapular fracture, deep learning model was adopted in ultrasound images of patients to locate the anesthesia point of patients during scapular fracture surgery treated with the regional nerve block. 100 patients with scapular fracture who were hospitalized for emergency treatment in the hospital were recruited. Patients in the algorithm group used ultrasound-guided regional nerve block puncture, and patients in the control group used traditional body surface anatomy for anesthesia positioning. The ultrasound images of the scapula of the contrast group were used for the identification of the deep learning model and analysis of anesthesia acupuncture sites. The ultrasound images of the scapula anatomy of the patients in the contrast group were extracted, and the convolutional neural network model was employed for training and test. Moreover, the model performance was evaluated. It was found that the adoption of deep learning greatly improved the accuracy of the image. It took an average of 7.5 ± 2.07 minutes from the time the puncture needle touched the skin to the completion of the injection in the algorithm group (treated with artificial intelligence ultrasound positioning). The operation time of the control group (anatomical positioning) averaged 10.2 ± 2.62 min. Moreover, there was a significant difference between the two groups ($p < 0.05$). The method adopted in the contrast group had high positioning accuracy and good anesthesia effect, and the patients had reduced postoperative complications of patients (all $P < 0.005$). The deep learning model can effectively improve the accuracy of ultrasound images and measure and assist the treatment of future clinical cases of scapular fractures. While improving medical efficiency, it can also accurately identify patient fractures, which has great adoption potential in improving the effect of surgical anesthesia.

1. Introduction

Scapular fracture was first described by Desault in 1805, who studied the characteristics of scapular fracture. Scapular fracture accounts for 1% of total body fractures and 5% of total shoulder fractures [1]. It is usually caused by accidents such as car accidents or falling from heights. The majority of young men and middle-aged men account for 64% to 90% [2]. Scapular fractures such as painful fractures and fall fractures (fatigue injuries) are rare. Scapular fracture is often part of multiple traumas and is often overlooked. With the development of society, science and technology, and transportation, its incidence is gradually increasing [3]. A combination of physical examination, x-ray, or CT examination can usually make a definitive diagnosis of shoulder and foot fractures. At present, most of the surgical treatments for scapular fractures focus on the shoulders, kidneys, and neck, including the articular surfaces, which need to be reduced anatomically as much as possible. However, the incidence of postoperative complications such as joint pain, instability, and shock is relatively high [4].

The local nerve block is mainly used for surgical anesthesia of the shoulder and wrist area. The requirements of local nerve block for patient's systemic physiological functions and hardware equipment are lower compared with general anesthesia, and postoperative pain relief is relatively less [5]. In addition, the local nerve block can reduce general anesthesia. In areas where the local nerve distribution is relatively concentrated, the local nerve block mainly forms various block paths, including muscle groove, subclavian, subclavian longitudinal penetration, subclavian polymorphic process, and axillary path [6]. The operation of traditional nerve fracture surgery requires that the patient should be awake and can assist to report feelings, and the puncture needle of the nerve trunk is contacted within a short period of time, which will cause the patient's subjective discomfort and may cause nerve damage during the puncture process [7]. The key to the success of nerve fracture surgery is the correctness of the position of the peripheral nerve. It requires the surgeon's high clinical experience, which has a great impact on the patient's various anatomical changes, so the success rate is not high. Nerve fracture surgery is often accompanied by lesions of blood vessels or important tissues and organs, which may cause serious complications or sequelae. The development and application of nerve stimulation devices have increased the success rate of nerve fracture surgery. However, puncture increases the discomfort of patients, and the use of intravenous analgesics and sedatives is gradually increasing [8]. In recent years, with the advancement of medical technology and the improvement of human medical treatment, the demand for rapid onset, long-term maintenance, high success rate, and uncomplicated nerve fracture surgery has also increased. With the help of the anatomical positioning of the nerve stimulator, the peripheral nerve block becomes wider and wider. In recent decades, the emergence of ultrasonic technology has made scapular fracture surgery safer and more effective and further expanded the scope of application [9]. This technology rapidly changed the way of clinical anesthesia, and local anesthesia can be performed in a visualized manner. Ultrasound is dynamic, real-time, recordable, and radiation-free, and ultrasound-guided nerve block technology has been developing and maturing in the past decade [10]. Ultrasound-guided nerve block is different from conventional techniques. Traditional methods identify target nerves by looking for paresthesia methods through body surface anatomical location or inducing neuromuscular contraction by nerve stimulator, but traditional methods cannot achieve visualization of puncture points [11]. Ultrasound imaging can visualize the nerve that needs to be blocked, as well as the accompanying blood vessels and important tissues around the nerve. By visualizing the nerve and the important structures surrounding the nerve, it is possible to ensure accurate diffusion of anesthetic drugs around the target nerve during nerve block. It also avoids damage to blood vessels and surrounding important tissue structures and reduces the incidence of adverse events such as intrathecal injection and intravascular injection [12].

Deep learning is a new research direction in the field of machine learning. Unlike traditional machine learning, deep learning neural networks include many hidden layers. The machine can automatically learn the characteristics of each level of the data and completely analyze and process the data information. The excellent results of deep learning technology in the medical field are mainly reflected in the processing and analysis of medical images [13]. It does not need to manually extract the function or preprocess the image. It can extract the information in the image and the depth features of the image, thus contributing to disease diagnosis and diagnosis. At present, the research and application of in-depth learning in the field of anesthesia are relatively rare, and the risk of death of patients after general anesthesia can be predicted based on the data extracted during surgery. In addition, deep learning has broad application prospects for its performance and scalability in anesthesia research.

The purpose of this research was discussing the following three issues: first, the difference in image accuracy between deep learning ultrasound images and ordinary ultrasound images; second, the adoption of artificial intelligence ultrasound to optimize anesthesia puncture path; third, the effectiveness of ultrasonographic imaging guided scapular regional nerve block in the treatment of surgical pain of fracture. It was hoped to provide reference for other regional nerve block anesthesia operations.

2. Methods

2.1. Research Objects. In this study, a total of 100 patients with scapula surgery who underwent surgery from July 2017 to July 2019 were recruited. This study had been approved by the Medical Ethics Committee of the Hospital, and the family members of the patients included in the study had signed the informed consent form.

Inclusion criteria were as follows: (i) patients with diseases such as hypertension, diabetes, and respiratory insufficiency according to the standards of the *American Society of Anesthesiology (ASA)*; (ii) scapular fracture surgery not exceeding four hours

Exclusion criteria were as follows: (i) patients with paralysis; (ii) patients with speech dysfunction; (iii) patients with skin infection at the puncture site; (iv) patients with arm nerve plexus injury; (v) patients with previous clavicle surgery experience; (vi) patients with pleural fluid or ascites

In 100 patients undergoing scapular surgery, 1% of the local anesthetic concentration and 7% of Lopimaran were injected into the area to be anesthetized. Patients were randomly rolled into control group (traditional body surface positioning) and algorithm group (ultrasound-guided positioning).

2.2. Experimental Environment

2.2.1. Construction of the Deep Learning Segmentation Model. Convolutional neural network is a commonly used deep learning algorithm [14]. The process is as follows. Triggered by the human visual system, the continuous modification is formed in a multilayer neural network suitable for processing and recognizing images. A classic convolutional neural network is composed of a convolutional neural layer and a normalization layer, and its structure is shown in Figure 1.

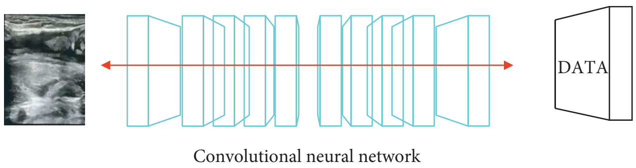

FIGURE 1: Convolutional neural network data analysis model.

3. SegNet Model

Seg is a brand-new deep fully convolutional neural network model (semantic pixel-wise neural network model) proposed by three deep learning experts (Yadri-narayanan, Kcndall, and Cipolla) from the University of Cambridge in 2010 that can perform image pixel-wise semantic division and image labeling [15]. The SegNet model is mainly composed of encoder, decoder, and oft-max layer. The encoder and decoder appear in pairs for image feature extraction and optimization. Its structure is shown in Figure 2.

The SegNet model divides an image into low-frequency part, which is obtained by low-pass filtering (smoothing and blurring) of the image, and high-frequency part, which is obtained by subtracting the low-frequency part from the original image [16]. The goal of the algorithm is enhancing the high-frequency parts that represent details, that is, multiplying the high-frequency parts by a certain gain value and then recombining them to obtain an enhanced image. Therefore, the core of the SegNet model is the calculation of the high-frequency part of the gain coefficient. One solution is setting the gain to a fixed value, and the other solution is expressing the gain value as a quantity related to the variance, which will be explained in the additional equation later.

It is assumed that the pixels in an image are represented as $x(i, j)$; then with (i, j) as the center, in the area where the window size is $(2n+1) * (2n+1)$, its local mean sum and variance can be expressed as the following equations:

$$m_x(i, j) = \frac{1}{(2n+1)^2} \sum_{k=i-n}^{i+n} \sum_{l=j-n}^{j+n} x(k, l),$$
$$\sigma_X^2(i, j) = \frac{1}{(2n+1)^2} \sum_{k=i-n}^{i+n} \sum_{i=j-n}^{j+n} \left[x(k, l) - m_x(i, j)\right]^2. \tag{1}$$

The mean value *mx* can be approximately regarded as the background part, at this time *x-m* is the high-frequency detail part, and the gain product for the high frequency is the following equation:

$$f(i, j) = m_x(i, j) + G(i, j)\left[x(i, j) - m_x(i, j)\right]. \tag{2}$$

For the gain G, the first option is taking a constant greater than 1 to achieve the enhanced effect, which is the following equation:

$$f(i, j) = m_x(i, j) + C\left[x(i, j) - m_x(i, j)\right]. \tag{3}$$

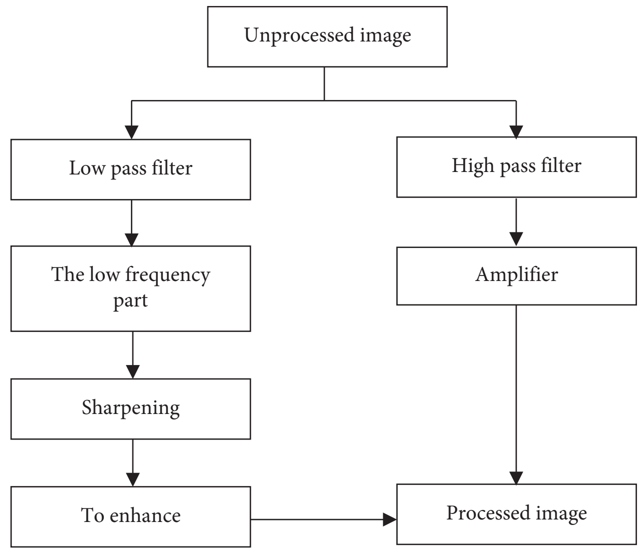

FIGURE 2: Image quality gain model.

Option two is that it is expressed as a change value inversely proportional to the local mean square error, which is the following equation:

$$f(i, j) = m_x(i, j) + \frac{D}{\sigma_x(i, j)}\left[x(i, j) - m_x(i, j)\right]. \tag{4}$$

The local mean square error is large in the high-frequency area of the image, and the gain value is small at this time, so that the result will not be too bright. However, the local mean square error is very small in the smooth area of the image, and the gain value is large at this time, which may amplify the noise signal. Therefore, it is necessary to limit the maximum gain to get better results.

3.1. Adaptive Contrast Enhancement.

3.1. Adaptive Contrast Enhancement. The principle of this network is classifying the image into two parts. The low-frequency part can be obtained by low-pass filtering of the image. The high-frequency part is obtained by subtracting the low-frequency part from the original image. The purpose of this algorithm is visualizing the image in detail, that is, multiplying the high-frequency part by a certain gain value to reconstruct the emphasized image. The core of enhancing image accuracy is repeatedly enlarging clear images in order to improve image quality.

Nowadays, medically generated images are mainly concentrated on low-frequency components, while noise and image details are concentrated on high-frequency components. The two components are separated in image processing, and different operations and processing are performed, which can avoid image detail loss and noise amplification when the histogram equalization algorithm is used. It aims to separate the high-frequency and low-frequency components of the input image. Medical ultrasound images have detailed and strict requirements, and blurring is not allowed, so Gaussian low-frequency filters were used in this study.

3.2. Anesthesia Methods. 4-5 μg/kg fentanyl, 1.5–2 mg/kg propofol, and 0.1 mg/kg vecuronium were used. After successful tracheal intubation, the anesthesia machine was connected to mechanical ventilation, the tidal volume was 8–10 mL/kg, and the respiratory rate was 8–12 times/min. During the operation, 0.06–0.1 μg/kg/min remifentanil was used for continuous intravenous pump injection, Sevoflurane 1.0–1.3 MAC inhalation maintained the depth of anesthesia within 40–60 BIS value, and intermittent intravenous injection of vecuronium was made to maintain muscle relaxation. If the heart rate was lower than 55 beats/min, 0.3 mg atropine was given, and when the systolic blood pressure was lower than 25% of the preoperative base value, 10 mg ephedrine was given to increase blood pressure.

3.3. Traditional Body Surface Localization of the Scapula Regional Nerve Block. The patient was anesthetized on the inner side and 1/3 of the unaffected side of the site to be anesthetized. The patient was supine with the head tilted to about 1.5–2.0 cm. After disinfection of the scapular fracture site, a 20 g puncture needle was inserted along the muscularly groove, and the needle was slowly inserted in the lower and lateral directions. The needle was inserted 1.5 to 2.0 cm, and the patient can feel the pain and location of the puncture, so that the physician was informed. 20 mL local anesthetic was injected into the muscle, and a 5-minute massage was made to spread the anesthetic fluid further away.

3.4. Artificial Intelligence Ultrasound-Guided Scapula Regional Nerve Block. The patient was anesthetized on the inner side and 1/3 of the unaffected side of the site to be anesthetized. The head should be tilted to about 1.5–2.0 cm and the patient should be supine with the scapula fracture in contact. After disinfection, ultrasound was used to detect the nerves that needed to be anesthetized. It was relatively more pronounced by detecting the neural structure at the margin lateral margin of the scapula. After the ultrasound showed the nerves at the anesthetic site, the location of the puncture should be determined and a local anesthetic of 20 mL was injected into the muscle. After 5 minutes of massage, the anesthetic fluid spread further.

3.5. Observation Indexes. The operative time, puncture depth, puncture adjustment time, time to start anesthesia, rate of good anesthesia, complication rate, and other indicators of the two localized nerve area approaches were shown. (I) The time of blocking action referred to the time from the contact with the skin of the puncture needle to the completion of the injection. The measuring tool of the ultrasonic device was used to measure the distance from the puncture point to the target, and the actual puncture depth was measured with a carrier. (II) The needle adjustment times during the puncture process were recorded, so did the occurrence of bone, needle head, and needle body defects during the puncture process. In addition, the number of cases of loss of electrical resistance when the transverse ligament of the upper arm was breached was also recorded. (III) The anesthetic effect was evaluated by other anesthesiologists, and the anesthetic level and effect were measured within 30 minutes after injection. The standard was as follows: excellent: completely painless; good: reduced sensation and mild pain; poor: normal feel and excruciating pain. (IV) The incidence of complications such as perceptual disturbance, vascular puncture injury, hematoma, puncture site pain, pneumothorax, and local anesthesia intoxication during the puncture process was recorded.

3.6. Statistical Methods. SPSS 16.0 was employed for analysis and statistics. Normally distributed measurement data were expressed as mean plus or minus standard deviation, and single-factor analysis of variance was used for comparison between groups. Nonnormally distributed measurement data were expressed as median and interquartile range, rank sum test rate was expressed as percentage (%), and Chi-square test was used. Chi-square test was also used for grade data. $P < 0.05$ suggested that the difference was statistically significant.

4. Results

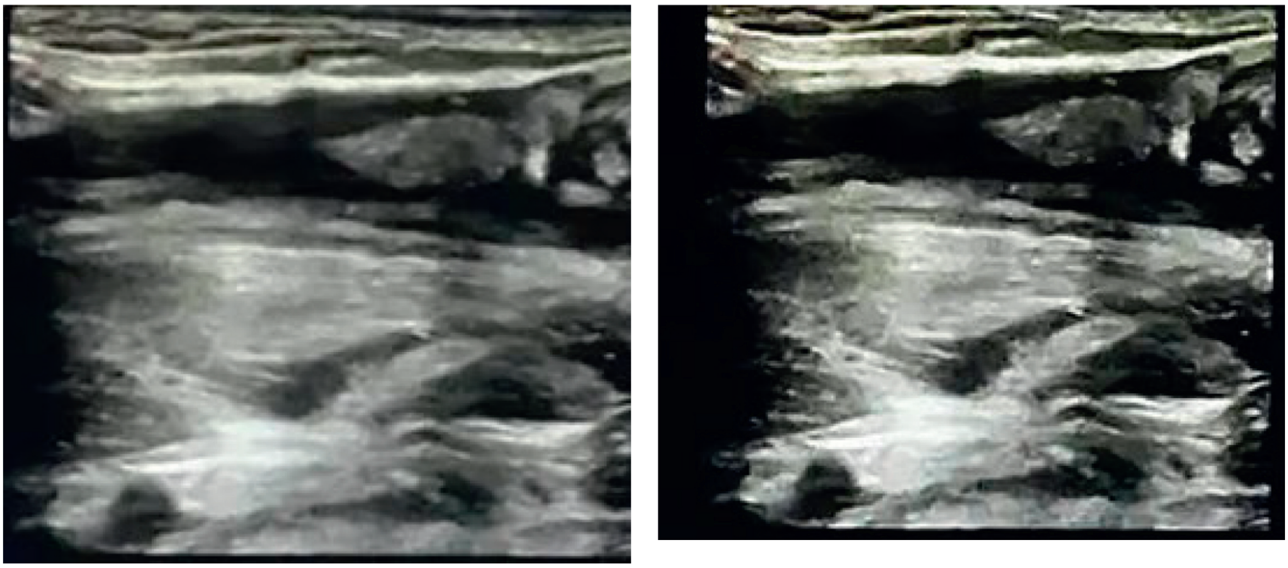
4.1. Visual Evaluation of the Accuracy of Deep Learning Model Images and Non-AI Images. The prototype of the scanned object with "tomography" was shown clearly, so that the doctor can identify it. In Figure 3, the scapula reached the cutoff frequency after being filtered by Gaussian low-pass. When the filter dropped to a certain value, the boundary was clearly demarcated, leaving a clear barrier between it and its surroundings.

In Figure 4, the second enhancement made the dark part of the scanned object and the background next to it have better contrast, and the color layering was obvious, which can clearly highlight the characteristics of the main part.

Figure 5 shows a group of images of patients with fractures. In the image before enhancement and optimization, the fracture at the bottom right of Figure 5 does not seem to be obvious. If it was not enhanced, it was easy to be misjudged as a nonfracture site and affect the doctor's judgment, while the enhanced ultrasound image can clearly show the location of the fracture.

The second boundary enhancement focused on the optimization of some edge contours and the increase of contrast, which further brought the segmented image closer to the real value. Figure 6 shows the enhancement curve of accuracy.

4.2. The Relationship between the Location of the Traditional Nerve Block in the Scapula Region and the Actual Surface Location of the Ultrasound Scapula Region. The location of the traditional nerve in the scapula region overlapped with the actual body surface location of the nerve in the scapula region under ultrasound, accounting for 60%. The traditional location of the nerve in the scapula region was 38% outside the actual body surface position of the nerve in the scapula region under ultrasound. The traditional location of



(a) (b)

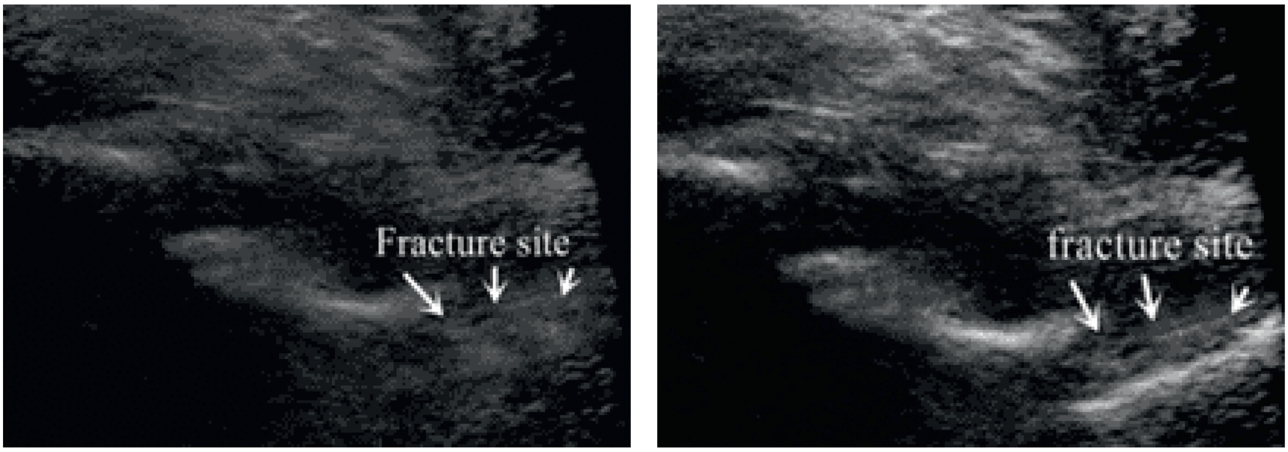
Figure 4: Comparison of the effect of scapula CT before and after artificial intelligence enhancement. (a) Unenhanced CT image of the scapula. (b) Enhanced CT image of the scapula.

the nerve in the scapula region was 2% inside the actual body surface position of the nerve in the scapula region under ultrasound (Figure 7). The traditional positioning of the body surface of the scapula region was 0.63 cm away from the actual body surface of the scapula region under ultrasound. The location area of traditional and artificial intelligence ultrasound overlapped greatly, and the location area of artificial intelligence outside is about 36% more than that of the inside.

4.3. Comparisons of Injection Time and the Distance between the Puncture Point and the Scapula between the Two Groups. In the contrast group (artificial intelligence ultrasound positioning), it took an average of 7.7 ± 2.1 min from the time the puncture needle touched the skin to the completion of the injection. The operation time of the control group (anatomical positioning) averaged 10.7 ± 2.4 min, and there was a significant difference between the two groups ($p < 0.05$). The actual puncture depth of the contrast group



(a) (b)

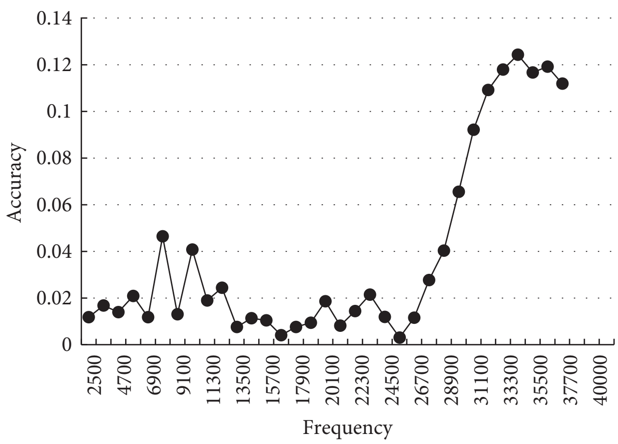

Figure 6: Accuracy enhancement curve.

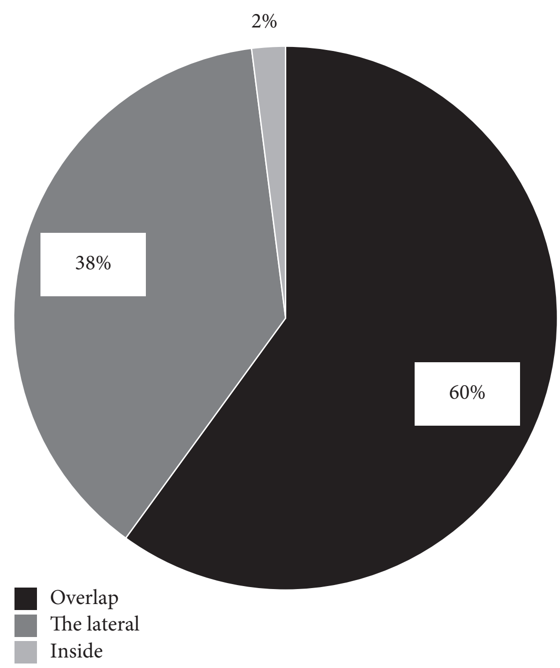

Figure 7: The proportion of the nerve location on the body surface in the scapula region of the traditional method and that under ultrasound.

was 62.5 ± 7.2 mm, and that of control group was 79.8 ± 8.9 mm. The difference between the two groups was significant ($p < 0.05$) (Figure 8).

4.4. Comparison of the Effects of the Motion Block between the Two Groups. The score of motion block effect in the contrast group and the control group is shown in Figure 9. The scores of clenched fist, elbow flexion, wrist extension, and arm lift were significantly different between the contrast group and the control group, and the motion block effect of the contrast group was better, with statistical difference ($P < 0.05$).

4.5. Comparison of Adverse Events during Puncture between the Two Groups. The number of needle tracks needed to be adjusted during puncture in the control group was 3.25 ± 1.36 times, and that in the contrast group was 2.11 ± 1.31 times. $P = 0.009$, with statistical difference. The times of encountering bone during puncture were 1.91 ± 1.34 times and 0.68 ± 0.73 times in the two groups, respectively, $P = 0.002$, with a statistical difference (Figure 10).

4.6. Evaluation of the Anesthesia Effect of the Two Groups. In the contrast group, there were 11 cases with excellent anesthesia effect and 9 cases with good anesthesia. There were 13 cases with excellent anesthesia effect and 7 cases with good anesthesia in the control group (Figure 11). The results showed that the anesthesia effect score of the contrast group was high and the anesthesia effect was good.

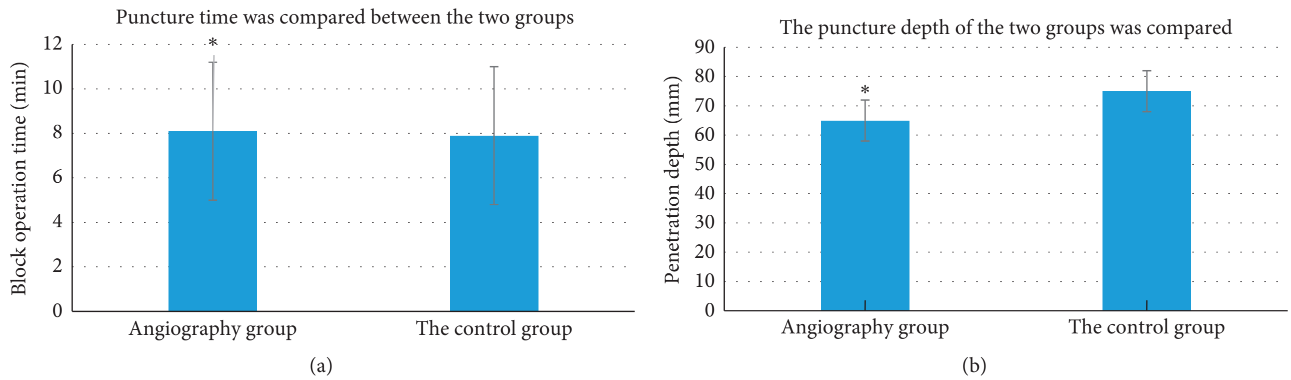

Figure 8: Comparison of puncture time and actual puncture depth between the two groups ($P < 0.05$). (a) Puncture time was compared between the two groups. (b) The puncture depth of the two groups was compared (*a considerable difference between groups).

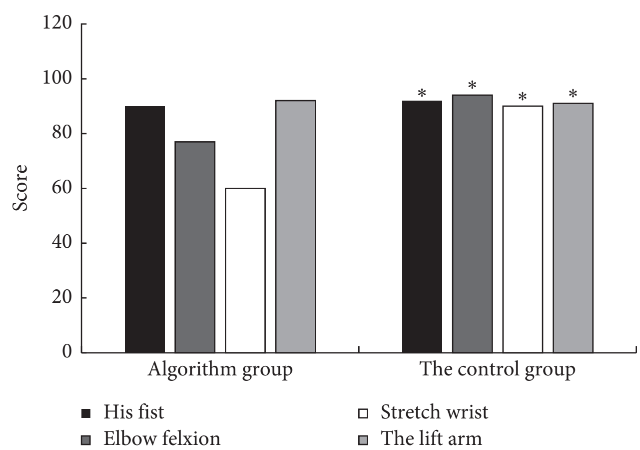

Figure 9: The score of motion block effect between the contrast group and the control group ($P < 0.05$) (*a considerable difference between groups).

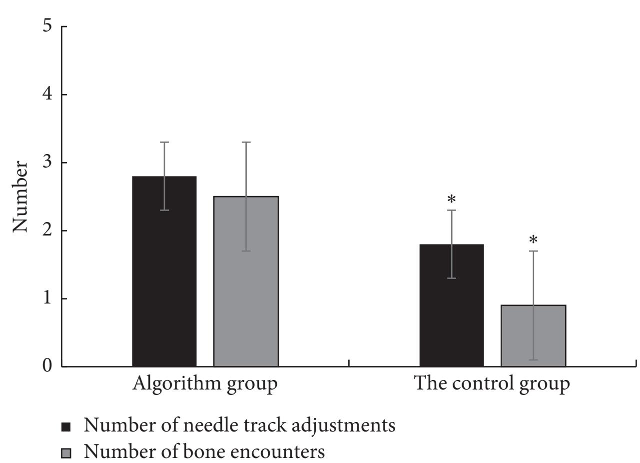

Figure 10: Adjustment of the number of needle tracks and the number of bone encounters between the two groups ($P < 0.05$) (*a considerable difference between groups).

4.7. Comparison of Puncture Sites and Puncture Adverse Reactions between the Two Groups of the Regional Nerve Block. In Figures 12 and 13, one patient in the control group had a transient abnormal sensation during puncture, while the contrast group did not show transient abnormal sensation. One case in the contrast group was found to have vascular injury, and hematomas were formed during the puncture of the injured blood vessel in the control group. The main

complaint of pain during puncture was obvious in the two groups, and there were six patients in the control group, which accounted for 30%. Patients in the contrast group did not have complain of significant pain, and there was a difference between the two groups ($p < 0.05$). There was no pneumothorax and local anesthetic poisoning in the two groups.

5. Discussion

The adoption of ultrasonic technology in regional nerve block has become a research hot issue in recent years. Ultrasound technology has produced revolutionary advances in nerve blocks, including the development of spinal regional nerve block [17]. However, there are few reports of the use of ultrasound for nerve block in thoracic paravertebral area. Nowadays, the application of ultrasound technology in clinical regional nerve block has harvested good results and accumulated experience related to real-time guidance of parathoracic region nerve block [18]. In ultrasound, the sagittal section scan block and the oblique section scan block use two modes. The patient can choose the position of the seated side and the position of the decubitus side, as well as the clinical anesthesia area or sitting position. The selection of ultrasonic detection mainly depends on the depth of puncture target and the body shape of the patient, and the weight of the patient has been shown in many studies to be an important factor affecting the depth of thoracic puncture [19]. An ultrasonic probe with the appropriate frequency must be selected by the scanning site. High-frequency linear detection was used for thoracic lateral spinal region nerve block [20]. Ultrasonic imaging is determined by the physical properties of the frequency and wavelength of the ultrasonic wave that detects radiation. Ultrasonic frequency units are related to resolution. The human ear can sense the frequency of sound waves within 20 Hz–20 kHz, and the medical

diagnostic frequency of ultrasonic waves is 1–30 MHz. The higher the frequency of ultrasonic detection, the better the transverse resolution. Ultrasound wavelengths mean the distance between adjacent particles in two vibrating regions, allowing a clearer distinction between nerves and surrounding tissue. The longer the wavelength, the higher the transmittance. The frequency of the linear probe is 6–13 MHz, which is suitable for photographing the tissue structure of the body surface. Most of the detection frequencies are 2–7 MHz, which can be used for deep tissue structure imaging [21]. Therefore, the appropriate probe is selected according to the body type of the patient and the depth of the site to be anesthetized. In this study, the body mass of patients was less than 30 kg/m^2 and good imaging results were obtained using a high-frequency linear probe. The ultrasonic waves emitted by the probes penetrated the surface and propagated into the interior, reflecting the reactions that arouse when obstacles were encountered. Various obstacles can produce different echoes, which are collected and displayed on the screen to get a real-time view of the various parts of the internal organs. In addition, the color Doppler model was combined, which is particularly sensitive to the flow of fluids. Therefore, the blood vessels can be better observed by color Doppler spectroscopy and the flow and diffusion of local anesthesia injection can be observed, which can enable physicians to better conduct the next operation [22].

On the whole, traditional puncture anesthesia lacks the sense of breakthrough during epidural puncture, so the success rate is low and complications are high. A safe and effective guiding puncture method is urgently needed in clinic. The results showed that the fracture site was not obvious in the image before enhancement and optimization, and it was easy to be misjudged as a nonfracture site, affecting the judgment of doctors. The enhanced sonogram clearly showed the fracture location. The localization area of traditional ultrasound and artificial intelligence ultrasound overlapped greatly, and the area of artificial intelligence localization was 36% more than that of inner ultrasound. The algorithm group had fewer puncture needle channels, fewer adverse reactions, and broken operation time, indicating that the ultrasonic positioning effect of the algorithm was better than that of traditional puncture. After the visualization and real-time properties of artificial intelligence ultrasound were used for two control groups, the feasibility of applying ultrasonic image-guided regional nerve block based on deep learning to scapula fracture anesthesia was demonstrated.

6. Conclusion

The deep learning-based ultrasound image-guided imaging during scapular fracture surgery with regional nerve block anesthesia was compared with the use of traditional puncture anesthetics. It was proved that the method proposed in this study was more efficient than the traditional method, regardless of whether the method of puncture accuracy evaluation or evaluation of anesthesia effect was used. This method significantly shortened the time required for puncture and reduced complications compared with traditional puncture. In the future, we need to verify the performance of our constructed model in more cases and more disease types. In addition, based on the statistics of various parameters formed by patients using this method, its clinical diagnosis and prognostic predictive effects need to be further studied.

Retracted: Effect Analysis of Epidural Anesthesia with 0.4% Ropivacaine in Transforaminal Endoscopic Surgery

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

In addition, our investigation has also shown that one or more of the following human-subject reporting requirements has not been met in this article: ethical approval by an Institutional Review Board (IRB) committee or equivalent, patient/participant consent to participate, and/or agreement to publish patient/participant details (where relevant).

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

Background. Epidural anesthesia used in percutaneous endoscopic lumbar discectomy (PELD) has the risk of complete neurotactile block. Patients cannot timely respond to the operator when the nerve is touched by mistake, so the potential risk of nerve injury cannot be avoided. According to pharmacodynamics, with the decrease of local anesthetic concentration, the nerve tactile gradually recovered; however, the analgesic effect also gradually weakened. Therefore, it is necessary to explore an appropriate concentration of local anesthetics that can keep the patients' nerve touch without pain. By comparing the advantages and disadvantages of 0.4% ropivacaine epidural anesthesia, local anesthesia and intravenous anesthesia on intraoperative circulation fluctuation, the incidence of salvage analgesia and the incidence of nerve non-touch, the feasibility of using low concentration epidural anesthesia in PELD to obtain enough analgesia and avoid the risk of nerve injury was confirmed. *Methods*. 153 cases of intervertebral foramen surgery from October 2017 to January 2020 were selected and divided into local anesthesia group (LA group), 0.4% ropivacaine epidural anesthesia group (EA group), and intravenous anesthesia group (IVA group) according to different anesthesia methods. The changes of blood pressure and heart rate, the incidence of rescue analgesia and nerve root non-touch were compared among the three groups. *Results*. The difference of map peak value among the three groups was statistically significant ($P < 0.001$); pairwise comparison showed that the map peak value of the LA group was higher than that of the EA group ($P < 0.001$) and IVA group ($P < 0.001$), but there was no statistical significance between the EA group and IVA group. The difference of HR peak value among the three groups was statistically significant; pairwise comparison showed that the HR peak value of the LA group was higher than that of the EA group ($P < 0.001$) and IVA group ($P < 0.001$), but there was no statistical significance between the EA group and IVA group. There was significant difference in the incidence of intraoperative hypertension among the three groups ($P < 0.05$); pairwise comparison showed that the incidence of intraoperative hypertension in the EA group was lower than that in the LA group ($P < 0.05$), while there was no significant difference between the IVA group, EA group, and LA group. There was significant difference in the incidence of rescue analgesia among the three groups ($P < 0.01$); pairwise comparison showed that the incidence of rescue analgesia in the EA group was lower than that in the LA group ($P < 0.05$) and IVA group ($P < 0.05$), but there was no significant difference between the LA group and IVA group. Due to the different analgesic mechanisms of the three anesthesia methods, local anesthesia and intravenous anesthesia do not cause the loss of nerve tactile, while the incidence of nerve tactile in 0.4% ropivacaine epidural anesthesia is only 2.4%, which is still satisfactory. *Conclusion*. Epidural anesthesia with 0.4% ropivacaine is a better anesthesia method for PELD. It not only has a low incidence of non-tactile nerve, but also has perfect analgesia and more stable intraoperative circulation.

1. Introduction

Percutaneous endoscopic transforaminal lumbar discectomy (PELD) is easy to touch or injure the spinal cord and nerve due to its close proximity to the spinal cord and dural sac. In order to avoid nerve injury, PELD is mainly local anesthesia, or intravenous anesthesia, general anesthesia or epidural anesthesia by anesthesiologists [1, 2]. General anesthesia can provide perfect analgesia, but it is difficult to find nerve injury due to unconsciousness of patients [3–5]. Spinal nerve function monitoring [6, 7] can provide protection for avoiding nerve injury under general anesthesia. However, additional equipment, personnel, and medical costs limit the popularization of the technology. Although patients with local anesthesia retain consciousness, previous studies have shown that analgesia is insufficient [8], and various analgesic drugs are needed to remedy [9, 10]. Epidural anesthesia can also retain the consciousness of patients and provide perfect analgesia. The other advantage is that the motor function of the lower limbs of the patients remains when the concentration of local anesthetics is low. The surgeon can detect the nerve injury by observing the movement of the toes of the patients [5, 11]. However, this is not the indicator that the surgeon really wants. Because of the sensory motor separation characteristics of ropivacaine, although a certain concentration of ropivacaine retains the motor function, the sensory fibers are completely blocked (including pain and touch), and the patients cannot perceive that the nerve tissue is touched by mistake during the operation. Therefore, in theory, blocking pain and retaining touch is a reliable index to avoid nerve injury. Pain was mainly transmitted by myelinated a δ fibers (2–6 μm) and unmyelinated C fibers (0.3–3 μm), while touch was mainly transmitted by myelinated a β fibers (6–12 μm). Different nerve fibers have different susceptibilities to local anesthetics. A δ nerve fiber is more susceptible to local anesthetics than a β nerve fiber, which leads to more pain block than touch [12]. Therefore, local anesthetics at appropriate concentrations can produce pain tactile separation block. Although some anesthesiologists [13] also recognize that low concentration of local anesthetics can retain the tactile sensation of nerve, there is no study to provide reference concentration of local anesthetics. Routine epidural anesthesia often uses 0.5% ropivacaine; although the analgesia is perfect, the nerve root tactile and lower limb motor function of patients are completely lost. Ren et al. [11] found that the analgesic effect of epidural anesthesia was satisfactory even when the concentration of ropivacaine was reduced to 0.375%. Therefore, when the concentration of ropivacaine is between 0.375% and 0.5%, there is an appropriate concentration, which can not only provide enough analgesia for patients but also retain nerve root tactile sensation. At this concentration, the patient's nerve root can be timely feedback when touched by mistake, and the operator can stop the operation in time to terminate the occurrence of nerve injury. Since October 2017, some patients with PELD in Zhejiang Litongde Hospital were treated with 0.4% ropivacaine epidural anesthesia, and the loss of nerve root tactile sensation was recorded in the electronic medical record.

2. Materials and Methods

2.1. Case Selection and Data Collection. Medical records of patients scheduled for PELD from October 2017 to January 2020 were collected from electronic medical record database (docare clinical anesthesia information system V5.0, madiston medical technology) of Zhejiang Litongde Hospital. Inclusion criteria were as follows: ASA grade I-II and patients scheduled for percutaneous transforaminal endoscopic discectomy. Exclusion criteria were as follows: age less than 18 or more than 80 years old; previous history of lumbar surgery; heart disease or cardiac insufficiency; liver and kidney dysfunction; patients with severe arrhythmia; patients with previous or current history of nervous system and mental disease; patients with abnormal coagulation function or platelet count; patients with other operations at the same time; and 2 or more segments of intervertebral disc nucleus pulposus removal. According to different anesthesia methods, they were divided into local anesthesia group (LA group), epidural anesthesia group (EA group), and intravenous anesthesia group (IVA group).

① Local anesthesia: 1% lidocaine infiltration anesthesia layer by layer. ② Epidural anesthesia with 0.4% ropivacaine: two segments of the lumbar spine were used as epidural puncture points on the cephalic side of the operation, and the epidural catheter was indwelled and placed toward the caudal side. After 5 minutes of 1% lidocaine test dose, 0.4% ropivacaine was given in batches until the anesthesia plane covered the operation area. ③ Intravenous anesthesia: 1 μg/kg fentanyl was slowly injected after prone position, and dexmedetomidine loading dose was 1 μg/kg (infusion time was 10 min), and then it was maintained at 0.3–0.5 $\mu g \cdot kg^{-1} \cdot H^{-1}$ for no more than 30 min. ④ Remedial analgesia: simple use of opioid remedy can obtain enough analgesic effect, but there is a risk of respiratory depression; especially in prone position, it will greatly increase the difficulty of rescue. Therefore, according to the patient's pain performance, anesthesiologists implement individualized multimodal analgesia (non-steroidal, weak opioid, and strong opioid analgesics) to remedy the pain, so as to minimize the occurrence of drug side effects.

2.2. Evaluating Indicator. Eneral information of patients enrolled in the study in the database, including gender, age, hypertension, height, weight, body mass index, basic mean arterial pressure (basicmap) and basic heart rate (basichr) at admission. The historical records of intraoperative vital signs were displayed intensively (data collection interval was 1 min), the mean arterial pressure (premap, postmap) and heart rate (prehr, posthr) at the moment of entering the operating room and at the end of the operation, the peak intraoperative mean arterial pressure (intramap) and the peak intraoperative heart rate (intrahr), the incidence of additional analgesics due to intolerance of pain, and the time of operation were registered the amount of transfusion during operation. Intraoperative hypertension was defined as a 20% or more increase in peak mean arterial pressure (figure) compared with baseline map. The presence of nerve root sensation was recorded (whether there was radiating pain or swelling sensation in the innervated area when the operator touched the nerve root consciously).

2.3. Statistical Analysis. SPSS 25.0 was used for statistical analysis and Graphpad Prism 8 was used for mapping. For continuous data, the Shapiro–Wilk test was used to test the normality. The measurement data conforming to the normal distribution were described by means and standard deviation (mean ± SD), and one-way ANOVA was used; the measurement data not conforming to the normal distribution were described by median (M) and interquartile (Q), and Kruskal–Wallis *h* test of independent samples was used. The counting data were described as percentages, and the χ^2 test was used. The Bonferroni method was used to correct the level of α. All tests were bilateral tests, and $P < 0.05$ indicated that the difference was statistically significant.

3. Result

In this study, 138 patients met the inclusion criteria, 15 patients met the exclusion criteria, and finally 123 patients were included in the study (Figure 1). There were 44 cases in the LA group, 41 cases in the EA group, and 38 cases in the IVA group. By the Shapiro–Wilk test, height, weight, BMI, basic map, basic HR, preoperative map, preoperative HR, intraoperative map peak, intraoperative HR peak, postoperative map, postoperative HR, and operation time were in normal distribution, and the data were analyzed by means of mean and standard deviation (mean ± SD). According to Levene's test of homogeneity of variance, the data were consistent with the homogeneity of variance; the age and infusion volume of patients in each group did not completely conform to the normal distribution, and the data were described by median (M) and interquartile (Q).

3.1. General Information. The height, weight, BMI, basic map, basic HR, and operation time of the patients were analyzed by one-way ANOVA. The Kruskal–Wallis *h* test of independent samples was used for age and infusion volume, and χ^2 test was used for gender and history of hypertension. The results showed that there was no significant difference among the groups (Table 1).

3.2. Comparison of Mean Arterial Pressure of Three Anesthesia Methods during Perioperative Period. One-way ANOVA showed that there was no significant difference in map before and after operation, but there was significant difference in map peak value during operation (Welch ANOVA was used for uneven variance; Welch $F = 9.828$, $P < 0.001$). The Games–Howell test showed that the peak value of intraoperative map in the LA group was 18.4 mmHg higher than that in the EA group (95% CI: 8.5–28.3 mmHg), and the difference was statistically significant ($P < 0.001$); the peak value of intraoperative map in the LA group was 13.3 mmHg higher than that in the IVA group (95% CI: 2.3–24.0 mmHg), and the difference was statistically significant ($P < 0.05$); there was no statistical significance between the EA group and IVA group (Figure 2).

3.3. Comparison of Perioperative Heart Rate among Three Anesthesia Methods. There was no significant difference in HR before and after operation in each group by one-way ANOVA, but there was significant difference in HR peak during operation between groups (uneven variance, Welch ANOVA; Welch $f = 24.166$, $P < 0.001$). The Games–Howell test showed that the peak value of intraoperative HR in the LA group was 17.7 bpm higher than that in the EA group (95% CI: 11.6–23.7 bpm), and the difference was statistically significant ($P < 0.001$); the peak value of intraoperative HR in the LA group was 14.30 bpm higher than that in the IVA group (95% CI: 5.9–22.2 bpm), and the difference was statistically significant ($P < 0.001$); there was no statistical significance between the EA group and IVA group (Figure 3).

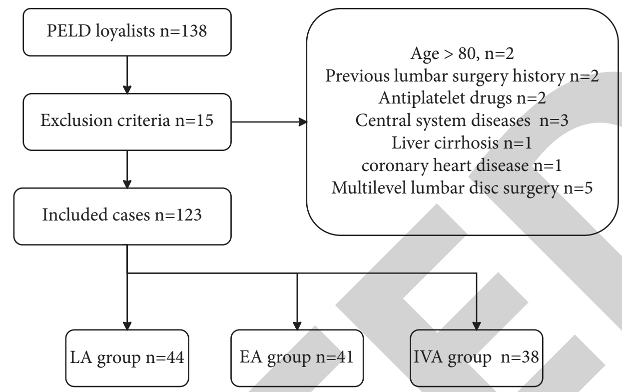

Figure 1: Patient flow diagram.

3.4. Comparison of the Incidence of Intraoperative Hypertension among Three Anesthesia Methods. The incidence of intraoperative hypertension in the LA group, EA group, and IVA group was 36.4%, 9.8%, and 18.4%, respectively. χ^2 test showed that there was significant difference in the incidence of intraoperative hypertension among the three groups ($\chi^2 = 9.175$, $P < 0.05$). Pairwise comparison showed that there was significant difference between the LA group and EA group ($P < 0.05$), but there was no significant difference between the LA group and IVA group and EA group and IVA group (Table 2).

3.5. Comparison of the Incidence of Intraoperative Salvage Analgesia among Three Anesthesia Methods. The incidence of intraoperative salvage analgesia in the LA group, EA group, and IVA group was 43.2%, 12.2%, and 36.8%, respectively. χ^2 test showed that there was significant difference in the incidence of intraoperative salvage analgesia among the three groups ($\chi^2 = 10.456$, $P < 0.01$) (Table 3). Pairwise comparison showed that there were significant differences between the EA group and LA group ($P < 0.05$) and EA group and IVA group ($P < 0.05$), but there was no significant difference between the LA group and IVA group (Table 3).

3.6. The Incidence of Non-Tactile Nerve Root in Three Anesthesia Methods. Because local anesthetics of LA mainly act on nerve endings to block the transmission of pain, while opioids of IVA mainly act on central opioid receptors to produce analgesic effect, neither of them can significantly affect the tactile sensation of nerve roots. EA not only blocked the pain fibers but also blocked the tactile fibers and motor nerves because of the action of local anesthetics on

Table 1: Information of patients.

Index	Group			Statistics	P value
	LA group	EA group	IVA group		
Sample size	44	41	38	—	—
Gender (example, %)					
Male	21 (7.7)	27 (53.7)	20 (52.6)	$\chi^2 = 2.977$	0.226
Age (years, M (Q))	52.5 (26)	58 (24)	54.5 (13)	$H = 2.199$	0.333

nerve roots and spinal cord. The degree of EA was positively correlated with the concentration of local anesthetics. In 41 patients undergoing epidural anesthesia with 0.4% ropivacaine, only one patient (2.4%) lost nerve root tactile sensation.

4. Discussion

To avoid nerve injury, local anesthesia with a low incidence of nerve root injury is usually recommended for PELD [14]. When a nerve is mistakenly touched, the patient can provide timely feedback. A study [3] showed that most patients with local anesthesia had moderate or severe pain when their nerve roots were stimulated, and 15 of 30 patients had fear of surgery. Therefore, anesthesiologists need to explore anesthesia methods that can not only provide effective analgesia, but also make the patient's feedback nerve be touched by mistake. Low-concentration ropivacaine epidural anesthesia is the most common research at present. It not only has good analgesic effect but also can preserve the motor function of patients' lower limbs. The operator can detect the nerve injury by observing the movement of patients' toes during the operation [5, 11]. But this method has a lag, and once the motor function is damaged, nerve damage occurs. Therefore, we need to find the local anesthetic concentration that can make the patient feedback the nerve touched immediately. 0.4% ropivacaine epidural anesthesia is a better choice, and only one of 41 patients in this study had complete loss of nerve root tactile. Because of the different mechanisms of action of drugs, 0.4% ropivacaine epidural anesthesia cannot completely retain the patient's nerve tactile, and only 2.4% of the incidence of nerve non-tactile is still satisfactory. The analgesic effect of epidural anesthesia is better than that of local anesthesia [15–18]. The analgesic effect of epidural anesthesia with 0.25% ropivacaine is close to that of local

Table 2: Comparison of the incidence of intraoperative hypertension among three groups.

Intraoperative hypertension	Grouping			Total	Statistic	P value
	LA group	EA group	IVA group			
Yes	16[a]	4[b]	7[a,b]	27		
Nothing	28	37	31	96	$\chi^2 = 9.175$	0.010
Total	44	41	38	123		

There was significant difference in the incidence of hypertension among the three groups ($P < 0.05$); the Bonferroni method was used to correct the level of blood pressure between two groups, and there was significant difference between the EA group and LA group ($P < 0.05$).

Table 3: Comparison of the incidence of analgesic rescue.

Remedial analgesia	Grouping			Total	Statistic	P value
	LA group	EA group	IVA group			
Yes	19[a]	5[b]	14[a]	33		
Nothing	25	36	29	90	$\chi^2 = 10.456$	0.005
Total	44	41	38	123		

There was significant difference in the incidence of intraoperative rescue among the three groups ($P < 0.01$); the Bonferroni method was used to correct the level of α, the difference was statistically significant between the EA group and LA group ($P < 0.05$), and the difference was statistically significant between the EA group and IVA group ($P < 0.05$).

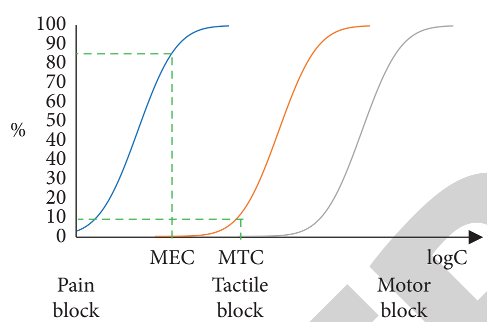

Figure 4: Dose effect curve of local anesthetics on pain, touch, and motor function.

anesthesia [18]. In this study, the incidence of rescue analgesia in 0.4% ropivacaine epidural anesthesia was significantly lower than that in local anesthesia, which indicated that the analgesic effect of 0.4% ropivacaine epidural anesthesia was better than that of local anesthesia, which was consistent with previous studies. Moreover, pain often leads to cardiovascular events. However, the peak value of mean arterial pressure, peak value of intraoperative heart rate, and incidence of intraoperative hypertension in 0.4% ropivacaine epidural anesthesia were significantly lower than those in local anesthesia, and the probability of cardiovascular events was lower. Therefore, epidural anesthesia has advantages over local anesthesia in reducing intraoperative salvage analgesia and stabilizing circulation. Compared with intravenous anesthesia, the incidence of rescue analgesia in 0.4% ropivacaine epidural anesthesia is much lower. However, this does not mean that its analgesic effect is better than intravenous anesthesia. Because the analgesic effect of intravenous anesthesia depends on the dose of opioids, the analgesic effect of intravenous anesthesia in this study can be improved by increasing the dose of opioids, but in the case of patients with PELD in prone position, adverse reactions such as respiratory depression caused by excessive dose are often more difficult to deal with. Therefore, the analgesic effect of 0.4% ropivacaine epidural anesthesia is better when the dosage of intravenous anesthesia is lower, and the safety of 0.4% ropivacaine epidural anesthesia is higher when the dosage of intravenous anesthesia is higher.

In summary, PELD with 0.4% ropivacaine epidural anesthesia can retain the nerve touch to a large extent to avoid nerve injury. At the same time, its analgesic efficacy and safety are better than local anesthesia and intravenous anesthesia. However, the choice of local anesthetic concentration in the study is based on the clinical experience of anesthesiologists, and it is not clear whether epidural anesthesia can reach the lower limit of effective analgesia concentration and the upper limit of nerve root tactile retention concentration. According to pharmacodynamics, for patients, the local anesthetic concentration just reached the pain disappeared, that is, the minimum effective concentration (MEC); with the increase of local anesthetic concentration, there is a suitable concentration, the patient's nerve tactile just disappeared, that is, the maximum tolerable concentration (MTC) of the patient's nerve tissue tactile is retained (Figure 4). The concentration of anesthetics is in the effective range between MEC and MTC. When the operation touches the nerve, the innervated area often shows slight radiation pain or acid swelling. When the operator receives feedback from the patient, the operation is terminated in time to avoid nerve injury. Therefore, the following study will apply biased coin design (BCD) to explore MEC and MTC of ropivacaine in PELD.

This study was to explore the clinical application value of computed tomography (CT) images based on a three-dimensional (3D) reconstruction algorithm for laparoscopic partial nephrectomy (LPN) in patients with renal tumors. 30 cases of renal cell carcinoma (RCC) patients admitted to the hospital were selected as the research objects and were rolled into two groups using a random table method. The patients who received PLN under the three-dimensional reconstruction and laparoscopic technique were included in the experimental group (group A), and the patients who received LPN using CT images only were included in the control group (group B). In addition, the treatment results of the two groups of patients were compared and analyzed. *Results*. The effective rate of the established model was 93.3%; the total renal arteriovenous variability of group A (13.3%) was higher than that of group B (6.7%), and the operation time (131.5 ± 32.1 minutes) was much lower than that of group B (158.7 ± 36.2 minutes), showing statistical significance ($P < 0.05$). *Conclusion*. CT images based on 3D reconstruction algorithms had high clinical application value for LPN in patients with renal tumors, which could improve the efficiency and safety of LPN.

1. Introduction

For early renal cell carcinoma (RCC), especially small RCC with a tumor diameter of less than 4 cm, the therapeutic effects of LPN and laparoscopic radical nephrectomy (LRN) are basically the same [1]. Because LPN only removes the tumor and part of the kidney tissue, the overall renal function after surgery is better than LRN [2]. Existing studies believe that LPN should be selected for isolated patients or patients with other diseases in the contralateral kidney. Compared with traditional open surgery, LPN not only greatly shortens the prognosis and hospitalization time of the patient but also reduces the economic burden of treatment for the patient and relieves the prognosis pain of patients due to surgery greatly [3, 4]. There are two approaches for LPN, namely, transabdominal and retroperitoneal. With the continuous updating of surgical instruments and the development of laparoscopic surgery technology in recent years, the retroperitoneal approach has gradually become a hot spot for scholars. In the past, conventional laparoscopy showed in two-dimensional (2D), which was difficult to achieve the ideal diagnosis and treatment effect. Moreover, in traditional medical imaging inspections, doctors mainly use tomographic images of a certain part of the human body and usually present the imaging results in two-dimensional images such as films or display screens. The result of this method is that the image results obtained are only judged by the personal subjective experience of the doctor. The doctor can only observe the subtleties of the image with the naked eye and the lack of objective evidence to support it, which may delay the condition of the patient [5].

With the continuous development of science and technology, medical imaging technology is also being updated simultaneously, making it possible to make up for the shortcomings in traditional imaging. In recent years, reports on three-dimensional (3D) reconstruction medical imaging technology are not uncommon, which have attracted widespread attention [6]. It uses visualization technology to provide greater assistance for the optimization of imaging effects, and the resulting images have a strong sense of reality, allowing doctors to observe and analyze images from multiple angles and levels. Studies have found that the use of the built-in software of the CT equipment can generate 3D reconstruction images, such as CT angiography (CTA) and CT urography (CTU), and obtain some reference information of the 3D anatomical structure with renal tumor and renal pedicle blood vessels (RPBV) [7]. However, this method does not use 3D image segmentation technology, so it is impossible to obtain a transparent and clear display of the organ structure image. In addition, the method does not use image fusion technology, so it cannot fuse the reconstructed model data information of multiple phases. The image information obtained is relatively scattered. Although it can provide valuable reference information for disease diagnosis, it cannot provide assistance for surgical planning, so the image obtained by this method cannot be called a true 3D reconstruction image [8].

Therefore, the study intended to explore the clinical application value of CT images based on a 3D reconstruction algorithm for LPN of patients with renal tumors by constructing a 3D reconstruction model of the kidney, so as to improve the efficiency and safety of LPN.

2. Materials and Methods

2.1. Research Objects. Thirty cases of renal cell carcinoma (RCC) patients admitted to the hospital from September 2018 to September 2019 were selected as the research objects and were rolled into two groups using a random table method. The patients who received PLN under the three-dimensional reconstruction and laparoscopic technique were included in the experimental group (group A), and the patients who received LPN using CT images only were included in the control group (group B). In addition, the treatment results of the two groups of patients were compared and analyzed. There were 15 cases in group A, including 8 males and 7 females, and they were 26~69 years old (with an average age of 52.40 ± 11.8 years). There were 15 cases in group B, including 9 males and 6 females, and they were 24~70 years old (with an average age of 50.5 ± 10.2 years). None of the selected patients had a previous medical history of contraindications for surgery, and none of them had any hypersensitivity to contrast agents. This study was approved by the hospital ethics committee, and all selected patients had signed the informed consent.

2.2. Variant Type of RPBV. Classification criteria of the renal artery were defined as follows: multiple renal arteries: there were other renal artery branches in addition to the main renal artery; premature renal artery branches: renal artery branches located at a distance ≤20 mm from the opening of the renal artery; and mixed type: a combination of above conditions.

Classification criteria of renal veins were defined as follows: multiple renal veins: the main branches of the renal veins could not merge into one branch before entering the kidney but still presented as branches; abnormal renal veins: the left renal vein run behind the left renal artery, the right renal artery run in front of the inferior vena cava, and there were 2 inferior vena cava; renal veins are abnormal: renal veins were anastomosed with reproductive veins and lumbar veins, respectively; others: renal tumor compressed the renal veins, causing deformation, and so on.

2.3. CT Scanning. A 64-slice spiral CT (Philips, Brilliance 64, Netherlands) was used for CT scanning. Before the scan, the patient was required to fast for 3 hours and drink 500 mL of water to fill the gastrointestinal tract, so as to enhance the contrast with the kidney tissue. In addition, the breathing exercises of patients had to be trained to minimize the artifacts caused by the breathing exercises on the CT scan, so as to ensure the reliability of collected data. The standard parameters of kidney CT scan were set to the following: the tube voltage was 120 kv, the tube current was 300 mA, the time per rotation was 0.5 s, the pitch was 0.984, the layer thickness was 5 mm, and the time for the tube to rotate a cycle was 0.5 s.

At the beginning of the scan, the patient was required to maintain a supine position and performed with CT plain scan and enhanced scan sequentially from the cartilage at the xiphoid process to the plane of the pubic symphysis. During the scanning, the patient was instructed to exhale and hold to the fullest body. When the contrast agent was not injected, a plain scan was performed. Then, the MEDRAD double-barreled high-pressure syringe (US) was adopted to inject the contrast agent (iopamidol solvent 370 in high concentration) intravenously at an injection rate of 5 mL/s, and the injection dose was 1.5 mL/Kg. After all the contrast agent was injected, the injection tube was flushed with a proper amount of saline, and the enhanced scan was started. The arterial phase scan setting was set as follows: the trigger threshold was set to 200 Hu, the contrast agent was injected, and the scan was performed by taking the abdominal aorta section as the region of interest (ROI). The scan in the venous phase was started from the intravenous injection of contrast agent until the delay 65 s. The scan in the excretory phase was started from the intravenous injection of contrast agent until the delay 600 s. After the scans in the above four phases were all completed, the original image with a thickness of 5 mm was thinned, and then all image data was imported into the MxView workstation equipped for the CT. Finally, all image data were recorded to a DVD disc.

2.4. Construction of 3D Reconstruction Model of Kidney. The key step of 3D reconstruction was image segmentation using RGM. The characteristic of RGM was to gather similar pixels to form a ROI. The specific operation method was given as follows: the data obtained from the arterial phase and venous phase scans were entered into mimics 17.0 (Materialise, Belgium), and the upper and lower threshold range was set to 210–1,615 Hu. The renal tumor, renal artery, and renal vein tissue structure were segmented with the RGM, and the other renal artery and renal vein branches outside the ROI were eliminated with artificial auxiliary software. Finally, an ideal 3D reconstruction model of the kidney was constructed. The flowchart of 3D reconstruction of medical images is in Figure 1.

After X-ray passed through the substance, the relationship between output intensity and input intensity was expressed as the following equation:

$$I_b = I_a e^{-\mu\triangle d}, \tag{1}$$

where Δd referred to the propagation distance of X-ray and μ was the X-ray attenuation coefficient of the substance. I_b referred to the output intensity, I_a represented the input intensity, and e referred to the input parameter.

When the X-ray passed through different tissue structures of the human body, the relationship between output intensity and input intensity was given as follows:

$$I_b = I_a\left(e^{-\mu_1\triangle d_1}e^{-\mu_2\triangle d_2}e^{-\mu_3\triangle d_3}\ldots\right). \tag{2}$$

The above equation could be converted into integral form as follows:

$$I_b = I_a e^{-\int \mu \mathrm{d}x}, \tag{3}$$

where x refers to the propagation distance.

CT was developed on the basis of Wratten transformation, the equation of which was as below.

It was known that the integral of a certain function $(x, y) = \hat{f}(r, \theta)$ along the straight line Z was as follows:

$$\begin{aligned} p &= \int_{-\infty}^{+\infty} f(x, y)\mathrm{d}z \\ &= \int_{-\infty}^{+\infty} \hat{f}(r, \theta)\mathrm{d}z, \\ &= \int_{-\infty}^{+\infty} \hat{f}\left(\sqrt{\sqrt{l^2 + z^2}}, \varnothing + \tan^{-1}\frac{z}{l}\right)\mathrm{d}z. \end{aligned} \tag{4}$$

Then, the Wratten equation could be inversely transformed into $\hat{f}(r, \theta) = 1/2\pi^2 \int_0^\pi \int_{-\infty}^{+\infty} (1/r\cos(\theta - \varnothing) - l)(\partial p/\partial l)\mathrm{d}l\mathrm{d}\varnothing$.

The pixel color values of the image were collected from back to front and from front to back, and the synthesis algorithm of which from back to front was given as follows:
