$$\begin{aligned} C_b &= C_a(1 - \alpha_i) + C_i\alpha_i, \\ \alpha_b &= \alpha_a(1 - \alpha_i) + \alpha_i, \end{aligned} \tag{5}$$

where C_a represents the initial color, C_b represents the final color, and α_i refers to the opacity.

The synthesis algorithm from front to back was given as follows:

$$\begin{aligned} C_b\alpha_b &= C_a\alpha_a + C_i\alpha_i(1 - \alpha_a), \\ \alpha_b &= \alpha_i(1 - \alpha_a) + \alpha_a. \end{aligned} \tag{6}$$

During the image synthesis, α could continue to increase, the threshold was 1, and the transparency of the image was close to zero at this moment.

2.5. Evaluation of the Image Quality of 3D Reconstruction Model of the Kidney. The quality of the 3D reconstruction image was evaluated by a senior urologist and a senior imaging physician. Before the evaluation, the 3D reconstruction CT image quality scoring standard was developed according to the renal artery scoring standard of Sahani et al. [9], which was to record the branches of renal arteries and renal veins in detail. The evaluation had to be carried out in strict accordance with this standard. If the scores of individual images were different, the final score can be determined by researching relevant information and discussion of the two physicians. The specific criteria were given as follows: 1 point meant that the main renal artery (renal vein) and its first-level branches showed blurred blood vessel edges, with or without respiratory movement artifacts; 2 points meant that the main renal artery and its first- or second-level branches could be visible clearly, with smooth blood vessel edges and without respiratory movement artifacts, and the secondary branches were less than 4; 3 points meant that the main renal artery and its first, secondary, and tertiary branches were visible clearly, with smooth blood vessel edges, without respiratory movement artifacts, and the tertiary branches were less than 5; 4 points represented that the main renal artery and its first, secondary, and tertiary branches could be seen clearly, with smooth blood vessel edges, without respiratory motion artifacts, and the tertiary branches were greater than or equal to 5; and 5 points represented that the main trunk of the renal artery and its first, secondary, tertiary, and forth branches could be showed clearly, with smooth blood vessel edges and no artifacts of respiratory movement.

In this study, the standard for 3D reconstruction CT image of the kidney was set as follows: the renal vein score was greater than or equal to 4 points, which meant that 3 to 4 renal arteries could be distinguished from the reconstructed image; the renal vein score was greater than or equal to 2 points, which meant that 1~2 renal veins could be identified based on the reconstructed image.

2.6. Preparation before LPN. LPN was performed using the 2D laparoscopic equipment (KARL STORZ, Germany). First, the 3D reconstruction model of renal tumor prepared above was incorporated into mimics 17.0 software, the simulated surgery function of which was adopted to observe the operation of the model in all directions, realize the surgical demonstrations, and formulate scientific and effective surgical plans. During the surgery, the surgeon was in charge of the model magnification and rotation, and the assistant took the specific operations. During this period, the image of the renal cortex was reconstructed by moderately

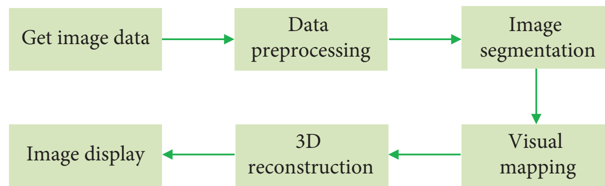

Figure 1: The flowchart of 3D reconstruction of medical images.

transparent processing so that the surgeon can clearly observe the structure of the RPBV and assist in the completion of the operation.

2.7. Application of 3D Reconstruction Model of Kidney in LRN. The practical application of the 3D model in LRN was to guide the operation through the artificial image fusion method; that is, the 3D reconstruction model image was fused and superimposed on the 2D laparoscopic image, and the fused image was displayed on a separate screen. Based on the results of the image fusion, the LRN was performed synchronously. The whole process was led by the surgeon and the surgical assistant performed the actual operation. Renal artery and renal vein can be clearly distinguished due to the different intensity of vascular pulsation, and operations such as ligation and disconnection were adopted accordingly. In group A, the 3D reconstruction model and artificial fusion image method were applied for preoperative guidance and intraoperative RPBV positioning and ligation. After the blood vessel and ureter were separated and cut, the patient's kidneys were freed and the kidney lesions were carefully removed, and then a drainage tube was placed between the peritoneum of the posterior abdominal wall and the intra-abdominal fascia. In group B, the CTA combined with CTU images were applied to guide the operation and to locate and ligate the renal artery and renal vein. After the blood vessel and ureter were separated and cut, the patient's kidney was freed and the renal lesion tissue was carefully removed. A drainage tube was placed between the peritoneum and the intra-abdominal fascia on the posterior wall of the abdomen. All patients underwent the surgery successfully without any accidental interruption.

2.8. Statistical Methods. The data were processed with SPSS 20.0 software for statistical analysis. The measurement data were indicated as mean ± standard deviation ($\overline{x} \pm s$), and an independent sample t-test was used; the count data was displayed as a percentage (%), and the X2 test was used for analysis. All data were considered statistically significant with $P < 0.05$, and there was no statistical difference when $P > 0.05$.

3. Results

3.1. Basic Information. There were 8 males and 7 females in group A, with an average age of 52.40 ± 11.8 years; there were 9 males and 6 females in group B with an average age of 50.5 ± 10.2 years old. As illustrated in Figure 2, there was no obvious difference between the two groups of patients in indicators such as age, gender, tumor distribution, body mass index (BMI), tumor maximum diameter (TMD), hemoglobin value, and the number of adrenal artery branches ($P > 0.05$). All selected patients did not withdraw due to accident event.

3.2. Visualization Results of the 3D Reconstruction Model of the Kidney. A 3D reconstruction model of the kidney of 15 patients in group A was successfully constructed. This model can clearly show the main renal artery and its fourth-level branches and the main renal vein and its second-level branches. The renal can be visually observed through this model. The outline of the tumor more objectively and effectively reflects the size of the renal tumor and its spatial distribution with other tissue structures; the kidney collecting system showed a clear structure and natural connections; the entire kidney system structure was clearly displayed with anatomical details. Figure 3 shows the images of image of renal tumor based on 2D CT and 3D reconstruction model for better comparison.

The use of a 3D reconstruction model of the kidney can clearly reflect the anatomical characteristics of RPBV. In Figure 4, the characteristics of renal artery variation were observed from the ventral and dorsal sides, so that the variation of the renal artery could be intuitively understood.

3.3. Image Quality Results of the 3D Reconstruction Model of the Kidney. Of the 15 kidney 3D reconstruction models prepared in this study, 14 cases met the standard, and the effective rate of the built model was 93.3% (as Figure 5). One case was unqualified because the patient's kidney was not filled with contrast medium enough, which resulted in fewer main branches of the renal artery in the 3D reconstruction model and incomplete display of the renal calyces in the renal collection system. Although the 3D reconstruction model of the kidney in this case was incomplete, it could still show the anatomical details of the renal artery and renal vein, so it had no effect on the LPN.

3.4. Classification on Variety of RPBV. Figures 6 and 7 show the comparisons on variations of renal artery vascular and variations on renal vein vascular in two groups, respectively. Most of the cases in both groups suffered from mixed renal artery variation, with 6 cases in group A and 7 cases in group B. The type of renal vein variation in group A was abnormal renal vein progression and other types, and there were only multiple vessels type renal vein variation in group B. There was no remarkable difference

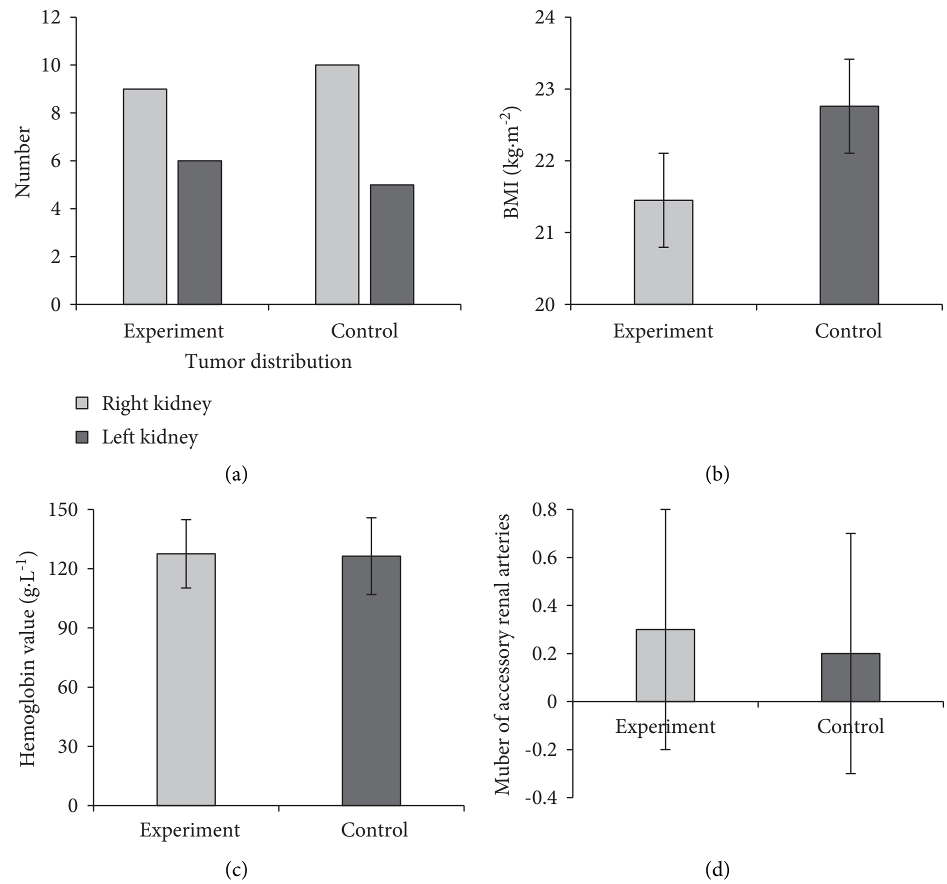

Figure 2: Basic information of patients in two groups.

between the two groups in the total renal artery variation rate and renal vein total variation rate ($P > 0.05$).

3.5. LPN Results. All the enrolled patients were diagnosed as RCC before surgery, followed by LPN, and there were no serious complications such as conversion to open surgery and major bleeding that occurred during the surgery. The 3D reconstruction model of the kidney used in group A could objectively and truly reflect the structural characteristics of the kidney, the type of RPBV variation, and the spatial position relationship of kidney tumors. The constructed 3D reconstruction model was adopted for preoperative scientific planning, and it was fused and superimposed with the 2D laparoscopic images during the surgery. The surgery of the patients in group A was successful. As shown in Figure 8, the RPBV variant type was that the left renal vein run behind the left renal artery. The 3D model showed that it was safer and more effective to ligate and cut the renal artery running forward.

The scan data obtained from CTA combined with CTU images were applied in group B for preoperative planning. The patients in group B had successful surgeries.

3.6. Analysis on Efficacy. The operation time, estimated blood loss, intraoperative blood transfusion number/rate, incidence of complication, postoperative hemoglobin value, tumor recurrence number/rate, and other index values were analyzed for the two groups of patients. The results given in Figure 9 revealed that the operation time of group A was visibly lower than that of group B, and the difference was great in statistics ($P < 0.05$), while the differences in other indicators were not extreme ($P > 0.05$). In addition, there was no tumor recurrence in the two groups.

4. Discussion

The clinical application value of CT images based on the 3D reconstruction algorithm for LPN in patients with renal tumors was discussed in this study, so as to improve the efficiency and safety of LPN. A 3D reconstruction model of the kidney was constructed, the image quality was evaluated, and the RPBV mutation of the patient was classified according to the kidney mutation classification standard. Then, the 3D reconstruction model of the kidney was applied to LPN, and the curative effect of two groups of patients was analyzed and compared. The results revealed that the constructed 3D reconstruction model of the kidney could objectively and truly reflect the structural characteristics of the kidney, the variant type of RPBV, and the spatial position relationship of the renal tumors, which was helpful for the rational planning and design of LPN before surgery. Applying the 3D reconstruction model of the kidney in LPN could greatly shorten the operation time without

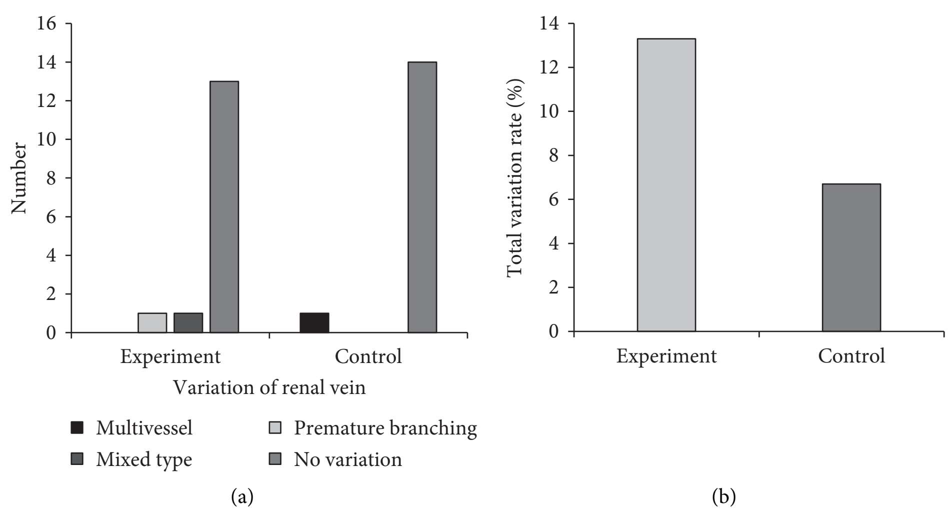

Figure 7: Variations on renal vein vascular in the two groups. "Other" refers to the deformation and variation of the renal vein on the affected side of the kidney due to compression by a larger tumor.

complications. Such a result was basically consistent with the research results of other scholars.

Malignant renal tumors mostly occur in the renal parenchyma, accounting for more than 80%, including RCC, renal sarcoma, renal metastases, Wilms tumor, and transitional cell carcinoma that occurs in the renal pelvis and calyx [10]. The adult renal tumor has the highest incidence rate of RCC, followed by transitional cell carcinoma originating from the collecting system of the kidney, so the renal tumor is also known as RCC. The human body is most likely to develop RCC when it is over 50 years old [11]. Compared with the transperitoneal approach, the surgeon can reach the kidney faster through the retroperitoneal laparoscopic approach and hardly interfere with other organs in the abdominal cavity. In addition, the renal arteries are mostly behind the renal veins, and the retroperitoneal approach facilitates direct exposure and treatment of the renal arteries [12]. However, because the target kidney is tightly connected with adjacent organs in the operation of the retroperitoneal approach, the operation space is narrow, and improper operation may cause damage to other organs of the patient. How to locate RPBV quickly and accurately and deal with it effectively has become a difficult topic for many scholars, and a comprehensive and accurate understanding of the anatomical characteristics of RPBV before surgery has become the key [13].

Huang et al. [14] used the 3D reconstruction model of the kidney to successfully implement the "zero ischemia partial nephrectomy," which not only effectively reduced the ischemic damage to the normal kidney during the operation but also promoted the research and development of partial nephrectomy with superselective renal artery occlusion. Xia et al. [15] reconstructed a digital 3D model of the kidney with clear blood vessel structure and strong stereo perception

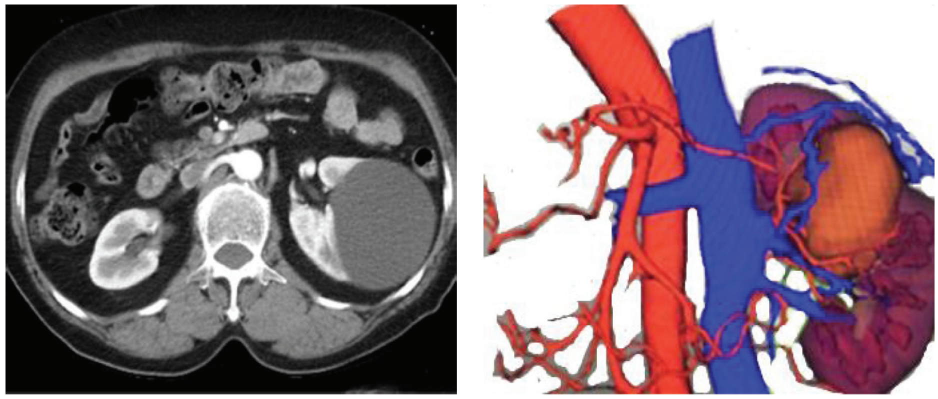

Figure 8: Images of RPBV laparoscopy and 3D reconstruction model of the kidney.

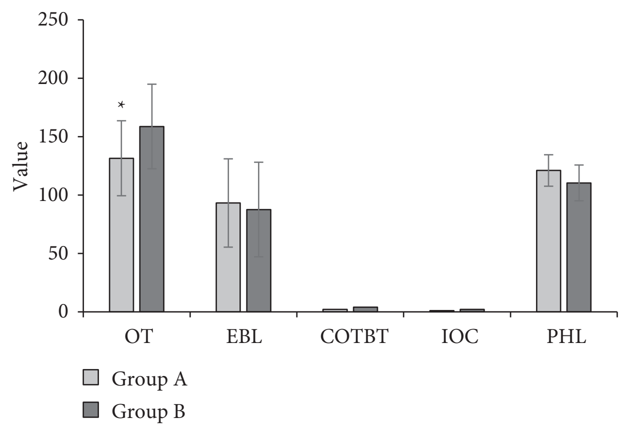

Figure 9: Comparison of the curative effect of patients in the two groups. ∗ indicates that group A is observably different from group B ($P < 0.05$); OT represents the operation time, EBL represents the estimated blood loss, COIBT represents the case of intraoperative blood transfusions, IOC represents the incidence of complication, and PHL represents postoperative hemoglobin value.

based on the CT scan data of preoperative patients and formulated a more reasonable surgical plan with the aid of simulated surgery; it was found that the actual operation was highly consistent with the 3D reconstruction; and based on this 3D model, clinical living kidney transplantation was successfully implemented, the prognosis was good, and there were no obvious surgical complications.

5. Conclusion

The conclusions of this study were summarized as follows: CT images based on the 3D reconstruction algorithm had high clinical application value for LPN in patients with renal tumors and could improve the efficiency and safety of LPN. It was necessary to further promote the application. However, there were still many shortcomings of this study. For example, the number of study subjects was small due to time and conditions, and the data results obtained had to be further researched. In future research, the number of samples had to be expanded to increase the persuasiveness of the data, so as to provide reliable reference information for clinical applications. The results of this study provided a reliable research basis for the clinical application of 3D technology and further demonstrated the good development prospects of 3D reconstruction technology in the medical field.

Goiter is thyroid enlargement, in China, *Sageretia hamosa Brongn* (SHB) can be used to treat goiter, but it has not been reported. Therefore, data analytics of SHB prescription on thyroid were explored in this study to provide a theoretical support for SHB in the treatment of goiter. In this study, rat in goiter model was constructed by using propylthiouracil (PTU) and treated with SHB prescription. Thyroid function about the triiodothyronine (T3), free thyroxine (T4), free triiodothyronine (FT3), free thyroxine (FT4), and thyroid-stimulating hormone (TSH) were measured by ELISA; thyroid coefficient was calculated after weighed thyroid; and HE staining was applied to assess the morphology of thyroid tissue. miRNA microarrays were employed to detect miRNA expression in thyroid tissue of rats. Expression of miR-511-3p was measured by RT-qPCR; expression of proteins (PTEN and apoptosis-related proteins) was tested by western blotting; relationship between miR-511-3p and PTEN was investigated by dual luciferase reporter gene assay; cell viability rate was determined by CCK-8; and cell cycle distribution and apoptosis rate were detected by flow cytometry. The results showed that SHB prescription ameliorated goiter and downregulated miR-511-3p. miR-511-3p targeted PTEN in thyroid cells and PTEN negatively regulated the activation of PI3K/Akt pathway. Furthermore, the inhibition of apoptosis in thyroid cells caused by the overexpression of miR-511-3p or the activation of PI3K/Akt pathway was reversed by treatment of SHB prescription, inhibition of miR-511-3p, or overexpression of PTEN. In conclusion, SHB prescription promoted apoptosis of thyroid through decreased miR-511-3p and regulated PTEN/PI3K/Akt pathway, it might suggest possible medical applications.

1. Introduction

Goiter is thyroid enlargement, which is caused by a large number of agents in the environment or medication, some kinds of goiter with obvious hyperthyroidism or hypothyroidism [1]. Most patients present with benign disease and are euthyroid at presentation, but without effective treatment in time, and it will lead to more serious thyroid pathological changes [2]. Nowadays, the main treatments are thyroidectomy, partial resection, and single or repeated radioiodine therapy [3]. Thyroidectomy is a standard therapy for young and otherwise healthy patients, radioiodine therapy is an attractive alternative to surgery in older patients with cardiopulmonary disease, and thyroxin therapy may be tried in young patients with small diffuse goiters [4], and all have their limitations. In addition, goiter can be cured by many kinds of traditional Chinese medicine (TCM) as well [5].

In many regions of China, a lot of TCM show great curative effect on goiter [6]. For example, Xing Qi Hua Ying Tang ameliorated clinical symptoms of patients that were accompanied with reduction in the size of goiter [7]; besides, Haizao Yuhu Decoction alleviated iodine-deficient goiter via regulating thyroid hormone synthesis [8, 9]. *Sageretia hamosa Brongn* (SHB) is one of the TCM [10], it is known as Que Mei Teng in China, which has been used to treat many different kinds of disease among the people in Yunnan for a long time. According to folk processing methods and purposes, SHB can be used to treat goiter as well, but it has not been reported. Therefore, in this study, the function of SHB prescription on thyroid and its mechanism were explored.

The study found that the proliferation and apoptosis of thyroid cells are involved in the development of goiter [11, 12]. There was also a study that found that TCM named Kang-Jia-Wan played a therapeutic role via apoptosis induction in the goitrous glands [13]. The research found that TCM take effect through microRNA (miRNA)-target network [14, 15]. Moreover, miRNA deregulation observed in human goiter influences thyroid diseases [16]. All of those reports inspired us to focus on the miRNA that SHB regulated in thyroid cells, we used to figure out whether SHB prescription affects the proliferation and apoptosis of thyroid cells through miRNA, in order to explore a possible mechanism.

Here, we aimed to explore the underlying mechanism that SHB prescription promotes apoptosis and inhibits proliferation of thyroid cells in goiter, provided theoretical support for SHB in the treatment of goiter.

2. Materials and Methods

2.1. Construction of Rat in Goiter Model. 48 SD rats (weigh 250–300 g, half male, healthy) were randomly classified into six groups (8 rats in each group), Group 1 was the normal group without any disposal. Groups 2–6 were administered intragastrically by of propylthiouracil (PTU, #Js30643-5g; YOYOBIO, Shanghai, China) $1\,mL\cdot 100\,g^{-1}$ one day for 28 days in order to induce goiter. Each rat was fed with 20 g one day and drank freely during the experiment. The behavior and hair color of rats were observed, and each of them was weighed once a week. Animal Care and Use Committee approved this study.

2.2. Prescription of Sageretia hamosa Brongn. Prescription of SHB was a compatibility agent including *Sageretia hamosa Brongn* （SHB）, *Scutellaria barbata* D. Don （SBD）, and *Hedyotis diffusa* Willd. （HDW） (purchased from Kunming traditional Chinese Medicine Factory Co., Ltd.), abbreviated as SHB prescription in this study. Soaked 30 g SHB, 10 g SBD, and 10 g HDW into 750 g water for 30 min and then boiling for 1 h, extracted twice and combined all the extracts, subsequently, filtered with 200 mesh, concentrated the filtrate, then collected the extract (55–60°C, specific gravity of 1.058–1.06), granulating and drying, respectively.

2.3. Treatment. Two days after discontinuation of construction of rat in goiter model, Group 2–6 were treatment with Levothyroxin Sodium Tablets (LST, #B14202007312; Merck KGaA, Germany) or SHB prescription for 28 d. Blank control group, rats in goiter model without any treatment; LST group, rats in goiter model treated with LST $0.07\,mg\,kg^{-1}$ one day; light concentration of SHB prescription, rats in goiter model treated with SHB prescription in $63\,mg\cdot 100\,ml^{-1}\cdot 100\,g^{-1}$; moderate of SHB prescription, rats in goiter model treated with SHB prescription in $126\,mg\cdot 100\,ml^{-1}\cdot 100\,g^{-1}$; high concentration of SHB prescription, rats in goiter model treated with SHB prescription in $252\,mg\cdot 100\,ml^{-1}\cdot 100\,g^{-1}$.

2.4. Thyroid Function Observation. Serum samples of rat in each group were collected to measure the triiodothyronine (T3, # KL-E12896; Kanglang), thyroxine (T4, # KL-E1937 R; Kanglang), free triiodothyronine (FT3, #KL-E1640 R; Kanglang), free thyroxine (FT4, #KL-E1006 R; Kanglang), and thyroid-stimulating hormone (TSH, #KL16995; Kanglang) by using ELISA purchased from Shanghai Kanglang Biotechnology Co., Ltd according to the manufacturer's instructions.

2.5. Thyroid Coefficient Calculation. Thyroid of rats in each group was taken and weighed, and the thyroid coefficient was calculated by the formula (weight of thyroid/body weight of rat) × 100%.

2.6. Hematoxylin-Eosin (HE) Staining. After weighed, thyroid of rats in each group was used for hematoxylin-eosin (HE) staining to observe morphology of thyroid. To be brief, thyroid tissues in each group were embedded in paraffin wax to prepare 5 μm wax pieces, followed by HE staining. Tissue sections were stained by using hematoxylin and eosin staining kit (#GV358430; Yiji, Shanghai, China) according to the manufacturer's instructions. After washed for 10 min, stained slices were checked and photographed under a 200-fold light microscope.

2.7. RNA Extraction and miRNA Microarrays. Total RNA in rat thyroid sample of each group was extracted by using Trizol Total RNA Extractor (#KL-14770; Kanglang) according to the manufacturer's instructions. Then, the extracted RNA was further purified by ammonium acetate/ethanol precipitation. Reverse transcription followed by PCR is used to create cDNA constructs. Subsequently, PCR is performed with two primers that anneal to the ends of the adapters. TruSeq Small RNA Sample Preparation Kits (#RS-122-2001; Illumina, San Diego, USA) were used according to the manufacturer's instructions.

2.8. Cell Culture. Rat thyroid cells (FRTL-5) (#FE325; ATCC, USA) and human thyroid cells (Htori-3) (#FE744; ATCC, USA) were purchased from Shanghai Qiming Biotechnology Co., Ltd. and cultured in Dulbecco's Modified

Eagle Medium/Nutrient Mixture F-12 (DMEM-F12, #SH30023.01; YOYOBIO, Shanghai, China) containing 5% fetal bovine serum (FBS, #12657-029-OJN; Gibco, USA), 100 U/ml penicillin, 100 mg/ml streptomycin, and 2 mM L-glutamine at 37°C and 5% CO_2. When the thyroid cells reached 70–80% confluence, they were passaged in accordance with standard procedures.

2.9. Drug-Contained Serum. 30 SD rats (weigh 250–300 g, half male, healthy) were randomly divided into two groups, 15 rats which used to produce drug-contained serum were treated with SHB prescription in 252 mg,·100 ml^{-1}, 100 g^{-1}, and the other 15 rats which used to produce blank serum received the same dose of normal saline for 10 d. After the last gastrogavage for 1 h, blood samples from femoral artery were collected, then coagulation for 2 h, and carefully collected the supernatant after centrifugation at 1500 rpm for 10 min, and placed in −80°C refrigerator. The samples were filtered through 0.22 μm membrane before being used, filtrates were drug-contained serum and blank serum, respectively.

2.10. Cell Transfection and Treatment. miR-511-3p mimics, miR-511-3p inhibitor, si-PTEN, and pcDNA-PTEN were designed and produced by Guangzhou Ruibo Biotechnology Co., Ltd. (China). Invitrogen™ Lipofectamine™ 2000 Transfection Reagent (#11668027; Invitrogen, USA) was used to perform FRTL-5 and Htori-3 transfection according to the manufacturer's instructions. After transfected with miR-511-3p mimics, FRTL-5 and Htori-3 cultured with 1% blank serum as blank group, and 1%, 5%, and 10% drug-contained serum as SHB prescription light, moderate, and high dose groups, respectively. According to the experiment, 50 μg/mL 740 Y–P (#TQ0003; TargetMo, USA) was used to treat FRTL-5 and Htori-3, and FRTL-5 and Htori-3 which cultured with 10% drug-contained serum or transfected with miR-511-3p inhibitor/pcDNA-PTEN for 48 h.

2.11. Quantitative Reverse Transcription Polymerase Chain Reaction (RT-qPCR). Total RNA was extracted from FRTL-5 and Htori-3 in each group by using TRIzol reagent (#ZC-0021A; ZCIBIO, Shanghai, China). After reversed extracted total RNA into cDNA by using reverse transcription kit (#DXT-218061; Qiagen, USA), RT-qPCR was performed by using SYBR® Premix Ex Taq™ II (#HRR820A-1; Takara, Japan). The reaction conditions were as follows: 95°C for 7 min, *f* 45 cycles of 95°C for 1 min, 60°C for 35 s, and 72°C for 30 s, and finally at 72°C for 2 min. The forward and reverse primers were as follows: miR-511-3p F: 5′-ACACCCATCGTGTCTTTTGC-3′ and *R* 5′-CAATG-GACCACCATTCTGTCT-3'; U6 F: 5′-CTCGCTTCGGCA GCACA-3′ and *R* 5′-AACGCTTCACGAATTTGCGT-3'. Expression of miR-511-3p was determined by using the $2^{-\Delta\Delta Ct}$ method.

2.12. Western Blotting. Total protein was isolated from FRTL-5 and Htori-3 in each group by using total protein extraction kit (#2140; Millipore, USA), after measuring the concentration of isolated total protein by using BCA protein quantification kit (#GV357593; Yiji), they were separated by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), subsequently, transferred onto polyvinylidene difluoride (PVDF) membrane and blocked with 5% skim milk, then incubated with primary antibodies against Bcl-2 (1 : 1000, #ER1802-97; HUABIO, Hangzhou, China), anti-Bax (1 : 1000, #ER0907; HUABIO), anti-caspase-3 (1 : 1000, #ET1602-39; HUABIO), anti-PTEN (1 : 1000, #RT1519; HUABIO), anti-PI3K (1 : 1000, #bs-0128R; Bioss, Beijing, China), anti-p-PI3K (1 : 1000, #bs-5587R; Bioss), anti-Akt (1 : 1000, #bs-2056R; Bioss), anti-p-Akt (1 : 1000, # bs-5188R; Bioss), and anti-GAPDH (1 : 1000, #ER1901-65; HUABIO) overnight. The next day, the PVDF membrane was treated with secondary antibody (1 : 1000, #HA1024; HUABIO) and visualized by using SuperBrite™ ECL Western Blot Substrate/Detection Kit (#BIV-K823-200; BioVision, USA). The gray values of bands were analyzed by using ImageJ used to software.

2.13. Cell Count Kit-8 (CCK-8). Cell Count Kit-8 (CCK-8, #BA00208; Bioss) was used to detect cell viability of FRTL-5 and Htori-3 in each group according to the manufacturer's instructions. Then, the absorbance value was detected at a wavelength of 450 nm by using microplate reader.

2.14. Flow Cytometry. Flow cytometry was employed to measure cell cycle distribution and cell apoptosis rate. In order to measured cell cycle distribution, FRTL-5 and Htori-3 were stained with 50 mg/mL propidium iodide (PI) and RNase at 37°C for 30 min and then analyzed by flow cytometry. In order to measure cell apoptosis rate, FRTL-5 and Htori-3 were treated with 10 μL Annexin-V–Fluorescein Isothiocyanate (FITC) and PI at 4°C for 30 min in the dark, and analyzed by flow cytometry.

2.15. Dual Luciferase Reporter Genes Gene Assay. Dual luciferase reporter gene assay kit (#GV357366; Yiji) was used to verify relationship between miR-511-3p and PTEN. In brief, the 3′-Untranslated Regions (UTR) of PTEN wild type (WT) or mutant type (MUT) was cloned into the pGLO luciferase vector and transfected them with or without miR-511-3p mimics into 293T by using Invitrogen™ Lipofectamine™ 2000 Transfection Reagent. After 48 h, the luciferase activity was detected by using dual luciferase reporter assay system.

2.16. Statistical Analysis. Data are expressed as means ± standard error of the mean (SEM). Statistical analysis was performed by using a Student's *t*-test between two groups and one-way analysis of variance (ANOVA) among groups with GraphPad Prism 7.0 software. *P* values < 0.05 were considered statistically significant.

3. Results

3.1. Effect of SHB Prescription on Rat in Goiter Model. To verify the function of SHB prescription in goiter rat, first, the goiter model rat was established by using PTU, after PTU applied for 28 d, rats showed rough fur, loose skin, and slow reaction, and as Table 1 showed, the body weight of rat in the goiter group is less than the normal group. Then, we treated goiter rat with light, moderate, and high concentration of SHB prescription, and the LST treatment was the positive medicinal control group, after treatment for 28 d, their body weight increased compared with goiter rat without any treatment (Table 1); besides, the rats showed smooth fur, tight skin, and faster reaction. Besides, both SHB prescription and LST treatment reduced the thyroid coefficient ($P < 0.05$) (Table 2 and Figure 1(a)) and improved thyroid function ($P < 0.05$; Figure 1(b)). Moreover, HE staining results also indicated that high concentration of SHB prescription promoted morphology of thyroid tissue return to normal as LST done (Figure 1(c)). These results suggested that SHB prescription ameliorated goiter in concentration-dependent manner.

3.2. Regulation of SHB Prescription on Expression of miRNAs in Goiter Rat. In order to further explore the underlying mechanism of therapeutic effect of SHB prescription on goiter, we employed miRNA microarrays to detect the relative miRNA expression levels in thyroid tissue of rats in the above experimental groups. From this analysis, there were many differentials expressed miRNAs in the normal, goiter, LST, and SHB prescription groups (Figure 2(a)). We identified the top 10 miRNAs whose expression was upregulated in the goiter group compared with normal and decreased with LST and SHB prescription treatment, besides there were also the top 10 miRNAs whose expression was downregulated in the goiter group, and increased after LST and SHB prescription treatment (Table 3 and Figure 2(b)). Finally, miR-511-3p was chose for further experiments. As a first step in confirming the validity of the array data, we performed RT-qPCR on miR-511-3p, as shown in Figure 2(c) ($P < 0.05$), these it was overexpressed in the goiter group compared with the normal group, while its expression decreased after LST or SHB prescription treatment, and this was statistically significant, consistent with the microarray experiments. Therefore, we speculated that one of the ways that SHB prescription might improve goiter was through downregulation of miR-511-3p.

3.3. SHB Prescription Effected Proliferation and Apoptosis of Thyroid Cells through miR-511-3p. miRNAs participate in the regulation of cell physiological process and can be regulated by TCM, based on the miRNA microarrays results, miR-511-3p mimics was transfected into thyroid cell lines FRTL-5 and Htori-3, after treated with SHB prescription in different concentration, cell cycle, viability, and apoptosis ability were measured. First, RT-qPCR results showed that compared with the normal and the blank group, expression of miR-511-3p significantly increased in miR-511-3p mimics group, while it decreased with the increase of SHB prescription concentration ($P < 0.05$; Figure 3(a)). Moreover, flow cytometry, CCK-8, and western blotting results indicated that the overexpression of miR-511-3p accelerated cell cycle, promoted proliferation, and inhibited apoptosis of FRTL-5 and Htori-3, but SHB prescription reversed it in concentration-dependent manner ($P < 0.05$; Figures 3(b)–3(e)). Hence, SHB prescription suppressed proliferation and promoted apoptosis of thyroid cells as observations in more cells in G_1 phase and less cells in G_2/M phase through downregulated expression of miR-511-3p.

3.4. Relationship between miR-511-3p, PTEN, and PI3K/Akt Pathway. The target genes of miR-511-3p have predicted by using bioinformatics. PTEN aroused our great interest, and the binding sites are shown in Figure 4(a). In order to confirm the relationship between miR-511-3P and PTEN, a dual luciferase reporter gene assay was carried out, and the results revealed that the luciferase activity of PTEN-WT was markedly reduced in miR-511-3p mimics ($P < 0.05$), but the luciferase activity of PTEN-MUT had no significant different between NC and miR-511-3p mimics group ($P > 0.05$; Figure 4(b)). Besides, western blotting indicated that the overexpression of miR-511-3p significantly reduced the expression of PTEN protein ($P < 0.05$; Figure 4(c)), in addition, both overexpression of miR-511-3p and knockdown of PTEN activated PI3K/Akt pathway, while overexpression of PTEN inhibited PI3K/Akt pathway and relaxed the activation of PI3K/Akt pathway caused by overexpression of miR-511-3p ($P < 0.05$; Figure 4(d)). These results indicated that miR-511-3p targeted PTEN and regulated PI3K/Akt pathway in thyroid cells.

3.5. SHB Prescription Effected Proliferation and Apoptosis of Thyroid Cells through Regulated miR-511-3p/PTEN/PI3K/Akt Pathway. Aimed to clarify whether SHB prescription regulated proliferation and apoptosis of thyroid cells through miR-511-3p/PTEN/PI3K/Akt pathway, we first activated PI3K/Akt pathway by using 740 Y–P and then treated with SHB prescription, transfected miR-511-3p inhibitor or pcDNA-PTEN into FRTL-5 and Htori-3 and then measured the expression of protein related to PI3K/Akt pathway ($P < 0.05$; Figure 5(a)) and apoptosis ($P < 0.05$; Figure 5(e)) by western blotting, detected cell viability by CCK-8 ($P < 0.05$; Figure 5(c)), and measured cell cycle ($P < 0.05$; Figure 5(b)) and apoptosis rate ($P < 0.05$; Figure 5(d)) by flow cytometry. The results showed that 740 Y–P activated PI3K/Akt pathway in thyroid cells, enhanced cell viability ability, and suppressed cell apoptosis through increased cell in G_2/M phase. However, treatment of SHB prescription, inhibition of miR-511-3p, or overexpression of PTEN reverted these functions. These results indicated that SHB prescription inhibited proliferation and promoted apoptosis of thyroid cells through regulated miR-511-3p/PTEN/PI3K/Akt pathway.

4. Discussion

In this study, we found that rat in goiter model could be cured by SHB prescription, and then we explored the molecular mechanism via which SHB prescription promotes apoptosis of thyroid cells. We confirmed that SHB prescription induced downregulation of miR-511-3p and promoted apoptosis of thyroid cells through PTEN/PI3K/Akt pathway. The results suggested that SHB prescription was shown to be a promising therapeutic regimen for the treatment of goiter.

Although, it has been used as a folk medicine for goiter by local people in Yunnan, regrettably, we did not collect enough and complete information about patients in goiter treated with SHB for the report. While, in our study, the results showed that SHB prescription decreased thyroid coefficient, improved thyroid function, and relieved goiter in rat as LST worked. As a synthetic thyroxine, LST is the treatment of choice for hypothyroidism, it also could be used to treat goiter; however, goiter patient treated with LST was diagnosed levothyroxine-induced liver injury, after cessation of LST, liver enzymes gradually returned to normal [17, 18]. Despite a few study found that SHB scavenges reactive oxygen radical species and increases the resistance of low-density lipoprotein to oxidation [19, 20], and there is no any other research on pharmacology of SHB up to now. While, TCM is relatively benign, that suggested SHB prescription might has advantages to goiter patient.

In our study, besides SHB, SHB prescription also included *Scutellaria barbata* D. Don (SBD) and *Hedyotis diffusa* Willd. (HDW). SBD is used in traditional Chinese and Korean medicine as a perennial herb, which has heat-clearing and detoxifying properties [21]. Recent studies have shown that SBD protects oxygen glucose deprivation/reperfusion-induced injuries of PC12 cells [22]. Besides, SBD has shown impressive antitumour activity in cancer [23]. HDW is also a well-known TMC with a variety of activities, especially its anticancer effect in the clinic [24]. The latest study demonstrated that HDW significantly reduced inflammatory lesion and inflammatory cell infiltration in a mouse model of experimental autoimmune prostatitis [25]. In addition, HDW as a complementary therapy is important for the treatment of advanced nasopharyngeal carcinoma patients [26]. Fortunately, our results suggested that SHB prescription effectively inhibited proliferation and promoted apoptosis of thyroid cells by arresting the cell cycle at G_1 phase. As a disease with thyroid enlargement, abnormal proliferation and apoptosis of thyroid cell exist in goiter. Thus, promoting apoptosis and inhibiting proliferation of thyroid cells are an effective method for the treatment of goiter. Therefore, our work further demonstrated that SHB prescription was an ideal technique for the treatment of goiter.

TCMs have been widely used against a broad spectrum of biological activities, and a kind of the underlying mechanism is the regulation of miRNA. Such as downregulation of miR-294 by Baicalin was its key mechanism of action in decreasing embryonic stem cells proliferation [27]. In our study, the overexpression of miR-511-3p in thyroid cells significantly stimulated cell proliferation and restrained cell apoptosis, while SHB prescription reversed it through downregulated expression of miR-511-3p in concentration-dependent manners. Although there was some study reported miR-511-3p involved in regulation of inflammation or progression of cancer [28], it is seldom reported miR-511-3p play a role in thyroid disease. Our study has demonstrated that miR-511-3p promoted proliferation, effected cell cycle, and inhibited apoptosis of thyroid cells, it might a prospective marker of goiter, while the newest research indicated that miR-511-3p is involved in cell cycle, proliferation, and metastasis through regulated AKT3 [29].

miRNAs take part in the regulation of cell physiological processes through binding its target genes. In our study, miR-511-3p targeting and downregulated the expression of phosphatase and tensin homolog deleted on chromosome ten (PTEN), which is a phosphatase, regulated cell cycle, migration, growth, DNA repair, and survival signaling [30]. It has been found that PTEN plays an important role in thyroid function and disease, and the loss of PTEN resulted in a

significant increase in the thyrocyte proliferative index [31]. PTEN serves as a negative regulator of phosphatidylinositol-3-kinase (PI3K)/Akt signaling pathway, which is an important regulator of many cellular events, including apoptosis, proliferation, and motility [32]. Our results fund that the activation of PI3K/Akt signaling pathway enhanced proliferation and inhibited apoptosis of thyroid cells, while SHB prescription treatment, miR-511-3p inhibition, or PTEN overexpression reversed these effects. Interestingly, PTEN is a tumor suppressor gene mutated in many human cancers [33], and the loss of PTEN function leads to activation of PI3K/Akt signaling pathway and is strongly associated with progression of cancer [34]. Therefore, our result might suggest that SHB prescription not only help to treat goiter but also may have the effect of preventing thyroid cancer.

In summary, our results showed that were found to cure rat in goiter model and downregulated miR-511-3p in thyroid tissues and cells in concentration-dependent manner. Besides, there was a target relationship between miR-511-3p and PTEN in thyroid cells, and PTEN negatively regulated the activation of PI3K/Akt signaling pathway. Furthermore, the inhibition of apoptosis in thyroid cells caused by overexpression of miR-511-3p or activation of PI3K/Akt signaling pathway was reversed by treatment of SHB prescription, inhibition of miR-511-3p, or overexpression of PTEN. Therefore, our results indicated that SHB prescription promoted apoptosis of thyroid through decreased miR-511-3p and regulated PTEN/PI3K/Akt pathway.

The greatest regret of this study is that not enough and complete data of SHB prescription treated goiter patient were collected. Besides, the function of miR-511-3p and PTEN/PI3K/Akt pathway in the treatment of SHB prescription in goiter rat are performing now. Importantly, our study confirmed that SHB prescription not only help to treat goiter but also may prevent thyroid cancer; thus, research on SHB is warranted.

5. Conclusion

This study demonstrated that SHB prescription relieved goiter through inhibited proliferation and promoted apoptosis of thyroid cells via downregulated miR-511-3p and PTEN/PI3K/Akt pathway.

Academic Editor: Enas Abdulhay

This work aimed to investigate values of contrast-enhanced ultrasound (CEUS) under DEFLATE in the classification and diagnosis of the common bile duct and superficial lymphoid lesions. 88 patients with lower common bile duct lesions and 126 patients with superficial lymphoid lesions were selected as the subjects investigated and examined by CEUS under DEFLATE to compare characteristics and diagnostic efficiency of CEUS in different types of lesions. The time-intensity curve (TIC) was for quantitative analysis on CEUS results. The results showed that there were statistically significant differences in the comparison of time to peak (TTP), area under the curve (AUC), and gradient (Grad) of common bile duct walls in patients from the malignant group ($P < 0.05$), while the comparison of three indicators of patients in the benign group was not statistically remarkable ($P > 0.05$). In addition, there were statistically great differences in TTP, AUC, and Grad among patients in the benign and malignant groups ($P < 0.05$). The sensitivity, specificity, accuracy, and positive/negative predictive value of CEUS + ultrasound (US) in the diagnosis of benign and malignant lymph nodes were 92.83%, 87.14%, 89.54%, 91.23%, and 86.43%, respectively. The values of maximal intensity ($I_{\max}$) in the reactive hyperplasia group (group A), lymphoma group (group B), and metastatic lymph nodes group (group C) were compared, showing statistical differences ($P < 0.05$). The TTP and AUC of group B were higher than those of groups A and C, respectively ($P < 0.05$), and the base-to-peak ascending slope (K_{UP}) and the absolute value of the semidescending slope (K_{DOWN}) in group C increased hugely compared to group A ($P < 0.05$). It indicated that CEUS examination under DEFLATE could be applied in the qualitative diagnosis of lower common bile duct lesions and superficial lymphoid lesions, which was worthy of clinical application.

1. Introduction

The lesions located in the lower common bile duct usually include a variety of lesions such as stone inflammatory stenosis and tumor, which often cause biliary obstruction [1]. Compared with other imaging diagnostic methods, US examination has become the preferred method for obstruction lesions due to its convenient operation and low cost. Although the conventional US can also play an important role in the diagnosis of lower common bile duct lesions, it is easy to be affected by gastrointestinal gas; thus, it is difficult to give an accurate assessment of lower common bile duct lesions. Contrast-enhanced ultrasound (CEUS) is a new examination technology developed based on US technology, which is a major innovation of US technology [2]. With the rapid development of US contrast agents, liver, kidney, and bile duct imaging has been greatly enhanced by CEUS, and CEUS is now widely applied in abdominal and small organ diseases [3, 4]. CEUS technology can not only increase the display rate of lower common bile duct lesions but also clearly observe the enhancement speed and intensity of tissues or tumors. It is a critical tool to assist doctors in the diagnosis of lower common bile duct lesions. Therefore, the identification of lower common bile duct lesions with CEUS technology can provide more accurate and valuable information for subsequent clinical treatment and survival prognosis assessment. CEUS was first used for the diagnosis and differentiation of liver or heart diseases. Due to its continuous development and maturity, CEUS is gradually applied to the diagnosis of superficial organ lesions, such as thyroid, breast, and lymph node [5, 6]. There are differences in pathophysiological basis on different types of lymphoid lesions, the differentiation of benign and malignant lymph nodes is of great significance for the diagnosis and prognosis analysis of tumor diseases, and US examination is the preferred diagnostic method for superficial lymphoid lesions [7]. CEUS has a marked advantage in the qualitative study of benign and malignant enlarged lymph nodes in contrast to the conventional US and Doppler US imaging. The blood perfusion and microvascular distribution in lymph nodes can be observed clearly and in real time through CEUS, which provides more abundant information for doctors' subsequent diagnosis [8]. Thus, the classification and differentiation of lower common bile duct lesions and superficial lymphoid lesions by CEUS have great meanings for the clinical diagnosis of this disease and the selection of subsequent treatment options.

Data compression refers to the application of an appropriate data compression algorithm to process redundant data, so as to achieve data compression, which can not only increase the internal storage space of the device but also extend the working time to effectively improve the detection efficiency of the device [9]. Therefore, US data compression is one of the key links to promote the working efficiency of US equipment. Lossless compression means that complete original data information is retained during data compression without loss of information, and the decompression algorithm can be adopted to recover the original data, which is suitable for all kinds of scenarios requiring the retention of ultrasonic detailed data [10]. As a lossless compression algorithm, DEFLATE is an improved version of Lempel-Ziv 1977 compression format (LZ77), which is widely applied in a variety of real-time compression scenarios.

Therefore, DEFLATE was employed to compress CEUS data and analyze its compression performance and speed. Moreover, patients with lower common bile duct lesions and superficial lymphoid lesions were selected as the subjects investigated, respectively. By analyzing characteristics and diagnosis efficiency of different pathological types in CEUS, the application value of classification and diagnosis for abdominal and superficial organs were further discussed under DEFLATE of CEUS.

2. Materials and Methods

2.1. Contrast-Enhanced Ultrasound Diagnosis of Lower Common Bile Duct Lesions. A total of 88 patients with lower common bile duct lesions, admitted to the hospital from October 2018 to October 2019, were selected and grouped into a benign group (32 patients) and a malignant group (56 patients) based on the pathological results. Meanwhile, 30 healthy volunteers were selected and grouped into a control group. The criteria for inclusion were defined to include patients who had more than 5 mm maximum diameter of lesion, had received US examination, had good image quality, and were able to cooperate with doctors to complete the examination of respiration, posture, and so on. The criteria for exclusion were defined to include patients younger than 18 years or older than 80 years, suffering from pulmonary insufficiency, in pregnancy or lactation period, and allergic to the contrast agent. This experiment had been approved by the Ethics Committee of the hospital, and all the patients contained in the experiment had known about the experiment and agreed to it.

Patients drank 1,000 mL of water before the examination. Their lesion sites were scanned by conventional US and color Doppler US to observe the morphology, size, echo characteristics, and surrounding tissues of lesion sites. After that, CEUS mode was activated, and patients were instructed to breathe calmly to ensure the quality of the obtained best sections of contrast-enhanced imaging. Sulfur hexafluoride was selected as the contrast agent, and 0.9% sodium chloride (NaCl) was added into it to prepare suspension that was extracted 1.5 mL each time. When the timing of the instrument was started, an appropriate amount of contrast agent was quickly injected into the peripheral vein. Patients held their breath for 10 seconds before the arterial phase and breathed calmly for 10 seconds after the arterial phase. When the contrast agent completely subsided, the observation was stopped and the dynamic graphs within 120 seconds were stored.

TIC was used for the quantitative analysis of CEUS in and around the lesions. The region of interest (ROI) was selected and delineated based on lesion size. TIC were drawn to record various indicators by the instrument's own CEUS software. Three indicators, namely, TTP, AUC, and Grad, were selected for subsequent analysis.

2.2. Superficial Lymphoid Lesions Diagnosed by Contrast-Enhanced Ultrasound. 126 patients with superficial lymphoid lesions, admitted to the hospital from October 2018 to October 2019, were selected to undergo US examination. There were 72 males and 54 females with an average age of 51.25 ± 15.26 years. The experiment had been approved by the Ethics Committee of the hospital, and all patients included in the study had signed informed consent. The criteria for inclusion were patients who were over 18 years old, had contraindication of CEUS, and had pathological results that were obtained by a needle biopsy or surgery. The criteria for exclusion were patients who had poor-quality CEUS images, were observed for less than 90 seconds through CEUS, had incomplete pathological results, and did not suffer from tuberculosis in TIC analysis.

All the patients had conventional US examination in advance, to mainly observe the grayscale of the target lymph nodes and color Doppler ultrasonic characteristics. After that, the patients had a CEUS examination combined with low mechanical index imaging technology. Besides, the mechanical index was set within the range of 0.03–0.07, and posterior lymph nodes were regarded as the focus of the image. Contrast agent SonoVue was selected, which had a white freeze-drier power shape, to be added with normal saline for adequate dissolution, to prepare emulsion microbubble suspension. 2.5 mL of the contrast agent was injected into the median vein of a patient, and then, 10 mL of normal saline was applied to rapidly wash pipe. A timer was started as soon as the beginning of contrast agent injection, dynamic image with the length of about 3 minutes was obtained and stored. Two experienced sonographers were selected to diagnose lymph nodes as benign or malignant based on the ultrasonic image. The patients were divided into a benign group (including group A and a tuberculous lymphadenitis group (group D)) and a malignant group (including groups B and C) based on the criteria of US-mediated puncture or surgery, to calculate their sensitivity, specificity, accuracy, and positive/negative predictive values.

SonoLiver software was applied to analyze the CEUS images, and lymph nodes were regarded as ROI to draw TIC, to obtain indexes such as RT, TTP, mean transit time (mTT), and $I_{\max}$. In addition, K_{UP} and K_{DOWN} were calculated, and AUC was obtained by Qontra Xt software.

2.3. Lossless Compression Algorithm of Ultrasonic Data. Ultrasonic data should be preprocessed before compression. According to different classification characteristics of ultrasonic data, preprocessing methods were also different. The grass wave data were preprocessed with smooth processing, and the defect wave data were preprocessed with differential processing. After the grass wave data were smoothed, the signal became smoother, the burr decreased, and the information entropy of the grass wave signal decreased accordingly, to facilitate the subsequent compression processing operation. If two peaks met the requirements and the directions of two adjacent peaks were opposite, the principle of "appear first, process first" was followed. After the first peak was smoothed, the second peak would disappear. The method of differential processing was for the defect wave. The amplitude value range of defect wave was relatively wide and the data information entropy was relatively large. After differential processing, the signal amplitude information was converted into the amplitude change information, as shown in

$$M(i) = \begin{cases} A(i) - A(i-1), & i > 1, \\ A(i), & i = 1. \end{cases} \tag{1}$$

In equation (1), A represents the original signal, M stands for the processed signal, and i expresses the signal number.

The calculation method of data information entropy is shown as follows:

$$S(i) = -\sum_{i} P(X_i)\log_2 P(X_i). \tag{2}$$

In equation (2), S stands for the information entropy and P and $-\log_2 P(X_i)$ express probability and self-information of X_i, respectively.

DEFLATE was mainly composed of two coding methods (Huffman and LZ77), and the coding process is shown in Figure 1. After the raw data was entered, LZ77 encoding was first applied to generate Literal, Distance, and Length. Then, Huffman coding was employed to compress and process Distance elements to obtain DIST data rate and corresponding Huffman code table. Literal and Distance elements were combined to adopt the same operation as Distance elements to obtain LIT data rate and corresponding Huffman data table. After that, the Huffman data table was compressed, CL sequence was adopted, and SQ sequence was obtained after CL run-length coding. After its coding was compressed, the SQ data rate and the corresponding Huffman code table were obtained, and the CCL data rate was obtained after further processing.

The evaluation criteria for compression algorithms included compression ratio (CR), relative root mean squared error (R^2MSE), algorithm complexity, and correlation coefficient r. CR referred to the proportion of the number of bytes after compression in the number of bytes of raw data, and the following equation could be adopted to calculate CR:

$$\mathrm{CR} = \frac{N_{\text{after}}}{N_{\text{before}}} \times 100\%. \tag{3}$$

R^2MSE represents that the difference between compressed restored data and raw data, as shown in the following equation:

$$\mathrm{R}^2\mathrm{MSE} = \sqrt{\frac{\sum_{i=0}^{N} \left(X(i) - X'(i)\right)^2}{\sum_{i=1}^{N} X^2(i)}} \times 100\%. \tag{4}$$

In equation (4), $X(i)$ and $X'(i)$ stand for the raw restored data and compressed restored data, respectively.

r expresses the correlation between the restored data and raw data after compression, which is represented as follows:

$$r = \frac{E\left(X(i)X'(i)\right) - E\left(X(N)X'(i)\right)}{\sqrt{D\left(X(i)\right)}\sqrt{D\left(X'(i)\right)}}. \tag{5}$$

In equation (5), $E(X)$ and $D(X)$ represent mathematical expectation and variance, respectively.

CR, R^2MSE, and r are all evaluation indexes at the mathematical level. However, the evaluation of compression algorithm complexity was indispensable in practical application, and indirect quantization representation was usually expressed by compression speed and decompression speed.

2.4. Statistical Analysis. SPSS20.0 software was used for statistical analysis. The measurement data were expressed as mean ± standard deviation, and t-test was adopted to compare the differences among the groups. Besides, the measurement data were represented as percentage, and the χ^2 test was applied to compare the differences among the groups. If $P < 0.05$, the difference was statistically significant.

3. Results

3.1. Results of Data Compression Examined by Ultrasound under Compression Algorithm. The run-length encoding (RLE) [11], Huffman [12], and DEFLATE were employed to

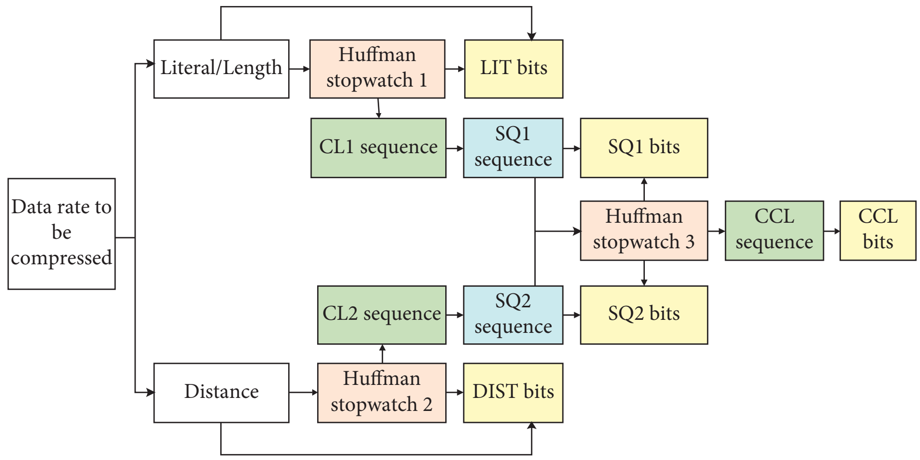

Figure 1: Flowchart of DEFLATE.

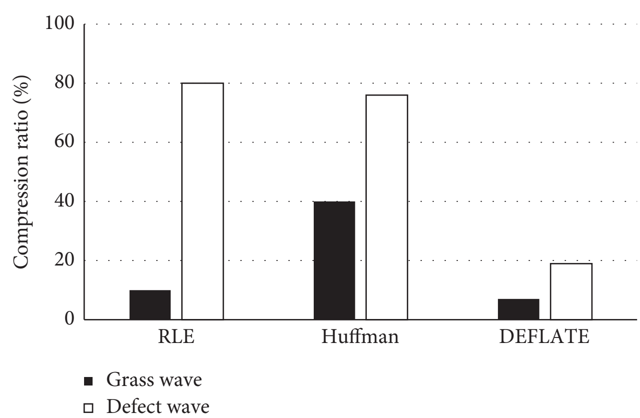

Figure 2: Comparison of compression performance of different algorithms.

compress grass wave and defect wave data. Figure 2 shows that CR of defect wave data obtained by different algorithms was higher than the ratio of grass wave data. The CR of grass wave data processed by RLE was markedly better than the ratio of defect wave data; CR of defect wave data processed by DEFLATE was the lowest; and CR of grass wave data processed by Huffman was the highest. Based on the above results, the compression effect of DEFLATE was better than the other two algorithms.

Under the two different platforms, the compression speed of each algorithm was lower than its decompression speed, and both the compression and decompression speed of RLE were the highest, while both the compression and decompression speed of DEFLATE were the lowest, as shown in Figure 3.

To sum up the above results, the speed of RLE, Huffman, and DEFLATE could all meet the real-time compression requirements in the personal computer (PC) platform, so DEFLATE with the best CR was selected. For the embedded platform, the compression speed of DEFLATE was too low to meet the requirements of real-time compression. Therefore, a balanced algorithm combination was selected; namely, RLE and DEFLATE were applied to compress grass wave and defect wave data, respectively.

3.2. The Contrast-Enhanced Ultrasound + Ultrasound Diagnosis of Lower Common Bile Duct Lesions. The results of patients' conventional US examination revealed that the lesions were located in the lower segment of the common bile duct, and lesions were $8 \times 8 \times 8\,mm^3$–$30 \times 32 \times 32\,mm^3$ with an average size of 15.6 ± 6.4 mm and a maximum diameter of 10–32 mm. The average maximum diameter of lesions was 22.3 ± 8.5 mm in patients from the malignant group, and there were 12 patients with isoechoic or hyperechoic and 44 patients with hypoechoic. The average maximum diameter of lesions in patients from the benign group was 13.8 ± 8.3 mm with 8 patients of hyper echo and 24 patients of hypo echo.

In the benign group, the lesions of 5 patients showed high enhancement in the arterial phase, among which lesions of 4 patients expressed synchronous regression in the venous phase compared with the bile duct wall and the lesion of 1 patient had a faster clearance rate compared to the bile duct wall and showed low enhancement. There were lesions of 23 patients representing isoenhancement in the arterial

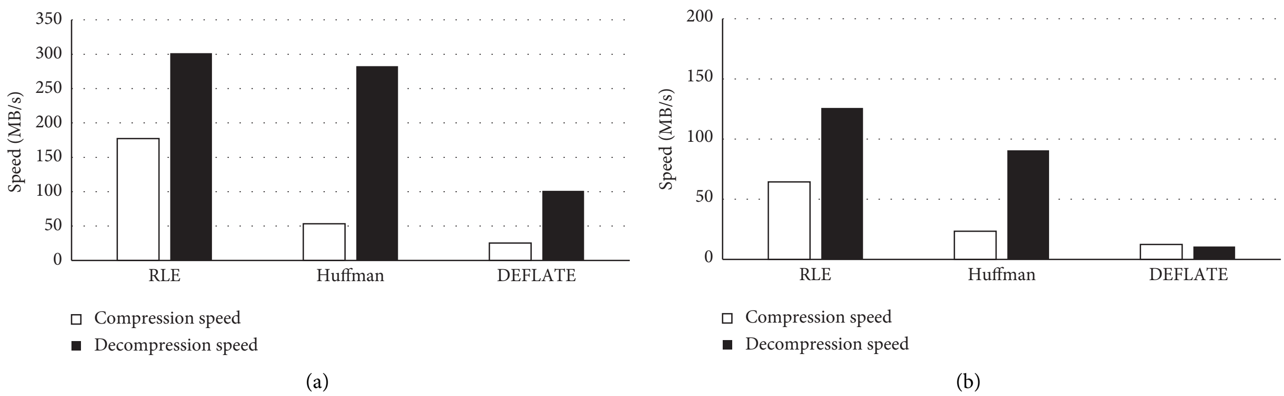

Figure 3: Comparison of the performance of different compression algorithms in the two different platforms. (a, b) The comparison of the performance of 3 compression algorithms in the PC and embedded platform.

phase, among which lesions of 19 patients had the clearance rate synchronized with the bile duct wall and expressed isoenhancement, and lesions of 4 patients had faster clearance rate compared with the bile duct wall in the venous phase and showed low enhancement, as shown in Figure 4(a).

In the malignant group, the lesions of 26 patients presented high enhancement in the arterial phase, among which lesions of 24 patients presented low enhancement in the venous phase and showed faster clearance in contrast to the bile duct wall, and lesions of 2 patients presented isoenhancement and had clearance synchronized with the common bile duct wall. There were lesions of 4 patients with isoenhancement in the arterial phase, lesions of 2 patients with low enhancement in the venous phase, and lesions of 2 patients with isoenhancement in the venous phase. In both phases, lesions of 3 patients showed low enhancement (Figure 4(b)).

The comparison results of CEUS indicators (TTP, AUC, and Grad) between lesions of patients in the benign group and surrounding bile duct walls are shown in Figure 5. The differences in CEUS indicators (TTP, AUC, and Grad) between lesions of patients in the benign group and surrounding bile duct walls were not marked with statistically obvious meanings ($P > 0.05$). Figure 6 indicates the comparison results of CEUS indicators (TTP, AUC, and Grad) between lesions in the malignant group and surrounding bile duct walls. The TTP of lesions in the malignant group was remarkably lower than that of the surrounding bile duct walls ($P < 0.05$), while AUC and Grad of lesions in the malignant group were greatly higher than those of the surrounding bile duct wall ($P < 0.05$).

The comparison of CEUS indicators (TTP, AUC, and Grad) among patients in the benign and malignant group is shown in Figure 7. TTP of patients in the malignant group was sharply lower than that of the benign group ($P < 0.05$), while AUC and Grad of patients in the malignant group were dramatically higher than those of the benign group ($P < 0.05$). Figure 8 illustrates the results of comparison of CEUS indicators (TTP, AUC, and Grad) of surrounding bile duct walls in patients from the control, benign, and malignant group. Besides, the comparison of TTP, AUC, and Grad of surrounding bile duct walls in patients from the three groups was not statistically substantial ($P > 0.05$).

3.3. Superficial Lymphoid Lesions Diagnosed by Contrast-Enhanced Ultrasound + Ultrasound. Pathological results demonstrated 126 patients with superficial lymphoid lesions including 52 patients in the benign group (18 patients with tuberculous lymphadenitis and 34 patients with reactive hyperplasia) and 74 patients in the malignant group (23 patients with lymphoma and 51 patients with metastatic lymph nodes). Table 1 shows the sensitivity, specificity, accuracy, and positive/negative predictive values diagnosed by CEUS. Moreover, the CEUS images of superficial lymphoid lesions are shown in Figure 9. In the benign group, the image of a patient with reactive hyperplasia shows uniform enhancement (Figure 9(a)) from center to periphery (Figure 9(b)). Figure 9(f) indicates that the image of a patient with tuberculous lymphadenitis presents uneven circular enhancement. In the malignant group, the image of a patient with metastatic lymph nodes shows the enhancement from periphery to center (Figure 9(c)) and manifested as a nonhomogeneous enhancement (Figure 9(d)), while the image of a patient with lymphoma presents as mixed enhancement with snowstorm shape (Figure 9(e)).

Figure 10 demonstrates that the RT and mTT of patients in groups A, B, and C were not extremely different ($P > 0.05$), while there was statistical meaning in I_{max} of the three groups ($P < 0.05$). TTP of patients in group B was higher than that of group C ($P < 0.05$). K_{UP} and K_{DOWN} of the patients in group C increased obviously in contrast to group A ($P < 0.05$), and AUC of the patients in group C was significantly higher than the value of groups A and B ($P < 0.05$), as shown in Figure 11.

4. Discussion

DEFLATE was applied to CEUS image processing and the results showed that the compression effect of DEFLATE was superior to that of RLE and Huffman, which was consistent with the research results of Bras and Velden [13],

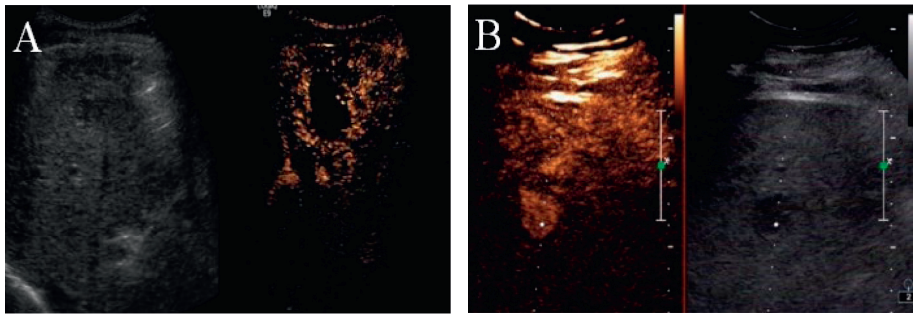

Figure 4: CEUS images of lesions located in the lower common bile duct. (a, b) The images of benign and malignant lesions, respectively.

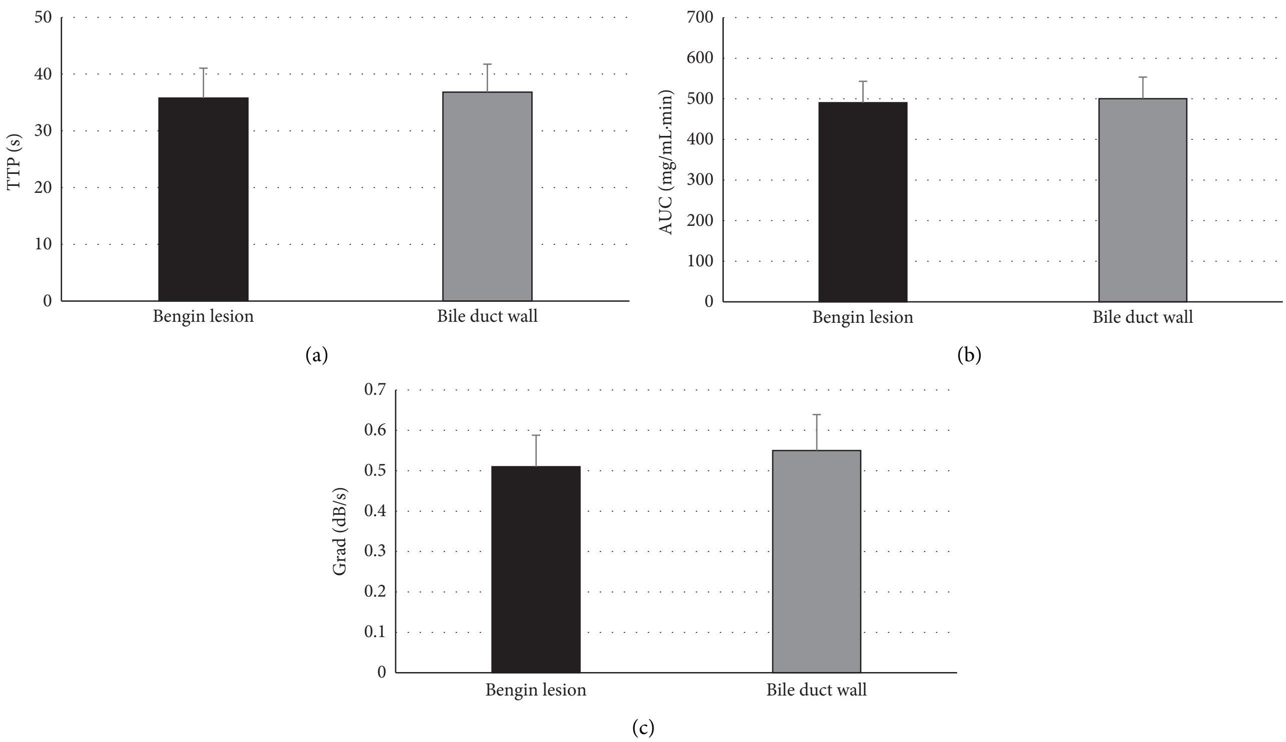

Figure 5: Comparison of CEUS indicators of lesions in the benign group and surrounding bile duct walls. (a–c) The comparisons of TTP, AUC, and Grad, respectively.

indicating that CEUS based on DEFLATE could increase the internal storage space of ultrasonic equipment to improve the detection efficiency. In this study, CEUS was applied to diagnose the lesions in the lower segment of the common bile duct. It was found that there were 25 patients with isoenhancement and 7 patients with high enhancement at the arterial phase in the benign group; and there were 8 patients with isoenhancement, 46 patients with high enhancement, and 2 patients with low enhancement at the arterial phase in the malignant group. This revealed that CEUS could effectively diagnose the benign and malignant lower common bile duct lesions, which is an effective imaging method for qualitative diagnosis of the lesions. The results showed that the differences in TTP, AUC, and Grad of lesions in the malignant group and common bile duct walls were statistically obvious ($P < 0.05$), while there were no statistically considerable differences in TTP, AUC, and Grad of lesions in the benign and malignant group ($P > 0.05$). AUC reflects the blood flow and the number of blood vessels at the lesion site. The AUC of lesions in the malignant group were higher than those of the benign group and surrounding normal bile duct walls because the microvessels inside the bile duct carcinoma were rich and densely distributed, and the bile duct carcinoma was a lesion rich in blood supply and had relatively more blood flow. The blood supply in the diseased area was more abundant than that in the normal bile duct wall, and the intervascular accesses were more complex so that the peak time was relatively short. However, when Grad of the malignant group was high, the malignant tissues grew rapidly and the blood vessel wall was easy to be damaged, to easily result in an arteriovenous short circuit [14].

Table 1: Diagnosis results of CEUS + US.

	Sensitivity (%)	Specificity (%)	Accuracy (%)	Positive predictive value (%)	Negative predictive value (%)
CEUS + US	92.83	87.14	89.54	91.23	86.43

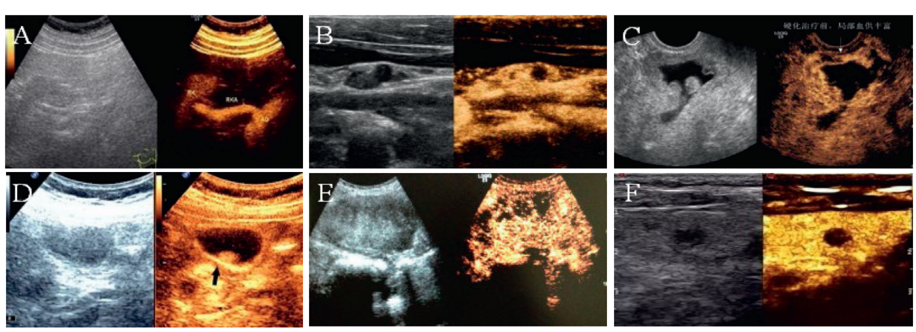

Figure 9: The CEUS images of superficial lymphoid lesions. (a, b) Images of a patient with reactive hyperplasia; (c, d) images of a patient with metastatic lymph nodes; (e) the image of a patient with lymphoma; (f) the image of a patient with tuberculous lymphadenitis.

Liu et al. [15] found that the sensitivity, accuracy, and positive/negative predictive values of conventional US in differentiating benign and malignant lymph nodes were 64.1%, 65.2%, 47.2%, and 66.7%, respectively, while the corresponding values of CEUS were 93.6%, 75.7%, 73.7%, and 83.9%, respectively. In addition, the sensitivity, specificity, accuracy, and positive/negative predictive values of CEUS + US in the diagnosis of benign and malignant lymph nodes were 92.83%, 87.14%, 89.54%, 91.23%, and 86.43%, respectively, which were in line with the results of Liu et al. [15]. The results of the study showed that there were statistical meanings in the comparison of I_{max} of patients from groups A, B, and C ($P < 0.05$). The TTP of patients in group B was extremely

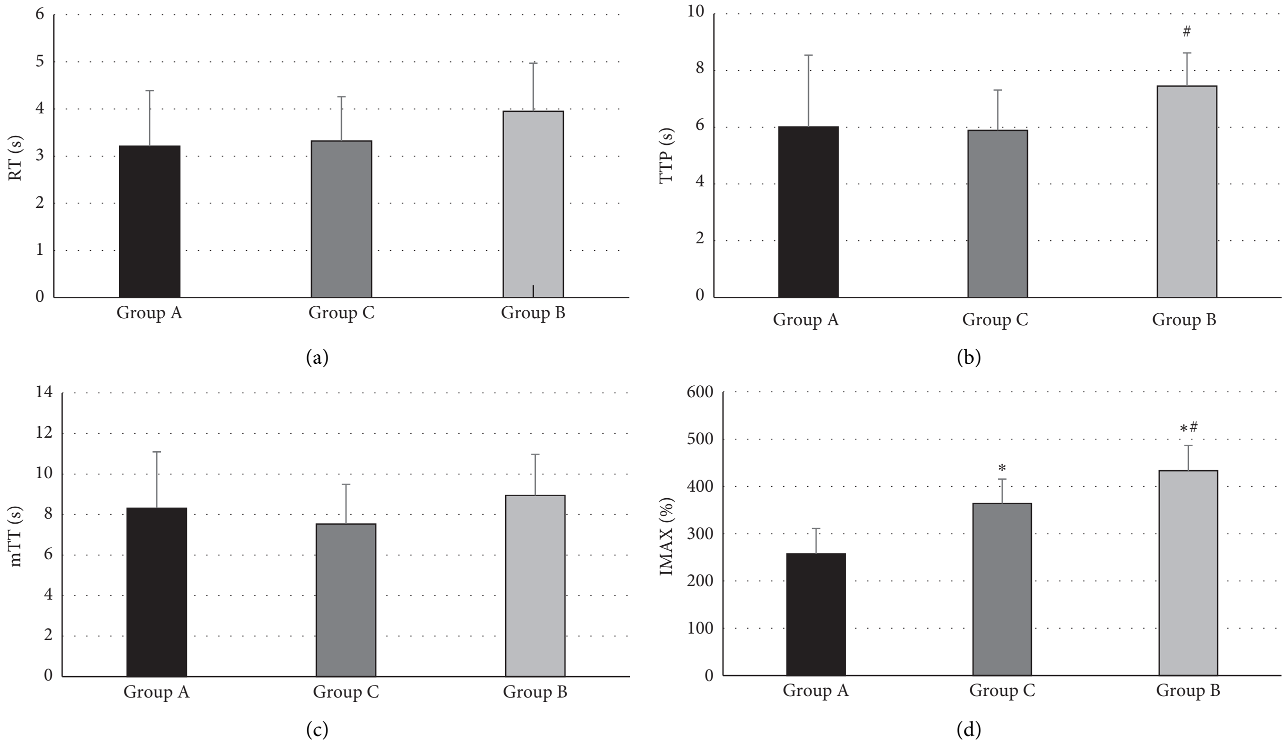

Figure 10: Comparison of CEUS indexes (a) RT, (b) TTP, (c) mTT, and (d) Imax of the patients in group A, B, and C. * and # stand for $P < 0.05$ in contrast to groups B and C, respectively.

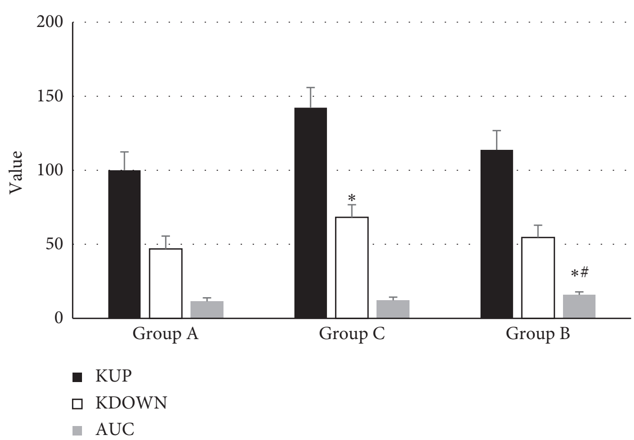

Figure 11: Comparison of K_{UP}, K_{DOWN}, and AUC of the patients in the three groups (* and # stand for $P < 0.05$ in contrast to groups A and C) respectively).

higher than that of group C ($P < 0.05$), K_{UP} and K_{DOWN} of patients in group C were obviously higher than those of group A ($P < 0.05$), and AUC of group B increased hugely in contrast to groups A and C ($P < 0.05$). Besides, RT and PI of patients in group A were markedly higher than the values of group B ($P < 0.05$). Therefore, it indicated that CEUS could effectively classify and diagnose superficial lymphoid lesions, which was consistent with the findings of Nie et al. [16].

5. Conclusion

Patients with the lower common bile duct lesions and superficial lymphoid lesions were taken as subjects investigated. CEUS based on DEFLATE was applied to analyze the CEUS characteristics and diagnostic efficiency for different lesion types. The results indicated that the DEFLATE-based CEUS proposed in this study could classify and diagnose the lower common bile duct lesions and superficial lymph nodes, which had reliable clinical application value. However, there were still some shortcomings in the study. For example, the number of subjects investigated was limited and distributed unevenly; many factors were affecting the morphology and indexes of TIC; and it was necessary to determine whether TIC could be considered as a standard for differentiating benign and malignant lymph nodes by further study. In subsequent studies, the number of samples could be increased and other TIC influence indicators should be supplemented for further research and analysis. In conclusion, the results of the study provided a critical basis for the imaging diagnosis of abdominal and superficial organ lesions.

Objective. The study focused on the correlation between lower extremity arteriosclerosis and diabetic mellitus (DM) foot, and it was explored by virtue of ultrasound images processed by an intelligent algorithm. *Methods*. A total of 60 DM foot patients admitted to our hospital in the past three years were selected and divided into two groups according to their condition. Patients with DM foot alone were in group B (30 cases), and patients with DM foot combined with lower extremity arteriosclerosis occlusion were in group C (30 cases). 30 healthy people were in group A as a control. Color Doppler ultrasound was used to examine the arteries of the lower extremities of all subjects. It the intramedia thickness (IMT) from the femoral artery to the dorsal foot artery was recorded, whether there was plaque in the artery or knowing the size of the plaque, its echo, and distribution, and whether the artery had stenosis. Next, the stenosis percentage was calculated. Additionally, the general information of patients was analyzed. At the same time, an intelligent algorithm was used to process ultrasound images, and its effects on image quality were evaluated. *Results*. Doppler ultrasound images processed by Artificial Bee Colony (ABC) had less noise and better quality, and key information about the lesion was clearly displayed. There was no statistical difference between the general data of the three groups of patients; group B and group C had higher IMT value, plaque incidence, arterial stenosis incidence, and degree of stenosis versus group A, and there were statistically significant differences between groups B and C. In particular, the incidence of femoral artery stenosis and the degree of stenosis were significantly higher in group C than in group B. The rate of stenosis above grade I in group C was as high as 71%, while that in group B was only 19%; in Group C, the incidence of stenosis above grade II was 30%, and that in group B was 13.1%. Compared with group A, group B and group C had decreased peak arterial blood velocity (PSV), resistance index (RI), and pulse index (PI), and there were statistically significant differences between groups B and C. *Conclusion*. DM foot is a risk factor for arteriosclerosis occlusion; color Doppler ultrasound demonstrates good diagnostic effects on arteriosclerosis occlusion; the algorithm proposed in this study can improve the quality of Doppler ultrasound images and has a high application value.

1. Introduction

In recent years, with the continuous improvement of people's living standards and changes in dietary structure, the incidence of diabetes mellitus (DM) foot has been increasing year by year [1]. It is the third most common disease after tumors and cardiovascular diseases. DM foot is a common complication of DM patients. Statistics show that 15% of DM patients worldwide have foot ulcers and gangrene [2]. 50% of patients with amputation each year are DM patients, and more than 85% of these patients are amputated because of worsening foot ulcers leading to deep infection or gangrene. Domestic clinical data show that DM foot patients account for 2% of outpatients and 8% to 12% of inpatients. The per capita treatment cost for DM foot is more than 10,000 yuan. Worldwide, the incidence of DM foot is high, and the prognosis is poor [3].

As for why DM patients develop DM foot, it may be related to the influence of DM on the cardiac and cerebral vessels. To some extent, DM can be regarded as a cardiovascular and cerebrovascular disease and affects almost every blood vessel. The abnormal metabolism caused by DM can lead to changes in the structure and functions of arteries. These changes occur even before DM is diagnosed [4]. Peripheral arterial disease (PAD) is common in DM patients. It is a lower extremity occlusive disease, and its clinical symptoms are not obvious. PAD is an important indicator of thrombotic diseases of arteriosclerosis [5]. Statistics reveal that more than 40% of PAD patients suffer from DM, and DM is the strongest threat factor for PAD. Unlike PAD caused by other factors, DM is closely related to femoral-popliteal PAD and tibial artery PAD (below the knee). The DM foot arises from lower limb ischemia caused by arteriosclerosis occlusion [6]. Above, there is a huge correlation between DM foot and lower extremity arteriosclerosis occlusion. There are many commonalities but are different. Research has found that patients with both PAD and DM foot have a more complicated condition than patients with one of them alone, and the probability of cardiovascular diseases is greatly increased [7]. At present, the relationship between the two remains unclear. In the study, the correlation between the two was explored, in order to provide reference and basis for clinical research.

At present, the methods to diagnose lower extremity arteriosclerosis occlusion mainly include digital subtraction angiography (DSA), magnetic resonance angiography (MRA), CT angiography (CTA), and Doppler ultrasound. Among them, DSA is the recognized gold standard for peripheral vascular examination, but it is often not easily accepted by patients because it is invasive and expensive. As ultrasound technology marches forward continuously, it has been widely used in the detection of vascular diseases, especially in the research of atherosclerosis, because of its advantages, such as noninvasive, fast, efficient, safe, and accurate [8]. Statistics show that the accuracy of ultrasound examination for intraplaque hemorrhage is 90% and the sensitivity is 96%. B-mode ultrasound can display the anatomical images of the artery at longitudinal axis and at the transverse axis, providing rich information, such as artery thickness, plaque shape, size, range, and lumen stenosis and occlusion. Color blood flow imaging can reflect the blood filling and distribution state, which is of great significance for the evaluation of hemodynamic changes. In the early stage of atherosclerosis, it mainly manifests as expansion of the arterial wall or the thickening of MIT, which can be observed by ultrasound scan [9]. Thus, ultrasound has great advantages in the diagnosis of vascular diseases.

Nevertheless, its imaging effects are poor thanks to the reflection and random scattering. As a result, it is difficult to recognize the edges and details of the organs. Recently, Internet technology has developed rapidly, and some medical image processing technologies have also been developed, such as the arterial detection and tracking algorithm developed on the basis of ultrasound imaging, various ultrasonic 3D reconstruction algorithms, and computer-aided diagnostic systems. At present, the most widely used feature extraction and classification method in the field of medical image processing is the support vector machine. However, a large number of studies have shown that support vector machines are susceptible to extreme values in data classification and training. Therefore, in this article, the Artificial Bee Colony (ABC) was used to perform noise reduction and feature extraction on the ultrasound images of diabetes and arteriosclerosis occlusion [10], aiming to provide a scientific basis for the diagnosis and treatment of related diseases.

2. Materials and Methods

2.1. Research Subjects. 60 patients with DM foot and DM foot combined with lower extremity arteriosclerosis occlusion who were hospitalized in the hospital from March 2019 to June 2019 were selected as the research subjects. 30 healthy subjects were selected into group A as a control. The 30 subjects in group B were patients with DM foot alone. The diagnostic criteria of DM foot were based on the standards drawn up by the first DM foot academic conference of the Chinese Medical Association Diabetes Mellitus Society. The 30 subjects in group C were patients with DM foot and lower extremity arteriosclerosis occlusion. The diagnostic criteria for lower extremity arteriosclerosis occlusion were as follows. (1) Those with intermittent claudication; resting pain; soreness, swelling, numbness, and numbness (patients with one or more of them was included); dystrophic changes in skin, hair, muscles, and nails; and ulcers or gangrene were included. (2) The affected swelled and the pulsation of the middle artery was weakened or disappeared. (3) Those with sclerosis changes on fundus examination; electrocardiogram showing coronary artery ischemia, left ventricular hypertrophy, or old myocardial infarction; and Doppler or angiography showing limb arteriosclerosis were also included. The subjects were 62×6.5 years old on average, including 44 males and 46 females. All subjects need to be free of coronary heart disease, hyperlipidemia, and other cardiovascular and cerebrovascular diseases, with no long-term smoking history. The study met the requirements of medical ethics and the patients had signed an inform consent form.

2.2. Examination Methods

2.2.1. Inspection Instrument. Philips iu22 color Doppler ultrasonic diagnostic instrument, with a linear array probe, the probe frequency is 2–9 MHz. During the inspection process, conditions, such as emission energy, total gain, contrast, time gain compensation, and lateral gain compensation, need to be kept basically unchanged.

2.2.2. Inspection Content. The patient stayed in the supine and prone positions, and two-dimensional ultrasound scan was performed on the femoral artery, popliteal artery, anterior tibial artery, posterior tibial artery, dorsal foot artery lumen, and inner membrane of both lower limbs. The lumen inner diameter and intramedia thickness (IMT) were measured. It was observed that there were plaques on the tube wall, the position of plaques, and that there was stenosis in the lumen. The stenosis percentage was then calculated. Color Doppler was used to observe the blood vessel filling, and spectrum Doppler was used to detect blood flow spectrum. After a clear spectrum appeared, the blood flow parameters PSV, RI, and PI were measured. During the inspection, it should be noted not to compress the artery too much, and the angle between the sound beam and the blood flow direction should be less than 60°; each index is measured 3 times, and the average value is taken.

2.3. Image Processing. A total of 220 ultrasound images are collected as research data. Then, the NL algorithm is used to reduce the noise of the image. The original noise image is $Y \in R^{M\times N}$, and the image $\mathrm{NL}(Y)$ after noise reduction was

$$\mathrm{NL}(Y(p)) = \sum_{q=1}^{M\times N} w(p,q) = 1, \tag{1}$$

where p are the pixels to be denoised and q are the other pixels. $w(p,q)$ is the weight, $0 \le w(p,q) \le 1$, and $\sum_{q=1}^{M\times N} w(p,q) = 1$. The calculation of $w(p,q)$ is as follows:

$$w(p,q) = \frac{1}{Z(p)} \exp\left(-\frac{d(p,q)}{h^2}\right). \tag{2}$$

Then, the weighted Gaussian distance is used to judge the similarity:

$$d(p,q) = G_p \left\| g(N_p) - g(N_q) \right\|^2, \tag{3}$$

where G_p is the Gaussian weighting function and $Z(p)$ is the normalization parameter:

$$Z(p) = \sum_{q=1}^{M\times N} \exp\left(-\frac{d(p,q)}{h^2}\right), \tag{4}$$

where h are the attenuation control parameters. This algorithm has good noise reduction effects but long calculation time. In order to reduce the amount of calculation and shorten the calculation time, the search range is controlled in the large search box of $(2\times R_{\text{search}}+1)\times(2\times R_{\text{search}}+1)$.

2.3.1. Feature Extraction. The ultrasonic image features are divided into basic texture features and gray-level cooccurrence matrix features. The gray mean value of the k subblock is defined as

$$\overline{y}_k = \frac{1}{L2} \sum_{i=1}^{L} \sum_{j=1}^{L} \left[y_k(i,j) - \overline{y}_k \right]^2. \tag{5}$$

The gray-level variance $\sigma^2(y_k)$ of the k subblock is defined as follows:

$$\sigma^2(y_k) = \frac{1}{L2} \sum_{i=1}^{L} \sum_{j=1}^{L} \left[y_k(i,j) - \overline{y}_k \right]^2. \tag{6}$$

The probability that the pixels (i', j') with distance d, angle θ, and gray value g_2 appear at the same time is as follows:

$$P_{\theta,d}(g_1, g_2) = \#\{(i,j), (i',j') \in M\times N \mid f(i,j) = g_1, f(i',j') = g_2\}, \tag{7}$$

where $\#\{\cdot\}$ represents the number of elements in the set. For the sake of simplicity, θ and d are ignored, and the matrix is normalized as follows:

$$\frac{P_{\theta,d}(g_1, g_2)}{R} \longrightarrow P(g_1, g_2), \tag{8}$$

where R is the normalization constant and its value is the total number of point pairs in the gray-level cooccurrence matrix. CON is the contrast, and it can reflect the clarity and texture of the image. A greater grayscale difference of the pixel pair value leads to a greater value of CON:

$$\mathrm{CON} = \sum_{g_1=0}^{N_g-1} \sum_{g_2=0}^{N_g-1} \left| g_1 - g_2 \right|^2 p^2(g_1 - g_2). \tag{9}$$

Entropy ENT can be a measure of the complexity of the image texture, and it is calculated as follows:

$$\mathrm{ENT} = -\sum_{g_1=0}^{N_g-1} \sum_{g_2=0}^{N_g-1} P(g_1, g_2) \log\left[P(g_1, g_2)\right]. \tag{10}$$

The linear dependence of the image gray level depends on COR:

$$\mathrm{COR} = \frac{\sum_{g_1=0}^{N_g-1} \sum_{g_2=0}^{N_g-1} g_1 g_2 P(g_1, g_2) - \mu_{g_1}\mu_{g_2}}{\sigma_{g_1}\sigma_{g_2}}. \tag{11}$$

Energy ENG can reflect the uniformity of the image gray distribution and the thickness of the texture:

$$\mathrm{ENG} = -\sum_{g_1=0}^{N_g-1} \sum_{g_2=0}^{N_g-1} p^2(g_1, g_2). \tag{12}$$

2.4. Observation Indicators. The measurement of intramedia thickness (IMT) takes the average value of the left and right sides, and the thickest part of the arterial wall is measured in the diastolic phase of each segment of the lower limbs. It should be noted to be away from the plaque position during the measurement. IMT $\le$ 0.9 mm is the normal value, and IMT > 0.9 mm is the thickened IMT. Plaque is defined as: localized thickening of blood vessel wall greater than 1.2 mm or diffuse thickening of blood vessel greater than 1.2 mm. The calculation of vascular stenosis rate depends on the percentage reduction of inner diameter: vascular stenosis rate = $((d_2 - d_1)/d_2) \times 100\%$ (d_1 is the inner diameter of the lumen at the stenosis and d_2 is the original inner diameter of the lumen). The grades of stenosis were as follows: grade 0, no stenosis; grade I, stenosis rate 1%~19%; grade II, stenosis 20%~49%; grade III, stenosis 50%~99%; grade IV, occlusion, no blood flow information. If there are multiple plaques or stenosis in the same segment of blood vessel, the most severe part of the stenosis shall prevail.

2.5. Statistics. The data was processed by SPSS 17.0 software. The measurement data were expressed as ($\overline{x} \pm s$). The comparison of data between groups adopted analysis of variance, and the x^2 test was used to test the count data. $P < 0.05$ was the threshold for significance.

3. Results

3.1. The Basic Information of Subjects. The basic information of the subjects was shown in Table 1. The average ages of A, B, and C groups were 65.1 ± 6.8, 66.2 ± 5.4, and 64.2 ± 5.9, respectively. The number of male subjects in the three groups was 16, 18, and 17, respectively, and the number of female subjects was 14, 12, and 13, respectively; the proportions of smokers in each group were 16%, 15.1%, and 15.3%. It was noted that there was no significant difference between the general data of the three groups of subjects and it was comparable.

3.2. Ultrasound Images and Processing Results. The original ultrasound image and the processed image were shown in Figure 1. From column A in Figure 1, it was noted that although Doppler color ultrasound can reflect the arterial thickness, plaque shape, size, range, luminal stenosis and occlusion, blood flow filling, and other information in a comprehensive and detailed manner, the figure had much noise, with poor clarity and quality. It failed to show the edge and detailed information of diseased parts and tissue. As for column B in Figure 1, the clarity of the image was improved a lot, and the noise has also been reduced. At the same time, the key information of the disease was extracted, and the redundant information was removed that had nothing to do with the disease, to highlight the focus of the disease.

3.3. The Intramedia Thickness and Hemodynamic Test Results of the Lower Extremity Arteries of Each Group. The IMT measurement results of both lower limbs in the three groups were shown in Figure 2. Compared with group A, subjects in groups B and C had thicker IMT in the lower limb femoral artery, popliteal artery, anterior tibial artery, posterior tibial artery, and dorsal foot artery, and the difference was statistically significant, $P < 0.05$. The thickening of IMT in group C was more obvious versus group B, and the difference was statistically significant, $P < 0.05$.

The hemodynamic results of each group were shown in Figure 3. The test indicators included peak systolic velocity (PSV), resistance index (RI), and pulse index (PI), and the detection was located in femoral artery, popliteal artery, anterior tibial artery, posterior tibial artery, and dorsal foot artery. Compared with group A, PSV, RI, and PI of groups B and C decreased, and the difference was statistically significant, $P < 0.05$, and the decrease in group B was more obvious versus group C, and the difference was statistically significant, $P < 0.05$.

Table 1: The basic information of subjects.

Item		A (30 cases)	B (30 cases)	C (30 cases)
Case		30	30	30
Age (year)		65.1 ± 6.8	66.2 ± 5.4	64.2 ± 5.9
Gender	Male	16	18	17
	Female	14	12	13
Proportion of smokers (%)		16	15.1	15.3
TC (mol/L)		4.66 ± 1.08	4.55 ± 1.13	4.61 ± 1.14
TG (mol/L)		2.06 ± 1.16	2.08 ± 1.12	4.07 ± 1.19

3.4. Occurrence and Distribution of Atherosclerotic Plaques in the Lower Extremities of Each Group. Two-dimensional ultrasound results showed that the intima surface of the lower extremity arteries in groups B and C were not smooth, and there were patches or dots with localized or diffuse distribution and uneven echo. The plaques at the femoral artery were mostly single and large in volume. The plaques were often found at the bifurcation. The plaques of the popliteal artery, anterior tibial, posterior tibial, and dorsal foot artery were mostly diffusely distributed dots echoes and small in volume. Figure 4 showed the plaque incidence in each group, where (a) was the total number of arteries, (b) was the number of plaque arteries in each arterial segment, and (c) was the probability of plaque in each arterial segment. Compared with A, the incidence of plaque in the lower limb femoral artery, popliteal artery, anterior tibial artery, posterior tibial artery, and dorsal foot artery in the groups B and C was higher, $P < 0.05$, and the difference was statistically significant. The incidence of arterial plaque in each segment of the C group was higher than that of the B group, and the difference was statistically significant, $P < 0.05$.

3.5. Occurrence of Arteriosclerosis and Stenosis of the Lower Extremities. Two-dimensional ultrasound results showed that the arterial intima of the lower extremities of the two groups B and C showed varying degrees of thickening and plaques of different sizes and irregular shapes protruding into the lumen, resulting in varying degrees of stenosis of the vascular lumen. Figures 5–9 showed the occurrence and distribution of stenosis in each group. Compared with group A, the lower extremity arterial stenosis rate of groups B and C was higher, and the difference was statistically significant, $P < 0.05$. The incidence of stenosis in of group C was higher than that of group B, and the difference was statistically significant, $P < 0.05$. In particular, the incidence of femoral artery stenosis and the degree of stenosis was higher in group C than in group B. The stenosis rate of grade I and above in group C was as high as 71%, while that in group B was only 19%; in group C, the stenosis rate of grade II and above was 30%, and that in group B was 13.1%.

4. Discussion

In China, diabetes is a common disease that threatens the lives and health of people. With the development of economy and the gradual westernization of lifestyle, the incidence of diabetes continues to rise [11]. DM foot is one of the most common complications of diabetes [12]. Studies have shown that 15 out of every 100 diabetic patients will suffer from DM foot. Clinical data show that diabetes is the culprit of 50% of amputation patients every year. In general,

DM foot can be divided into two types. One is DM foot combined with lower extremity arteriosclerosis occlusion, with the lower extremity arteriosclerosis being the main pathological change. It manifests as the coldness of the lower extremities, numbness, poor skin nutrition, and weakened or disappeared artery pulsation in distant end of lower extremities, that is, ischemic diabetes [13]. The other is DM foot with no obvious arteriosclerosis of the lower extremities, that is, nonischemic diabetes. Such patients have no obvious symptoms of lower limb ischemia, and the pulsation of dorsal foot artery and posterior tibial artery is also good. Clinical statistics show that the proportion of DM foot combined with lower extremity arteriosclerosis occlusion is different among countries, regions, and races [14]. The reason may be that we have different definitions of the two diseases, which has caused ambiguity. The international definitions of DM foot and fine arteriosclerosis occlusion are as follows. DM foot refers to the foot ischemia, infection, or neuropathy in diabetic patients; lower extremity arteriosclerosis occlusion is a systemic arterial disease, and it manifests as the appearance of atherosclerotic plaque, degeneration or calcification of the middle layer of the tissue, and the formation of secondary thrombosis in the lumen, which will eventually narrow or even completely occlude the lumen. In severe cases, ischemia in lower extremities may cause acronecrosis [15]. As per the definition, both DM foot and lower extremity arterial occlusion are related to ischemia. When a diabetic person has lower extremity arterial bleeding, whether it should be diagnosed as

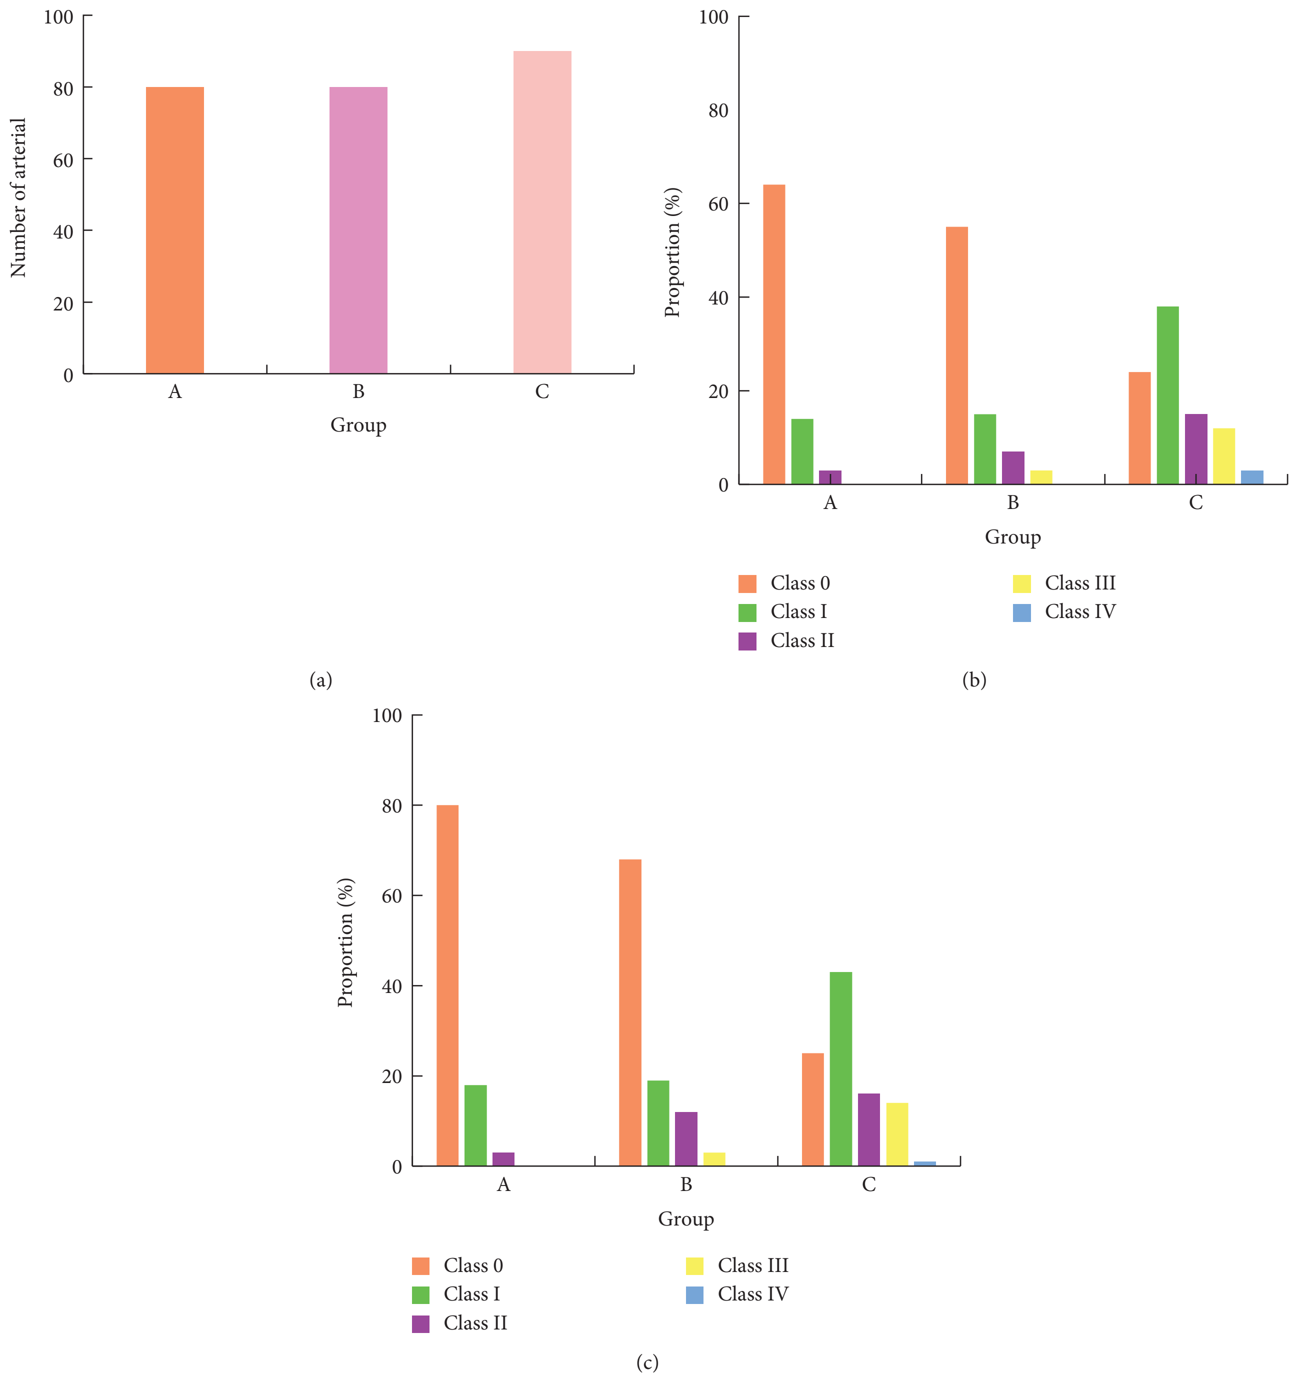

FIGURE 5: The occurrence of femoral artery stenosis in each group. (a) Total number of arteries in each group. (b) The number of arteries with stenosis in each group. (c) The occurrence probability of arterial stenosis in each group.

diabetic foot or lower extremity arteriosclerosis occlusion is a common problem that currently plagues clinicians [16]. If diagnosed as DM foot, it will enlarge the influence of DM foot and reduce the detection rate of arteriosclerosis occlusion; if diagnosed as lower extremity arteriosclerosis occlusion, it will reduce the detection rate of DM foot combined with lower extremity arteriosclerosis occlusion [17]. For the relationship between the two, scholars have used mathematical sets to express it; that is, those with DM foot alone and those with lower extremity arteriosclerosis occlusion alone are in mutually independent subsets, and those in the intersection have DM foot combined with arteriosclerosis occlusion. Hence, it is important to explore the difference and connection between the two [18].

Currently, except for the diagnosis method based on the clinical systems, the main methods to diagnose DM foot and

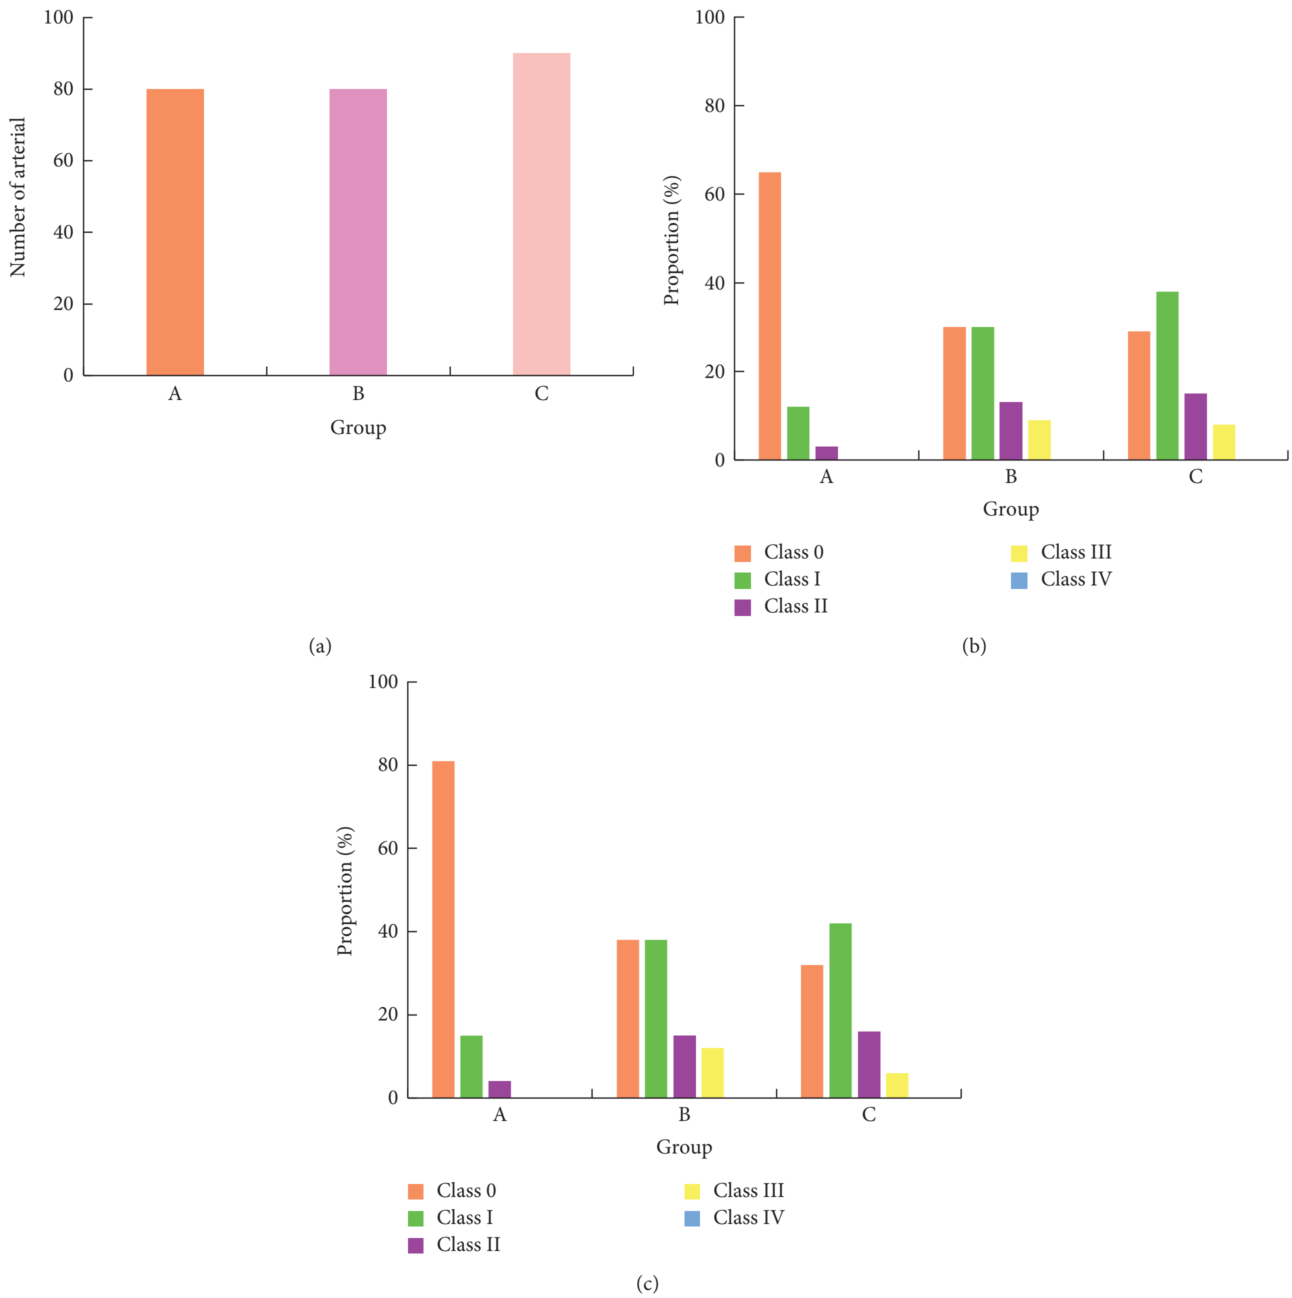

Figure 6: The occurrence of popliteal artery stenosis in each group. (a) Total number of arteries in each group. (b) The number of arteries with stenosis in each group. (c) The occurrence probability of arterial stenosis in each group.

lower extremity arteriosclerosis occlusion include DSA, MRA, CTA, and Doppler ultrasound. Among them, DSA is the gold standard for peripheral blood vessel examination, but it is invasive and expensive and thus poorly accepted by patients. Ultrasound examination has been widely used in clinical vascular examinations, especially the diagnosis of atherosclerosis, because of its fast speed, noninvasiveness, accuracy, and simple operation. It can detect early atherosclerosis and the location of small nonstenotic atherosclerotic plaques. Despite many advantages, the ultrasound examination is affected by reflection and random scattering, the image has large noise, and the edge of the lesion is often blurred. To further improve the quality of ultrasound images to more accurately grasp the patient's disease information, researchers have applied various image processing techniques to ultrasound image processing, such

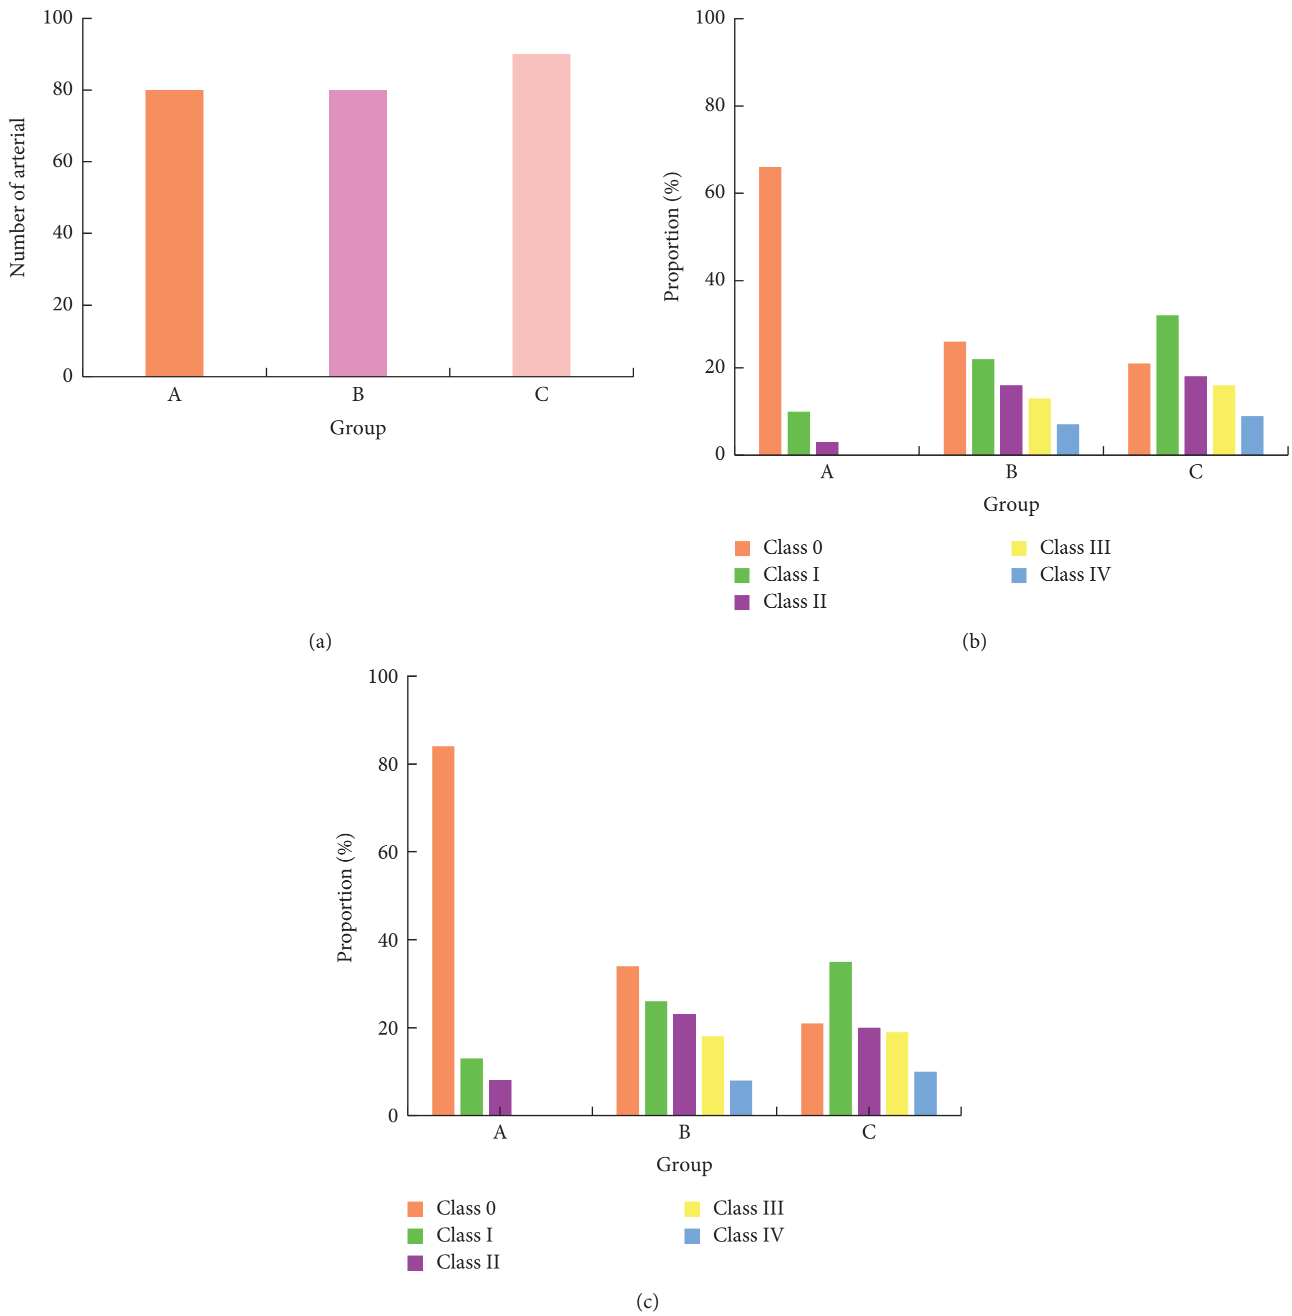

Figure 7: The occurrence of anterior tibial artery stenosis in each group. (a) Total number of arteries in each group. (b) The number of arteries with stenosis in each group. (c) The occurrence probability of arterial stenosis in each group.

as the arterial detection and tracking algorithm developed on the basis of ultrasound images [19]. In this study, the ABC algorithm was used to process the Doppler ultrasound images of all subjects. The study found that compared with the original image, the processed image was clearer, and the lesion features were more prominent. Then, the relationship

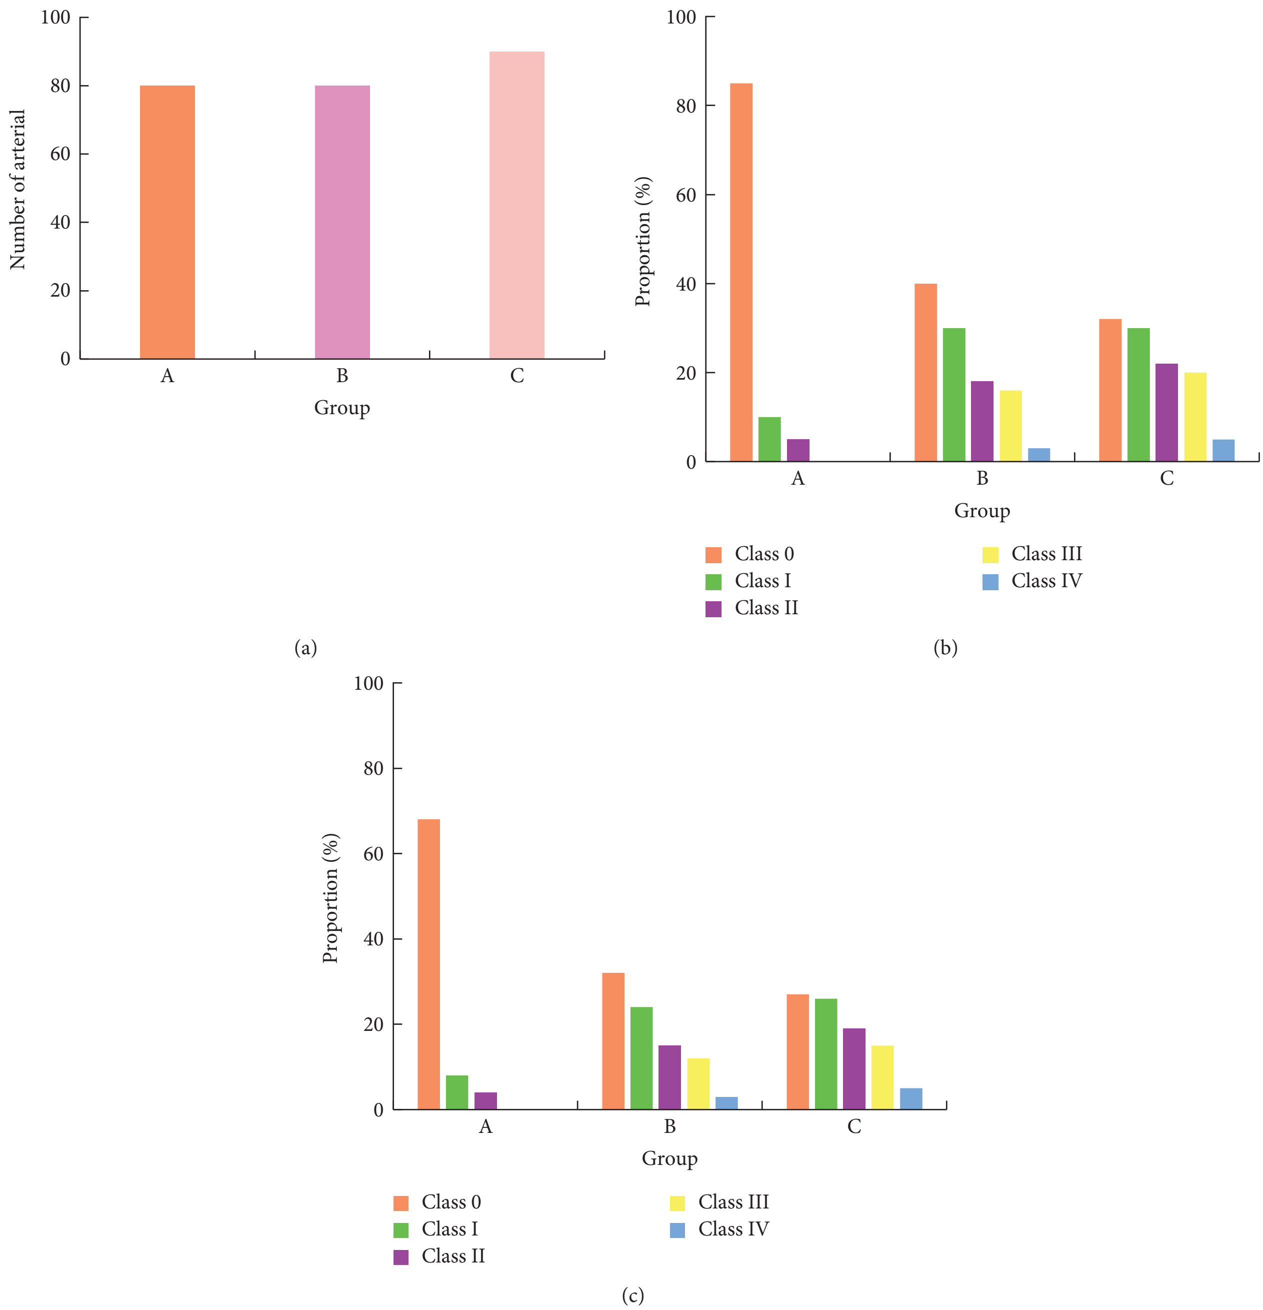

Figure 8: Occurrence of posterior tibial artery stenosis in each group. (a) Total number of arteries in each group. (b) The number of arteries with stenosis in each group. (c) The occurrence probability of arterial stenosis in each group.

between DM foot and lower extremity arteriosclerosis occlusion was analyzed on the basis. The study found that patients with DM foot combined with lower extremity arteriosclerosis occlusion had a higher incidence of lower extremity plaque and severe vascular stenosis compared with patients with DM foot alone. This suggested that DM foot is a risk factor for lower extremity arteriosclerosis occlusion.

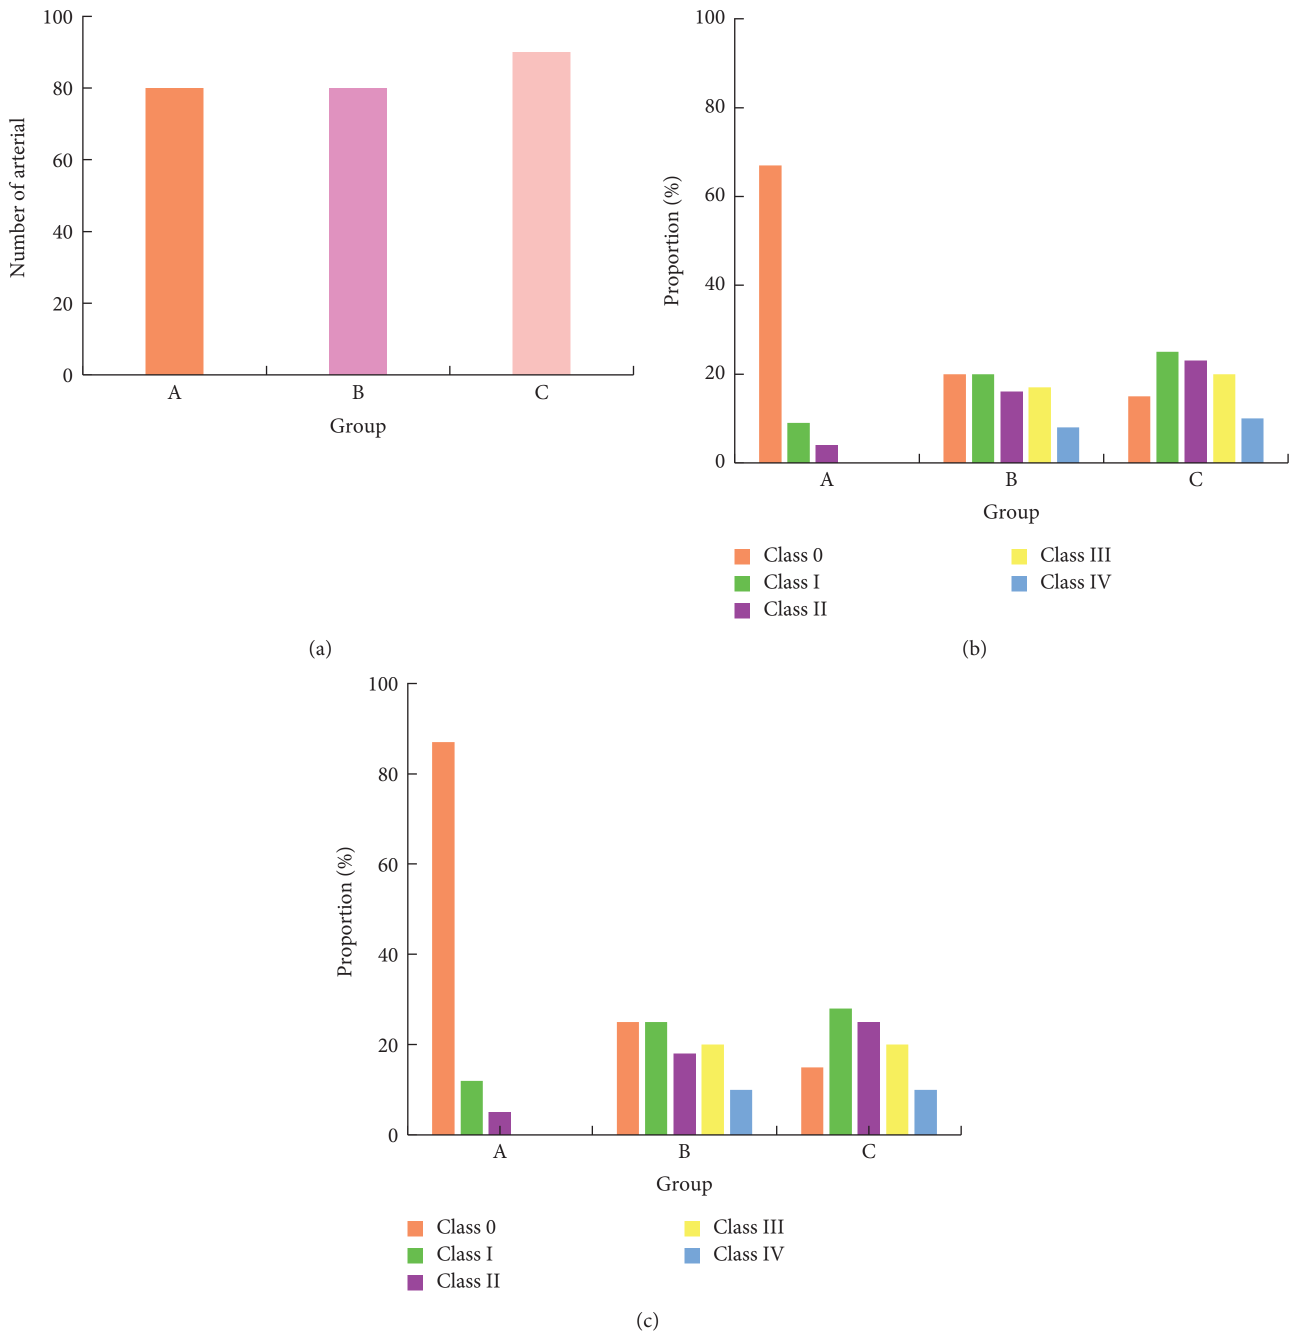

Figure 9: Occurrence of dorsal artery stenosis in each group. (a) Total number of arteries in each group. (b) The number of arteries with stenosis in each group. (c) The occurrence probability of arterial stenosis in each group.

5. Conclusion

In this study, patients with DM foot combined with PDA were selected, and they were analyzed for lower extremity arterial stenosis and plaque occurrence, as well as MIT thickness. Then, the correlation between DM foot and lower extremity arteriosclerosis occlusion was explored. It was found that DM foot was one of the risk factors for lower extremity arteriosclerosis occlusion, which negatively affect the prognosis of extremity arteriosclerosis occlusion. Meanwhile, an intelligent algorithm was used to process Doppler ultrasound images. It was found that the algorithm can highlight lesion information and improve image quality, with high application value and prospects. However, some limitations in the study should be noted. The sample size is small, which will reduce the power of the study. In the follow-up, an expanded sample size is necessary to strengthen the findings of the study.

Academic Editor: Enas Abdulhay

Background. The treatment results of core decompression (CD) and biomechanical support are not always satisfactory in osteonecrosis of the femoral head (ONFH). Stem cell therapy has been incorporated into traditional treatment in order to promote bone regeneration. The efficacy and safety of stem cell therapy combined with CD or biomechanical support on advanced and long-term patients with ONFH were unknown. The aim of this study was to assess whether stem cell combination therapy is superior to single CD or porous tantalum rod implantation treatment in ONFH. *Methods*. A systematic search of the literature was performed to evaluate all included randomized controlled trials (RCTs) on stem cell combination therapy for patients with ONFH in PubMed, Cochrane Library, Web of Science, and Embase sites. We assessed the quality and risk of bias for the included studies. And the outcomes of Harris hip score (HHS), visual analogue scale (VAS), and adverse events were statistically analyzed. *Results*. We included 10 randomized controlled trials, containing a total of 498 patients with 719 hips. Stem cell therapy combined with CD versus CD alone for HHS of ONFH was different (MD = 8.87, 95% CI = [5.53, 12.22], $P < 0.00001$). The combination of stem cell therapy and CD can effectively improve HHS. Similarly, the VAS of the stem cell combination therapy group also differed compared with the control group (MD = −14.07, 95% CI = [−18.32, −9.82], $P < 0.00001$). The result showed that stem cell combination therapy can relieve the pain of patients with ONFH. There was no significant difference in adverse response outcome events between the combination therapy group and the control group (RR = 1.57, 95% CI = [0.62, 3.97], $P = 0.34$). *Conclusions*. Stem cell therapy combined with core decompression is an effective and feasible method with few complications in the clinical treatment of early-stage ONFH. Even in the combination of porous tantalum rod implantation and peripheral blood stem cells, stem cell combination therapy is superior to single biomechanical support treatment. But high-quality, large-sample, multicenter, and long-term follow-up RCTs are still needed to corroborate the efficacy and safety of stem cell combination therapy in ONFH treatment.

1. Introduction

Osteonecrosis of the femoral head (ONFH) is a prevalent disease in relatively young patients, usually caused by hip trauma, alcoholism and long-term administration of steroid, which may lead to significant hip pain, articular surface collapse, and eventual osteoarthritis [1]. In clinical treatment, various methods are employed to avert or impede the progression of ONFH. The most common form of therapy is core decompression (CD) that has been universally administered for more than 30 years [2]. However, the treatment results of CD are not always satisfactory. This method of reconstructing necrotic areas may result in not only inadequate creeping substitution and but also bone remodeling [3]. Therefore, in order to promote bone regeneration, stem cell therapy has been incorporated into traditional CD treatment. When compared with treating ONFH with CD alone, the combined application of stem cell therapy and CD, in early treatment, has superior analgesic and clinical effects, and can more effectively delay the progress of femoral head collapse [4]. However, the efficacy and safety of these methods have been controversial and have yet to be proven in patients with advanced and long-term ONFH [5, 6].

To investigate the efficacy and safety of stem cell therapy combined with CD or porous tantalum rod implantation in ONFH patients, especially those with advanced stage and long-term follow-up [7], our research systematically retrieved the latest randomized controlled trials on stem cell combination therapy for ONFH according to the PRISMA guidelines [8]. Furthermore, the positive role and improvement of the new technologies in treatment were discussed, with a view of providing clinicians with scientific evidence for the treatment of ONFH patients.

2. Materials and Methods

2.1. Search Strategy. Two researchers independently searched databases from Cochrane Library, Web of Science, PubMed, and Embase. We integrated published randomized controlled studies of cell therapy for femur head necrosis in any language. The search period was from the date of the database establishment to January 2020. A manual supplementary search was performed before submission. The search terms were adjusted according to each database.

Taking PubMed database as an example, the search terms were as follows: ((Femur* Head Necros* [Title/Abstract]) OR (Necros* of Femur* Head [Title/Abstract]) OR ("Femur Head Necrosis" [Mesh])) AND (("Cell-and Tissue-Based Therapy" [Mesh]) OR (Cell-[Title/Abstract] AND Tissue-Based Therapy [Title/Abstract]) OR (cell therapy [Title/Abstract]) OR (Cell [Title/Abstract] AND Tissue Based Therapy [Title/Abstract]) OR (Cell Transplantation [Title/Abstract])) AND ((randomized controlled trial [Publication Type]) OR (controlled clinical trial [Publication Type]) OR (randomized [Title/Abstract]) OR (placebo [Title/Abstract]) OR (randomly [Title/Abstract]) OR (trial [Title]) OR ("Clinical Trials as Topic" [Mesh: noexp])).

2.2. Criteria for Inclusion and Exclusion. In our qualitative and quantitative analysis, only the studies that satisfied the following PICOS criteria were considered: (1) population: patients with stages I to IV of ONFH diagnosed by the Association Research Circulation Osseous classification (ARCO) [9] diagnostic criteria; (2) intervention: cell therapy combined with core decompression or porous tantalum rod implantation; (3) comparator: single core decompression or porous tantalum rod implantation therapy; (4) outcome: HHS, VAS, and adverse events; and (5) study design: randomized controlled trial (RCT).

We excluded studies with the following criteria: (1) republished studies with similar or identical content; (2) dissertation, conference, and review articles; (3) research in animal and basic experimental literature; (4) non-English published research; and (5) nonrandomized controlled trial or other irrelevant studies.

Two researchers followed the criteria for inclusion and exclusion separately. In case of disagreement, a third researcher intervened to resolve it.

2.3. Data Extraction. Two reviewers performed data extraction independently. In case of disputes, differences can be resolved through discussion or third parties until consensus was reached. The extracted information contained baseline information and feature information. The baseline information included: title, study ID, publication country, diagnostic criteria and stages, participants, age, sex ratio, intervention/control group, stem cell source, stem cell counts, the number of hips, and follow-up periods. The feature information included outcome indicators (HHS, VAS), adverse events, effect size, and 95% confidence interval.

2.4. Quality Assessment. The included studies were independently evaluated by two researchers in accordance with the Cochrane Handbook for Systematic Reviews of Interventions [10]. Cochrane Collaboration Risk of Bias Tool primarily includes selection (taking into account both allocation hiding and random sequence generation), execution (blinding of both subjects and researchers), measurement (research outcomes blind evaluation), and follow-up (outcome data completeness). A total of seven items in six aspects including gender, reporting, and further potential sources of bias were used to assess the bias risk. For each item, a categorization was specified, counting "low-risk bias," "high-risk bias," and "unclear," with this decision being made in accordance with the bias risk assessment criteria.

2.5. Statistical Analysis. Continuous variable values were expressed in mean difference (MD), and a 95% confidence interval (CI) was calculated for both. Regarding dichotomous variables, we used the risk ratio (RR) and 95% CI to describe. When $I^2 > 50\%$, heterogeneity was present within the data; hence, a random-effect model was used. When $I^2 < 50\%$, there was no heterogeneity present; hence, a fixed effects model was used. The findings of the meta-analysis were shown by the forest plot. We utilized RevMan 5.3 software for statistical analysis. $P < 0.05$ was used to evaluate statistical significance. If the number of the included studies was greater than ten, we would use a funnel plot to detect publication bias.

3. Results

3.1. Search Results. After searching various databases and a manual search method, we retrieved a total of 123 articles. Mechanical check and manual deduplication were performed by EndNote X9, 47 duplicate articles were deleted, 59 articles were excluded from our analysis after abstract screening, and 7 articles were omitted following a full-text screening, resulting in 10 randomized controlled trials being included in our qualitative and quantitative analysis [5, 6, 11–18]. The flowchart is shown in Figure 1.

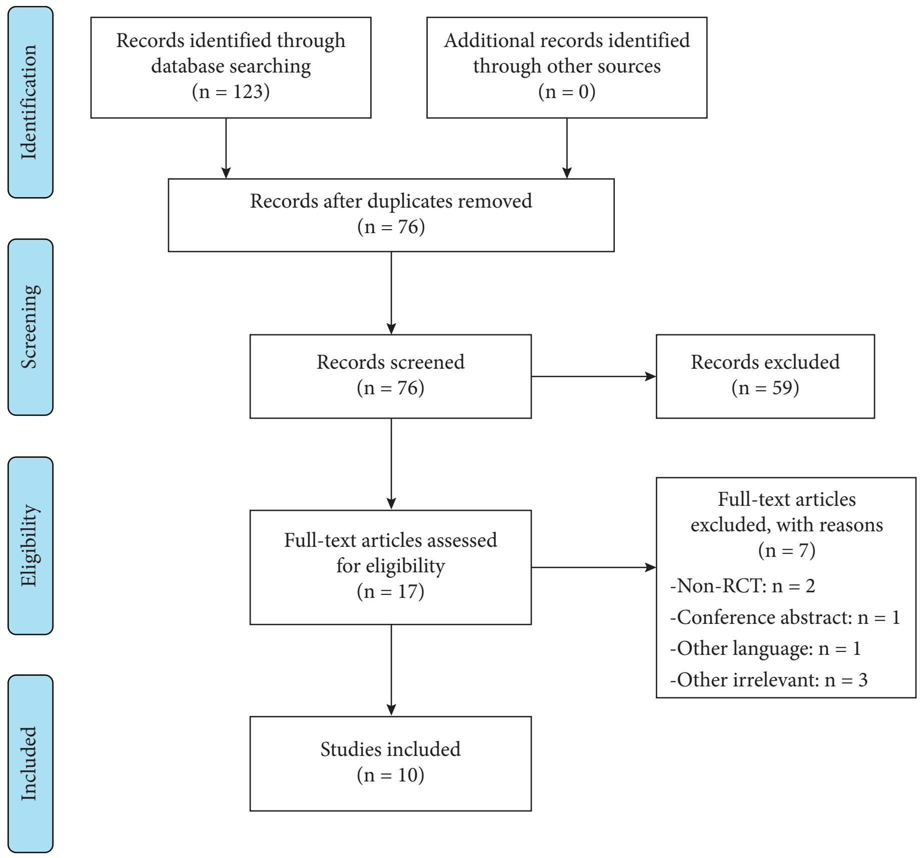

Figure 1: Flowchart of literature searching and screening process.

3.2. Study Characteristics. The publication dates of the included RCTs ranged from 2011 to 2018 and belonged to two regions in India [14, 15], one in Iran [16], one in Germany [13], three in China [11, 12, 17], two in Belgium [5, 18], and one in France [6]. All the studies used the ARCO stage as the diagnostic criteria. And the disease stage of the included patients with ONFH was mainly seen in the early phase. A total of 498 participants with 719 hips were included in this study. The longest average follow-up time was up to 25 years. See Table 1 for details.

3.3. Quality Assessment. According to the bias risk assessment method recommended by Cochrane Assistance Network, of the 10 studies included, 6 studies [5, 12, 13, 16–18] described the specific random grouping methods, 2 studies [11, 15] mentioned random grouping but did not detail the specific method, and the remaining 2 studies [6, 14] had a high risk of bias; 4 studies [6, 11, 14, 17] showed the unclear risk of bias for the allocation concealment assessment. As for the blinding of participants and personnel, 4 studies [6, 11, 13, 14] did not report whether double-blind information was used, and one study [17] had a high risk of bias; 4 studies [6, 11, 13, 14] showed the unclear risk of bias for the blinding of outcome assessment. Regarding the incomplete outcome data, one study [13] had an unclear risk of bias, and one study [17] showed a high risk of bias. All studies clearly described the selective reporting and had no other risk bias (Figures 2 and 3).

3.4. Meta-Analysis Results of HHS. Harris hip score was recorded in six studies [6, 12–15, 17] involving 572 hips. Stem cell therapy combined with core decompression treatment had higher heterogeneity ($\text{Chi}^2 = 34.21$, $I^2 = 85\%$, $P < 0.0001$) than core decompression alone, and a random effect model was used. The combination treatment group can effectively improve the Harris hip score (MD = 8.87, 95% CI = [5.53, 12.22]), and the difference was statistically significant ($P < 0.00001$). The forest plot is shown in Figure 4.

3.5. Meta-Analysis Results of VAS. Five studies [5, 6, 11, 16, 18] including a total of 397 hips reported visual analogue scales. It was evident that stem cell combination therapy yielded a higher heterogeneity than solely administering core decompression or porous tantalum rod implantation ($\text{Chi}^2 = 54.20$, $I^2 = 93\%$, $P < 0.00001$), and a random effect model was used. Stem cell combination therapy group can effectively relieve the patients' pain (MD = −14.07, 95% CI = [−18.32, −9.82]), with the difference observed between the two groups being statistically significant ($P < 0.00001$). See the forest plot in Figure 5.

3.6. Meta-Analysis Results of Adverse Events. The perioperative adverse events were reported in five studies [5, 12, 13, 17, 18]. Of these studies, three studies [5, 12, 18] reported the adverse response outcome events, including the postoperative pain at the great trochanter and iliac crest,

Table 1: Baseline characteristics of included RCTs.

Study	Year	Country	Study type	Diagnostic criteria	Disease stage	Patient	Age (years)	Sex ratio (M/F)	Intervention/control	Stem cell source	Stem cell counts	Hips	Follow-up (years)
Gangji [18]	2011	Belgium	RCT	ARCO	I/II	19	42.2 ± 2.6	NA	CD + cell therapy	BMMSCs	$92.6 \pm 22.4 \times 10^7$	13	5

NA = not available; CD = core decompression; BBC = bone marrow buffy coat; BMMSCs = bone marrow mesenchymal stem cells; PBSCs = peripheral blood stem cells.

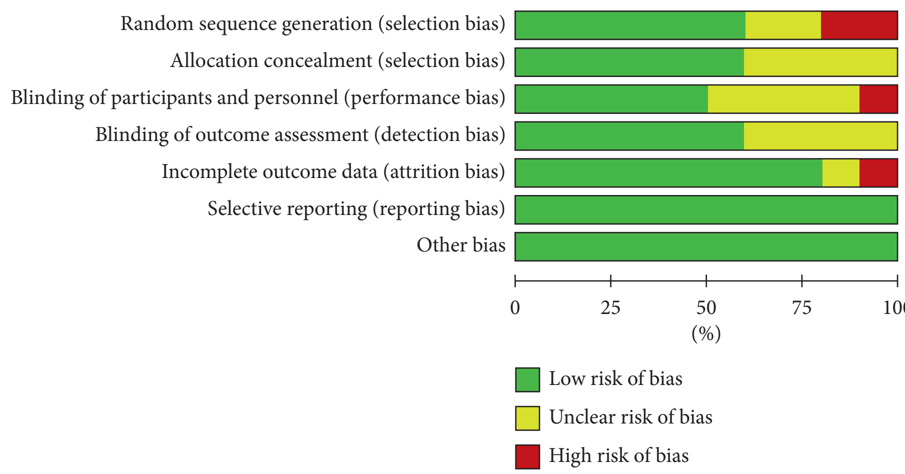

Figure 2: Bias graph risk.

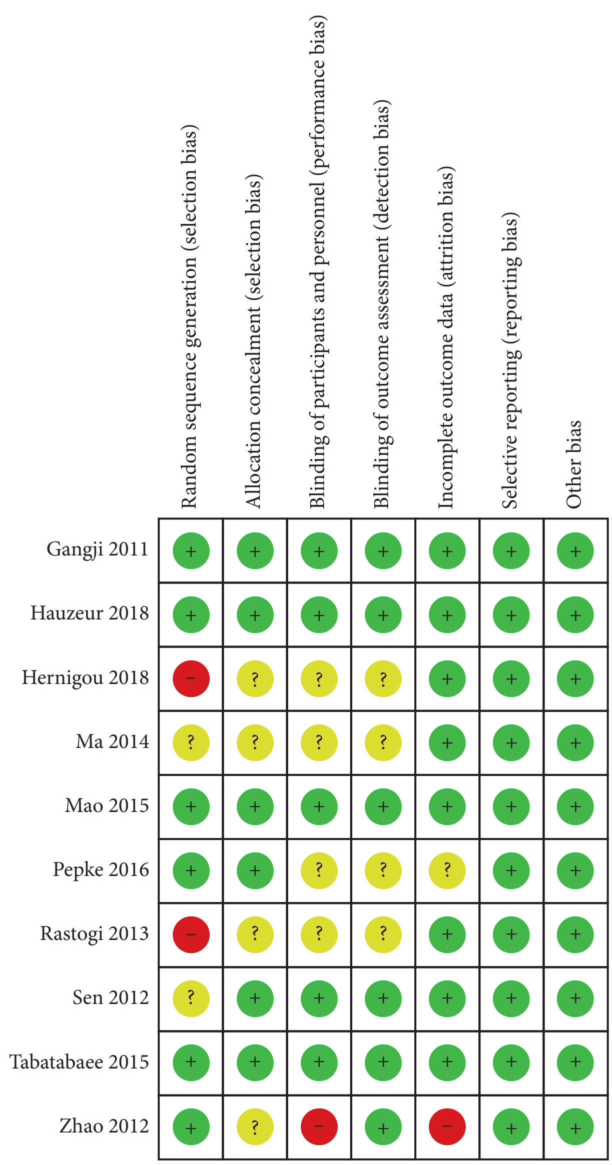

Figure 3: Bias summary risk.

hematoma, fever, nausea, infection, and porous tantalum rod displaced. Two studies [13, 17] reported that no adverse events were observed in both groups during the study period. The analysis showed that there was no significant difference in adverse events between the stem cell combination therapy group and the control group ($RR = 1.57$, 95% $CI = [0.62, 3.97]$, $P = 0.34$). The forest plot is shown in Figure 6.

3.7. Publication Bias. As no more than ten published studies were included, it was not possible to assess publication bias for the time being.

4. Discussion

4.1. Main Findings. Our findings demonstrate that in early-stage ONFH, stem cell therapy combined with core decompression is far more effective than core decompression alone. And the combination therapy has good safety with few complications. Moreover, even in the combination of porous tantalum rod implantation and peripheral blood stem cells, stem cell combination therapy is superior to single biomechanical support treatment.

4.2. Effectiveness of Stem Cell Combination Therapy. Stem cell combination therapy can relieve the symptoms of hip pain, improve patients' HHS, halt disease progression, and result in a reduction in the incidence of total hip replacement for the early-stage ONHF patients. This was confirmed in three independent systematic reviews conducted by Papakostidis et al. [19], Piuzzi et al. [20], and Wang et al. [4], respectively. However, in advanced patients, the evolution of necrosis was not significantly improved by stem cell therapy after core decompression [5]. Furthermore, the results of a network meta-analysis study by Yoon et al. [21] questioned the natural course of ONFH by CD treatment. The findings of this study suggested that the small lesions will not collapse, even without treatment being administered. This conclusion

Study or Subgroup	Combination therapy Mean	SD	Total	Control Mean	SD	Total	Weight (%)	Mean Difference IV, Random, 95% CI	Year

took into account that the extent of the decaying component was the primary factor of the necrotic femoral head fracture's collapse. However, even though the progression of osteonecrosis may result from numerous factors [6], an average follow-up time of 25-year prospective randomized study by Hernigou et al. [6] established that bone marrow cell implantation of necrotic lesions may potentially offer an effective treatment for early femoral head necrosis and impede the evolution of ailment, lessen the incidence of femoral head collapse, and elude the arthroplasty even at long-term follow-up.

4.3. Safety of Stem Cell Combination Therapy. The probability of adverse complications was extremely low, especially in the aspects of infection, excessive new bone formation, tumor induction, and local complications on the surviving side [13]. Stem cell therapy was safe for the treatment of ONFH. Even after 3–10 years of follow-up, there were no complications related to malignant tumors, bone overgrowth, core tract fractures, perforation of femoral head, deep vein thrombosis, infection, and so forth [7]. Ma et al. [11] conducted a prospective, double-blinded, randomized, controlled investigation. In order to reduce the failure rate, they improved the technology and used autologous bone grafts obtained by ring drilling with bone marrow buffy coat. Hernigou et al. [6] corroborated these findings and noted that computer navigation had the potential to be safely implemented in a basic procedure for the injection of stem cells. They all improved the overall safety of stem cell therapy and reduced the probability of complications. Additionally, Ciapetti et al. [22] demonstrated that, compared with bone marrow mesenchymal stem cells under normal conditions, the proliferation and colonization capacity of these stem cells were significantly enhanced in a hypoxic environment.

4.4. Strengths and Limitations. This systematic review was ultimately included in ten studies. All the studies were RCTs of stem cell combination therapy for ONFH, which would provide us with strong evidence for the efficacy and safety of this method in ONFH treatment. Owing to the small number of included studies, we could not make funnel charts to determine publication bias. The heterogeneity in the outcome indicators was large, which may result from certain differences in the included studies in aspects of stem cell concentration, treatment time, and the quality of the literature, leading to greater heterogeneity in each clinical study, and some outcome indicators were not stable.

The findings of this meta-analysis still had certain limitations: (1) the overall quality of the scope of included literature was not high, the sample size was small, and the short follow-up time in some studies may also lead to potential bias; (2) as no more than ten studies were included, publication bias cannot be assessed; (3) publication in English may result in language or regional bias; and (4) there was some heterogeneity in outcome indicators. High-quality, large-sample, multicenter, and long-term follow-up randomized controlled trials are still warranted to corroborate the differences in the efficacy and safety of stem cell combination therapy in ONFH.

5. Conclusion

Stem cell therapy combined with core decompression is an effective and feasible method with few complications in the clinical treatment of early-stage ONFH. Even in the combination of porous tantalum rod implantation and peripheral blood stem cells, stem cell combination therapy is superior to single biomechanical support treatment. But high-quality, large-sample, multicenter, and long-term follow-up RCTs are still needed to corroborate the efficacy and safety of stem cell combination therapy in ONFH treatment.

Objective. To perform gene set enrichment analysis (GSEA) and analysis of immune cell infiltration on non-small-cell lung cancer (NSCLC) expression profiling microarray data based on bioinformatics, construct TICS scoring model to distinguish prognosis time, screen key genes and cancer-related pathways for NSCLC treatment, explore differential genes in NSCLC patients, predict potential therapeutic targets for NSCLC, and provide new directions for the treatment of NSCLC. *Methods*. Transcriptome data of 81 NSCLC patients and the GEO database were used to download matching clinical data (access number: GSE120622). Form the expression of non-small cell lung cancer (NSCLC). TICS values were calculated and grouped according to TICS values, and we used mRNA expression profile data to perform GSEA in non-small-cell lung cancer patients. Biological process (GO) analysis and DAVID and KOBAS were used to undertake pathway enrichment (KEGG) analysis of differential genes. Use protein interaction (PPI) to analyze the database STRING, and construct a PPI network model of target interaction. *Results*. We obtained 6 significantly related immune cells including activated B cells through the above analysis (Figure 1(b), $p < 0.001$). Based on the TICS values of significantly correlated immune cells, 41 high-risk and 40 low-risk samples were obtained. TICS values and immune score values were subjected to Pearson correlation coefficient calculation, and TICS and IMS values were found to be significantly correlated (Cor = 0.7952). Based on non-small-cell lung cancer mRNA expression profile data, a substantial change in mRNA was found between both the high TICS group as well as the low TICS group (FDR 0.01, FC > 2). The researchers discovered 730 mRNAs that were considerably upregulated in the high TICS group and 121 mRNAs that were considerably downregulated in the low TICS group. High confidence edges (combined score >0.7) were selected using STRING data; then, 191 mRNAs were matched to the reciprocal edges; finally, an undirected network including 164 points and 777 edges was constructed. Important members of cellular chemokine-mediated signaling pathways, such as CCL19, affect patient survival time. *Conclusion*. (1) The longevity of patients with non-small-cell lung cancer was substantially connected with the presence of immature B cells, activated B cells, MDSC, effector memory CD4 T cells, eosinophils, and regulatory T cells. (2) Immune-related genes such as CX3CR1, CXCR4, CXCR5, and CCR7, which are associated with the survival of NSCLC, affect the prognosis of NSCLC patients by regulating the immune process.

1. Introduction

The occurrence of tumors is not only related to the biological characteristics of the tumor cells themselves. And the interaction between cancer cells and tumor immune microenvironment and immune system also plays a very significance role. One of the problems that should be investigated is whether immune cell infiltration in tumor tissues is connected to tumor treatment and prognosis.

Lung carcinoma is a major cancer that has a high risk of morbidity and mortality, and data show that one person dies from lung cancer every 30 s worldwide [1] Lung tumor is

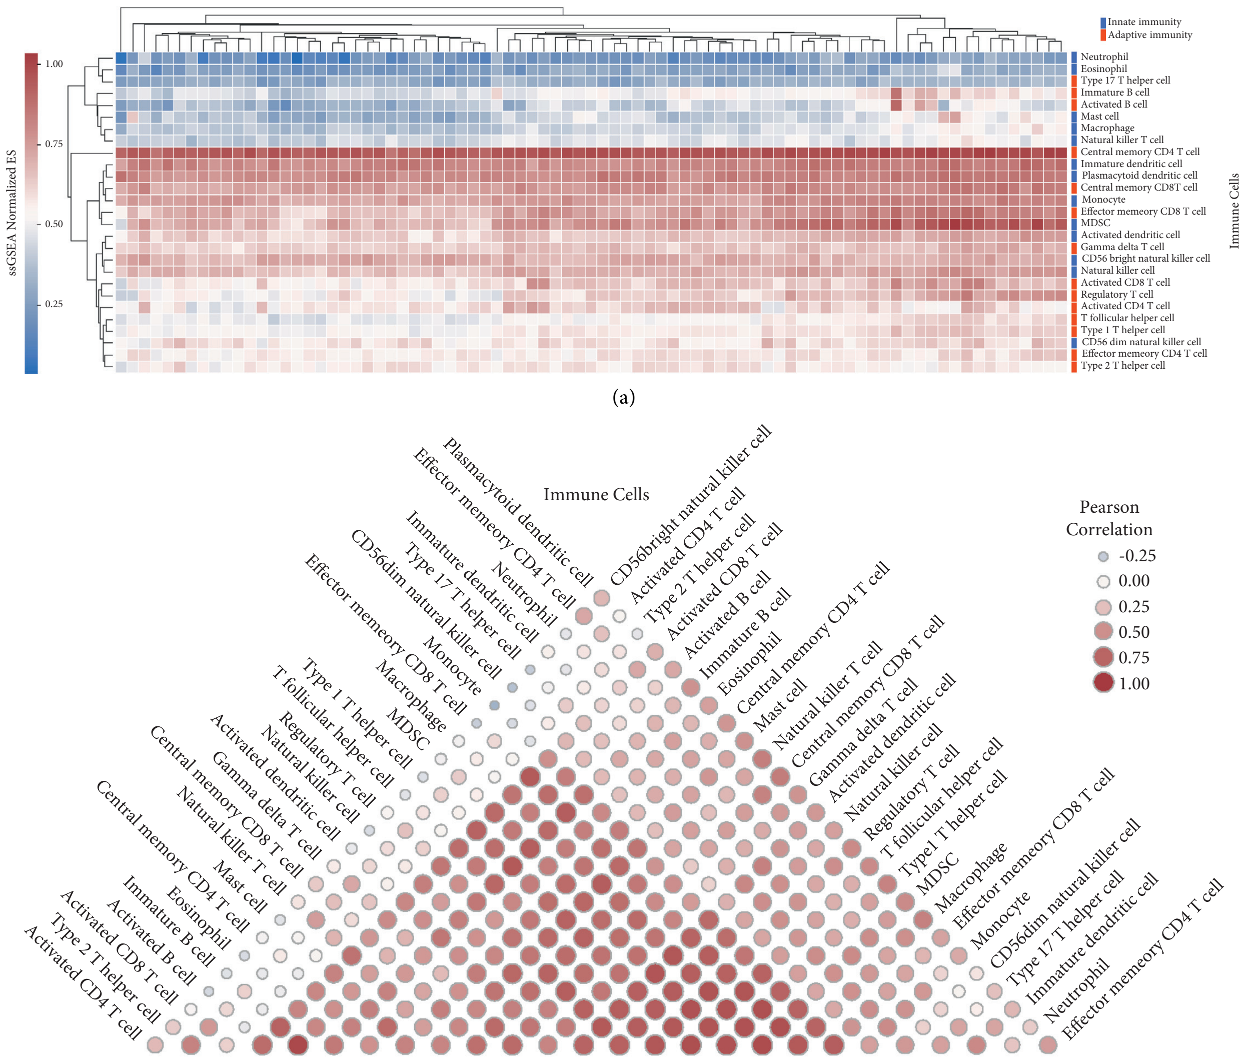

Figure 1: (a) Heat map of immune cell infiltration with the ssGSEA algorithm. (b) Construction of immune cell map based on the Pearson correlation.

divided into 2 types: small-cell lung cancer (SCLC) and non-small-cell lung cancer (NSCLC). Small-cell lung cancer (SCLC) accounts for around 85% of all lung cancer cases [2]. Because of the insidious onset, diversity of clinical manifestations, and lack of specificity of primary lung cancer patients, most patients are already in the middle and late stages of the disease when they are diagnosed with lung cancer, so whether lung cancer patients can be screened, diagnosed, and treated early becomes a key factor in prognosis.

The tumor microenvironment (TME) is a bidirectional, dynamic, and intricate network system composed of various cells (T cells, B lymphocytes, macrophages, NK cells, etc.) and extracellular components (cytokines, chemokines, and receptors, etc.), and each element of this network is capable of promoting malignant transformation and influencing both the onset, progression, and metastasis of lung cancer, development and metastasis, and the response to drug therapy [3] T-cell surface programmed cell death protein 1 (PD-1) in TME has been demonstrated to bind to programmed cell death ligand-1 (PD-L1) on the surface of cancer cells in recent years, causing T-cell dysfunction or depletion, resulting in immune tolerance and tumor cell response. Immune tolerance occurs, leading to immune escape of tumor cells [4], and in the process of killing tumor cells, the most central role in TME is played by CD8+ T cells [5], the quality and quantity of which are critical for immunotherapeutic efficacy [6]. Studies of PD-1 inhibitors for melanoma [7] have found that the number of CD8+ T cells correlates with efficacy. Tumor-infiltrating B cells are an important part of the immune system's microenvironment. In NSCLC patients, CD4+ T lymphocytes can be seen in tumor cells infiltrated by B cells and tumor cells with tertiary lymphoid structure. And high density of follicular B cells is associated with a better prognosis in NSCLC patients [8]. Bruno et al. [9] found that tumor-infiltrating B cells can present endogenous tumor antigens to CD4+ TIL and alter them in vitro. It has also been reported that bone marrow-derived suppressor cells (MDSCs) are able to produce factors like TGF-p and IL-10, which promotes the development of initial CD4+ T cells into Treg cells, resulting in the increase of Treg cells, thereby suppressing body immune response [10]. In addition, MDSC can block the secretion of natural killer cells (NK). IFN-NK cells in secreted substances refer to innate immune cells that can kill cancer cells and virus-infected cells. And IFN-NK cells can regulate the functions of other immune cells and promote tissue growth.

Chemokines are a group of small molecules (mostly 8–10 kD in molecular weight) that are capable of chemotactic cell movement. Chemokines can be classified into four groups according to the number and location of N-terminal cysteine residues: C, CC, CXC, and CX3C. For example, CCL2 chemokine has the ability to chemoattract monocytes, macrophages, and T lymphocytes [14]. It has been shown that anti-CCL2 antibodies blocking the effects of CCL2 such as reducing MDSC, increasing CD4+ and CD8+ T cell infiltration, and promoting IFNy secretion can enhance the tumor immune effect of PD-1 in treating lung cancer in mice [15]. CX3CL1 (FKN, fractalkine) is the only member of the CX3C type chemokine family, which possesses chemotactic functions common to chemokines and mediates the wandering and activation of leukocytes, especially lymphocytes and phagocytes. Li et al. [16] used gene silencing technology to confirm the stable high expression of CX3CL1 in the hepatocellular carcinoma cell line HepG2, which inhibited tumor angiogenesis. In breast cancer studies, CX3CL1 was found to have a possible role in tumor metastasis [17,18], and high CX3CL1 expression correlates with good prognosis in breast cancer [19] and can also be used as one of the indications for immunomodulatory therapy.

In summary, only a few reports have investigated the clinic pathological significance of immune cells in recent years, and the overall expression level and prognostic value of immune cell infiltration, especially in NSCLC patients, require further investigation. Therefore, in this study, we collected data from public databases and constructed statistical scoring models to analyze multiple datasets independently and pooled the analysis results in order to elucidate the prognosis-related molecular mechanisms of NSCLC, which not only helps to further understand the pathogenesis of NSCLC but also provides new ideas and targets for the early diagnosis and treatment of NSCLC.

2. Materials and Methods

2.1. Preprocessing of Data. The transcriptome and clinical data of NSCLC patients were obtained from the GEO database, using the study cohort GSE1206222 ($n = 81$). The enrolled patients' relevant somatic mutation data were also acquired from the aforesaid database. The original file was used to apply the robust multiarray average (RMA) technique on all of the expression data. Besides, "DeEseq2" and "affy" R packages were used to adjust the background, and log2 conversion was performed for the results of this analysis.

2.2. Immune Score, TICS Score, and Pearson Immune Cell Correlation Coefficient Calculation and Immune Cell Infiltration

(1) The relative abundance of 28 immune cells of tumor infiltrating in 81 patients with non-small-cell lung cancer was quantified using single-sample gene set enrichment analysis (ssGSEA). The prognosis of 28 immune cells was assessed using Cox risk regression analysis. The TICS value was calculated in terms of the risk value of immune cells and ssGSEA's NES value, and the Z-score was also calculated.

(2) We conducted principal component analysis on 81 patients' transcripts. In order to obtain genes related to high infiltration, *T*-test and FDR correction were performed. Then, we acquired upregulated and downregulated genes related to high infiltration and clustered upregulated genes and sample, comparing TICS value and immune score value and calculating Pearson correlation coefficient.

2.3. Enrichment Analysis on Function and Path.

(1) We explored the biological process of these different genes by GO and KEGG functional annotations. In addition, we used the "cluster analysis software" *R* package to implement the characteristic genes based on alternative TICS. Meanwhile, the overall relationship between GO terms and immune cells was acquired by the usage of GSEA.

(2) In order to find the relationship between GO terms, the signal pathways related to immune infiltration and the related genes involved were firstly used to construct network by STRING database. Secondly, we mined network modules and analyzed the correlation between genes and the biological processes involved.

(3) We examined and projected the survival of patients with non-small-cell lung cancer and drew a survival curve based on immune factor analyses.

3. Result 1: Construction of Immune Microenvironment Map of NSCLC

One of the most important treatments for non-small-cell lung cancer is immunotherapy (NSCLC). The heterogeneity of immune microenvironment of patients' tissues potentially affects the therapeutic effect. Therefore, the composition of immune cells in tumor tissue must be understood. First, we downloaded the transcriptome data and matched clinical data of 81 patients with NSCLC from GEO database (access number: gse120622). Based on ssGSEA algorithm, we used mRNA expression data of each patient to construct immune cell infiltration maps of NSCLC including 27 types of adaptive and innate immune cells. Central memory CD8 T cell, central memory CD4 T cell, and plasmacytoid dendritic cells are common immune cells in NSCLC tissues, which all exist in 81 patients. In addition, there are some individual specific immune cells, such as immature B cell (Figure 1(a)). We discovered that most immune cells had a high link with activated CD8 T cells, activated B cells, immature B cells, monocytes, effector memory CD8 T cells, and other cells. However, there is no evident link between some immune cells and others, such as the brilliant natural killer cell, activated CD4 T cell, and plasmacytoid dendritic cell (Figure 1(b)). This potentially indicates that there are complex interaction patterns among immune microenvironment of NSCLC patients.

4. Result 2: Construction of TICS Scoring Model Based on Immune Microenvironment of NSCLC Patients

Then, we used Cox regression to analyze and explore the relationship between 27 kinds of infiltrating immune cells and survival time on the basis of the survival data of patients. Meanwhile, we obtained the risk ratio and coefficient of 27 immune cells. The results showed that individual specific immune cells were significantly associated with the survival of NSCLC patients (Figure 2(a)). There was a high correlation between MDSC cells and other five kinds of immune cells (Figure 2(b)). We calculated a TICS score for each patient based on the quantity of these six tumor-infiltrating immune cells (see procedure) and then divided patients into high and low TICS groups based on the median TICS score. In the high TICS group, we discovered that immature B cells, activated B cells, MDSC effector memory CD4 T cells, eosinophils, and regulatory T cells had higher ssGSEA scores ($P < 0.01$) (Figure 2(c)). Various studies have found that the overall survival of many solid tumors, including NSCLC, is positively linked with tumor-infiltrating B cells [8, 20–26]. In addition, tumor-infiltrating B cells and tumor-infiltrating CD4 + T cells created three-level structures of lymphoid that was positively correlated with the survival rate of NSCLC [8, 26]. Furthermore, we analyzed the prognosis of NSCLC patients in accordance with the clinical survival data. We found a substantial difference in prognosis between the two groups, with the high TICS group having a much better prognosis than the low TICS group. This shows that the TICS score constructed can be a reference for clinical prognosis (Figure 2(d)).

5. Result 3: Related Genes of TICS Participate in Important Immune Pathways in NSCLC

Further study on the biological progress related to TICS will help to analyze the molecular mechanism affecting the prognosis of NSCLC. Firstly, we used mRNA expression data based on TICS group to conduct GSEA in patients with NSCLC. The results showed that the up-regulated genes affecting the prognosis of nonsmall cell lung cancer in the high TICS group were significantly related to the signal pathways of T cells and B cells (Figure 3(a)). This indicates that immune regulation is an important biological process affecting the prognosis of NSCLC, and the upregulated genes in the high TICS group are important molecules involved in its immune regulation. Next, we identified significantly different mRNA (FDR <0.01, FC > 2) between high TICS and low TICS groups based on the mRNA expression data of NSCLC.

Finally, 730 significantly upregulated mRNAs in the high TICS group and 121 significantly downregulated mRNAs in the low TICS group were obtained (Figure 3(b)). In accordance with our results, the upregulated mRNA is more likely to be associated with immune function such as CX3CR1, which mediates the migration and adhesion of leukocytes; CCL21 has no chemotactic effect on B cells, macrophages, or neutrophils. In order to further analyze the function of differential mRNA, we used DAVID tool to enrich it. Gene Ontology (GO) results showed that the upregulated mRNA was enriched in the top 10 biological functions. It mainly includes some function related to immune response. Similarly, the upregulated mRNA was enriched in the top ten pathways of Kyoto Encyclopedia of Genes and Genomes (KEGG). It mainly includes cell adhesion molecules and immune and other related signaling pathways. These results fully show that genes related to immune function can affect the prognosis of NSCLC. In addition, we also explored whether the top 10 biological functions (GO) are related. The result shows that these biological functions are closely related and can share the same gene set, indicating that these biological functions have some similarities.

6. Result 4: Immune-Related Genes Are the Key to Distinguish TICS

Next, we explored the interactions among the top 10 biologically functional related mRNAs. Firstly, we select high reliability edge (combined score >0.7) from STRING data. Then, 191 mRNAs were matched to the interaction edge. Finally, an undirected network with 164 points and 777 edges is constructed (Figure. 4(a)). Then, we used MCODE plug-in to obtain subnetworks and selected the subnetwork with high reliability for biological function annotation (Figures 4(b)–44(e)). We found that there was a close interaction among mRNA related to signaling pathway mediated by chemokine. At the same time, we explored whether the four subnetworks can effectively distinguish high TICS from low TICS. We find that the four small networks can distinguish high TICS from low TICS by drawing the ROC curve and calculating the area under the curve, indicating that they are potential markers to distinguish TICS (Figure 4(f)). Among them, CCL19 which is as an important member of chemokine-mediated signaling pathway has demonstrated that its expression level in tumor FSC is related to the degree of immune cell infiltration of CD8 + T cells and tumor accumulation (29391257). In conclusion, the level of CCL19 expression is related to tumor size. The lower the expression level, the larger the tumor. Besides, CX3CR1 is also a marker of T cell differentiation (33658501). These chemokines are also significantly associated with the survival of patients with NSCLC. It is reported that the expression levels of CX3CR1, CXCR4, CXCR5, and CCR7 in tumor tissues are

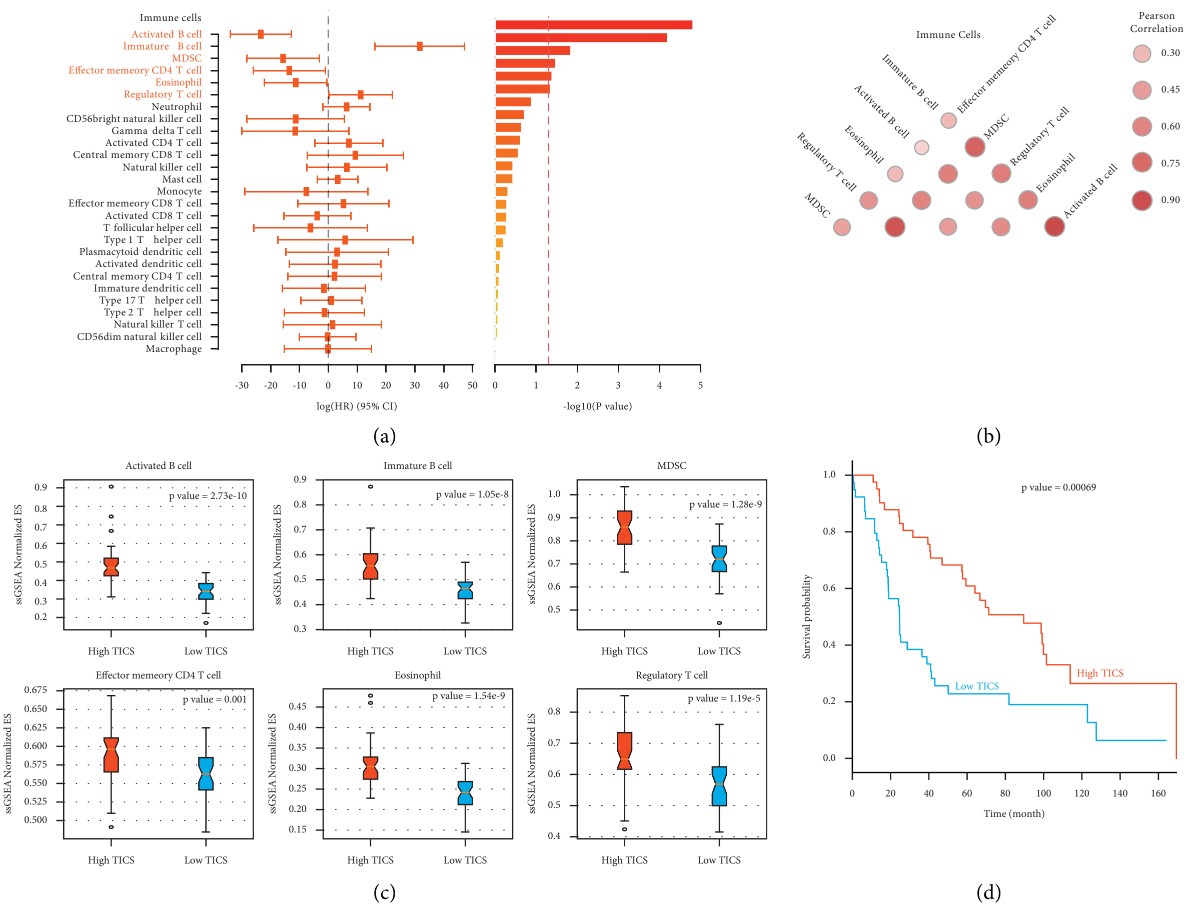

Figure 2:

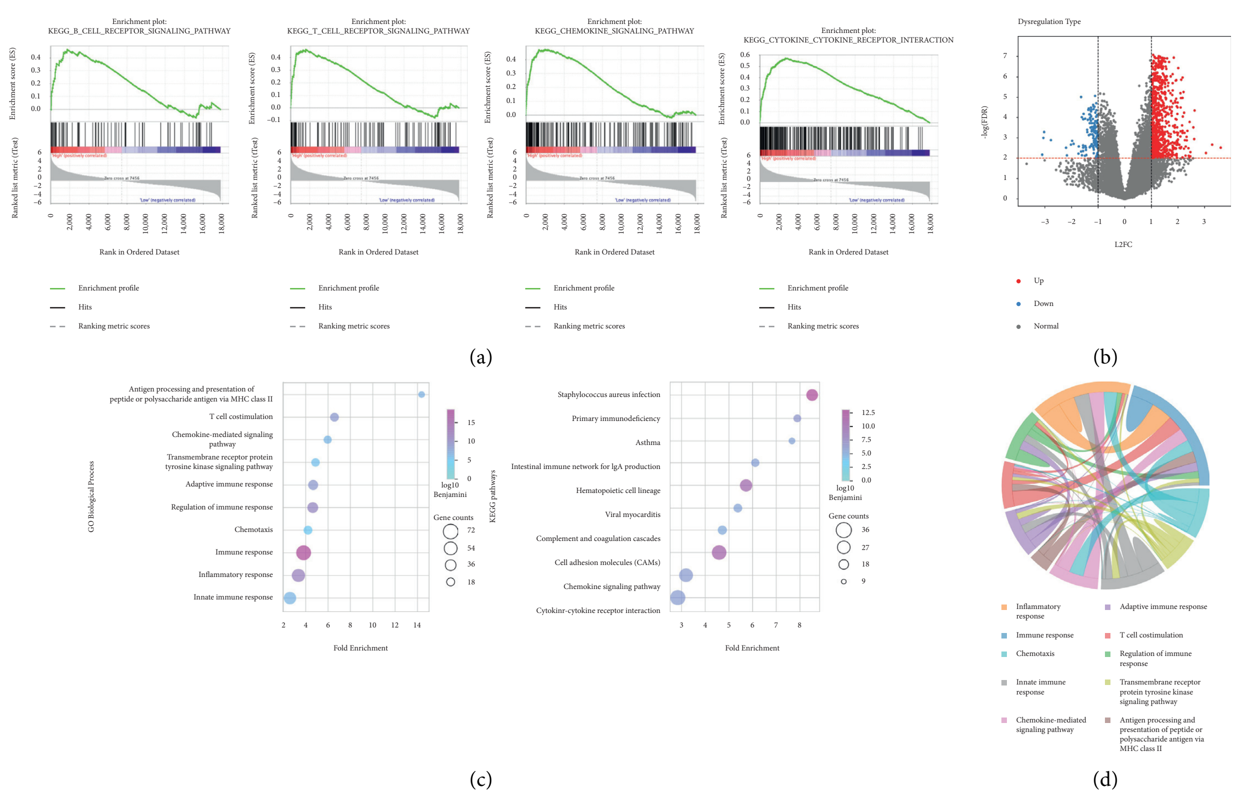

Figure 3:

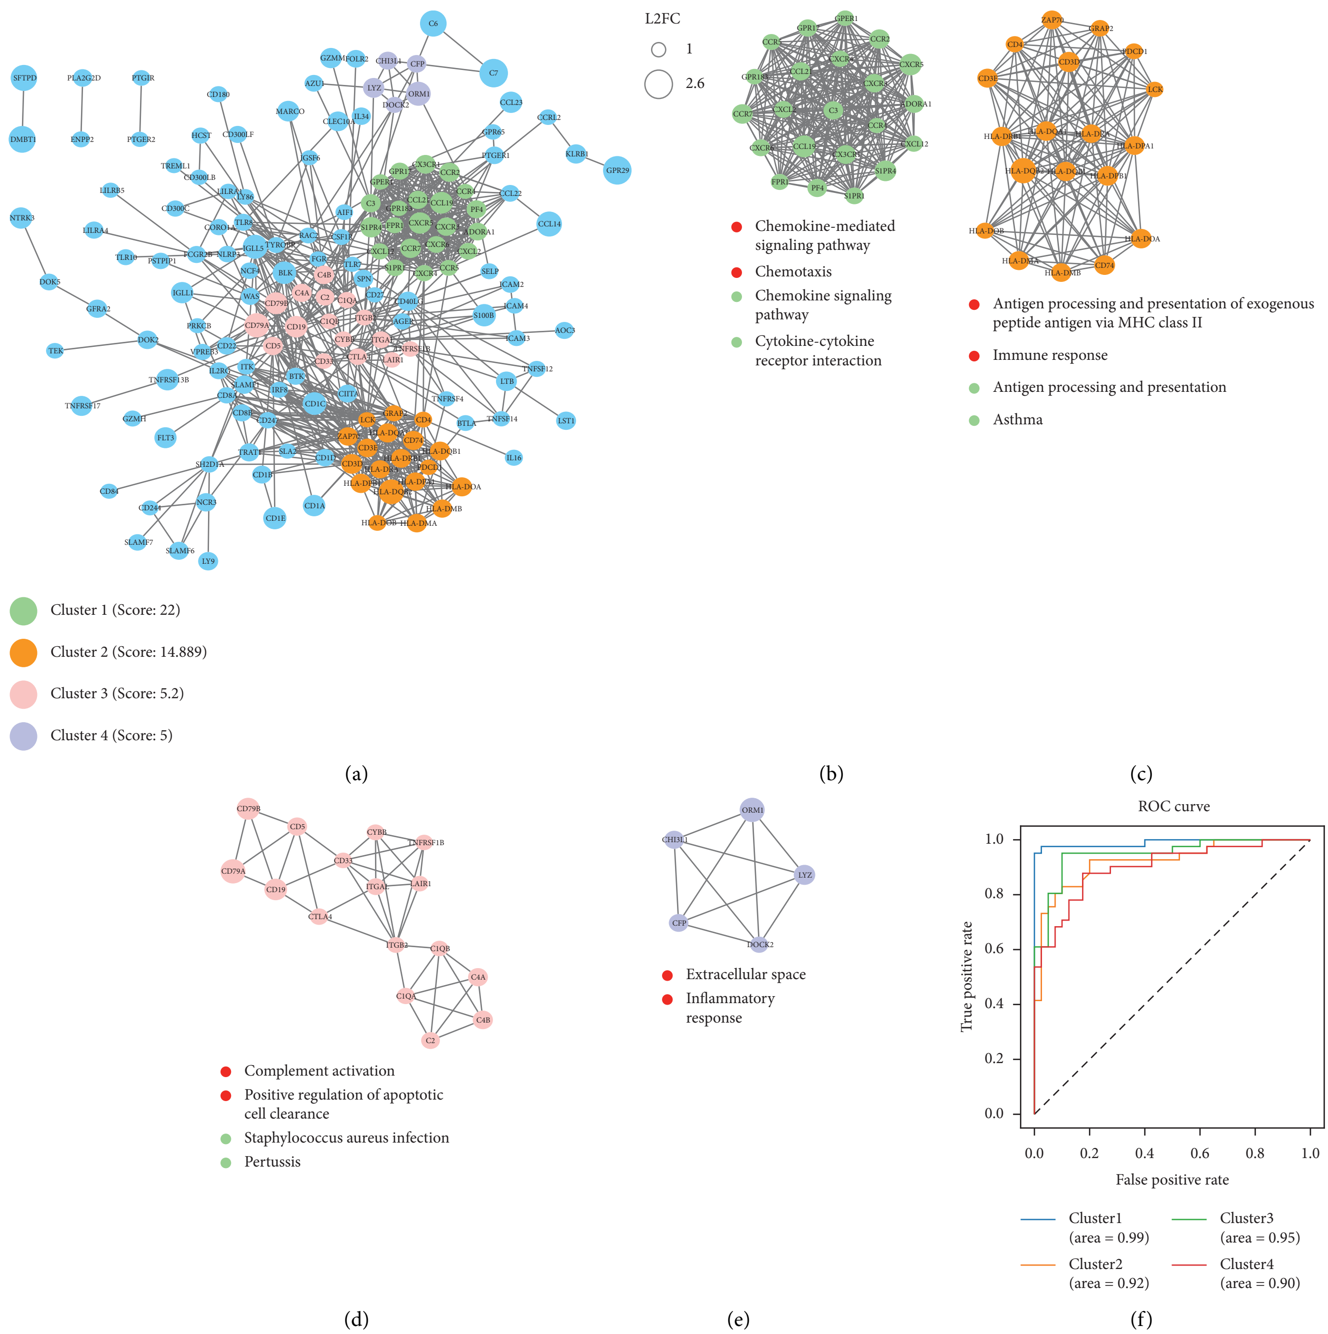

FIGURE 4:

significantly increased, which is able to affect the survival time of patients. The 5-year DFS and 5-year OS of patients with positive CCR7 expression are significantly higher (32896997).

7. Discussion

Tumor cells, fibroblasts, immune cells, different signal chemicals, and extracellular matrix make up the majority of the tumor microenvironment. Tumor microenvironment significantly affects diagnosis, survival, and clinical treatment sensitivity of tumor. Relevant studies have shown that immune cells of adaptive immune and innate immune system can penetrate into tumor tissue, forming tumor immune microenvironment and affecting tumor progression. Patients' survival following chemotherapy is influenced by the quantity of immune cells in the tumor. In this work, we used non-small-cell lung cancer mRNA expression data to create a microenvironment map of the internal immune system of tumor tissue. Combined with the analysis on immune cells combined with survival data of patients, it was found that there was a significant correlation between the survival of NSCLC patients and immature B cell, activated B cell, MDSC, effector memory CD4 T cell, eosinophil, and regulatory T cell. Next, we constructed the TICS scoring model and graded specific TICS score for patients in terms of prognosis-related immune cell content and its relationship with survival. TICS score can discriminate between patients with non-small-cell lung cancer who have a favourable prognosis and those who have a bad prognosis in terms of survival time.

Furthermore, we identified TICS-related genes by using prognostic markers and mRNA expression profiles. We found that many chemokines were significantly upregulated in the high TICS group. For example, there are CX3CR1, CXCR4, CXCR5, and CCR7 which are commonly associated with the survival of NSCLC. Also, high expression of CX3CR1 and CCL19 can affect the immune differentiation of T cells, such as CD8 + T cells. Previous studies have shown that C3 level in biopsy tissues of NSCLC is certainly correlated (24819254) with infiltrating CD4 + and CD8 + T lymphocytes. Moreover, the result of functional enrichment showed that TICS-related genes were involved in a variety of immune-related biological progresses and signaling pathways, which indicates that immune-related genes affect the prognosis of NSCLC patients by regulating the immune process.

We established PPIs among immune genes and high-confidence PPI network by using the top ten genes in biological function. PPI network results show that there is a close interaction between these genes, which indicates that immune genes may have complex coordination and interaction by which they can regulate the body's immune response. Furthermore, we explored four important subnetworks in PPI network. By drawing the ROC curve and calculating the area under the curve, we found that these four subnetworks are important molecular markers to distinguish patients from TICS. In conclusion, our study depicts a comprehensive immune map of NSCLC and constructs a TICS scoring model on the basis of the content of immune cells that can effectively distinguish the prognosis time of patients. Differential gene and enrichment analysis explains the prognosis-related molecular mechanism of NSCLC. PPI network and subnetwork mining effectively identified potential markers to distinguish TICS classification. We hope that the prognosis-related immune markers identified in our study will provide guidance for clinical diagnosis, medication, and prognosis prediction of patients.

This paper aimed to study the adoption of deep learning (DL) algorithm of oral lesions for segmentation of cone-beam computed tomography (CBCT) images. 90 patients with oral lesions were taken as research subjects, and they were grouped into blank, control, and experimental groups, whose images were treated by the manual segmentation method, threshold segmentation algorithm, and full convolutional neural network (FCNN) DL algorithm, respectively. Then, effects of different methods on oral lesion CBCT image recognition and segmentation were analyzed. The results showed that there was no substantial difference in the number of patients with different types of oral lesions among three groups ($P > 0.05$). The accuracy of lesion segmentation in the experimental group was as high as 98.3%, while those of the blank group and control group were 78.4% and 62.1%, respectively. The accuracy of segmentation of CBCT images in the blank group and control group was considerably inferior to the experimental group ($P < 0.05$). The segmentation effect on the lesion and the lesion model in the experimental group and control group was evidently superior to the blank group ($P < 0.05$). In short, the image segmentation accuracy of the FCNN DL method was better than the traditional manual segmentation and threshold segmentation algorithms. Applying the DL segmentation algorithm to CBCT images of oral lesions can accurately identify and segment the lesions.

1. Introduction

In recent years, with the development of computer technology and its popularity in various fields, medical institutions and other fields have been combined with computer technology, and computer-aided means are widely utilized. At present, computed tomography and magnetic resonance imaging (MRI) are widely adopted in the medical field [1]. CT is a type of X-ray computed tomography, in which different tissues absorb different amounts of X-rays. This technology can be applied to display the internal structure of the human body in the form of three-dimensional imaging, thus providing convenience and basis for clinical diagnosis and treatment of diseases and related research [2]. As a feedforward neural network, the CNN can effectively reduce the complexity of the feedback neural network, which can be utilized to identify some two-dimensional images with distorted and nondeformed forms such as displacement and scaling. The extensive application of DL in medical image classification, such as CNN, can provide convenience for researchers based on traditional research methods [3, 4]. CBCT is a cone-beam projection computer recombination tomography influence device. The X-ray generator surrounds the projection body with a low amount of radiation to make a circular digital projection [5, 6]. The projection data are two-dimensional, and a three-dimensional image will be obtained after reconstruction. Image segmentation is the main step and operation from image processing to image analysis. At present, the most commonly utilized segmentation methods are threshold-based, region-based, edge-based, and specific theory-based techniques [7, 8]. In addition, the artificial neural network recognition technology has begun to attract attention and is widely applied in image segmentation. The neural network has a large number of connections and is easy to introduce spatial information, which can better solve the problems such as uneven distribution and noise in image recognition [9].

Oral lesions include apical periodontitis, alveolar abscess, pericoronitis, periodontitis, and jaw osteomyelitis. When the oral lesion is stimulated by the external environment, the pathogenic microorganisms and related products in the lesion will diffuse outward. Then, damage to other systems or tissues and organs is caused, such as rheumatoid arthritis, chronic glomerulonephritis, erythema multiforme, and purulent nephropathy, which will aggravate the condition. However, the application of DL segmentation algorithm to oral lesion CBCT images is relatively lacking, and it is imperative to conduct in-depth research to study its clinical application [10, 11].

In this work, patients with oral lesions treated in the hospital were selected and divided into three groups and then the manual segmentation method, threshold segmentation algorithm, and FCNN DL algorithm were adopted for comparative research. They were applied to oral lesion CBCT image recognition and segmentation, so as to analyze and discuss the influence of FCNN DL algorithm on oral lesion and its effect on CBCT image analysis.

2. Materials and Methods

2.1. Selection and Grouping of Research Subjects. 90 patients who underwent oral lesion treatment in the hospital from September 2018 to September 2020 were selected as the research subjects, including 48 male patients and 42 female patients. Patients who voluntarily withdrew and transferred to the hospital were excluded. The included patients were randomly classified as three groups, blank group (manual segmentation method), control group (threshold segmentation algorithm), and experimental group (FCNN DL segmentation algorithm), with 30 cases in each group.

Inclusion criteria were as follows: (i) patients aged between 40 and 60; (ii) patients with clear consciousness and who could cooperate with treatment and sample collection; (iii) patients diagnosed with oral lesions; (iv) patients with complete clinical data and information; (v) patients without a history of mental illness and emotional stability.

Exclusion criteria were as follows: (i) patients who withdrew and transferred for treatment due to personal reasons; (ii) patients with other serious diseases or infectious diseases; (iii) patients with severe oral lesions or patients who had undergone treatment for similar diseases; (iv) patients with diseases of other systems or organs; (v) patients who had not received cooperative treatment due to personal or other reasons.

2.2. CBCT Data Set and Indicators. CBCT data of selected experimental sample patients were collected, and 90 patients with oral lesion CBCT data containing the final pathological test report were screened and selected. The CBCT data set contained CBCT cross-sectional images of patients with various oral lesions such as jaw osteomyelitis, periapical periodontitis, periodontal abscess, and pericoronitis. The image contained the overall three-dimensional structure of each patient's oral cavity, and the entire data set contained multiple CBCT images. The images were marked according to the type of the corresponding patient's lesion, and the above image marking was based on the medical gold standard of pathology test report and was jointly marked by multiple professional medical staff. After the labeling was completed, the corresponding preprocessing of the image was carried out. The CBCT images with value less than 0 were screened and set to 0, and the CBCT images with value greater than 3000 were screened and set to 3000. Then, the resulting image was divided by 3000 and multiplied by 255 to convert it into unit 8 digital format, and the preprocessed image was saved in the JPG image format. Finally, the accuracy and sensitivity of its classification were taken as evaluation indicators. The function of the denoising method in the two-dimensional image is defined as equation (1), and the function of the denoising method in the CBCT data CNN is defined as equation (2) in the three-dimensional space.

$$A(x, y) = \frac{1}{2\pi\theta^2} a^{\left(x^2+y^2/2\theta^2\right)}, \tag{1}$$

$$A(x, y, z) = \frac{1}{2\sqrt{2}\pi^{1.5}\theta^3} a^{\left(x^2+y^2+z^2/2\theta^2\right)}. \tag{2}$$

A represents the weight of each pixel; θ is the Gaussian distribution standard deviation parameter; the value of θ is 1.5; x is the abscissa value of the current pixel relative to the center pixel; and y is the abscissa value of the current pixel relative to the center pixel.

2.3. Three Different Segmentation Algorithms for CBCT Image Segmentation. Manual segmentation: manual image segmentation should be performed by doctors with rich clinical experience and over 10 years of experience in the evaluation of oral diseases. The doctor evaluated and analyzed oral lesions and utilized mimics14.11 software to sketch out the edge of lesions on the oral CBCT image by hand.

Threshold segmentation algorithm: the segmentation method referred to CBCT image segmentation by setting appropriate tissue threshold in advance. The threshold was set on the mimics14.11 software, and the threshold of the 3D oral image model was set. The HU value region was preliminarily selected and the tissues under this region were monitored in real time. The selected area was slightly adjusted by medical professionals with extensive clinical experience until the threshold was set to the segmentation edge.

FCNN DL segmentation algorithm: the CNN can identify the image through sliding window, selective search, and other methods. This algorithm can identify and judge whether the window is the target object. Its recognition is defined as the regression problem of the occurrence probability of each target in image segmentation. This method adopts FCNN DL based on CBCT image segmentation to perform image segmentation on oral lesion evaluation and utilizes average crossover ratio as the final indicator.

$$R = \frac{|M \cap N|}{|M \cup N|}. \tag{3}$$

R represents the average cross-union ratio, $M = \{(i, j)\}$ represents the point set that satisfies $Y_{i,j} = 1$ in the image, and $N = \{(i, j)\}$ represents the point set that satisfies $Y_{i,j} > 0.5$ in the image. The learning algorithm flow is shown in Figure 1.

2.4. Evaluation Indicators. The oral lesions of blank, control, and experimental groups were segmented according to the corresponding algorithm. The traditional manual segmentation, threshold segmentation algorithm, and FCNN DL algorithm were compared regarding the oral lesion CBCT image recognition and segmentation performance. Moreover, the running time, segmentation volume and surface area, image segmentation accuracy, and effect on lesions and lesion model segmentation of three methods were analyzed. The performances of the three algorithms were compared through the above indicators, and their recognition rate and accuracy of oral lesion image segmentation were studied.

2.5. Statistical Analysis. The data were processed via the SPSS19.0 version software. Measurement data were expressed as mean ± standard deviation, and count data were expressed as percentage. The t test was adopted to compare the segmentation volume and surface area, as well as running time of manual segmentation, threshold segmentation, and FCNN algorithm. Analysis of variance was utilized to compare the segmentation effect of lesions and lesion models. The difference was statistically significant at $P < 0.05$.

3. Results

3.1. Location and Type of Oral Lesions in Patients of the Three Groups. The 90 patients selected for the treatment of oral lesions were diagnosed in the experiment, and the location of the lesion was judged, as shown in Figure 2. The oral lesions of the three groups of patients were mainly periodontal, pulpal, periapical, and other chronic oral inflammations. The incidence of periodontal lesions was the highest, reaching 38%, followed by dental pulp and periapical infectious lesions, which was 29% and 17%, respectively.

The types of lesions were periodontal abscess, apical periodontitis, and jaw osteomyelitis. The types of oral lesions that occurred in the three groups of patients and the number of patients with each type of lesion are statistically shown in Figure 3. Three oral lesions of periodontal abscess, periapical periodontitis, and jaw osteomyelitis occurred in each group of patients, and there was no evident difference in the number of patients with different types of oral lesions in the three groups ($P > 0.05$).

3.2. Local Oral Lesion. Figure 4 is a partial view of the lesion in a patient with periodontal abscess. The gums at the lesion site were red and swollen, with protruding abscess formation accompanied by abscess flow and submaxillary lymph node enlargement.

Figure 5 is a partial view of the lesion in a patient with apical periodontitis. There were obvious inflammatory changes in the surrounding tissues and swelling of the surrounding tissues, apical cysts, discoloration of teeth, and hyperplasia of granulation tissue at the mouth of the apical mucosal fistula.

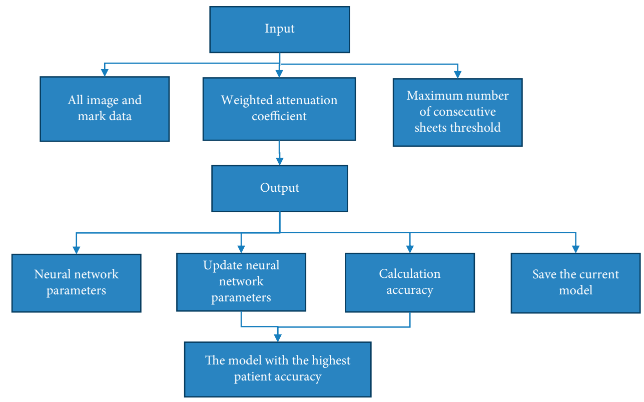

Figure 1: Schematic diagram of the DL segmentation algorithm flow.

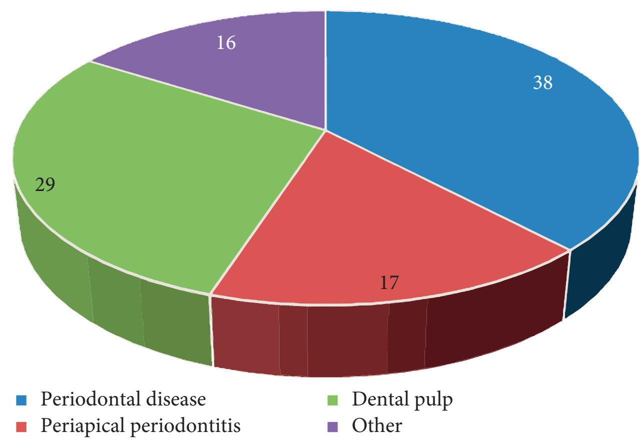

Figure 2: Location of the patients' oral lesions.

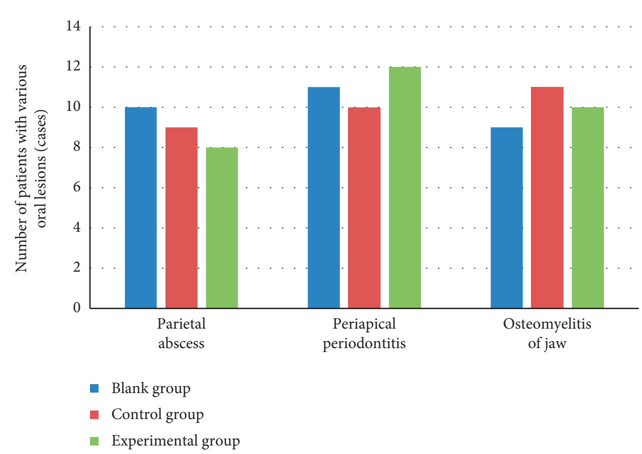

Figure 3: Types of oral lesions and number of patients.

3.3. Local Oral Lesion by Different Algorithms. Figure 6 shows the CBCT image of a patient with periapical periodontitis obtained by the traditional segmentation algorithm. The

Figure 4: Periodontal abscess.

Figure 5: Periapical inflammation.

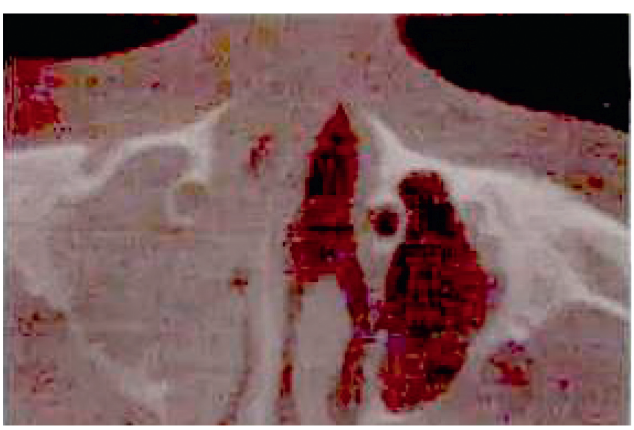

Figure 6: Traditional segmentation of the CBCT image of apical periodontitis.

lesion site showed continuous and complete low signal; obvious edema, abscess, and inflammatory reaction were observed at the lesion site; and the lesion edge segmentation was incomplete.

Figure 7 is a CBCT image of a patient with apical periodontitis obtained by the tissue threshold segmentation algorithm. The lesion site showed uneven high signal, and the surrounding tissue showed a flat oval low-signal shadow. There were obvious inflammatory changes in the lesion site,

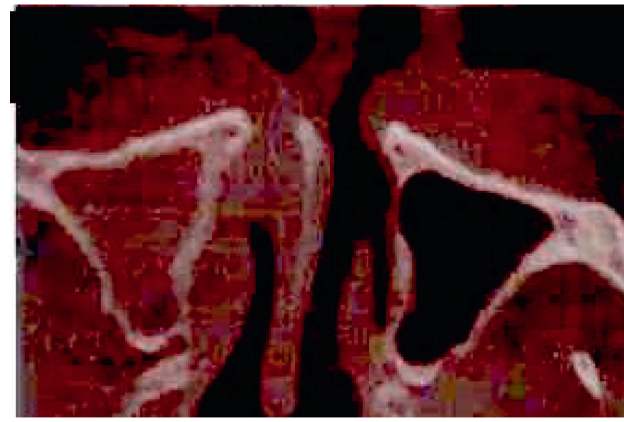

Figure 7: CBCT image of apical periodontitis by the threshold segmentation algorithm.

and the lesion edge segmentation was relatively complete and clear.

Figure 8 is a CBCT image of a patient with periodontal abscess by FCNN DL segmentation. Obvious abscesses appeared around the lesions and manifested as relatively loose mid-to-low-signal shadows, the edges of the lesions were completely segmented, and the lesion location was accurately identified.

3.4. Contrast of Segmentation Time and Accuracy of Three Segmentation Algorithms. Figure 9 shows the accuracy comparison results of the traditional segmentation algorithm, the tissue threshold segmentation algorithm, and the FCNN DL segmentation algorithm for oral lesion CBCT image segmentation. The segmentation accuracy of lesions in the experimental group was relatively higher and reached 98.3%, while those of the blank and control group were 78.4% and 62.1%, respectively. In contrast to the blank group, the accuracy of segmentation of CBCT images in the control and experimental group was notably higher ($P < 0.05$) and the accuracy of segmentation in the experimental group was considerably higher than in the control group ($P < 0.05$).

Figure 10 shows the comparison results of three segmentation algorithms for oral lesion CBCT image segmentation. The segmentation time of the FCNN DL segmentation algorithm was 10.2 ± 1.4 min, and that of threshold segmentation algorithm was 16.3 ± 1.6 min. The segmentation time of CBCT images in control and experimental groups was evidently shorter than in the blank group ($P < 0.05$), and the segmentation time in the experimental group was shorter than in control group ($P < 0.05$).

3.5. Contrast of Lesion Volume and Surface Area Obtained by Three Segmentation Algorithms. Figure 11 shows the comparison results of the volume and surface area of the oral lesion CBCT image segmentation by three segmentation algorithms. No evident difference was seen between the blank and experimental group in terms of split surface area and volume ($P > 0.05$). The volume and surface area in the

Figure 8: CBCT image of the lesion by DL segmentation.

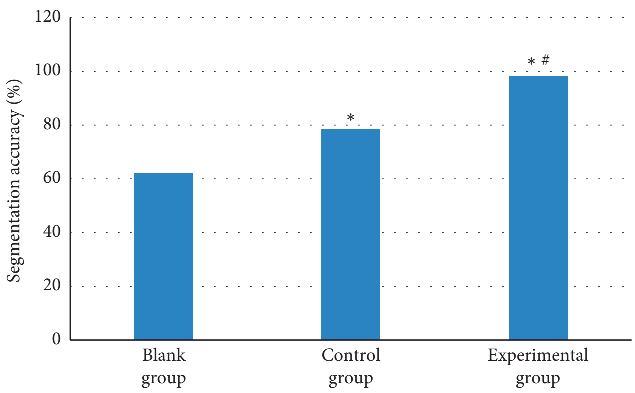

Figure 9: Contrast of accuracy of three segmentation algorithms. Note: the symbols * and # indicate that the difference was substantial, versus the blank group and control group, respectively ($P < 0.05$).

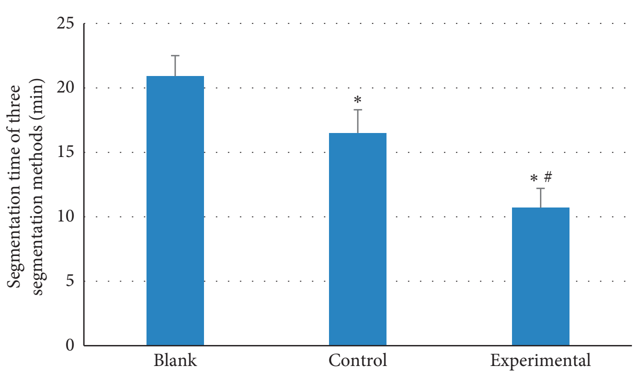

Figure 10: Contrast of running time of three segmentation algorithms. Note: the symbols * and # indicate that the difference was substantial, versus the blank group and control group, respectively ($P < 0.05$).

control group were considerably smaller than in the blank group ($P < 0.05$), and the split volume and surface area in the experimental group were remarkably larger than in the control group ($P < 0.05$).

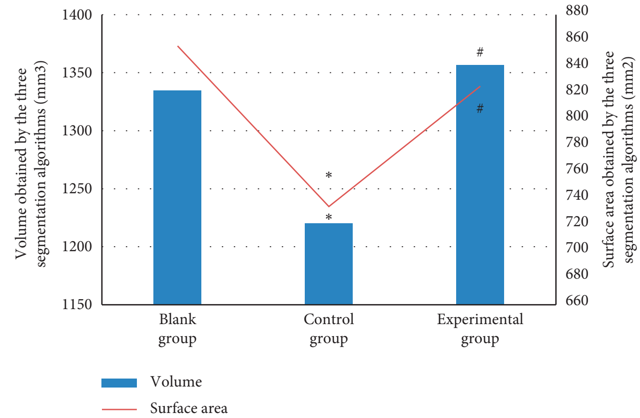

Figure 11: Contrast of the surface area and volume of the three segmentation algorithms. Note: the symbols * and # indicate that the difference was substantial, versus the blank group and control group, respectively ($P < 0.05$).

3.6. Segmentation Effect Comparison. Figure 12 shows the comparison results of the segmentation effects of the three segmentation algorithms on oral lesions and oral lesion models. The threshold segmentation algorithm and the FCNN DL algorithm had favorable segmentation effects on the lesion and the lesion model. The segmentation effect on the lesion and the lesion model in the experimental and control group was obviously superior to that in the blank group ($P < 0.05$). There was no substantial difference in the segmentation effect on lesions and lesion models between the control and experimental group ($P > 0.05$).

4. Discussion

With the application and popularization of CBCT and other three-dimensional medical imaging technologies in medical testing and treatment, as well as the improvement of human lifestyle, oral health has gradually attracted attention [12]. Stomatologists have begun to try to apply CBCT to the detection and treatment of oral lesions. Since the visualization of CBCT images and data provides important reference value for medical personnel to detect through image segmentation and analysis, the occurrence and development of diseases can be monitored intuitively [13, 14]. Early medical image research and learning algorithms often have large limitations and are not suitable for the diagnosis and treatment of all diseases. In addition, most of the research is on the human brain, chest, and abdominal organs. Therefore, it is necessary to conduct in-depth research on image analysis and algorithms and apply them to oral diseases [15, 16]. According to statistics, the rate of oral diseases in China is only 9~10%, which also has a great impact on oral health. Oral diseases, however, can cause serious bacterial or viral diseases if they fail to receive prompt diagnosis and treatment. Systemic diseases will even appear, such as chronic pharyngitis, rheumatoid arthritis, coronary heart disease, and chronic nephritis [17, 18]. In addition, relevant studies have found that oral therapy, such as periodontitis, has a bidirectional relationship with diabetes mellitus, in that

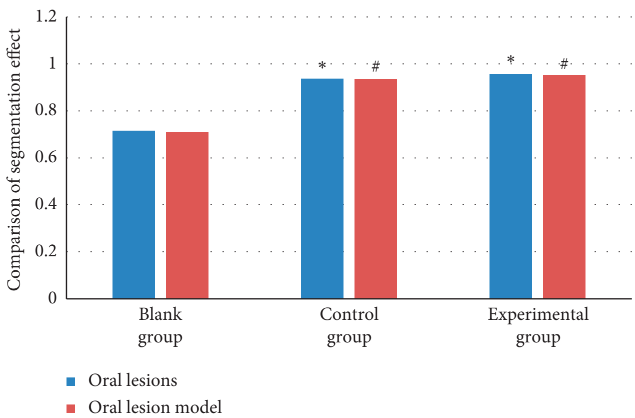

Figure 12: Comparison of the segmentation effects of three segmentation algorithms. Note: the symbols * and # indicate that the difference was substantial, versus the blank group and control group, respectively ($P < 0.05$).

severe periodontitis can aggravate diabetes mellitus and that patients' glycemic control ability is obviously worse than that of normal people. On the contrary, diabetes can also cause periodontitis and the bacteremia of periodontitis is likely to induce myocardial infarction and coronary heart disease [19]. Therefore, it is necessary to pay close attention to oral evaluation.

In this work, patients with oral lesions were selected and classified into three groups and then the manual segmentation method, threshold segmentation algorithm, and FCNN DL algorithm were adopted for comparative study. They were applied to oral lesion CBCT image recognition and segmentation, to analyze and discuss the influence of FCNN DL algorithm on oral lesions and its effect on CT images. The results showed that the experimental group was remarkably better than the blank and control group in terms of running time and accuracy of lesion segmentation. The experimental group and control group were remarkably better than the blank group in terms of the segmentation effect of lesions and lesion models ($P < 0.05$). The results were consistent with the research results of Sharma et al. [20], showing that the image segmentation accuracy of the FCNN DL method was better than the traditional manual segmentation and threshold segmentation algorithms, for it reduced the running time. Applying the DL segmentation algorithm to oral lesion CBCT images can accurately identify and segment the lesions, providing convenience for treatment, which can be applied to clinical diagnosis and treatment.

5. Conclusion

Based on the oral lesion CBCT images, the analysis and research on the FCNN DL segmentation algorithm were carried out. 90 patients were selected, and then, the DL algorithm was applied to their oral lesion CBCT images. The manual segmentation method, threshold segmentation algorithm, and FCNN DL algorithm were adopted to process images of patients in different groups for comparative study. It was found that the image segmentation effect accuracy of the FCNN DL was better than that of the traditional manual segmentation and threshold segmentation algorithms and the running time was notably reduced. The adoption of DL segmentation algorithm in oral lesion CBCT image segmentation can accurately identify and segment the lesions, which could provide convenience for treatment, and it was suitable to be applied in clinical diagnosis and treatment. However, the sample size selected in this study is small, which may have a certain impact on the experimental results, and the representativeness is low. Therefore, the sample size will be increased in subsequent experiments, and the influence of FCNN DL algorithm on oral lesion and CT image analysis will be further analyzed and discussed. In conclusion, this research provides data support and theoretical basis for the clinical diagnosis and treatment of oral lesions, as well as the adoption effect of FCNN DL segmentation algorithms on oral CBCT images.

Norovirus monitoring and early warning can be used for diagnosis without etiological testing, and the treatment of this disease does not require the antibiotics. It often occurs in preschool children and affects their growth and development, so the coping measures for this disease are more prevention than treatment. In this study, the clinical data of 2133 children with diarrhea were collected. Based on the artificial intelligence (AI) algorithm of wavelet transform, a related model for data mining and processing of children's intestinal ultrasound images and stool specimens was constructed. Then, the norovirus infection trend was warned based on the wavelet analysis algorithm model. The results showed that the intestinal ultrasound image processed by the wavelet transform algorithm was clearer. The positive detection rate of norovirus in children with clinical diarrhea was as high as 59%, and the children had different degrees of body damage, of which the probability of compensatory metabolic acidosis was the highest. The epidemiological analysis found that children with norovirus infection were mainly concentrated in the age group under 2 years old and over 5 years old and showed a peak of infection in December. In summary, the intelligent algorithm based on wavelet transform can realize the noise reduction of intestinal ultrasound, and it should protect children with susceptible age and susceptible seasons to reduce the clinical infection rate of norovirus.

1. Introduction

Norovirus, also known as Norwalk virus, is highly similar to common viruses except for antigenicity [1]. The diarrhea caused by the virus is extremely prevalent, and infection can occur throughout the year. The main population of the disease includes adults and school-age children, with a high incidence in cold seasons [2]. In Western developed countries, more than 80% of all nonbacterial diarrhea outbreaks are infected by the virus every year. Besides, there are similar results in many developing countries [3]. Among children patients with diarrhea under 6 years old in China, the detection rate of norovirus is about 17%, and it has been found that the infection of this virus is also extremely common in the population of China through blood routine investigation [4]. The virus has distinct characteristics such as rapid mutation, strong resistance, and diverse transmission routes. Patients may have clinical manifestations such as diarrhea, vomiting, and fever after illness [5]. According to relevant investigations and studies, norovirus outbreaks have been dominated by other infectious diarrheal diseases in China since 2010. Especially, since the winter of 2014, norovirus outbreaks have increased significantly, higher markedly than previous years, so monitoring and early warning of this virus has become particularly important [6].

Clinical examinations for diarrhea caused by the virus usually use X-ray, endoscopy, B-mode ultrasound, and other examinations, among which B-mode ultrasound has become one of the main examination methods due to its noninvasive and nonradioactive advantages [7]. A large amount of information of the children patients have been recorded by B-mode ultrasound, such as abdominal changes after infection. It is necessary to carry out data mining and summarize the main data information so as to analyze the massive and complex data [8]. However, information deviation is caused due to the influence of noise during B-mode ultrasound examination, so the artificial intelligence algorithm is needed to deal with it [9]. Wavelet transform is a new type of the transform analysis method, which is evolved from the idea of localization of short-time Fourier transform. It overcomes the disadvantage that the window size does not change with frequency and provides a "time-frequency" window, which is an ideal tool to realize signal time-frequency analysis and processing at present [10]. Using the wavelet transform, noise and useful signal can be decomposed to different scales, and wavelet coefficients can be converted, so that useful signal can be distinguished from noise [11]. At present, the application in the science and technology information industry has made remarkable achievements, and it has become a critical part of contemporary scientific and technological work [12]. What is more, its application research in epidemic diseases is relatively small. In order to evaluate the feasibility and effectiveness of data mining technology based on the wavelet transform artificial intelligence algorithm for norovirus monitoring and early warning, wavelet transform artificial intelligence algorithm-based data mining technology was adopted in this study, so as to discuss the diarrhea caused by norovirus infection. Therefore, its feasibility in the monitoring and early warning of virus infection could be obtained, thereby providing reference significance for the application of other diseases.

2. Materials and Methods

2.1. General Data. 2,133 children patients with diarrhea admitted to hospital from April 2016 to June 2020 were selected as the research objects in this study. Among them, 1,154 were boys and 979 were girls, aged 30 days–6 years old after birth, with an average age of 2.13 ± 0.22 years old. The inclusion criteria were as follows: children patients defecated more than 3 times a day and had abnormal changes in fecal characteristics; children patients were younger than 6 years old and did not suffer from other diseases such as pus and blood in the stool and pneumonia; children patients had congenital digestive system diseases; and the family members of the children patients were aware of this study and signed the informed consent forms. The exclusion criteria were as follows: children patients were combined with other basic diseases that affected digestive function; the parents of the children patients did not cooperate with the researcher; the children patients had poor compliance; and the children patients were infected with other epidemic diseases during the research period. Most importantly, the medical ethics committee of hospital reviewed and approved this study.

2.2. Methods

2.2.1. Specimen Collection. 5 mL of the stool specimen of each included child patient was taken and put into a sterile and dried container. Then, it was placed in phosphate buffer, which was mixed into a 15% stool suspension. Afterwards, the suspension was divided into two evenly. One part was used to detect rotavirus, and the remaining one part was stored in a water tank at a temperature of −80°C to extract deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) from the child patient.

2.2.2. Virus Detection. The norovirus detection kit (produced by Shanghai Fusheng Industrial Co., Ltd.) was adopted in this study, and the detection was carried out based on the operating instructions of the immunochromatography kit. The supernatant was extracted from the stool suspension, which was mixed with the enzyme marker evenly. Next, the mixture was added to the specimen well, which was placed at room temperature and then added with enzyme marker for incubation at room temperature. Finally, the incomplete binding peroxidase was rinsed with lotion, and the results in the kit were observed.

The rotavirus antigen kit (produced by Shanghai Kemin Biotechnology Co., Ltd.) was applied in this study, and the operating instructions of the enzyme-linked immunosorbent assay kit were refereed for detection. The specimens and standard specimens were added in the coated micropores with prereported captured antibodies and washed thoroughly after incubation. Then, the substrate tetramethylbenzidine (TMB) was used for color development. The absorbance value was calculated at 420 nm by using the enzyme-plate method.

2.3. Ultrasonic Testing. The Siemens 18L6HD and other color Doppler ultrasound diagnostic equipment was adopted in this study, with the high-frequency probe (7.0–12.0 MHz). Before the examination, the children patients should fast for 3-4 hours, the infants who used milk should fast for more than 4 hours, and the infants and children patients after supplementary food should be fasted for more than 6 hours. During the examination, each child patient was placed in a supine position. The examiner would probe coated with a small amount of the coupling agent and then put on the latex sleeve; in the case of children relaxed, the probe would slowly contact the skin of children, began ultrasound scanning, and carefully observe the stomach and intestinal wall layer changes of children patients.

2.4. Analysis of Wavelet Transform Algorithm. The wavelet analysis algorithm belonging to a kind of window size is fixed but the shape can be changed, which is called the "mathematical microscope." Moreover, it can play its high time resolution and low frequency resolution in the high-frequency part, which shows that the wavelet transform has the self-adaptability to the signal. The wavelet change algorithm was adopted in the denoising of the intestinal ultrasound images of children in this study, so as to provide data for the follow-up exploration of the body damage of children.

In the wavelet transform algorithm, the following can be obtained if $P(t)$ represents a square cocoa integrable function.

$$P(t) \in R^2(e). \tag{1}$$

In equation (1), e stands for a constant, R means the upper limit of space, and its Fourier transform $P(w)$ satisfies the following equation.

$$C_P = \int_{-\infty}^{+\infty} \frac{|P(w)|^2}{w} lw < \infty. \quad (2)$$

Then, the frequency domain of wavelet transform can be expressed as follows.

$$wt_i(a,s) = \frac{\sqrt{a}}{2\Pi} \int_{-\infty}^{+\infty} i(w)^P (awe)^{ws} w. \quad (3)$$

In equation (3), a represents different transformation scales, the signal to be analyzed is represented by i, and s indicates the displacement of the fundamental wavelet function.

Continuous wavelet transform is to expand and shift the mother wavelet $P(t)$ to obtain the function $P_{a,s}(t)$, which is expressed in the following equation.

$$P_{a,s}(t) = \frac{1}{\sqrt{a}} P\left(\frac{t-s}{a}\right). \quad (4)$$

In (4), $P_{a,s}(t)$ is the wavelet basis function that depends on the parameters. The expansion and contraction in the time domain and the time translation can be expressed in Figures 1 and 2.

Discrete wavelet transform usually adopts binary discrete form, as shown in the following equation.

$$a = 2^x. \quad (5)$$

Thus, (6) can be attained.

$$P_{x,s}(t) = 2^{x^2} P(2^x t - s). \quad (6)$$

The basic principle of wavelet transform noise reduction is presented in the following equation.

$$Y(o) = G(o) + e(o), \quad o = 1, 2, \ldots, n-1. \quad (7)$$

Among them, $Y(o)$ represents the signal with noise, $G(o)$ stands for the actual signal, and $e(o)$ expresses the magnitude of the noise.

Wavelet transform can decompose signal and noise and separate useful and useless signals. The specific performance is that useful signals have larger decomposition coefficients in some components, while the decomposition coefficients of noise are smaller. In addition, some components have the opposite performance. The decomposition coefficient of noise is large, while the decomposition coefficient of useful signal is small. Finally, the final result can be obtained by coefficient reconstruction after transformation (Figure 3).

The signal-to-noise ratio (SNR), root mean square error (MSE), and carrier-to-noise ratio (CNR) were adopted to evaluate the denoising effect of the algorithm. The calculation equations of SNR, MSE, and CNR are as follows:

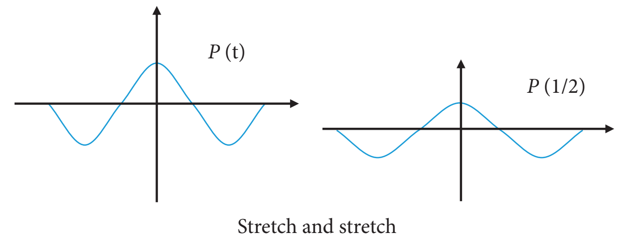

Figure 1: The stretching transformation of wavelet in time domain.

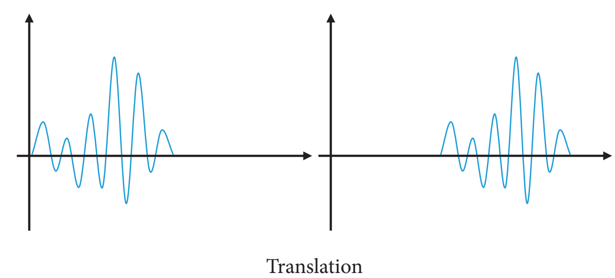

Figure 2: Time shift of wavelet.

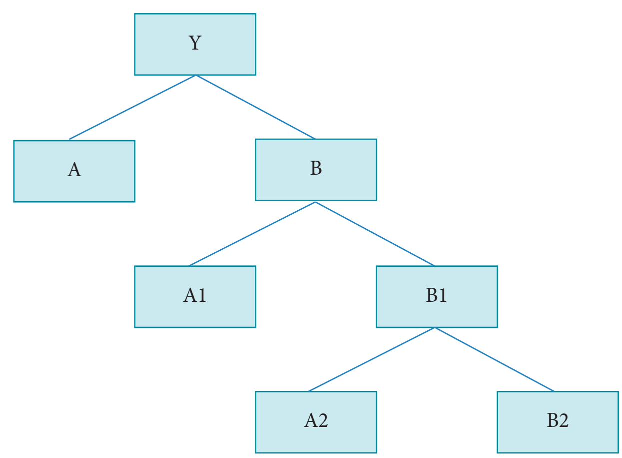

Figure 3: Three-layer decomposition of wavelet transform. A and B stand for weight.

$$\mathrm{SNR} = \frac{S}{N0B},$$
$$\mathrm{MSE}(y, \hat{y}) = \frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{y})^2. \quad (8)$$
$$\mathrm{CNR} = \frac{S}{N0}.$$

In the above equations, S represents the signal power, $N0B$ represents the noise power, and $N0$ represents the noise power spectral density. The higher the SNR, the more prominent the signal and the better the quality of the original signal or transmission information signal. The smaller the MSE value, the better the accuracy of the processed image.

Figure 4: Intestinal ultrasound images of a child patient. (a) The image of a child, female, 10 years old, suffered from abdominal pain and diarrhea for 2 weeks. (b) The image of a child, male, 9 years old, suffered from a tight abdomen, obvious diarrhea, and abdominal pain.

3. Results

3.1. Processing Performance and Results of Wavelet Transform Algorithm. The ultrasound examination results of a child patient with confirmed norovirus infection were selected randomly from the included research objects. Figure 4 shows that there was inhomogeneous echo in the center of the intestine of this child patient, hypoecho in the outer circle, and thickening of the mesentery at the margin of part of the intestinal wall with enlarged lymph nodes. Figure 5 shows the results of the noise reduction effect evaluation. Compared with the Contourlet threshold and Donoho threshold, the wavelet transform algorithm used in this study showed a higher SNR value after ultrasonic image denoising and a smaller MSE value. As illustrated in Figure 6, with the increase of the ultrasonic imaging parameter b value, the CNR value after wavelet transform denoising was always lower than the SNR value.

3.2. Detection Rate of Positive Virus. Figure 7 shows that the positive detection rate of norovirus was higher greatly than the positive detection rate of rotavirus, and the difference was statistically substantial ($P < 0.05$).

3.3. Laboratory Test Results of Children Patients with Positive Infections. Figure 8 shows that children patients with positive infections had different degrees of body damage. Among them, there were 132 cases of decompensated metabolic acidosis, 144 cases of compensatory metabolic acidosis, 32 cases of hypokalemia, 25 cases of hyponatremia, and 39 cases of liver damage.

3.4. Age Distribution Results of Children Patients Infected with the Virus and Seasonal Distribution of Virus Infection in Children Patients. Table 1 suggests that the age of children patients infected with the virus was concentrated in children under 2-3 years old and above 5 years old. In addition, the children patients were susceptible to the virus in winter, with the majority in December (Table 2).

4. Discussion

Norovirus belongs to a subfamily of Norovirus, namely, the prototype representative strain of human Caliciviridae [13]. Norovirus infections were first detected in China in the early 1990s. Besides, there were outbreaks all over the country since then. In recent years, the infection caused by this virus still shows an increasing trend [14]. The incubation period of the disease is within 1-2 days, which is relatively short [15]. There are two studies comparing the symptoms of diarrhea and vomiting in cases of different age groups [16]. The course of norovirus infection is relatively short, and the duration of clinical symptoms such as diarrhea and fever is only about 3 days. In addition, the patients show poor immunity, and the recovery time after infection is longer [17, 18]. Although the consequences caused by norovirus infection are not very serious, it still cannot be ignored. There are still cases of death caused by infection in clinical practice, and there is also the probability that healthy people will develop into severe cases after being infected with norovirus. Therefore, monitoring and early warning of norovirus has become an essential link.

Wavelet denoising is to eliminate noise through short waves, which is consistent with the basic principle of Gaussian denoising [19]. In recent years, the wave theory has developed rapidly, and it has been widely used in practice due to its good time-frequency characteristics. In new fields, the wave theory has also attracted the attention of many scholars because of its good application effects [20]. In mathematics, denoising is essentially a function approximation problem, that is, how to find the best approximation to the original signal in the function room, and the wave-generating function is expanded and shifted according to the proposed criteria, in order to complete the distinction between the original signal and the noise signal. In other words, the best mapping is found from the actual signal space to the wave function space. From the point of view of

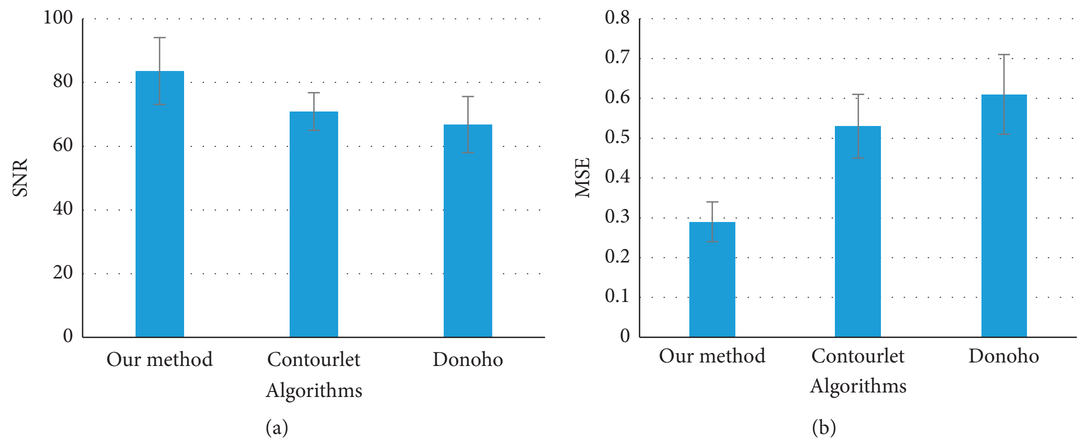

Figure 5: Evaluation of the noise reduction effect. (a) The comparison on SNR. (b) The comparison on MSE.

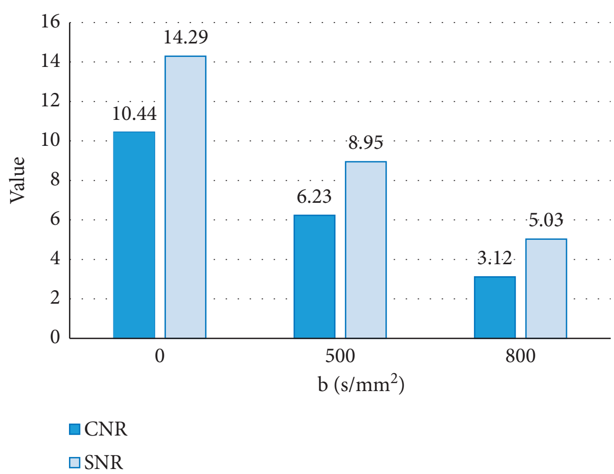

Figure 6: Comparison on SNR of images under different b values.

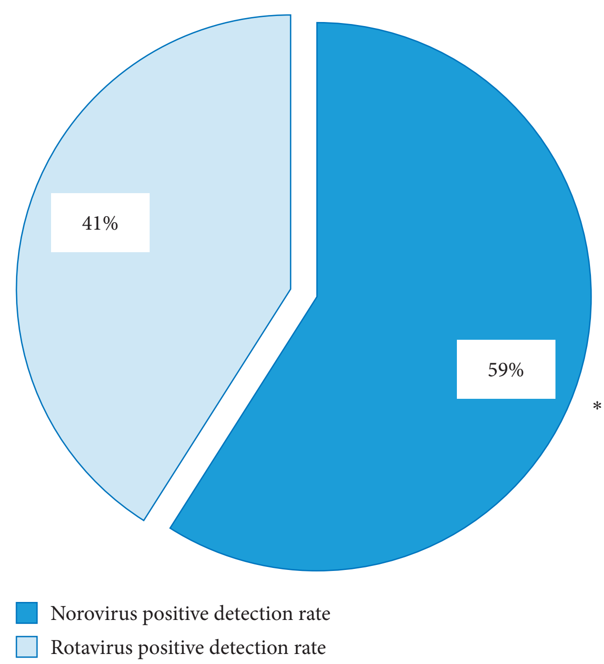

Figure 7: Detection rate of positive virus. *The difference among the groups was statistical obvious ($P < 0.05$).

signal science, denoising is a problem of signal filtering. Although denoising can be regarded as low-pass filtering to a large extent, it is better than the traditional low-pass filtering in retaining signal features completely after processing [21]. Thus, it is found that wavelet denoising is actually a combination of feature extraction and low-pass filtering. Through collecting a large number of cases, all the research objects underwent the ultrasound examinations in this study, and the results were processed by the wavelet transform algorithm, so the following conclusions were drawn. The positive detection rate of norovirus was higher than that of rotavirus. The age of children patients infected with norovirus was concentrated in children under 2-3 years old and above 5 years old, and the children were susceptible to norovirus in winter and most of them were in December. From this, the susceptible population and susceptible season of norovirus could be known.

Data mining technology is to obtain valuable knowledge and rules that users may be interested in from a large amount of data in the storage space, so as to tap out the potential of users [22]. These rules can provide useful information for business decisions and financial forecasts. In 1990, with the wide application of the network system and the rapid development of network technology, database technology has stepped into a new stage of management of graphs and images from the management of some simple data in the past, and the amount of data is also increasing [23]. According to the analysis, data mining is mainly carried out from the four aspects of classification, estimation, prediction, and clustering. Therefore, it is necessary to make sufficient preparations for the purpose of the operation and data collection before the operation. In this study, the ultrasound examination results and virus detection results of a large number of children patients were collected and analyzed, so as to construct the correlation model of related

Table 1: Age distribution results of children patients infected with the virus (cases).

Age distribution (years old)	Positive norovirus	Positive rotavirus
<1	211	214
1-2	204	131
2-3	122	83
3-4	79	60
4-5	65	54
>5	162	47

Table 2: Month distribution of virus infection in children patients (cases).

Month	Positive norovirus	Positive rotavirus
1	11	87
2	10	97
3	12	99
4	10	13
5	6	14
6	8	7
7	10	12
8	17	13
9	75	17
10	132	21
11	241	96
12	311	113

feature transformation. What is more, the data acquisition was mainly to prepare for the subsequent data mining. When data mining is performed, it is necessary to select data from the dataset and select the data needed to build the model from the original dataset. In this study, the data mining results found that the early ultrasound examinations of children patients in the susceptible age group showed slight intestinal edema or effusion and slight changes in gastrointestinal function, which affected the diet and rest of children. Some children patients might have clinical manifestations of vomiting, which was basically in line with the observation results of clinicians.

5. Conclusion

In this study, the main focus was the application of monitoring and early warning detection technology of norovirus, namely, data mining technology. Therefore, a large number of children patients with diarrhea symptoms were selected, and the ultrasonic examination results were collected. Meanwhile, the wavelet transform algorithm was applied to denoise processing of ultrasonic images to facilitate the normalization and collation of data. The research results showed that the ultrasound images processed by the wavelet transform algorithm had higher quality, which was convenient for doctors to diagnose the diseases of children in combination with the image data. Based on the results of data mining technology analysis of children infected with norovirus, it was found that in clinical practice, children with diarrhea were more likely to be infected with norovirus than rotavirus, and children younger than 2 years old or older than 5 years old are more susceptible to norovirus in December. In summary, data mining technology based on the wavelet transform artificial intelligence algorithm had a relatively accurate warning effect and could also predict the future trend of disease data, so it could be promoted and applied clinically. The disadvantage of this study is that the presentation of case data is less, which makes the research results lack of intuitive data support. Therefore, further research and analysis are needed to provide more effective clinical reference value.

This study was to analyze the effect of the combined application of deep learning technology and ultrasound imaging on the effect of breast-conserving surgery for breast cancer. A deep label distribution learning (LDL) model was designed, and the semi-automatic segmentation algorithm based on the region growing and active contour technology (RA) and the segmentation model based on optimized nearest neighbors (ON) were introduced for comparison. The designed algorithm was applied to the breast-conserving surgery of breast cancer patients. According to the difference in intraoperative guidance methods, 102 female patients with early breast cancer were divided into three groups: 34 cases in W1 group (ultrasound guidance based on deep learning segmentation model), 34 cases in W2 group (ultrasound guidance), and 34 cases in W3 group (palpation guidance). The results revealed that the tumor area segmented by the LDL algorithm constructed in this study was closer to the real tumor area; the segmentation accuracy (AC), Jaccard, and true-positive (TP) values of the LDL algorithm were obviously greater than those of the RA and ON algorithms, while the false-positive (FP) value was significantly lower in contrast to the RA and ON algorithms, showing statistically observable differences ($P < 0.05$); the actual resection volume of the patients in the W1 group was the closest to the ideal resection volume, which was much smaller in contrast to that of the patients in the W2 and W3 groups, showing statistical differences ($P < 0.05$); the positive margins of the patients in the W1 group were statistically lower than those in the W2 and W3 groups ($P < 0.05$). In addition, 1 patient in the W1 group was not satisfied with the cosmetic effect, 3 patients in the W2 group were not satisfied with the cosmetic effect, and 9 patients in the W3 group were not satisfied with the cosmetic effect. Finally, it was found that the ultrasound image based on the deep LDL model effectively improved the AC of tumor resection and negative margins, reduced the probability of normal tissue being removed, and improved the postoperative cosmetic effect of breast.

1. Introduction

Breast cancer is a malignant tumor that occurs on the ductal epithelium and terminal ductal epithelium of the breast. It can manifest as breast lumps, nipple discharge, nipple retraction, skin adhesions, skin edema, and breast pain [1]. The invasive breast cancer is still major diseases threatening the lives and health of women [2]. In the past, the breast cancer was treated by removing the breasts for the classic surgical treatment, the expanded radical mastectomy, and modified radical mastectomy, which would leave women's chest long and ugly scar after the surgery [3]. In addition, large-scale mastectomy and axillary lymph node dissection will inevitably bring more surgical complications, such as the formation of postoperative scar tissue, which limits the range of movement of the upper limbs; the lymphatic circulation of the upper limbs is blocked, which leads to swelling of the upper limbs [4]. Therefore, modern clinical treatment recommends breast cancer conserving surgery. Compared with radical mastectomy, breast-conserving surgery has the characteristics of less trauma and less pain. While preserving the integrity of the breast shape, it also takes into account postoperative functional recovery, so the curative effect can be comparable to radical mastectomy by combining with postoperative comprehensive treatment [5, 6]. Although the current surgery is still generally based on modified radical mastectomy, breast-conserving surgery will gradually replace modified radical mastectomy as the main surgical procedure with the development of early diagnosis technology.

At present, the auxiliary methods suitable for breast-conserving surgery for breast cancer include intraoperative ultrasound guidance and palpation guidance. Although palpation guidance is a clinical standard surgical procedure, its performance in assessing the extent of resection of the disease is low, and excessive resection scope and positive margins may occur, which will not only affect the surgical effect but also lead to low cosmetic effect and unsuccessful surgery [7]. Ultrasound, as an imaging method widely used in clinical purposes, has developed from the initial diagnosis of breast cancer to aid surgical treatment. It can play an important role in breast cancer conserving surgery, and clinical ultrasound-guided breast-conserving surgery is necessary [8]. Deep learning, as a new field in machine learning research, allows computers to simulate the mechanism of the human brain to solve problems and enables the computers to improve their ability to solve problems on their own without human supervision [9, 10]. Clinical application of deep learning technology to ultrasound image segmentation is also a major trend. For example, the shape, color, and texture of the lesion can be classified through accurately segmenting the lesion, so that the machine can complete the doctor's diagnosis process or visualizing the images in three dimensions can effectively improve the diagnostic performance of doctors [11]. A multilabel classification task refers to a piece of data that may have one or more labels. For example, a patient's physical examination report may be labeled with multiple labels, such as high blood pressure and high blood sugar. Multilabel learning algorithms can be divided into problem conversion methods and algorithm adaptation methods. The problem conversion method is to convert the multilabel classification into other mature scenarios, so that the data can adapt to the algorithm, and the algorithm adaptation method is to adapt popular learning techniques to deal with multilabel data and let the algorithm adapt to the data. Therefore, it is necessary to combine the deep learning and ultrasound.

In short, the combined application of deep learning technology and imaging technology can be well developed in the field of medical diagnosis and treatment. In this study, a deep LDL model was designed and applied to breast cancer patients during breast-conserving surgery. The combined application of deep learning technology and ultrasound imaging on the effect of breast-conserving surgery for breast cancer was comprehensively evaluated by analyzing the amount of tumor resection, margins, and postoperative cosmetic effects in breast cancer patients.

2. Materials and Methods

2.1. Research Objects. One hundred and two female patients with early breast cancer (the clinical TNM staging is stage I and II) admitted in the hospital from February 10, 2018, to February 10, 2021, were selected as the research subjects. The patients with multicenter lesions, preoperative neoadjuvants, breast cancer surgery history, nontactile breast cancer, and invasive breast cancer were excluded. According to the different guidance methods used in the surgery, the research objects were rolled into three groups: 34 cases in W1 group (ultrasound guidance based on deep learning segmentation model), 34 cases in W2 group (ultrasound guidance), and 34 cases in W3 group (palpation guidance). This study had been approved by the Medical Ethics Committee of hospital, and the patients and their families had known the situation of the study and signed the informed consent forms.

2.2. Guidance Methods. Ultrasound guidance was performed as follows: Before the surgery, SonoScape was used to open the M11 ultrasound color Doppler diagnostic instrument to mark the tumor boundary on the patient's skin surface, and set 1 cm around the tumor as the ideal resection margin. After anesthesia, an appropriate incision was made, and an ultrasound probe was adopted to guide the surgical resection in real time. During the process, it had to pay attention to the gentle operation to avoid tumor compression. Ultrasonic testing was performed on the isolated specimens after surgery to ensure that the tumor was cleanly removed.

Palpation guidance was performed as follows. The SonoScape was adopted to open the M11 ultrasound color Doppler diagnostic instrument to mark the tumor boundary on the skin surface of the patient before the surgery, and set 1 cm around the tumor as the ideal resection margin. After anesthesia, a suitable incision was cut on the skin, and the palpation guidance was realized by figures. The tumor was marked and then completely removed based on past experience.

2.3. Pathological Examination and Data Collection. The pathological examination was performed on the tumor tissue resected by the two guiding methods; the circumferences (length, width, and height) of the tumor and the resected tissue were measured and the distance between each resection edge and the tumor edge was measured (obtain the longest/shortest resection edge). The resection edge was observed to check if the tumor cells were visible. Under a microscope, if there was no ink staining on the tumor tissue, it can be judged as a negative margin.

The tumor volume (V1), ideal resection tissue volume (V2), and actual resection tissue volume (V3) were calculated with following equations:

$$V1 = \frac{4}{3}\pi\bullet\frac{\alpha}{2}\bullet\frac{\beta}{2}\bullet\frac{\lambda}{2}, \tag{1}$$

$$V2 = \frac{4}{3}\pi\bullet\left(\frac{\alpha}{2}+1\right)\bullet\left(\frac{\beta}{2}+1\right)\bullet\left(\frac{\lambda}{2}+1\right), \tag{2}$$

$$V3 = \frac{4}{3}\pi\bullet\frac{\alpha *}{2}\bullet\frac{\beta *}{2}\bullet\frac{\lambda *}{2}. \tag{3}$$

In (1)–(3), α, β, and λ referred to the length, width, and height of the tumor, respectively, and α^*, β^*, and λ^* represented the length, width, and height of the actual resection tissue, respectively.

The age, weight, height, and tumor location of the patients were collected before the surgery. Long-term follow-up was carried out after the surgery. The breast shape, incision healing, and nipple, and areola positions of the patients were observed 2 and 5 months after the surgery.

2.4. Deep LDL Model. LDL can label an instance very naturally and assign a performance value to each label of the instance as much as possible. Compared with the traditional single-label learning, it showed more degrees of freedom to obtain more effective information [12]. Therefore, an encoder-decoder architecture deep network was designed based on LDL (Figure 1), which was composed of input layer, convolution module, pooling layer, subsequent branches of the convolution module, and softmax layer.

The network can perform Softmax operation [13] to obtain the label distribution map required. When the classification probability and cross entropy loss were calculated, the equations could be written as follows:

$$P_i = \frac{a^i}{\sum_i a^i}, \tag{4}$$

$$\text{Loss} = -\sum_m y_m \log P_m. \tag{5}$$

In (4) and (5), P was the classification probability, a_i was the element contained in the input data, and $y = \{y_0, y_1, y_2, \ldots, y_n\} \in \{0, 1\}$ represented the category. There were two categories in this study: tumor and background. When it was the tumor category, $\text{Loss}(P, y) = -\log P_1$ could be met; when it was the background category, $\text{Loss}(P, y) = -\log P_0$ was satisfied. From this, the fuzzy label distribution map can be initially obtained.

A label distribution fitting term [14] was proposed in this study to further integrate the obtained fuzzy label distribution map into the LDL model; then, the new energy function could be expressed as follows:

$$H = \varepsilon + \phi + D. \tag{6}$$

In equation (6), ε represented the gray-scale fitting term; ϕ and D represented the label fitting term and the regularization term, respectively. The following equation could be obtained by introducing the bias field hypothesis theory:

$$\varepsilon = \int_\Phi (M(x,y) - C(x,y)N(x,y))^2 \mathrm{d}x\mathrm{d}y. \tag{7}$$

In the above equation, M represented the image to be observed, N represented the real image, C was the bias field, and Φ referred to the interval. Then, the concept of local clustering properties was introduced. It was assumed that there was a circle with r as radius and s as center, the paranoid field value of any point s^* in this circle was similar to the center s. In addition, the values of the real image on multiple intervals [$\Phi 1$, $\Phi 2$, ... Φn] were [$v1$, $v2$,... v_n], respectively; then, equation (7) could be evolved as follows:

$$\varepsilon = \int \left(\sum_{i=1}^{n} \int L(s - s*)(M(s*) - C(s)v_i)^2 \right) \mathrm{d}s. \tag{8}$$

A label distribution fitting item was also added, which was different from the traditional model:

$$\phi = \sum_{i=1}^{n} \int_\Phi (S(s*) - v_i)^2 \mathrm{d}s. \tag{9}$$

In equation (9), $S(s^*)$ was the pixel value obtained from the label learning map and represented the tumor probability value in this study. Adding the abovementioned label distribution fitting item can solve the different qualitative gray levels. Therefore, the final energy function can be expressed as:

$$\begin{aligned} H = {} & \int \left(\sum_{i=1}^{n} \int L(s - s*)(M(s*) - C(s)v_i)^2 \right) \mathrm{d}s \\ & + \sum_{i=1}^{n} \int_\Phi (S(s*) - v_i)^2 \mathrm{d}s + |D|. \end{aligned} \tag{10}$$

2.5. Evaluation Indicators of Segmentation Performance. The semiautomatic segmentation algorithm based on the region growing and active contour technology (RA) and the segmentation model based on optimized nearest neighbors (ON) were introduced for comparison to further analyze the performance of the designed model. The accuracy (AC), true positive (TP), false positive (FP), and Jaccard were selected as the evaluation indicators, which could be expressed as follows:

$$\begin{aligned} \text{AC} &= \frac{|T_1 \cap T_2| \cup |C_1 \cap C_2|}{T_1 \cap C_1}, \\ \text{TP} &= \frac{|T_1 \cap T_2|}{T_1}, \\ \text{FP} &= \frac{|T_1 \cap T_2 - T_1|}{|T_1|}, \\ \text{Jaccard} &= \frac{|T_1 \cap T_2|}{|T_1 \cup T_2|}. \end{aligned} \tag{11}$$

In the above equations, T_1 referred the tumor area obtained by manual segmentation, and T_2 represented the tumor area obtained by the model segmentation.

2.6. Statistical Analysis. The data of this study was analyzed by SPSS19.0 version statistical software; the measurement data were expressed by the mean ± standard deviation ($\bar{x} \pm s$), and the count data were expressed in the form of percentage (%). One-way analysis of variance was used for pairwise comparison. The difference was statistically significant at $P < 0.05$.

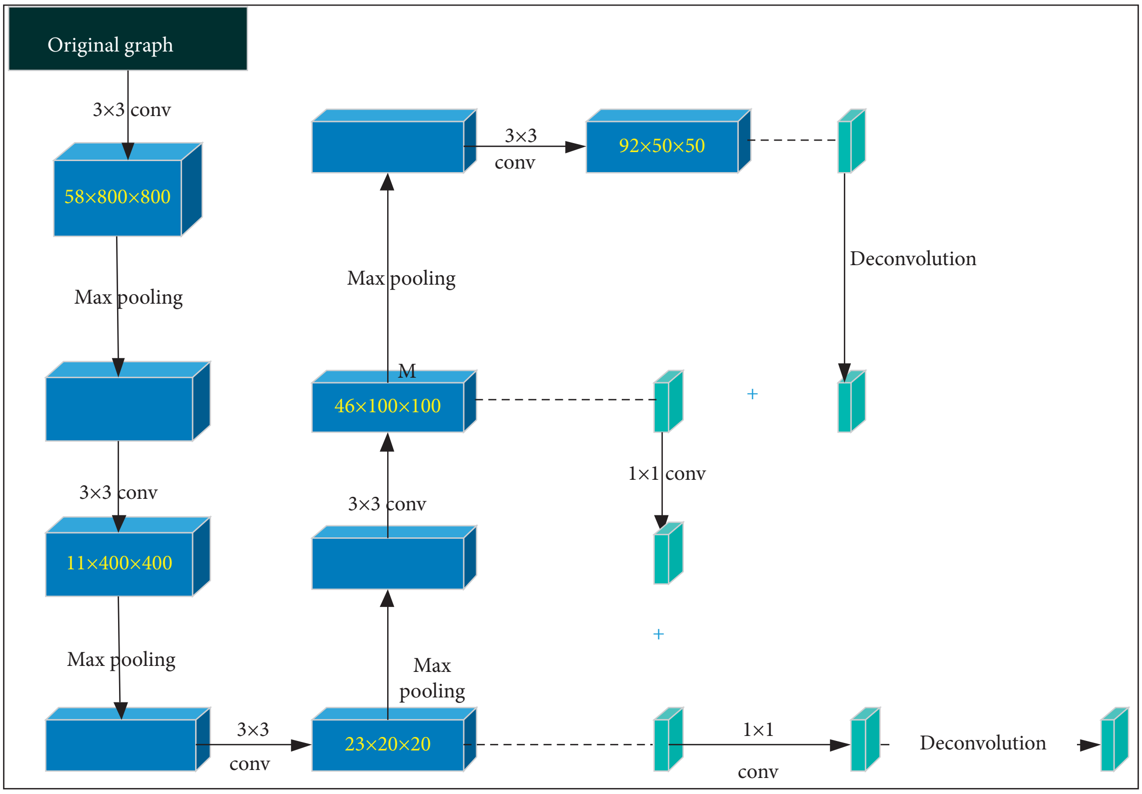

Figure 1: The architecture of LDL.

3. Results

3.1. Image Segmentation Performance of Deep LDL Model. Figure 2 shows the image segmentation effects of the three algorithms on some samples. It revealed that the tumor area segmented by the LDL algorithm constructed was closer to the real tumor area. Although the RA algorithm and the ON algorithm could also identify the tumor area better, the area selection range was too large, so that it was easy to include the background area, showing poor segmentation effect.

The quantitative indicators were compared to further clarify the segmentation performances of the three algorithms. As shown in Figures 3 and 4, the AC, Jaccard, and TP values of the LDL algorithm were greatly larger than those of the RA and ON algorithms, showing statistically obvious differences ($P < 0.05$); the FP value of the LDL algorithm was much smaller in contrast to that of the RA and ON algorithms, showing statistically great difference ($P < 0.05$).

3.2. Comparison on Basic Information of the Patients. As illustrated in Figures 5 and 6, the pairwise comparisons of age, body mass index (BMI), and tumor stage ratio of patients in W1, W2, and W3 groups were not statistically observable ($P > 0.05$).

Figure 7 shows an ultrasound image of a 46-year-old female patient with breast cancer. Ultrasound showed that the breast tissues on both sides were slightly thickened, the lobule structure was slightly thick and disordered, and the internal distribution was uneven. There were two hypoechoic masses of different sizes in the upper outer quadrant, with irregular shapes, and there was no echo in the capsule. The internal echo was uneven, and several sand particles showed strong echoes with weak sound shadows. In addition, the color Doppler ultrasound showed that there was no blood flow signal, right axillary lymph node was not reached, and multiple hypoechoic nodules were visible in the axillary.

3.3. Comparison on Resection Volume of Tumor. As given in Figure 8, the tumor volume and ideal resection volume of patients in the W1, W2, and W3 groups were relatively close, and the difference was not statistically significant ($P > 0.05$); the actual resection volume in the W1 group was the closest to the ideal resection volume and was greatly smaller than that in the W2 and W3 groups ($P < 0.05$).

Figure 9 shows the images of ultrasound reexamination in some patients after surgery. As shown in Figure 9(a), the ultrasound reexamination found that the right breast cancer of the patient was treated for one year after radiotherapy; the sonographic features were obvious, and the multiple hypoechoic nodules showed target ring signs, which were multiple liver metastases. Figure 9(b) reveals that the patient's left side breast cancer had an obstruction of lymphatic drainage, that is, lymphatic fluid accumulated in the axilla and formed a lymphatic cyst.

3.4. Comparison of Patient Margin Performance. As revealed in Figure 10, the positive margins and negative margins of the patients in the W1 group were 7.43% and 92.57%, respectively; the positive and negative margins of the patients

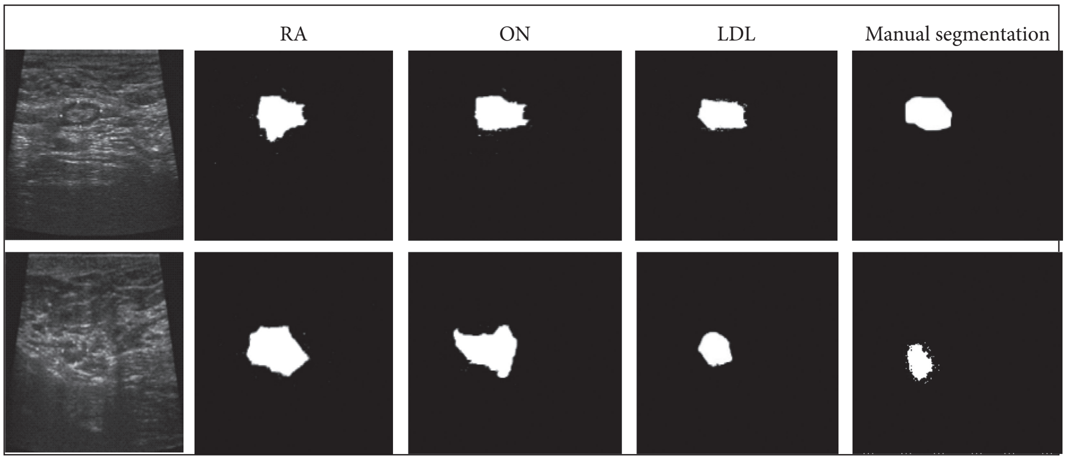

FIGURE 2: Comparison on image segmentation effects of different algorithms. (a, b) Original images.

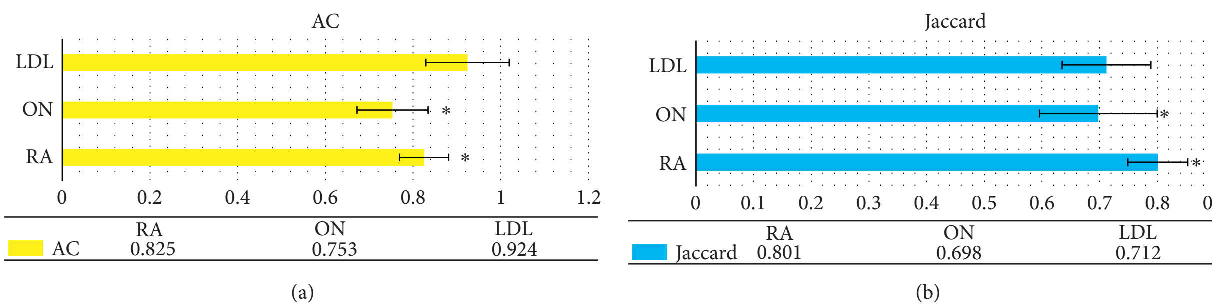

FIGURE 3: Comparison on AC and Jaccard of various algorithms. (a) The AC indicator and (b) the Jaccard indicator. * indicates that the difference was statistically obvious in contrast to the LDL algorithm ($P < 0.05$).

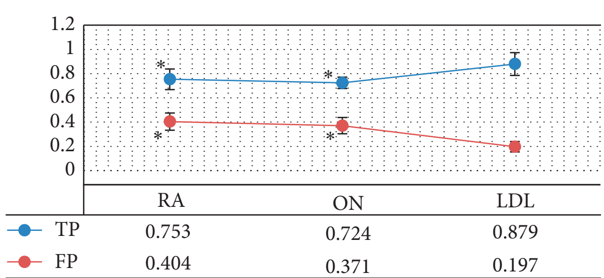

FIGURE 4: Comparison on TP and FP of various algorithms. * suggests that the difference was statistically obvious in contrast to the LDL algorithm ($P < 0.05$).

in the W2 group were 15.31% and 84.69%, respectively, and the positive and negative margins of the patients in the W3 group were 26.07% and 73.93%, respectively. It was clear that the positive margins of the patients in the W1 group were dramatically less than those in the W2 and W3 groups, and the differences were statistically observable ($P < 0.05$).

Figure 11reveals that the longest margin (1.35 cm) of the patients in the W1 group was smaller in contrast to that of the patients in the W2 and W3 groups, while the shortest margin (0.67 cm) was greater. Based on the difference between the longest resection margin and the ideal resection margin and the difference between the shortest resection margin and the ideal resection margin, it can be concluded that the longest and shortest resection margins of the patients in group W1 were closer to the ideal resection margin, and the variation among individuals was smaller.

3.5. Analysis on Postoperative Cosmetic Effect of Patients. The postoperative cosmetic effects of the three groups of patients were compared, and the results are shown in Figure 12. There was 1 patient in the W1 group who was not satisfied with the cosmetic effect because there was an obvious shift in the position of the nipple. In the W2 group, 3 patients were not satisfied with the cosmetic effect: 1 case suffered from a significant deviation in the position of the nipple, and 2 suffered from larger breast scar areas. In the W3 group, 9 patients were not satisfied with the cosmetic effect, including 3 patients with obvious deviation of the nipple position, 2 patients with large breast scar areas, 3 patients with visible breast deformation, and 1 patient with postoperative infection. As a result, patients in the W1 group were more satisfied with the cosmetic effect than those in the W2 and W3 groups, and the differences were statistically notable ($P < 0.05$).

4. Discussion

With the development of medical technology, the clinical treatment of breast cancer is constantly updated and progressed. Great changes have been realized from the initial

huge traumatic treatment to today's minimally invasive treatment. The breast-conserving surgery has become the best treatment way for early breast cancer in current years. On the other hand, the application of imaging methods in the surgical process is the current trend. As a diagnostic tool for early breast cancer, ultrasound has also been used in breast cancer, which shows very important value [15]. Therefore, a deep LDL model was designed for breast cancer patients during the breast-conserving surgery in this study. The semiautomatic segmentation algorithm based on the region growing and active contour technology (RA) and the segmentation model based on optimized nearest neighbors (ON) were introduced for comparison to further analyze the performance of the designed model. The results revealed that the tumor area segmented by the LDL algorithm was closer to the real tumor area; although the RA algorithm and the ON algorithm could also identify the tumor area better, the area selection range was too large, so that it was easy to include the background area, showing poor segmentation effect. The quantitative results suggested that the AC, Jaccard, and TP values of the LDL algorithm were greatly larger than those of the RA and ON algorithms, and the FP value of the LDL algorithm was much smaller in contrast to that of the RA and ON algorithms, showing statistically differences

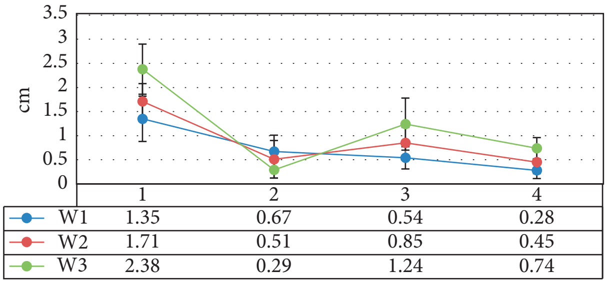

Figure 11: The longest and shortest margins of the three groups of patients.1 means the longest margin, 2 refers to the shortest margin, 3 marks the difference between the longest margin and the ideal margin, and 4 represents the difference between the shortest margin and the ideal margin value.

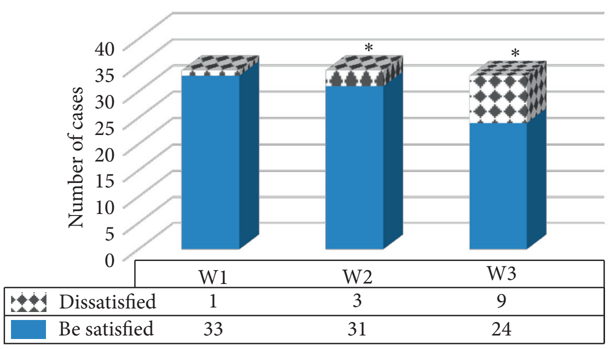

Figure 12: Comparison on postoperative cosmetic effects of patients in different groups. * indicates that the statistically visible difference could be found in contrast to the W1 group ($P < 0.05$).

($P < 0.05$). Such results were similar to the findings of Wang et al. [16], indicating that the LDL algorithm constructed in this study showed a good effect on tumor segmentation, improving the accuracy of tumor segmentation, so it was suitable for clinical promotion.

According to the difference in intraoperative guidance methods, 102 female patients with early breast cancer were divided into three groups: 34 cases in W1 group (ultrasound guidance based on deep learning segmentation model), 34 cases in W2 group (ultrasound guidance), and 34 cases in W3 group (palpation guidance). The results suggested that the actual resection volume of the patients in the W1 group was the closest to the ideal resection volume, which was much smaller in contrast to that of the patients in the W2 and W3 groups, showing statistical differences ($P < 0.05$). The amount of breast tissue removed will affect the appearance of the patient's breast after surgery. Excessive removal may cause the breast to collapse and deform, so it is necessary to reduce the amount of breast tissue resection under the premise of negative margins during the surgery to improve the success rate of breast preservation [17]. It was concluded that the ultrasound images based on the deep LDL model could effectively improve the AC of tumor resection and reduce the probability of normal tissue being resected. The positive margins of the patients in the W1 group were statistically lower than those in the W2 and W3 groups ($P < 0.05$), which was different with the research results of Guo et al. [18]. Resection margins are closely related to the postoperative recurrence of patients. Obtaining satisfactory negative margins is a topic of clinical concern. It was found in this study that ultrasound images based on the deep LDL model could effectively reduce the positive rate of resection margins in patients.

There are many side effects after breast cancer surgery, and the breast cosmetic effect has a great impact on the patient's physical and mental health. Previous studies have shown that breast asymmetry will make women's quality of life worse [19]. A follow-up survey was performed for the three groups of patients 6 months after the surgery. There was 1 patient in the W1 group who was not satisfied with the cosmetic effect because there was an obvious shift in the position of the nipple. In the W2 group, 3 patients were not satisfied with the cosmetic effect: 1 case suffered from a significant deviation in the position of the nipple, and 2 suffered from larger breast scar areas. In the W3 group, 9 patients were not satisfied with the cosmetic effect, including 3 patients with obvious deviation of the nipple position, 2 patients with large breast scar areas, 3 patients with visible breast deformation, and 1 patient with postoperative infection. Such results revealed that the ultrasound image based on the deep LDL model exerted reliable positive impacts on the cosmetic effect of the patient's breast after surgery, which was different from the results obtained by An et al. [20]. The possible reason may be that the resection amount of breast tissue during surgery could affect the postoperative cosmetic effect, resulting in significant differences in the cosmetic effect of the three groups.

5. Conclusion

A deep LDL model was designed, and the semiautomatic segmentation algorithm RA and the segmentation model ON were introduced for comparison. The designed algorithm was applied to the breast-conserving surgery of breast cancer patients. According to the difference of intraoperative guidance methods, 102 female patients with early breast cancer were divided into three groups: 34 cases in W1 group (ultrasound guidance based on deep learning segmentation model), 34 cases in W2 group (ultrasound guidance), and 34 cases in W3 group (palpation guidance). It was found that ultrasound images based on the deep LDL model effectively improved the tumor resection AC and negative margins, reduced the probability of normal tissue being removed, and enhanced the postoperative breast cosmetic effect. However, the constructed deep LDL model cannot be applied to all situations due to the complicated tumor edge characteristics, and the number of patients was small, so further empirical research was necessary in the follow-up. In summary, the image segmentation model proposed in this study showed a good application value for the implementation of clinical breast-conserving surgery for breast cancer.

The aim of this study is to explore the clinical effect of deep learning-based MRI-assisted arthroscopy in the early treatment of knee meniscus sports injury. Based on convolutional neural network algorithm, Adam algorithm was introduced to optimize it, and the magnetic resonance imaging (MRI) image super-resolution reconstruction model (SRCNN) was established. Peak signal-to-noise ratio (PSNR) and structural similarity (SSIM) were compared between SRCNN and other algorithms. Sixty patients with meniscus injury of knee joint were studied. Arthroscopic surgery was performed according to the patients' actual type of injury, and knee scores were evaluated for all patients. Then, postoperative scores and MRI results were analyzed. The results showed that the PSNR and SSIM values of the SRCNN algorithm were (42.19 ± 4.37) dB and 0.9951, respectively, which were significantly higher than those of other algorithms ($P < 0.05$). Among patients with meniscus injury, 17 cases (28.33%) were treated with meniscus suture, 39 cases (65.00%) underwent secondary resection, 3 cases (5.00%) underwent partial resection, and 1 case (1.67%) underwent full resection. After meniscus suture, secondary resection, partial resection, and total resection, the knee function scores of patients after treatment were (83.17 ± 8.63), (80.06 ± 7.96), (84.34 ± 7.74), and (85.52 ± 5.97), respectively. There was no great difference in knee function scores after different methods of treatment ($P > 0.05$), and there were considerable differences compared with those before treatment ($P < 0.01$). Compared with the results of arthroscopy, there was no significant difference in the grading of meniscus injury by MRI ($P > 0.05$). To sum up, the SRCNN algorithm based on the deep convolutional network algorithm improved the MRI image quality and the diagnosis of knee meniscus injuries. Arthroscopic knee surgery had good results and had great clinical application and promotion value.

1. Introduction

The knee joint is the largest, most complex, and weight-bearing main joint in the human body. Patients with tibial plateau fractures are often accompanied by meniscal injuries, and the incidence is about 50% [1]. Meniscus injuries are difficult to repair themselves, which is a difficult and urgent problem in orthopedic treatment. Meniscus injuries are often diagnosed by arthroscopy, knee ultrasound, CT, and magnetic resonance imaging (MRI). Arthroscopy is the gold standard for meniscus diagnosis, but it is invasive and increases the probability of infection in patients [2]. The diagnostic accuracy of B-ultrasound for knee joint meniscus injury is not high [3]. CT cannot correctly grade the diagnosis. MRI has the characteristics of noninvasiveness, nonradiation, high soft tissue resolution, and high specificity. Moreover, MRI has high sensitivity and specificity to the injured area, so MRI has become an important method for knee joint injury following arthroscopy [4]. However, affected by the resolution of MRI images, the false positives and false negatives of meniscus injury diagnosis are relatively high.

MRI images are susceptible to noise pollution, resulting in distortion of MR images [5]. At present, MRI images are often processed by filtering-based denoising methods, but the image information is lost seriously in the denoising process, and additional noise may be introduced [6]. Convolutional neural networks have achieved very good results in natural image processing. At present, some scholars have applied them in the field of medical images. High-resolution MRI images can be obtained after being processed by super-resolution reconstruction algorithm [7]. Kobayashi et al. [8] pointed out that the image resolution processed by the three-layer convolutional neural network (CNN) (super-resolution CNN, SRCNN) was significantly improved. However, there are still obvious misdiagnosis and missed diagnosis in the diagnosis of clinical diseases, which need to be further improved.

In summary, the resolution of MRI images requires to be further improved. SRCNN based on deep CNN algorithm should be further optimized to increase its image quality. Therefore, SRCNN was optimized based on the deep CNN algorithm in this research. Patients with knee meniscus injury were taken as the research object to explore the diagnostic value of MRI images of deep CNN algorithm for meniscus injury. Moreover, the clinical effect of arthroscopic surgery based on MRI images in knee meniscus injuries was evaluated to provide guidance for the treatment of knee meniscus injuries.

2. Materials and Methods

2.1. Research Objects and Grouping. Sixty patients with knee meniscus injury who were admitted to the Orthopedics Department of our hospital from August 2019 to December 2020 were selected as the research objects. The age range was 18–70 years old, and the average age was (48.54 ± 5.46) years old. Among them, 41 were males and 19 were females. The meniscus injury time was seven days to five years, and the average injury time was (2.24 ± 1.04) years. There were 37 cases on the left and 23 cases on the right knee. All patients had no history of knee surgery and received knee MRI and knee arthroscopy during examination and treatment. Inclusion criteria were as follows: (i) age> 18 years; (ii) MRI examination showing meniscus injury, which was confirmed by knee arthroscopy; (iii) those who were hospitalized in time and can receive surgery; and (vi) those with no contraindications to surgery. Exclusion criteria were as follows: (i) patients with other fractures or severe system diseases; (ii) patients with meniscus congenital diseases or developmental abnormalities; (iii) patients combined with knee joint infection, tuberculosis, and so on; and (iv) meniscus injury caused by severe bone and joint disease. The experimental procedure had been approved by the hospital ethics committee, and all subjects included in the study had signed the informed consent form.

2.2. MRI Image Super-Resolution Algorithm Based on Deep CNN Algorithm. The convolutional layer of the deep CNN (DCNN) is mainly responsible for extracting features from the input data [9], and the extracted feature map X_l output by the first layer is expressed as follows:

$$X_l = X_{l-1} \odot A_l + b_l, \tag{1}$$

where X_{l-1} is the output of the l-th layer, $\odot$ is the convolution operation, A_l is the convolution layer parameter, and b_l is the bias. The activation function in DCNN can improve the expressive power of the entire network by introducing nonlinear operations [10]. The ReLU function can avoid the disappearance of the gradient when the input is saturated [11]. The ReLU function is expressed as follows:

$$g(x) = \begin{cases} x, & (x \geq 0), \\ 0, & (x < 0). \end{cases} \tag{2}$$

The training goal of DCNN is minimizing the loss function of the network [12]. The commonly used loss functions include mean square error loss function, cross-entropy loss function, and log-likelihood loss function. The mean square error loss function is expressed as follows:

$$B = \frac{\sum_{i=1}^{m} (y_i - \hat{y}_i)^2}{m}. \tag{3}$$

The cross-entropy loss function is expressed as follows:

$$B = \frac{1}{m} \sum_{i=1}^{m} y_i \log[h_0(x_i)] + (1 - y_i)\log[1 - h_0(x_i)]. \tag{4}$$

The log-likelihood loss function is expressed as follows:

$$B = -\sum_{i=1}^{m} y_i \ln h_0(x_i), \tag{5}$$

where m is the number of input samples, $\hat{y}_i$ is the corresponding model output of x_i, y_i is the corresponding target output, and $h_0(x_i)$ is the corresponding model probability output of x_i.

The DCNN-based super-resolution reconstruction algorithm (SRCNN) mainly includes image feature extraction, nonlinear mapping, and image reconstruction when processing low-resolution images. After the low-resolution images go through image data preprocessing, DCNN feature extraction, and nonlinear mapping and image reconstruction modules in the SRCNN module, a high-resolution MRI image is obtained. SRCNN processing flow for low-resolution images is shown in Figure 1.

Before low-resolution MRI image processing, it is necessary to perform preprocessing such as normalization, low-resolution image generation, image feature extraction, and data enhancement. The data types of MRI images are mostly 32-bit floating-point numbers. The calculation method for normalizing MRI images is as follows:

$$C_i' = \frac{C_i}{\max(C_i)}, \tag{6}$$

where C_i is the matrix of the original i-th MRI image and $C\prime$ is the normalized MRI image of the i-th image.

The neural network training process is divided into forward propagation process and backpropagation process. The forward propagation process uses the network input and existing parameters to calculate the network output. The backpropagation process first calculates the loss based on the network output and then transmits the loss back to each node in the network, thereby updating the weight value of each node [13]. For the simplest gradient descent algorithm, the weight update process is expressed as follows:

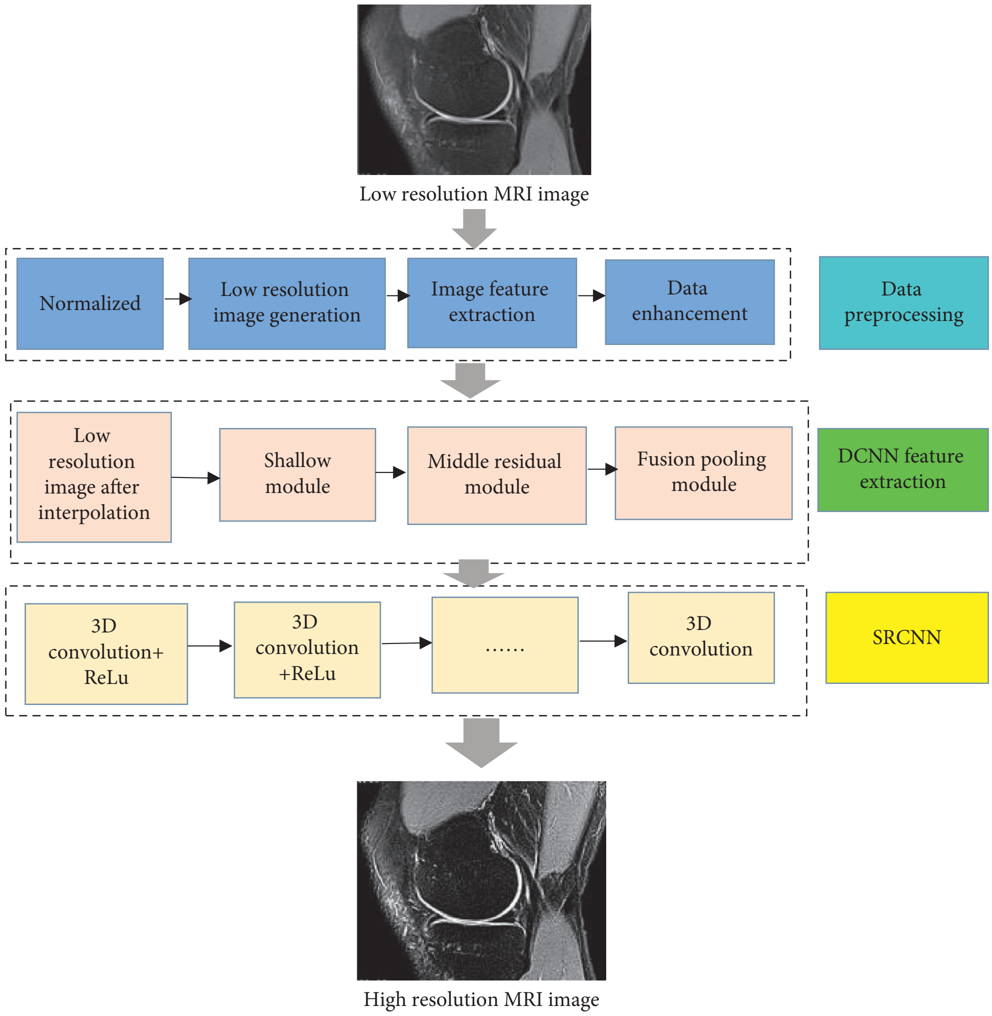

Figure 1: SRCNN processing flow for low-resolution image.

$$\begin{cases} \omega_{i+1} = \omega_i - \alpha \mathrm{d}\omega, \\ e_{i+1} = e_i - \alpha \mathrm{d}e, \end{cases} \tag{7}$$

where ω_i is the current weight, $\mathrm{d}\omega$ is the gradient of the loss function to ω, ω_{i+1} is the updated weight, e_i is the current bias term weight, $\mathrm{d}e$ is the gradient of the loss function to e, e_{i+1} is the updated bias term weight, and α is learning rate.

The momentum gradient descent algorithm is a common algorithm for parameter update in the network, and its update parameters are expressed as follows:

$$\begin{cases} D_{\mathrm{d}\omega} = \beta D_{\mathrm{d}\omega} + (1-\beta)\mathrm{d}\omega, \\ D_{\mathrm{d}e} = \beta D_{\mathrm{d}e} + (1-\beta)\mathrm{d}e, \\ \omega_{i+1} = \omega_i - \alpha D_{\mathrm{d}\omega}, \\ e_{i+1} = e_i - \alpha D_{\mathrm{d}e}, \end{cases} \tag{8}$$

where $\mathrm{d}\omega$ and $\mathrm{d}e$ represent the current gradients, $D_{\mathrm{d}\omega}$ and $D_{\mathrm{d}e}$ represent momentums, and β is a self-set hyperparameter.

The RMSProp algorithm has the advantages of fast convergence speed and small oscillation amplitude [14], and its parameter update process is expressed as shown in equation (9), where θ is a very small constant.

$$\begin{cases} E_{\mathrm{d}\omega} = \beta E_{\mathrm{d}\omega} + (1-\beta)(\mathrm{d}\omega)^2, \\ E_{\mathrm{d}e} = \beta E_{\mathrm{d}e} + (1-\beta)(\mathrm{d}e)^2, \\ \omega_{i+1} = \omega_i - \alpha \dfrac{\mathrm{d}\omega}{\sqrt{E_{\mathrm{d}\omega}} + \theta}, \\ e_{i+1} = e_i - \alpha \dfrac{\mathrm{d}e}{\sqrt{E_{\mathrm{d}e}} + \theta}. \end{cases} \tag{9}$$

Adaptive moment estimation (Adam) optimization algorithm combines the momentum gradient descent algorithm and the RMSProp algorithm, which can reduce the oscillation amplitude and accelerate the convergence speed of the network [15]. The Adam optimization algorithm was used to update the parameters. The parameter update process during the initial training of the Adam optimization algorithm is expressed as follows:

$$\begin{cases} D_{d\omega} = \beta_1 D_{d\omega} + (1-\beta_1)d\omega, \\ D_{de} = \beta_1 D_{de} + (1-\beta_1)de, \\ E_{d\omega} = \beta_2 E_{d\omega} + (1-\beta_2)(d\omega)^2, \\ E_{de} = \beta_2 E_{de} + (1-\beta_2)(de)^2. \end{cases} \tag{10}$$

At the t-th iteration, the cumulative amount of the modified gradient is expressed as follows:

$$\begin{cases} D^n_{d\omega} = \dfrac{D_{d\omega}}{\left(1-\beta_1{}^t\right)}, \\ D^n_{de} = \dfrac{D_{de}}{\left(1-\beta_1{}^t\right)}, \\ E^n_{d\omega} = \dfrac{E_{d\omega}}{\left(1-\beta_2{}^t\right)}, \\ E^n_{de} = \dfrac{E_{de}}{\left(1-\beta_2{}^t\right)}. \end{cases} \tag{11}$$

The parameters are updated according to the momentum and RMSProp algorithm, which are expressed as follows:

$$\begin{cases} \omega_{i+1} = \omega_i - \alpha \dfrac{D^n_{d\omega}}{\sqrt{E^n_{d\omega}} + \theta}, \\ e_{i+1} = e_i - \alpha \dfrac{D^n_{de}}{\sqrt{E^n_{de}} + \theta}. \end{cases} \tag{12}$$

In equations (9)-(12), β_1 and β_2 are 0.9 and 0.999, respectively, θ is 10^{-8}, y_i is the corresponding target output, and $h_0(x_i)$ is the corresponding model probability output of x_i.

2.3. Analysis of Reconstruction Performance of MRI Image Super-Resolution Algorithm Based on Deep CNN Algorithm. To avoid the impact of loss function, SRCNN still uses the same loss function as DCNN. The quality of the reconstructed image is evaluated regarding peak signal-to-noise ratio (PSNR) and structural similar image metric (SSIM). PSNR is commonly used to evaluate the differences between the image to be estimated and the ideal image, and its calculation equation is as follows:

$$\mathrm{PSNR}(f,g) = 10\log_{10}\left(\frac{L^2}{\mathrm{MSE}(f,g)}\right), \tag{13}$$

where L is the peak signal, f is the ideal image, g is the image to be estimated, $\mathrm{MSE}(f,g)$ is the mean square error of the image, $\mathrm{MSE}(f,g) = 1/\mathrm{MN}\sum_{i=1}^{M}\sum_{j=1}^{N}(f(i,j) - g(i,j))^2$, and $M \times N$ is the size of the image to be estimated.

The structural similarity (SSIM) evaluation result is similar to the human senses, which is calculated as follows:

$$\mathrm{SSIM}(f,g) = (L(f,g))^{\alpha} \cdot (C(f,g))^{\beta} \bullet (S(f,g))^{\gamma}, \tag{14}$$

where μ_f, μ_g, σ_f, and σ_g are the mean values and standard deviations of the ideal image f and the image g to be evaluated, respectively, σ_{fg} is the covariance of f and g, $c_1 = (k_1\ R)^2$, $c_2 = (k_2 R)^2$, R is the range of image pixel values, k_1 and k_2 are 0.01 and 0.03, respectively, $c_3 = c_2/2$, $\alpha = \beta = \gamma = 1$, and $L(f,g)$, $C(f,g)$, and $S(f,g)$ represent image brightness, structure, and contrast, respectively.

2.4. Knee MRI Examination and Diagnostic Criteria. 1.5 T superconducting MRI (Siemens, Germany) was used to examine the patient that was in the supine position, the knee joint was naturally externally rotated 25° during the examination, and the knee joint was fixed during the scan. The scanning layer thickness was 3 mm, the layer spacing was 0.2~0.4 mm, the matrix was 256×256, and the joint space was used as the scanning center. All patients underwent coronal and sagittal scans. The repetition time (TR) of T2WI was 800–1000 ms, and the echo time (TE) was 26 ms. The spin echo sequence T1WI had TR of 450–500 ms and TE of 14 ms. MRI diagnostic criteria were as follows: all patients' MRI scan images were individually read by three radiologists with senior titles, who provided reports to evaluate the lateral meniscus injury and its damage morphology.

2.5. Surgical Methods and Observation Indicators. Schatzker classification standard in the study of Kumar et al. [16] was referred, and the types of platform fractures of MRI images of all patients in the study were classified into six types. Different types of platform fractures received different surgical treatments.

The grading standard of meniscus injury was as follows. Grade 1: there is a patchy signal, showing mild degeneration. Grade 2: there is a linear signal, showing serious degeneration. Grade 3: there is a linear signal, showing a meniscus tear [17]. All patients were scored according to Lysholm knee joint function score before and after surgery, and the changes of knee joint function scores before and after treatment were compared to analyze the effect of surgical treatment.

2.6. Statistical Methods. The test data were processed using SPSS 19.0. The results of intraoperative exploration or arthroscopy were used as the standard to analyze the accuracy of MRI diagnosis. Enumeration data were expressed as a percentage (%), tested by the χ^2 test. $P < 0.05$ indicated that the difference was statistically considerable.

3. Results

3.1. The Influence of Loss Function and Number of Convolution Kernels on Reconstruction Performance. The comparison of training curves of the three loss functions is shown in Figure 2. PSNRs of the three loss functions all increased first and then became stable with the increase of the number of iterations. The PSNR of the mean square error loss function

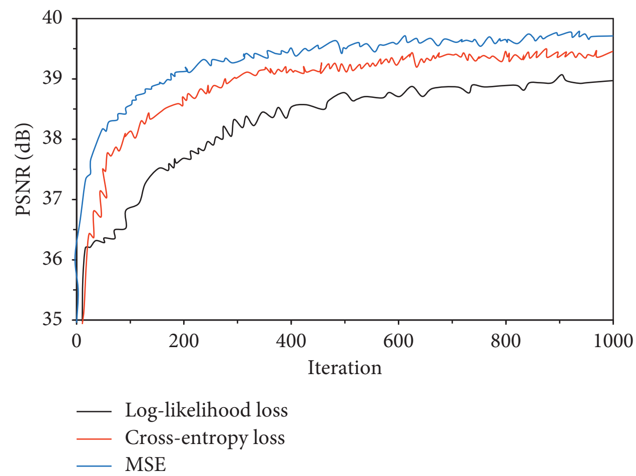

Figure 2: Comparison of training curves with the same loss function.

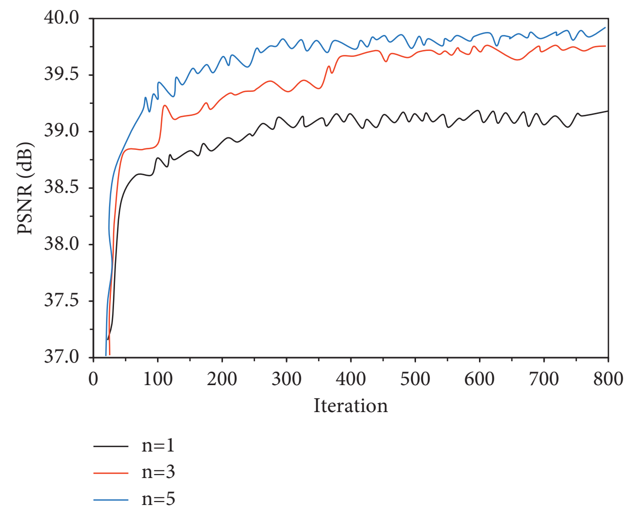

Figure 3: The influence of the number of convolution kernels on reconstruction performance.

was relatively higher under the same number of iterations, and the convergence was relatively faster during the training.

PSNRs of MRI reconstructed images under different numbers of convolution kernels are compared in Figure 3. With the increase of the number of iterations, the PSNR of the MRI reconstructed image under different convolutions and numbers showed a state of increasing first and then being stable in a certain region. As the number of convolution kernels increased, the PSNR of the MRI reconstructed image increased significantly. The number of convolution kernels was increased from 1 to 3, and the PSNR of the MRI reconstructed image was increased by 0.68 dB. The number of convolution kernels was increased from 3 to 5, and the PSNR of the MRI reconstructed image was increased by 0.16 dB.

3.2. Quality Analysis of Reconstructed MRI Image. PSNR value of the SRCNN algorithm was compared with the average PSNR value of DCNN, cubic spline interpolation, and deeply recursive convolutional network (DRCN) based on the residual learning algorithm (Figure 4). The PSNR of the SRCNN algorithm was (42.19 ± 4.37) dB, which was greatly higher than that of other algorithms, and the difference was remarkable ($P < 0.05$).

The average SSIMs of different algorithms were compared (Figure 5). The average SSIM of DCNN, cubic spline interpolation, DRCN, and SRCNN algorithms was 0.9447, 0.9316, 0.9764, and 0.9951, respectively. The SSIM of SRCNN algorithm was notably higher than that of other algorithms, and the difference was substantial ($P < 0.05$).

3.3. MRI Diagnosis Results of Meniscus Injury. The MRI results of patients with meniscus injury before and after treatment were analyzed (Figure 6). The normal meniscus MRI image showed uniform low signal and regular shape (Figure 6(a)). The MRI signal of meniscus injury patients showed focal ellipse or round high signal, which did not touch the articular surface of the meniscus (Figure 6(b)). The

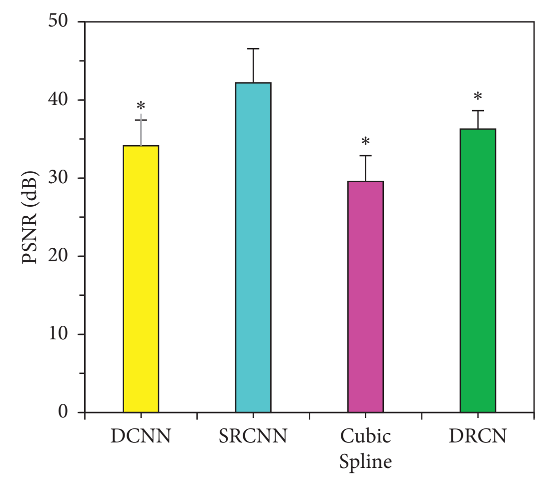

Figure 4: Comparison of PSNR of reconstructed MRI images with different algorithms.

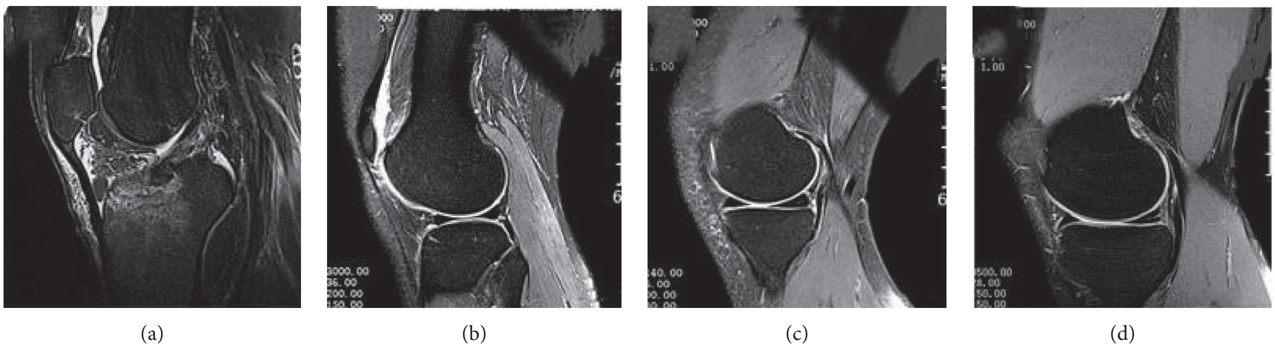

Figure 6: MRI image of meniscus. (a) MRI image of normal meniscus. (b) MRI image of grade I injury in the posterior horn of the medial meniscus (female, 24 years old). (c) MRI image of grade II injury of the posterior horn of the medial meniscus (female, 62 years old). (d) MRI image of grade III injury of the posterior horn of medial meniscus (male, 36 years old).

horizontal linear hyperintensity shadow extended to the edge of the joint capsule of the meniscus but did not exceed the articular surface of the meniscus (Figure 6(c)). In addition, there was an irregular high signal shadow in the meniscus (Figure 6(d)).

3.4. MRI Diagnosis Result of Meniscus Injury Degree. The results of arthroscopy or intraoperative exploration were used as the gold standard to evaluate the accuracy of MRI in the diagnosis of meniscus injury (Figure 7). There were 19 cases (31.67%), 34 cases (56.67%), and 7 cases (11.67%) of meniscus injury diagnosed by arthroscopy as grades I, II, and III, respectively. There were 20 cases (33.33%), 27 cases (45.99%), and 13 cases (21.67%) of meniscus injuries diagnosed by MRI as grades I, II, and III, respectively. There was no obvious difference in the grading of meniscus injury between results of MRI and arthroscopy ($P > 0.05$).

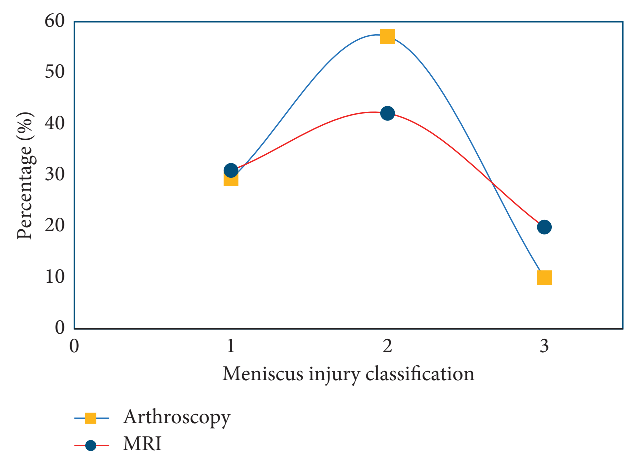

Figure 7: Analysis of the accuracy of MRI in the diagnosis of meniscus injury.

3.5. Statistics of Treatment Methods of MRI-Diagnosed Meniscus Injury. According to the degree and type of meniscus injury, different treatment methods were implemented for the 60 patients included in the study, and the proportion of patients in different methods was calculated (Figure 8). Seventeen cases (28.33%) were treated with meniscus suture, 39 cases (65.00%) underwent secondary resection, 3 cases (5.00%) underwent partial resection, and 1 case (1.67%) underwent total resection.

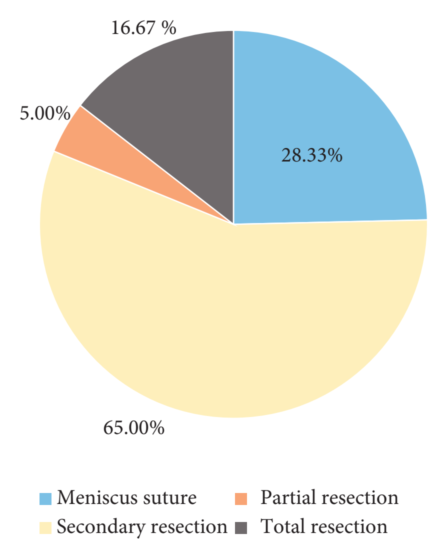

Figure 8: Statistics of treatment methods of MRI-diagnosed meniscus injury.

3.6. Knee Function Scores of Patients Treated with Different Methods before and after Treatment. The knee function scores of patients with different treatment methods were compared before and after treatment (Figure 9). There was no statistical difference in the knee function scores of all patients before treatment ($P > 0.05$). After meniscus suture, secondary resection, partial resection, and total resection were used to treat meniscus injury patients, and the knee function scores were (83.17 ± 8.63), (80.06 ± 7.96), (84.34 ± 7.74), and (85.52 ± 5.97), respectively. In addition, there was no great difference in the knee function scores among patients treated by different treatment methods after treatment ($P > 0.05$). The knee function scores of each group after treatment were significantly different from those before treatment ($P < 0.01$).

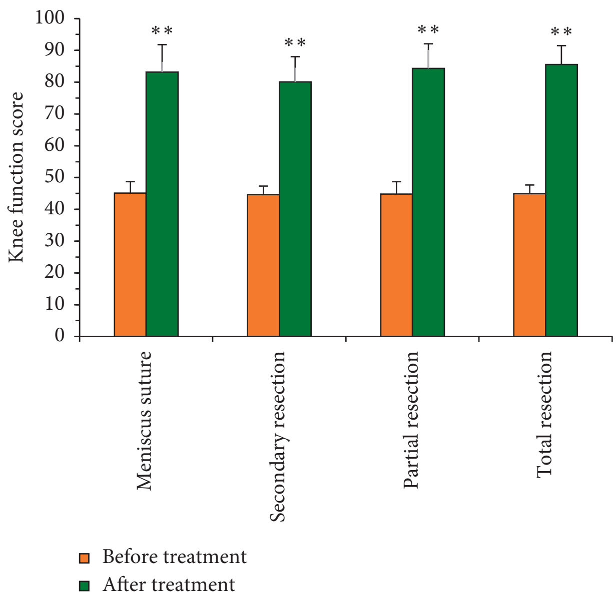

Figure 9: Comparison of knee joint function scores of patients with different treatment methods before and after treatment (** indicated a significant difference versus that before treatment, $P < 0.01$).

4. Discussion

The entire training process of SRCNN based on the deep CNN algorithm was calculating this round of loss according to the loss function after all levels and processing are passed through the input previous to the propagation. In this research, appropriate optimization methods such as stochastic gradient descent was adopted to update the parameters of each layer in the direction of reducing the loss. Therefore, the loss function was the instructor of the entire network learning, which had a great influence on the quality of the final learning result [18]. Then, the training curves of the three commonly used loss functions were compared. It was found that the PSNR of the mean square error loss function was high, and the convergence was fast during the training. The mean square error loss function belongs to the pixel-by-pixel loss function, which can well converge to the local minimum [19]. Therefore, the mean square error loss function was selected as the loss function. The depth of CNN has a great impact on network performance, and the depth of SRCNN is mainly determined by the number of convolution kernels in the network [20]. PSNRs of MRI reconstructed images under different numbers of convolution kernels were compared. It was found that as the number of convolution kernels increased, the PSNR of the MRI reconstructed image increased significantly. The number of convolution kernels was increased from 1 to 3, and the PSNR of the MRI reconstructed image was increased by 0.68 dB. The number of convolution kernels was increased from 3 to 5, and the PSNR of the MRI reconstructed image was increased by 0.16 dB. These results indicated that the PSNR increased with the increase in the number of S3D-RDBs, suggesting that the quality of the MRI images reconstructed by the SRCNN network was getting better and better. It was because the more the number of convolution kernels in the SRCNN network, the deeper the network depth, which can capture more feature maps of different levels to highlight more detailed information [21]. As the number of convolution kernels increased, the increase in PSNR became small. It may be because as the network deepened, information loss still occurred when information was transmitted in the network, which made the backpropagation of the gradient in the network more difficult [22].

Meniscus injury has a significant correlation with the stability of the knee joint, postoperative inflammation, and other complications [23]. Iqbal et al. [24] found that MRI diagnosis of articular surface collapse was consistent with the arthroscopic diagnosis. In this research, the results showed that the different degrees of MRI meniscus injury were not statistically significant with the results of arthroscopy ($P > 0.05$). It showed that there were still a small number of false positives and false negatives in MRI diagnosis. It may be related to the uneven confounding signal of connective tissues such as synovium and muscle health, which led to artifacts of meniscus damage during MRI scan. However, there was no considerable difference between MRI diagnosis results and arthroscopic diagnosis results, indicating that MRI had a certain potential value in the diagnosis of meniscus injury. Lu et al. [25] pointed out that arthroscopy had the characteristics of less surgical trauma and fast recovery speed and is used in the clinical treatment of meniscus injuries. Based on the imaging characteristics, different methods were used to treat patients with different degrees of meniscus injury. The results showed that there was no great difference in knee function scores among patients treated by different treatment methods after treatment ($P > 0.05$). The knee function scores of each group after treatment were significantly different from those before treatment ($P < 0.01$), which suggested that the effect of arthroscopic surgery on knee meniscus injury was significant.

5. Conclusion

Based on the deep CNN algorithm, the Adam optimization algorithm was introduced to optimize it, which was then applied to the knee joint meniscus injury diagnosis. The clinical effect of arthroscopic surgery in knee meniscus injury based on MRI images was evaluated. The results revealed that SRCNN based on deep CNN algorithm significantly improved the quality of knee MRI images. However, there are still some shortcomings in this research, which does not perform a statistical analysis on the parameters and calculation cost of the algorithm in MRI image processing. In the future work, we will further analyze it to clarify the value and significance of SRCNN based on deep CNN algorithm in the diagnosis of knee meniscus injury. In summary, the SRCNN algorithm based on the deep convolutional network algorithm improved the MRI image quality and the diagnosis of knee meniscus injuries. Moreover, arthroscopic knee surgery had good results and had great clinical application and promotion value.

To explore the application effect of the big data medical imaging tertiary diagnostic system in improving the medical and health examination, cases in township health centers were collected by the medical imaging tertiary diagnosis system. Clinical cases examined by the tertiary diagnostic system of big data medical imaging will be set as the observation group. Clinical cases not involved in the tertiary diagnostic system of big data medical imaging were set as the control group. The qualified rate, film positive rate, and film diagnosis accuracy between the two groups are compared, and X-ray perspective, X-ray examination, and CT multiple medical imaging examinations are used in two groups. The experimental results showed that the pass rate was 86.57%, positive rate was 72.32%, and diagnosis rate was 80.17%. Pass rate, positive rate, and diagnostic accuracy were higher than the control group ($P < 0.05$). X-line film is the most cost effective. CT examination has a high diagnostic sensitivity and can achieve a clear diagnosis of the benign and malignant diseases. The three-level diagnosis system of medical imaging has significantly improved and improved the technical level in the medical and health examination, which has good practical value.

1. Introduction

China's medical resources are relatively lacking and highly unbalanced in distribution. With the accelerating aging process in China, the contradiction between high-quality medical resources and the people's ever-improving demand for health services is becoming more and more serious [1]. Regional sharing of medical image information is the key to solve this problem. At present, with the implementation of China's "Internet +" development strategy and the active promotion of medical reform on hierarchical diagnosis and treatment and medical consociation construction, many places in China are trying to conduct regional PACS [2]. Medical imaging software, diagnostic medical imaging software, is suitable for almost all types of images. It can diagnose computer X-ray, digital photography, active imaging radiography, angiography, ultrasound, nuclear medicine, endoscopy, and ophthalmic diseases [3]. It can help doctors view 3D images and combine them with other images to get more information about the diagnosis. Godinho et al. found in their 2012 investigation that, in processing CT scan images of stroke patients, radiologists using the ResolutionMD mobile terminal can improve the speed by 24% compared with the PACS workstation, saving one patient every 11 minutes on average [4]. Kong and Chen estimated that the gap of talents in relevant majors in China in the next five years would be as high as 1.3 million; especially, big data talents with solid theoretical foundation and business practice experience across biomedical science and information science are in great shortage [5]. Zhou et al. believed that the future development of teleradiology would be more important [6]. On the basis of the present research, this paper expounds the characteristics of several radiological examinations commonly used in health examination in order to make reasonable application of this kind of examination. Specific x-ray fluoroscopy, health examination, X-ray, and multiple medical imaging tests are involved in the physical examination program. Through discussion and comparison, it is concluded that the X-ray film is the first choice and the most cost-effective method for screening chest diseases in the routine physical examination of most people at present. Ultrasound shows a high diagnostic sensitivity and can make a clear diagnosis of benign and malignant diseases [7, 8].

2. Materials and Methods

2.1. Clinical Data. The patients received imaging health examination in the mobile health center and were set as the control group. There were 2316 cases in the observation group, including 1169 males and 1147 females, aged from 2 to 83 years, with an average age of 55 ± 16.9 years. In the control group, there were 1,982 cases, including 1006 males and 976 females, ranging in age from 1 to 81 years, with an average age of 52 ± 18.3 years. There was no significant difference in age and gender between the two groups ($P \geq 0.05$).

2.2. Research Methods. Doctors will upload the image data to the medical image level-3 diagnosis platform, so county hospital diagnostic center doctors can receive mobile phone SMS alerts and receive township hospital patients examination data. Doctors in the diagnostic center of county hospital can read diagnosis online, review, and issue diagnosis report and reply with electronic signature. Township health work site timely obtains and prints diagnostic reports to patients. For difficult cases, township doctors can upload the examination data to the central hospital for imaging consultation and generally complete the diagnosis or consultation within 1 hour [9].

2.3. Statistical Analysis. Data analysis was performed using SPSS 13.0. The measurement data are represented by mean ± standard difference ($x \pm s$), compared using the t-test and χ^2 test, and $P < 0.05$ is of statistical significance.

3. Results and Discussion

Among 2316 cases in the observation group, 2005 cases were qualified and 311 cases were unqualified, with a pass rate of 86.57%. In the control group of 1982 cases, 1391 cases were qualified and 591 cases were unqualified, with a qualified rate of 70.18%. The difference was statistically significant ($P < 0.05$), as shown in Table 1.

The main factors for unqualified cases are unphotographed positive position (32.13%), uploaded image quality defects (exposure, artifacts, and poor image quality) (28.58%), unmarked image left and right parts (25.12%), and failure to provide a complete medical history (14.17%).

In the observation group, 1675 cases were positive and 641 cases were negative, and the positive rate was 72.32%, while in the control group, 1167 cases were positive and 815 cases were negative, and the positive rate was 58.88%, among the 2316 cases. The difference was statistically significant ($P < 0.05$), as shown in Table 2.

Table 1: Comparison of imaging quality between the observation group and the control group.

Group	Qualified	Unqualified	Percentage of pass
Observation group ($n = 2316$)	2005	311	86.57
Control group ($n = 1983$)	1391	591	70.18

Table 2: Comparison of the positive rate of radiography between the observation group and the control group.

Group	Positive	Negative	Positive rate
Observation group ($n = 2316$)	1675	641	72.32
Control group ($n = 1982$)	1167	815	58.88

The use of the medical imaging system for sentinel lymph nodes in the treatment of breast cancer is characterized by the ability to detect sentinel lymph node metastasis through some diagnostic methods. At present, the main methods for the clinical diagnosis of sentinel lymph node micrometastasis include continuous section, immunohistochemistry, and biopsy. However, in the actual operation process of the former two methods, all lymph nodes of patients need to be tested, which is a heavy workload and has great limitations in practical use; it is difficult to achieve the purpose of detection, so sentinel lymph node biopsy for breast cancer has become a widely used means in clinics. However, with the continuous development of medical technology, some scholars have proposed that colour ultrasound has a good effect on the diagnosis of sentinel lymph node micrometastasis [10].

Sixty cases of breast cancer patients admitted to a hospital from December 2014 to December 2015 were randomly selected as the research objects. All the selected patients were female, aged from 21 to 68 years, with an average age of 50.6 ± 5.7 years. Sites: 33 on the right side and 27 on the left side; there were 22 cases of invasive ductal carcinoma, 7 cases of mucinous adenocarcinoma, 8 cases of invasive lobular carcinoma, 10 cases of papillary adenocarcinoma, and 13 cases of medullary carcinoma. According to TNM stage T1-2N0M0, 25 cases were of the T1 stage (tumor diameter: <2 cm), 35 cases were of the T2 stage (tumor diameter: 2–5 cm), as shown in Table 3.

According to the material of the X-ray bulb tube anode, there are tungsten target and rhodium target. At present, molybdenum target is more commonly used for X-ray photography, which is of great value for the examination of breast cancer, the classic textbook description of the X-ray signs of breast cancer typically involves lesions that have formed masses or prominent nodules, with the improvement of people's health awareness and the popularization of medical knowledge, and the typical breast cancer is rarely found in the health examination; however, mammography is more difficult to diagnose early breast cancer with no history, no symptoms, no signs, and lesions of less than a certain volume than breast cancer with a history, symptoms, signs, and lesions of a certain volume; it depends even more

Table 3: Colour ultrasound results of breast cancer patients.

Position and type	This is an infiltrating ductal carcinoma	Mucous adenocarcinoma	This is an invasive lobular carcinoma	Papillary adenocarcinoma	Medullary carcinoma
On the right side	10	3	4	3	5
On the left side	12	4	4	7	8

Table 4: CT examination data of thyroid cancer patients.

	The number of people	Age	You have thyroid nodules	Thyroid cancer	Papillary carcinoma of the thyroid	Medullary thyroid carcinoma
Man	50	40–50	16	3	2	0
Woman	95	19–75	45	6	5	1

Table 5: Comparison of diagnostic rates between observation and control imaging subjects.

Group	Clarify a diagnosis	No clear diagnosis	Positive rate (%)
Observation group ($n = 2316$)	2213	103	95.55
Control group ($n = 1982$)	1589	384	80.17

on the personal experience of the diagnostician and the thinking environment at the time of reading the film, especially in women of reproductive age whose breast tissue has not degenerated; the value of mammography may be higher for those who have already been examined or self-examined by a doctor, especially for those who have been found to have suspicious nodules by ultrasound. Molybdenum target mammography of the breast generally takes a total of four films for the comparison between the upper and lower positions of both sides of the breast and the internal and external oblique positions, and the total amount of X-ray radiation cannot be ignored. Therefore, the indications for mammography should be mastered from the aspects of family history, age, medical history of the present illness, marriage, and child history to prevent the abuse from causing harm to women [11]. Some foreign anthologies suggest annual mammography and MRI examination for high-risk groups, and Liu Peifang also advocates MRI participation in the census of high-risk groups in China. Regular screening for breast cancer is necessary for high-risk groups. If mammography has the most comprehensive advantages compared with MRJ and ultrasound, another method of screening for breast cancer, it is worthwhile to make mammography the preferred method for early breast cancer screening in high-risk groups.

Due to the popularity of CT, in routine physical examination, further CT examination of lesions of solid organs in the digestive system, urogenital system, and other systems found by ultrasound examination and lung lesions found by the chest X-ray film can be used to differentiate benign from malignant lesions or evaluate their functions: patients with special indications of biochemical examination results can be screened for diseases of related organs: for patients with frequent dizziness and headache, in order to exclude cerebrovascular lesions, head CT can be included in the physical examination items if conditions permit; as a routine test, because of the high dose of X-ray radiation, how to use this new technique to maximize the diagnostic effect and accord with the principle of X-ray examination optimization is a subject worth studying. So, people tend to use low-dose spiral CT scans to screen for early lung cancer, and because of the low dose X-ray scans in low dose spiral CT scans, the thin-layer reconstruction technique is used instead of the thin-layer scan so that the dose of iatrogenic X-ray radiation of the subject is greatly reduced, and because the low-dose spiral CT scan requires less X-ray dose, the thermal effect of the CT tube is reduced, the loss of the CT tube is correspondingly reduced, the life of the tube is prolonged, and it is possible to reduce the charge reasonably. In addition, CD is used instead of film, which further saves the cost and makes it possible to charge the same fee for the low-dose spiral CT scan and chest CR and DR examination, which is easy to be accepted by people. For patients with cardiac symptoms, CT coronary imaging is undoubtedly necessary, but this examination can increase the amount of X-ray radiation in the subject, and the screening for coronary artery disease in the routine physical examination is still under study and questionable; some occupations have special physical requirements for practitioners. After a certain age, CT coronary imaging can be performed to screen for coronary artery lesions. In any case, you should respect the advice of your doctor as to whether or not to have a CT scan on a healthy subject, and you should never ask for a CT scan unless recommended by your doctor.

A total of 150 patients (55 males and 95 females) underwent thyroid nodule examination. The average age was 45.39 ± 5.96 years from 19 to 75 years. For all physical examination personnel, colour Doppler ultrasound was selected to carry out thyroid nodule disease diagnosis. The frequency of the ultrasonic probe was adjusted from 7.5 to 12 MHz such as Table 4.

Patients with hyperplasia of thyroid tissue are more likely to present with thyroid nodules. If the nature of the thyroid nodule is different, different clinical intervention measures should be selected [12]. For patients with benign thyroid nodule, conservative treatment and follow-up observation were mainly selected clinically. For physical examination personnel in the implementation of the thyroid nodule diagnosis process, the method of ultrasound examination is chosen, showing a high diagnostic sensitivity, and can be a clear diagnosis of benign and malignant diseases so as to ensure the smooth implementation of clinical effective thyroid nodule treatment methods.

As shown in Table 5, in the observation group of 2316 cases, 2213 cases were clearly diagnosed, 103 cases were undiagnosed, and the diagnosis rate was 95.55%. In the control group, 1589 cases were definitely diagnosed, 384 cases were undiagnosed, and the diagnosis rate was 80.17%. The difference was statistically significant ($P < 0.05$).

4. Conclusions

This paper discusses the application of several radiological images in normal physical examination. X-ray fluoroscopy; X-ray photography; color Doppler imaging; X-ray radiography has developed from screen radiography to computer radiography (CR) and the latest digital X-ray radiography (DR). Through the comparison of the positive rate of radiography in the observation group of 2316 cases, 1675 cases were positive and 641 cases were negative, and the positive rate was 72.32%, while in the control group of 1982 cases, 1167 cases were positive and 815 cases were negative, and the positive rate was 58.88%. Thus, this demonstrates that X-rays are the preferred and most cost-effective method of screening for chest disease during routine physical examinations. The choice of the ultrasound examination method shows a high diagnostic sensitivity, and the benign and malignant disease can be clearly diagnosed so as to ensure the successful implementation of the clinical effective treatment of thyroid nodules. The development of information technology has indeed provided us with great convenience and also promoted the development of medical imaging, teaching, and scientific research. It is combined with biotechnology, genetic engineering, and medical engineering. Hospitals at all levels should improve the understanding of digital large imaging, update their ideas, actively promote its application in hospitals, and strengthen personnel training. The rapid development of video technology has promoted the explosive coverage of video visual culture in today's society. When video visual culture enters the field of education, it will have a huge impact on the educational mode.

Imaging examination plays an important role in the early diagnosis of myeloma. The study focused on the segmentation effects of deep learning-based models on CT images for myeloma, and the influence of different chemotherapy treatments on the prognosis of patients. Specifically, 186 patients with suspected myeloma were the research subjects. The U-Net model was adjusted to segment the CT images, and then, the Faster region convolutional neural network (RCNN) model was used to label the lesions. Patients were divided into bortezomib group (group 1, $n = 128$) and non-bortezomib group (group 2, $n = 58$). The biochemical indexes, blood routine indexes, and skeletal muscle of the two groups were compared before and after chemotherapy. The results showed that the improved U-Net model demonstrated good segmentation results, the Faster RCNN model can realize the labeling of the lesion area in the CT image, and the classification accuracy rate was as high as 99%. Compared with group 1, group 2 showed enlarged psoas major and erector spinae muscle after treatment and decreased bone marrow plasma cells content, blood M protein, urine 24 h light chain, pBNP, *ß*-2 microglobulin (β2MG), ALP, and white blood cell (WBC) levels ($P < 0.05$). In conclusion, deep learning is suggested in the segmentation and classification of CT images for myeloma, which can lift the detection accuracy. Two different chemotherapy regimens both improve the prognosis of patients, but the effects of non-bortezomib chemotherapy are better.

1. Introduction

Myeloma leads to increased levels of monoclonal immunoglobulin, which is attributed to malignant proliferation and abnormal accumulation of clonal plasma cells [1]. Studies have shown that the incidence of multiple myeloma has significantly exceeded that of acute leukemia and ranks second among hematological malignancies [2]. With the progress in research on treatment methods and the clinical promotion of hematopoietic stem cell transplantation technology, the complete remission rate of multiple myeloma has reached approximately 75% [3]. It has been confirmed that the median survival time of patients with multiple myeloma has been extended to 5 to 8 years [4]. Thanks to the unclear cause, the insidious onset, and low progress of myeloma, it is easy to cause the missed diagnosis and misdiagnosis [5]. In the treatment of myeloma, the chemotherapy regimen containing high-dose dexamethasone was generally selected in the past. This regimen has a rapid onset for newly discovered myeloma patients, with a median onset time of 1–1.5 months, which can quickly relieve patient symptoms. In recent years, with the emergence of new drugs such as immunomodulators and protease inhibitors, treatment programs have been further optimized. Nowadays, it is common to choose a combination of new drugs and traditional chemotherapy drugs for combined chemotherapy in clinical practice. This new combination chemotherapy regimen can significantly improve the remission rate of myeloma patients and the survival rate.

The clinical diagnosis method of myeloma is different from other general tumors. It requires obvious clinical symptoms of peripheral organ damage, such as renal function damage and osteolytic bone damage [6]. Recently, imaging techniques have been widely used in the diagnosis, differentiation, staging, and evaluation of therapeutic effects of multiple myeloma. Multiple myeloma is a blood system disease, involving multiple systems/organs. Systemic bone disease and extramedullary lesions have implications for the identification, diagnosis, and staging of the disease [7]. X-ray is always used in the imaging diagnosis of multiple myeloma, but it is positive only when more than 30% of the trabecular bone is destroyed and so it is easy to cause missed diagnosis [8]. CT imaging is characterized by cross-sectional scan, high-density resolution, and reconstruction. It is superior to X-ray scan in the diagnosis of multiple myeloma [9].

However, CT imaging cannot be used to stage the disease when there is no change in bone marrow infiltration and cortical bone. One of the most classic methods of deep learning is convolutional neural networks. Among them, Faster RCNN and U-Net are both earlier algorithms that use full convolutional networks for image segmentation. Deep learning used in the segmentation of medical images can greatly improve the segmentation effects [10]. The fully convolutional network (FCN) optimizes the fully connected layer in the traditional convolutional neural network into a convolutional layer, which reduces the complexity of the calculation and lifts the segmentation efficiency [11]. Compared with the FCN model, the U-Net model has higher segmentation accuracy and is not limited by the input sample size [12]. Using deep learning to process medical images can assist doctors in detecting lesions. It not only reduces the workload of doctors but also overcomes problems, such as poor diagnosis due to subjective differences.

In this study, a deep learning-based model was used to process CT images of patients with myeloma and then the effects of different chemotherapy treatments on the prognosis of patients were compared, aimed to provide reference for improving the clinical diagnosis, treatment, and staging effects of myeloma.

2. Methods

2.1. Research Subjects. A total of 186 suspected myeloma patients were selected, among whom 123 were initially diagnosed as myeloma by Durie–Salmon (DS) and International Staging System (ISS) methods. They all underwent surgery, pathological examination, and bone marrow aspiration biopsy and were diagnosed with myeloma. There were 93 males and 93 females, and the age ranged from 35 to 82 years, with an average age of 58.54 ± 10.15 years. The average interval between bone marrow biopsy and imaging examination was about 20 days.

The subjects were selected as per the following inclusion criteria: (i) those who met the diagnostic criteria for myeloma; (ii) those who had not received any radiotherapy, chemotherapy, or other therapies before treatment; (iii) those who had no other malignant tumors; and (iv) those agreeing with and accepting the study.

Exclusion criteria were as follows: (i) those with incomplete imaging data and (ii) those who cannot cooperate to complete the imaging examination. All patients have signed an informed consent form. All studies in this article have been approved by the Medical Ethics Committee.

2.2. CT Examination. The whole-body low-dose CT examination was performed using the Philips Brilliance ICT instrument. Under 120 kV and 50 mAs, the slice thickness was 2 mm, the slice spacing was 1 mm, the reconstruction slice thickness was 3 mm, the screw pitch was 0.811, and the collimation was 128×0.873 mm. During CT examination, the patient was in a supine position with arms crossed and placed on the lower abdomen. The scan was from the top of the skull to the proximal end of the tibia. After the scan, the collected images need to be transmitted to the image-processing workstation. The standardized bone algorithm was used to perform sagittal and coronal reconstruction.

2.3. CT Image Segmentation Based on U-Net. The U-Net model is used to segment skeletal CT images, and it is a typical "end-to-end" U-shaped network structure. To improve the segmentation effects, the original U-Net model was optimized, and the structure of the adjusted model is shown in Figure 1.

A loss function based on the Dice coefficient is used to balance the ratio of pixels in the bone area to the background area. The Dice coefficient is to measure the similarity between functions [13], and the Dice coefficient and its loss function are calculated as follows:

$$\begin{aligned} \text{Dice} &= \frac{2 \cdot \text{TP}}{2 \cdot \text{TP} + \text{FP} + \text{FN}}, \\ \text{loss} &= 1 - \frac{2 \cdot \text{TP}}{2 \cdot \text{TP} + \text{FP} + \text{FN}}, \end{aligned} \tag{1}$$

TP is the number of positive samples predicted as positive samples, FP is the number of positive samples predicted as negative samples, and FN is the number of positive samples predicted as negative samples.

Intersection over union metric (IOU) is used to evaluate the segmentation effects. IOU calculates the intersection ratio, which is often used in the field of image segmentation [14]. The calculation of IOU is as follows:

$$\text{IOU} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{FN}}. \tag{2}$$

2.4. Myeloma Detection Based on Faster RCNN. In order to realize the intelligent detection of myeloma using CT images, the Faster RCNN model is used to detect the lesion area. The Faster RCNN model mainly consists of two parts, namely, the region proposal network (RPN) and the region convolutional neural network (RCNN) [15]. The specific image processing steps using this model are as follows: First, the network classification model is used to extract the feature map, and then, the RPN is used to generate the region of interest (RoI), followed by the pooling operation. Finally, RCNN is used to classify the feature map and assign

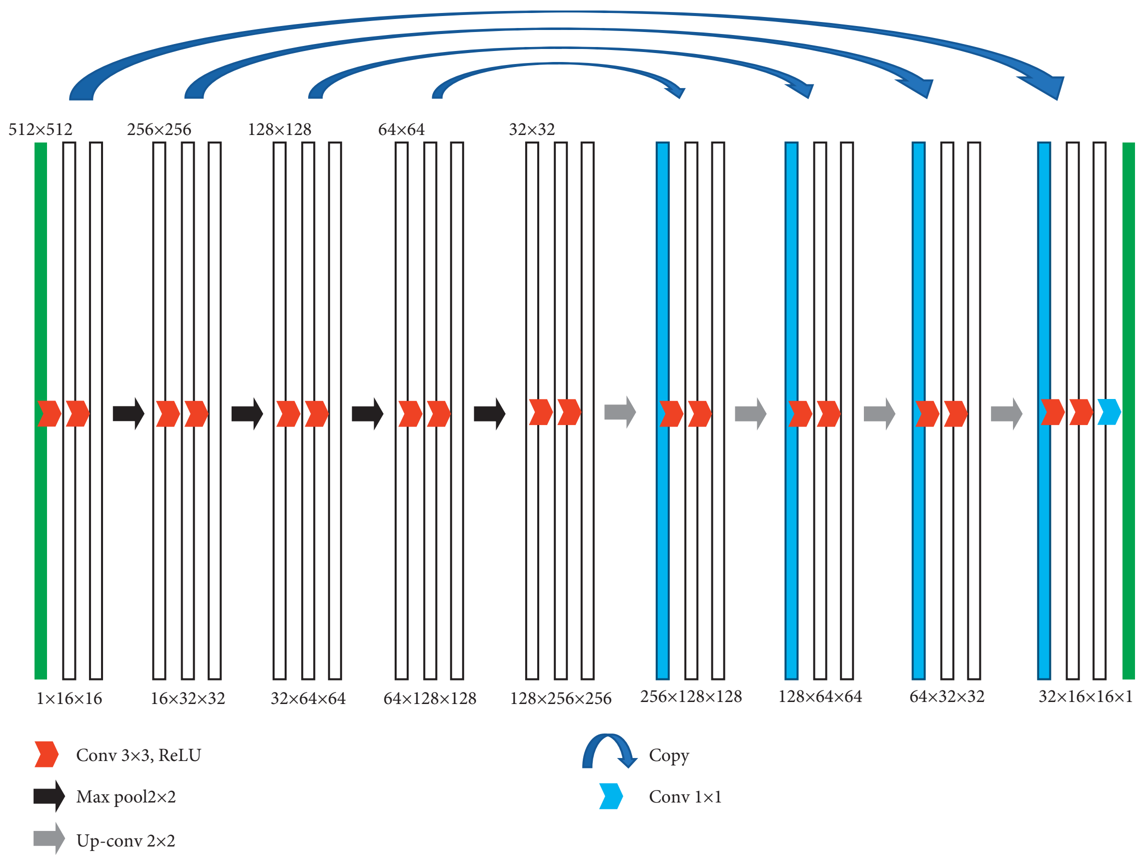

Figure 1: Basic framework and parameter settings of the U-Net model.

the probability value to the target category. The basic structure and parameters of Faster RCNN are shown in Figure 2.

The VGG basic model is used to extract the feature map. The basic structure of the VGG model is shown in Figure 3. The convolutional kernel sizes in the VGG model are 1×1 and 3×3. The activation function is a softmax function, and the reshape operation is performed before and after treatment to improve the classification effects.

The sample is input into the model for training, and the loss function of the model needs to include the RPN and detector, but the loss function is composed of classification loss and regression loss function, expressed as follows:

$$L(\{p_i\}, \{t_i\}) = \frac{1}{N_c} \sum L_c(p_i, p_i^*) + \alpha \frac{1}{N_r} \sum p_i^* L_r(t_i, t_i^*), \tag{3}$$

where p_i is the probability of the target area in the prediction box and p_i^* is the multiclass labels in softmax regression.

The mathematical expressions of classification loss L_c and regression loss L_r are as follows:

$$\begin{aligned} L_c(p_i, p_i^*) &= -\log(p_i^* p_i + (1 - p_i^*)(1 - p_i)), \\ L_r(t_i, t_i^*) &= R(t_i, t_i^*), \end{aligned} \tag{4}$$

where R is the smooth $L1$ function, t_i is the offset of the prediction frame during the RPN training process, and t_i^* has the same dimension as t_i. With the iteration of the loss function, the parameters of the softmax classifier are further optimized and clarified, which can distinguish different training samples.

2.5. Remission Induction Treatment Plan. With patients' economic levels and clinical differences taken into account, there were mainly two treatment plans: group 1 underwent bortezomib treatment, and group 2 underwent non-bortezomib treatment. There were 128 patients in group 1, and 58 patients in group 2.

2.6. Evaluation and Follow-Up. All patients were tested for laboratory indicators before treatment and after induction treatment, including blood routine, serum/urine protein electrophoresis, biochemical items (albumin, globulin, and blood creatinine), urine routine, and bone marrow examination, to explore clinical efficacy. All patients were followed up from the first visit, and the follow-up time was approximately 40 months. The overall survival time in this study was from the time of diagnosis to the end of the last follow-up. When patients were transferred halfway or gave up treatment, they were not included in the study of overall survival.

2.7. Statistical Processing. SPSS19.0 was used to process the data. Measurement data conforming to normal distribution were expressed as mean ± standard deviation, and

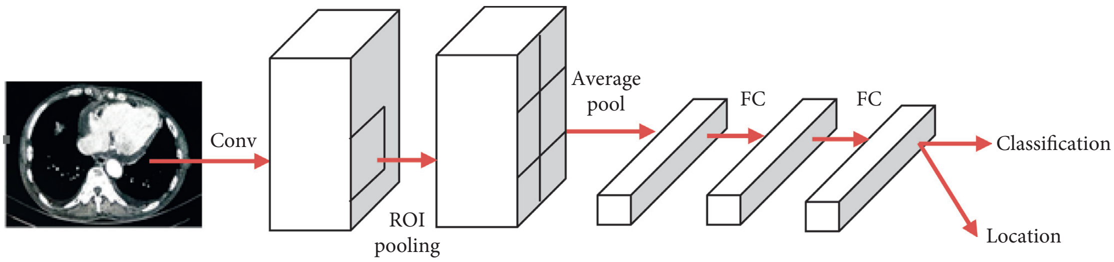

Figure 2: Basic structure of Faster RCNN.

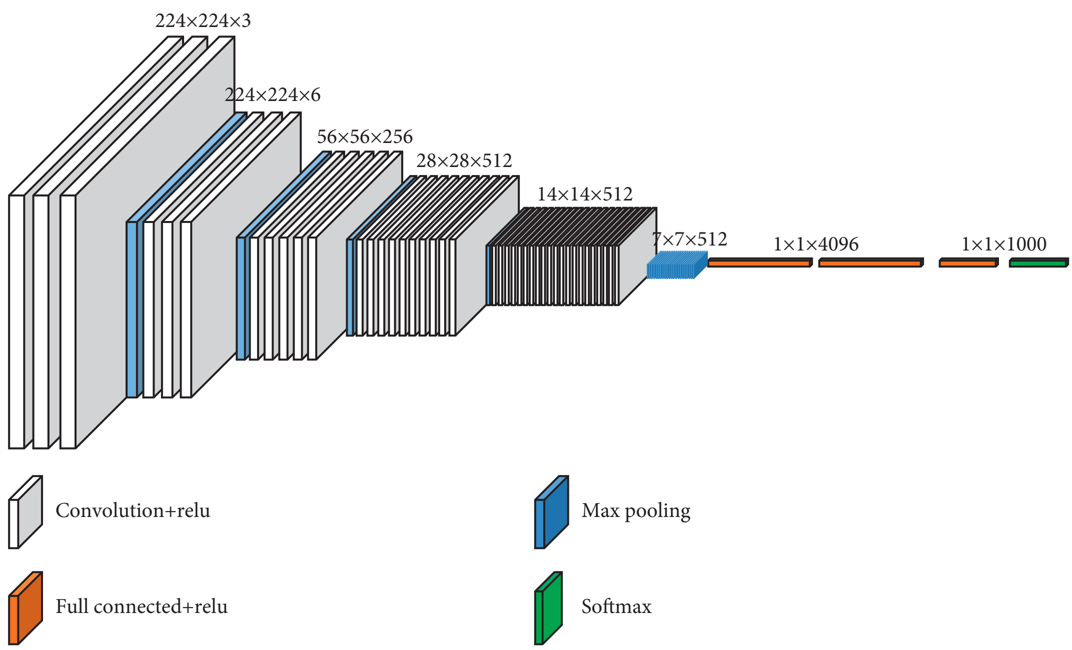

Figure 3: Basic structure of the VGG model.

comparisons between groups adopted the independent sample t test; measurement data that did not conform to normal distribution were represented by the median value, and the nonparametric rank sum test was used to analyze the difference between groups. The count data were expressed by percentage n, and the χ^2 test was for comparison between groups. $P < 0.05$ was the threshold for significance.

3. Results

3.1. Segmentation Performance of the U-Net Model. U-Net and the improved U-Net′ network were trained for 50 rounds, and the loss curve and IOU curve of the two models on the training set and the test set were compared before and after chemotherapy. It is noted in Figure 4 that the loss curve of the U-Net′ model on the training set and the test set converged more quickly, while the area under the IOU curve was larger.

The loss value and IOU value were compared between the U-Net and U-Net′ model when the maximum training times are reached, and the results are shown in Figure 5. It was noted that the loss values of the U-Net′ model on the training set and the test set were larger, than the IOU value.

Subjectively, the segmentation effects of the U-Net and U-Net′ model on CT images were compared for multiple myeloma, and the results are shown in Figure 6. The segmentation effects of the lesion area on the T1 and T2 images were compared. It was noted that the U-Net model had poor effects when segmenting small lesions in the CT image and the improved U-Net′ model can realize the segmentation of small lesions. The red area in the figure is the segmentation of the lesions of myeloma patients under the U-Net model algorithm.

3.2. Detection and Verification of the Faster RCNN Model. The Faster RCNN model was trained, and the training results are shown in Figure 7. It was noted that when training iterations were below 10 times, the classification accuracy and loss value of the model gradually stabilized. The classification accuracy of the Faster RCNN model was approximately 0.966, and the loss value was approximately 0.092.

The trained Faster RCNN model was then used to detect multiple myeloma, and the results are shown in Figure 8. It was noted that the classification results displayed the

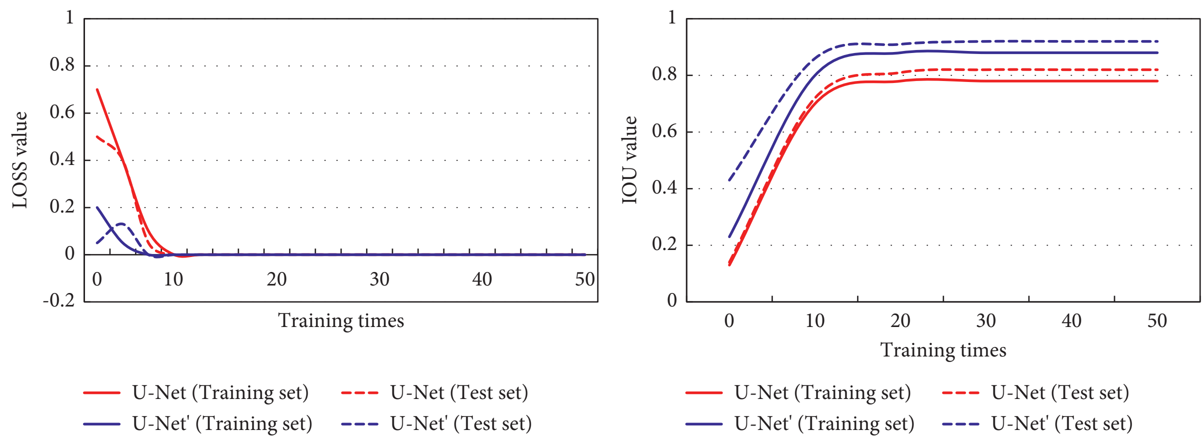

FIGURE 4: Loss and IOU curves on the training set and test set.

prediction frame, the corresponding category, and the probability value of the target area. The red area in the figure is the part of the myeloma patient's lesion that was separated under the Faster RCNN model algorithm.

3.3. Basic Information of Patients. The baseline data of patients in group 1 and group 2 were compared, and the results are shown in Table 1. It was noted that there was no statistically significant difference between the two groups of patients in age, height, weight, gender, DS staging, and ISS staging ($P > 0.05$). Hence, the baseline data of the two groups were comparable.

3.4. CT Imaging for Waist Muscle of the Patient before and after Chemotherapy. The fat in psoas major, quadratus lumborum, erector spinae, and erector spinae was compared before

TABLE 1: Comparison of baseline data between the two groups.

Project		Group 1 ($n = 128$)	Group 2 ($n = 58$)	Statistics	P
Age (year)		58.93 ± 9.65	57.69 ± 11.12	$t = 0.771$	0.441
Height (m)		1.66 ± 0.08	1.65 ± 0.10	$t = 0.453$	0.652
Weight (kg)		67.52 ± 10.51	66.85 ± 11.86	$t = 0.317$	0.752
Gender (n/%)	Male	69/53.91	24/41.38	$\chi^2 = 0.839$	0.334
	Female	59/46.09	34/58.62		
DS staging (n/%)	I	3/2.34	4/6.90	$\chi^2 = 0.873$	0.467
	II	9/7.03	4/6.90		
	III	2/1.56	1/1.72		
	IV	9372.66	39/67.24		
	V	20/15.63	9/15.52		
ISS staging (n/%)	I	17/13.28	10/17.24	$\chi^2 = 0.797$	0.562
	II	54/42.19	22/37.93		
	III	52/40.63	22/37.93		
	IV	0/0.00	0/0.00		
	V	1/0.78	0/0.00		

and after chemotherapy, and the results are shown in Figure 9. It was noted that in group 2, the quadratus lumborum muscle was significantly reduced and the erector spinae muscle was significantly enlarged after treatment ($P < 0.05$) compared to before treatment; the psoas major and erector spinae muscle were significantly enlarged after treatment in group 2 compared to group 1, and the erector spinae muscle fat was significantly reduced ($P < 0.05$).

3.5. Biochemical Indicators before and after Chemotherapy. The ratio of bone marrow plasma cells, monoclonal immunoglobulin (M protein), urine 24 h light chain, pBNP, and β-2 microglobulin (β2MG) levels were compared before and after chemotherapy, and the results are shown in Figure 10. It was noted that compared to before treatment, the levels of urine 24 h light chain, pBNP, and β2MG in group 2 were significantly reduced ($P < 0.05$) while the level of β2MG in group 1 was also significantly reduced ($P < 0.05$). Compared with group 1, the ratio of bone marrow plasma cells, blood M protein, urine 24 h light chain, pBNP, and β2MG levels were significantly reduced after treatment in group 2 ($P < 0.05$).

3.6. Blood Routine Indexes before and after Chemotherapy. The blood routine indexes of ALP, LDH, Cr, Alb, Ca, WBC, Hb, and Plt were compared before and after chemotherapy, and the results are shown in Figure 11. It was noted that compared with before treatment, the Cr levels of group 1

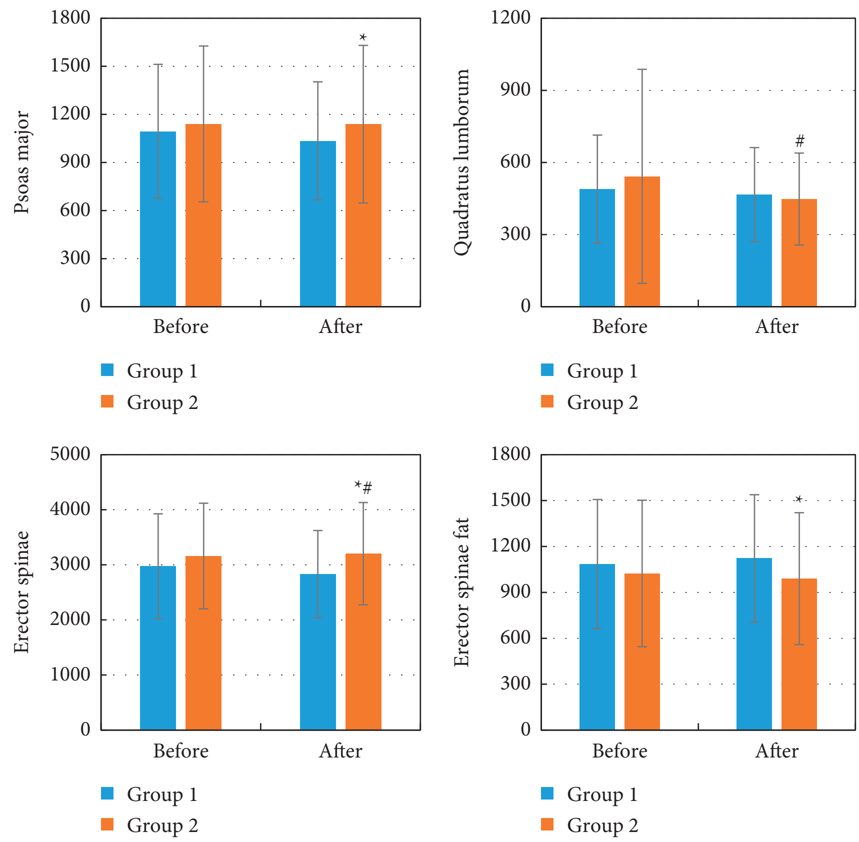

Figure 9: CT results of the patient's psoas major before and after chemotherapy. The four pictures show (a) psoas major, (b) quadratus lumborum, (c) erector spinae, and (d) erector spinae fat. Compared to before treatment, $^{\#}P<0.05$; compared to group 1, $^{*}P<0.05$.

and group 2 were significantly reduced ($P<0.05$). Compared with group 1, ALP before and after treatment in group 2 was significantly lower ($P<0.05$), the LDH level before and after treatment was significantly higher ($P<0.05$), and the WBC level after treatment was significantly lower ($P<0.05$).

4. Discussion

Threshold segmentation is the most common image segmentation method. The pixel values in the target area and background are similar, but the pixel values of different target areas are different. The algorithm segments the target area according to the peak value displayed in the histogram [16]. Traditional segmentation algorithms are affected by image noise and other factors, and thus, they tend to have poor segmentation results. The U-Net model has been proved to have excellent segmentation results [17], so it was used in the study. Its parameters were adjusted based on the original one, and then, the adjusted one was used to segment the lesion area in CT images. It was found that compared to the original one, the improved U-Net model demonstrated better convergence effects and the area under the IOU curve was larger. It suggested that the adjusted U-Net model had better segmentation effects on the CT image of multiple myeloma. Image processing is an integral part in the detection of lesion area [18]. The deep learning-based model needs to classify the target areas after the recognition and positioning [19]. Therefore, the Faster RCNN framework was used to detect the lesion area on CT images for myeloma and to locate the target area in the CT image and label the category. The results showed that the Faster RCNN model can realize the positioning and category labeling of the lesion area, which lifted the diagnosis efficiency.

Plasma cells are transformed into protoplasmic cells by B lymphocytes after antigen stimulation, and protoplasmic cells evolve into mature plasma cells through processes such as differentiation and reproduction [20]. M protein is an abnormal immunoglobulin produced by the monoclonal malignant proliferation of plasma cells or B lymphocytes [21]. Studies have confirmed that the proportion of plasma cells and the level of M protein in patients with multiple myeloma are significantly increased [22]. The results of this study found that the proportion of bone marrow plasma cells and the level of M protein in patients undergoing chemotherapy were significantly reduced and the decrease in the non-bortezomib group was more obvious. The molecular structure of immunoglobulin can be divided into two types: heavy chain and light chain, of which the light chain is divided into κ type and λ type [23]. The multiple myeloma arises from excessive proliferation of abnormal plasma cells in the bone marrow, which in turn causes an increased level of M protein, lifting

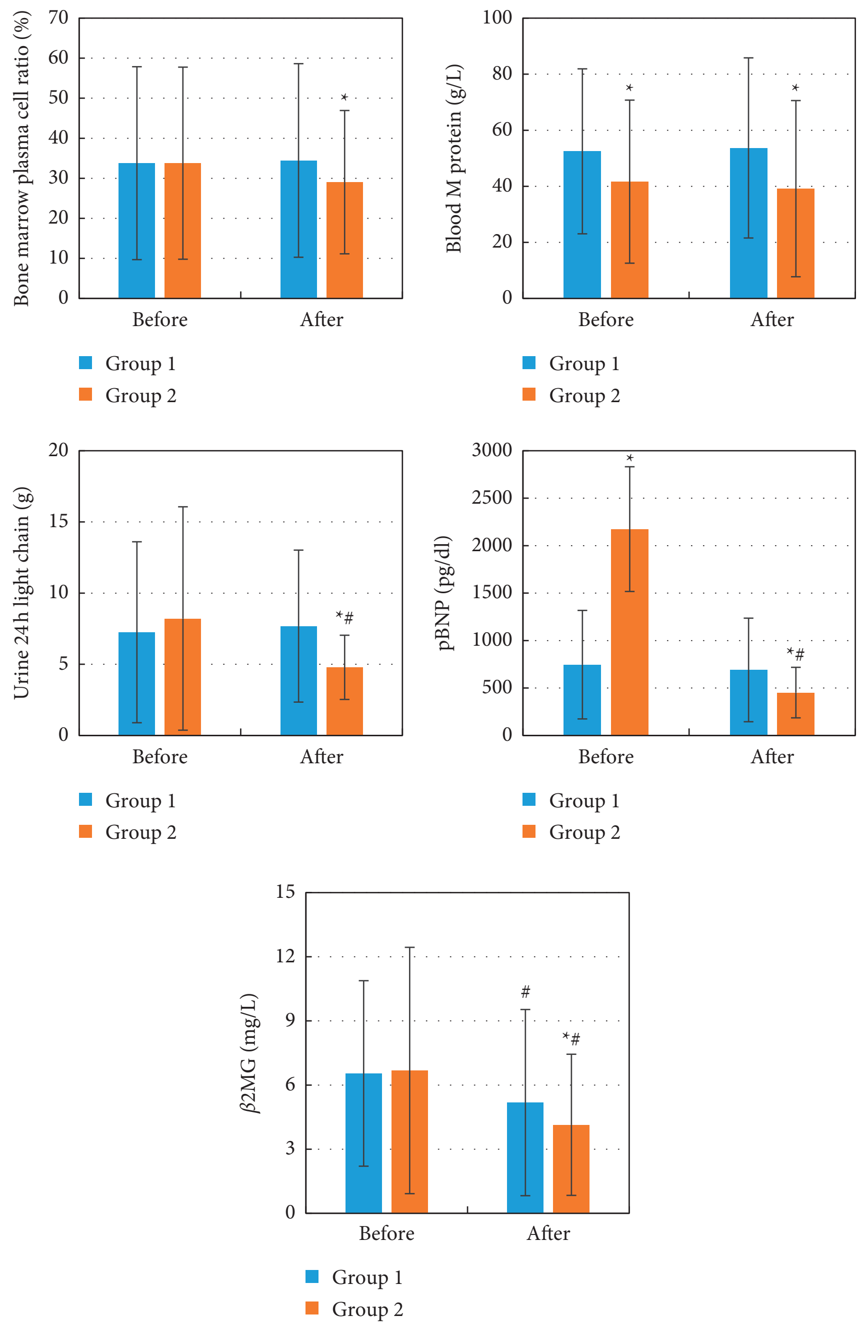

Figure 10: Biochemical indicators of the patient before and after chemotherapy. The five pictures show (a) bone marrow plasma cell ratio, (b) blood M protein, (c) urine 24 h light chain, (d) pBNP, and (e) β2MG. Compared to before treatment, $^{\#}P < 0.05$; compared to group 1, $^{*}P < 0.05$.

the level of urinary light chains, so the level of light-chain type of urine protein is an indicator for the diagnosis of multiple myeloma [24, 25]. β2MG is a small molecular protein synthesized by lymphocytes, which can be used to assess kidney function and can also be used for auxiliary diagnosis of malignant tumors [26, 27]. It was found in the study that, after non-bortezomib treatment, the patients' urine 24 h light chain and β2MG levels were significantly reduced, indicating that the treatment can effectively improve the prognosis of patients.

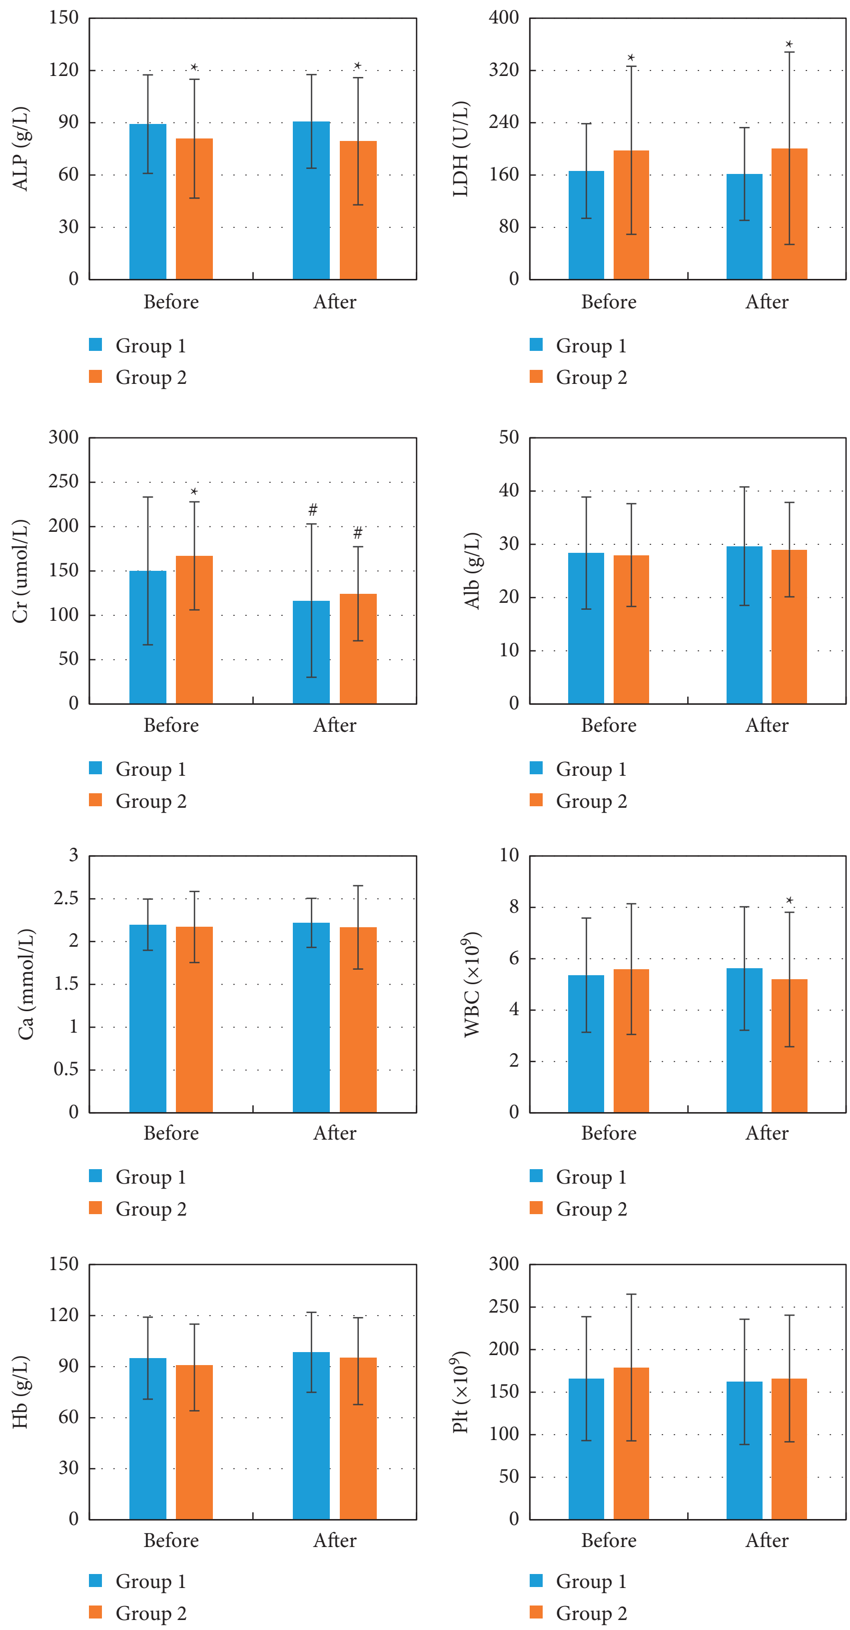

FIGURE 11: Routine blood indicators of patients before and after chemotherapy. The eight pictures were ALP, LDH, Cr, Alb, Ca, WBC, Hb, and Plt. Compared to before treatment, $^{\#}P < 0.05$; compared to group 1, $^{*}P < 0.05$.

5. Conclusion

The purpose of this article is to use deep learning technology to segment and classify myeloma CT images and to further improve the clinical diagnosis and treatment of myeloma patients. The results showed that U-Net and Faster RCNN models can realize lesion area segmentation and labeling. The effects of different chemotherapy treatments on the prognosis of patients were compared. It was found that non-bortezomib treatment can significantly reduce the proportion of bone marrow plasma cells, M protein, urine 24 h light chain, β2MG, and WBC levels, indicating that the treatment plan can improve the patient's chemotherapy effects. However, some limitations in the study should be noted. The deep learning is only used to segment and classify the lesion area in the CT image and not applied to the CT image after chemotherapy. However, the research content of this article still has certain limitations. The article does not analyze the correlation between different prognostic indicators and the overall survival of patients. And, this article only studies a single imaging diagnostic method, so more imaging diagnostic methods will be studied in depth in the future. Therefore, more clinical indicators will be involved in the follow-up, to strengthen the findings of the study. In summary, the results of this study can effectively improve the diagnostic accuracy of patients with myeloma, provide certain guidance for subsequent clinical treatment, and significantly improve the prognosis of patients. It provides a certain theoretical basis for the subsequent research on imaging examination methods.

The objective of this study was to explore the application value of intracavitary electrocardiogram- (IEGM-) guided diagnosis of occult heart disease and conventional electrocardiogram (EGM) in the diagnosis of occult coronary heart disease (CHD) based on the classification and regression tree (CART) mining algorithm, hoping to provide a more effective basis for clinical diagnosis of the occult CHD. In this study, 100 patients with occult CHD admitted to our hospital from February 2016 to December 2020 were selected as the research objects. Based on the random number table method, 100 patients were randomly rolled into two groups, each with 50 cases. The patients diagnosed with conventional ECG were set as the control group, and patients in the experimental group were diagnosed with IEGM under the data mining algorithms. The diagnostic effects of the two groups were compared. The results showed that the processing effect of the CART algorithm (94%) was much better than that of the multiple linear regression algorithm (78%) and the random forest algorithm (69%) ($P < 0.05$), the agreement between the results of the experimental group and the results of coronary angiography (80%) and Kappa (0.7) was higher than those of the control group (55%, 0.45), and the difference was statistically significant ($P < 0.05$). In addition, the sensitivity (93%) and accuracy (80%) of the experimental group were obviously higher than those of the control group (62% and 55%), and the differences were remarkably significant ($P < 0.05$). In conclusion, the consistency ratio of the IEGM examination was higher, showing high accuracy; the intracavitary examination was invasive, so IEGM was not recommended when the diagnosis result of the examination may cause more harm than good.

1. Introduction

The economic, cultural, and technological development of today's society is quite rapid, including the medical technology. With the development of society, it is not only people's living standards that have been improved, but the incidence of various diseases has also increased, which has had a great impact on people's lives and health, including the hidden coronary heart disease (occult CHD) [1, 2]. The pathogenesis of coronary heart disease (CHD) is mainly due to coronary artery stenosis that causes the circulatory system to not provide enough blood to the body, which indirectly leads to myocardial dysfunction. CHD can be said to be a common disease with a high clinical incidence, and its occurrence trend is also increasing year by year with time [3, 4]. The occult CHD, also known as painless myocardial ischemia, is a special type of CHD [5]. Most people with occult CHD are middle-aged or older. Simply speaking, it means that there is no obvious clinical manifestation. However, myocardial ischemia and coronary atherosclerosis can be found under the relevant examinations of electrocardiogram (EGM), dynamic EGM, and cardiac color Doppler ultrasound [6, 7].

Since the diagnosis of occult CHD is relatively difficult, the clinically frequently used diagnostic method is EGM, including dynamic EGM and stress test EGM. However, the operations of these two examination methods are more complicated and difficult to use, which makes it difficult for their clinical applications to be popularized. Although selective coronary angiography can improve the clinical detection rate, it is an invasive operation. To a certain extent, the patient's tolerance must be taken into account, so it will lead to high clinical misdiagnosis and missed diagnosis [8, 9]. As a mapping technique that places electrode catheters in different parts of the heart to record cardiac indicators, intracavitary electrocardiogram (IEGM) uses the guide wire in the catheter as the electrode and monitors the changes in the EGM P wave that occur during catheter placement to determine the tip of the catheter location [10]. The IEGM is a new cutting-edge positioning method for peripherally inserted central venous catheters (PICC), which can effectively dilute high-concentration and irritating drugs, protecting the blood vessels and relieving patients' pain [11]. But there are still limitations in the application of this technology. It is difficult to distinguish between atrial and ventricular waves by observing the results of IEGM alone, and the extracavitary electrocardiogram has to be required during the analysis process.

With the widespread application of intelligent algorithms in the medical field, people also try to combine intelligent algorithms with intracavitary electrocardiogram inspection methods to obtain a good diagnosis of occult coronary heart disease. However, there are relatively few researches on this type. Data mining algorithm is a set of heuristics and calculations to create a data mining model based on data. The provided data were analyzed firstly using the algorithm, and a specific type of pattern and trend would be found to create the model [12]. This study was intended to explore the application value of IEGM based on data mining algorithms and conventional EGM in diagnosis of occult CHD, hoping to provide a more effective basis for its clinical diagnosis.

2. Methods

2.1. Research Objects. 100 patients with occult CHD admitted to the hospital from February 2016 to December 2020 were selected as the research objects. There were 52 males and 48 females, aged 45–72 years (with an average age of 56.1 ± 3.8 years). Based on the random number table method, 100 patients were randomly rolled into two groups, each with 50 cases. The patients diagnosed with conventional ECG were set as the control group, and patients in the experimental group were diagnosed with IEGM under the classification and regression tree (CART) data mining algorithm. The diagnostic effects of the two groups were compared. The general clinical data of the two groups of patients (Table 1) revealed that the comparison was not statistically significant ($P > 0.05$) but comparable, suggesting the feasibility of this experiment. This study had been reviewed by the Ethics Committee of our hospital.

The inclusion criteria were given as follows: patients over 18 years, patients who suffered with coronary atherosclerosis and myocardial ischemia without pain, patients with at least one coronary artery stenosis $\geq 50\%$ diagnosed by selective coronary angiography, and patients who were informed about the study and signed the informed consent forms.

The exclusion criteria were defined as follows: patients with malignant tumor disease; patients with severe immunization and infectious diseases; patients with cognitive impairment and unable to complete the study; patients with pacemakers and 24 h dynamic EGM; patients who had been diagnosed with atrial fibrillation, supraventricular tachycardia, pulmonary heart disease, and other heart diseases that affected the shape of the P wave; patients who were prone to muscle tremor, such as hyperthyroidism; and patients whose basic EGMs were difficult to clearly identify.

2.2. Research Methods. The conventional EGM was performed as for patients in the control group. The posture of the patient was guided by professional person so that they were relaxed enough. The specific operation process is shown in Figure 1.

The IEGM was performed for patients in the experimental group, and the involved materials and instruments included catheter material (1.9 F PICC catheter with guide wire), EGM monitor (PHILPS MP20), IEGM wire, EGM electrode clips, and conversion adapter.

The specific operation process is shown in Figure 2: the catheter placement was performed by the static therapy specialist nurses in accordance with the PICC catheter placement in the hospital and the standardized operating procedures for IEGM positioning.

2.3. Analysis Model of Data Mining Algorithm. In this study, the classification and regression tree (CART) mining algorithm in the data mining algorithm was adopted to build the analysis model. The CART is commonly used to process continuous data, and heuristic methods are used to minimize the quadratic variance of each node, thus completing the division of the input space [13].

The n^{th} variable x^n and its value m were selected as the segmentation variable and segmentation point, respectively, and two regions Q_1 and Q_2 were defined as shown in the following equations:

$$Q_1(n,m) = \{x \mid x^n \leq m\}, \tag{1}$$

$$Q_2(n,m) = \{x \mid x^n > m\}. \tag{2}$$

Then, the best segmentation variable n and segmentation point m were found out, and the specific solution process is shown as follows:

$$\min_{n,m}\left[\min_{z_1}\sum_{x_1\in Q_1(n,m)}(y_i - z_1)^2 + \min_{z_2}\sum_{x_1\in Q_2(n,m)}(y_i - z_2)^2\right], \tag{3}$$

$$Z_1 = \mathrm{ave}(y_i \mid x_i \in Q_1(n,m)), \tag{4}$$

$$Z_2 = \mathrm{ave}(y_i \mid x_i \in Q_2(n,m)). \tag{5}$$

In the above equation, x_i, y_i, and Z_1 referred to independent variable, dependent variable, and optimal solution,

Table 1: The general clinical data of the two groups of patients.

Group	Gender		Age range (years)	Average age (years)
	Males ($n = 52$)	Females ($n = 48$)		
Experimental group (50 cases)	27	23	45–70	56.4 ± 3.1
Control group (50 cases)	25	25	45–71	55.8 ± 3.8
χ^2	3.182	2.198	2.391	2.981
P	0.121	0.081	0.096	0.101

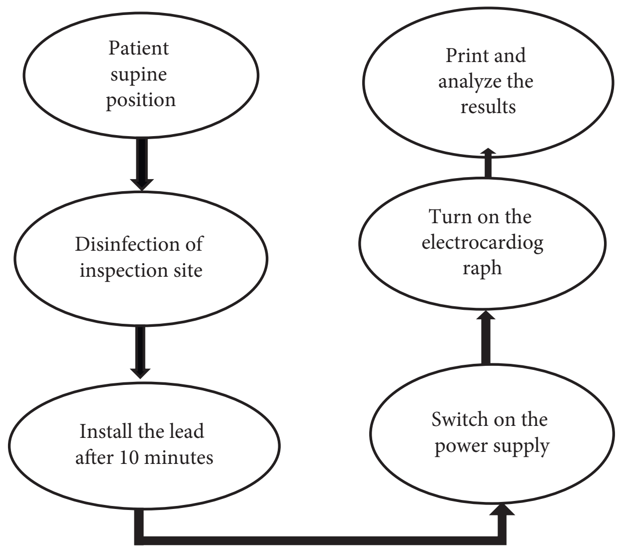

Figure 1: The specific operation process of conventional EGM.

respectively. In this study, the CART mining algorithm was adopted to process a large amount of particle information in the IC-EGM detection to increase the accuracy of the inspection results.

2.4. Observation Indicators. Two experienced and highly qualified physicians were invited to judge all examination results. The result of coronary angiography was undertaken as the gold standard to compare the consistency of the results. The sensitivity, specificity, accuracy, positive predictive value, and negative predictive value were calculated based on the test results. The calculation standard of curative effect was shown in Table 2.

2.5. Statistical Methods. The SPSS22.0 was adopted for data entry, sorting, and statistical analysis. The enumeration data were compared using χ^2 test; and the measurement data were compared using t-test. The multiple sample means were compared with the analysis of variance. The LSD method was used when the variance was uniform, and the Dunnett T3 method was used when the variance was uneven. $P < 0.05$ indicated that the difference was statistically significant. Kappa test was performed on the consistency ratio between the examination result and the coronary angiography results in two groups. When Kappa > 0.75, the consistency rate between the two results was high; when $0.4 \leq$ Kappa < 0.75, the consistency rate was normal; and when Kappa < 0.4, the consistency rate was low.

3. Results

3.1. Comparison on IC-EGM Processing Effect. In the research process, the effect of multiple linear regression algorithm, random forest algorithm, and CART algorithm were compared on IC-EGM processing. The final diagnosis result was undertaken as the gold standard to compare the accuracy of the diagnosis result. The results showed that the accuracy of the IC-EGM detection results processed by the multiple linear regression algorithm was 78%, and that was 69% for the random forest algorithm and 94% for CART algorithm. The comparison revealed that the processing effect of the CART algorithm was much better than the multiple linear regression algorithm and the random forest algorithm ($P < 0.05$), as shown in Figure 3.

3.2. Comparison of EGM Results of Healthy Person and Patients with CHD. Figure 4(a) shows the standard EGM results of normal people, and Figure 4(b) shows the EGM manifestations of patients with CHD. Comparison of the two EGM results revealed that the trend of P wave in the EGM of patients with CHD weakened and decreased, with basically disappeared Q wave and lower position of ST segment compared with the results of normal people, showing an oblique ST segment decline, inverted T wave, and basically normal QRS band.

3.3. Comparison on the Diagnosis Results of the ECG of the Two Groups of Patients. Figure 5 shows the test results under a conventional EGM. It disclosed that there were 31 patients

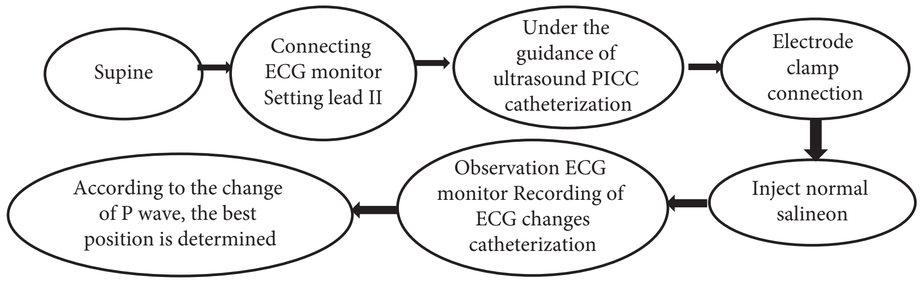

Figure 2: The specific operation process of IEGM.

Table 2: The calculation standard of curative effect.

Indicators	Calculation methods
Sensitivity	Number of true-positive cases/(number of true-positive cases + number of false-negative cases) × 100%
Specificity	Number of true-negative cases/(number of true-negative cases + number of false-positive cases) × 100%
Accuracy	EGM result/coronary angiography result × 100%

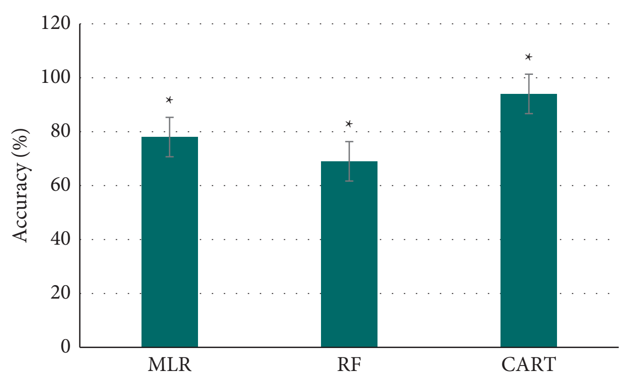

Figure 3: Comparison on diagnosis accuracy of different algorithms. *Note.* $^*P < 0.05$.

with positive test results and 19 with negative results in the control group. The comparison between the positive rate and the negative rate in this group of patients suggested that the positive rate was higher than the negative rate, and the difference was statistically significant ($P < 0.05$). Figure 6 shows the test results under IEGM. It revealed that there were 46 patients with positive test results and 4 patients with negative results in the experimental group. The comparison showed that the positive rate was higher than the negative rate, and the difference was statistically obvious ($P < 0.05$).

3.4. Comparison on the Consistency between Examination Results and the Coronary Angiography Results between Two Groups. Table 3 shows the statistics of the results in the control group. It disclosed that in the control group, there were 28 cases with the consistent results between the conventional EGM and the coronary angiography, including 21 positive cases and 7 negative cases. Therefore, the consistency ratio was 55%. Table 4 shows the statistics of the results in the experimental group. It was clear that in the experimental group, there were 42 cases with the consistent results between the IEGM examination and the coronary angiography, including 39 positive cases and 3 negative cases, so the consistency ratio was 80%. The consistency ratios between the examination results and the coronary angiography results and the Kappa test results were compared, and the results are illustrated in Figure 7. The results in the experimental group were higher than those of the control group, showing statistically great difference ($P < 0.05$), indicating the IEGM examination showed higher consistency, so the accuracy was higher.

3.5. Comparison on Diagnostic Effect of Two Different Examinations. The diagnostic effect between the experimental group and the control group after examination was compared, as illustrated in Figure 8. The diagnostic sensitivity and accuracy in the experimental group were 93% and 80%, respectively, while those in the control group were 62% and 55%, respectively. Thus, the diagnostic sensitivity and accuracy in the experimental group were much higher in contrast to those in the control group, and the difference was statistically great ($P < 0.05$). The specificity in control group was slightly higher in contrast to the experimental group, showing not statistically obvious difference ($P > 0.05$).

4. Discussion

As the quality of life of people in today's society has been greatly improved, the food, clothing, housing, and transportation have been greatly improved, especially in terms of diet [14]. As the pace of people's lives continues to accelerate, the dietary structure, types of diet, and dietary styles have become diversified. In addition, the diseases have become diversified, and the incidence of various diseases has increased year by year [15]. At present, the incidence of CHD is showing a slow upward trend. CHD is mainly due to the vascular blockage or stenosis caused by coronary atherosclerosis in patients. The blood circulation in the patient's blood vessels is blocked, so that the normal function is affected, and then convulsions occur, which eventually leads to myocardial hypoxia and ischemia [16]. If the patient cannot be treated in time after the onset of the CHD, it will lead to sudden death and endanger the patient's life. According to clinical studies, the types of CHD are relatively diverse, mainly manifested as angina pectoris, myocardial infarction, and occult [17, 18]. The occult CHD has a particularly high clinical incidence, and it is mainly in the elderly. As a CHD lacking relevant clinical symptoms, occult CHD is also a cardiovascular event with higher risk factors, and it is affected by no obvious clinical symptoms,

Table 3: The statistics of the results in the control group.

Control group	Coronary angiography		Total
	Positive	Negative	
Positive	21	10	31
Negative	12	7	19
Number of consistent results	21	7	28

Table 4: The statistics of the results in the experimental group.

Experimental group	Coronary angiography		Total
	Positive	Negative	
Positive	39	7	46
Negative	1	3	4
Number of consistent results	39	3	42

so the missed diagnosis rate is high, which brings great hidden dangers to the life safety of patients [7, 19].

In order to effectively improve the diagnostic accuracy of patients with occult CHD, the current clinical diagnosis is mainly based on EGM, which greatly improves the clinical diagnosis effect of patients. However, there are still some shortcomings in conventional EGM diagnosis. Therefore, the conventional EGM was adopted to diagnose 50 patients with suspected occult CHD in the control group, and the IEGM based on data mining algorithms was adopted to diagnose and analyze the other 50 patients in the experimental group in this study. In addition, the consistency between the examination results of the coronary angiography results was calculated and compared between two groups. According to the diagnosis results, the diagnostic sensitivity and accuracy in the experimental group were higher than those in the control group, and the specificity was basically similar, indicating that the IEGM showed higher diagnostic accuracy in occult CHD patients clinically. The application of IEGM not only is applicable in the diagnosis of heart disease, but also can assist the positioning of the PICC catheter to reduce the occurrence of neonatal complications. Many experts have discussed the impacts of IEGM-assisted positioning technology on the complications of PICC in neonates. Research results have shown that in the process of neonatal PICC catheterization, the use of IEGM-assisted positioning can reduce catheter-related complications [20, 21]. There are also research experts selected by typical EGMs of different parts of the heart cavity and their evolutionary characteristics as the guidance to replace the X-ray fluoroscopy for bedside temporary endocardial pacing of 22 cases; the success rate was 100%, the average operation time was 18 minutes, the average pacing from intubation to the right ventricle was 48 seconds, and the average pacing threshold was 0.72 V; there were no other complications except for electrode dislocation. Compared with 30 cases of temporary pacing under traditional fluoroscopy, there was no significant difference in various indicators. The results showed that cardiac IEGM-guided bedside pacing was a first-aid measure that was reliable, easy to operate, safe, practical, and easy to popularize [22]. The retrospective analysis in this study suggested that the high-frequency wavelet part had to be filtered in the conventional EGM examination to keep the waveform smooth and clear. As a result, the high-frequency signal cannot be fully displayed in the conventional EGM examination result, which in turn caused some high-frequency signals to be lost in the EGM result. Therefore, conventional EGM examination is only suitable for patients with a wide range of myocardial ischemic necrosis, and occult CHD patients with mild myocardial ischemia cannot show typical EGM signs of CHD [23].

Lupi et al. (2016) [24] found that IEGM is more sensitive than the extracavitary electrocardiogram in reflecting the myocardial ischemia during percutaneous transluminal coronary angioplasty (PT-CA). Drago et al. (2018) [25] suggested that the change of IEGM into the ST segment can reflect the viability of the residual myocardium to a certain extent. Moreover, some people have studied and proposed that IEGM can detect the viable myocardium at the infarcted area of patients with acute myocardial infarction and predict the postoperative efficacy of coronary intervention. Therefore, the clinical application value of IEGM is very high [26].

5. Conclusion

Based on the above research results, it could be concluded that the sensitivity and accuracy of IEGM results based on data mining algorithm analysis were higher than those of conventional EGM, and it showed very high application value in diagnosis of related diseases and in the guidance for treatment of related diseases, reflecting the good development prospects of IEGM in the clinical field. However, the intracavitary examination was invasive, so it was not recommended when the diagnosis result of the examination may cause more harm than good.

Academic Editor: Enas Abdulhay

This study aimed to analyze the application of ultrasound images of lung recruitment (LR) nursing treatment guided by positive-end expiratory pressure (PEEP) in patients with acute respiratory distress syndrome (ARDS). An ultrasound image enhancement algorithm (UIEA) wavelet transform (WT) was constructed, and the soft threshold (ST) and adjacent region average (ARA) were introduced for simulation comparison. In addition, the signal-to-noise ratio (SNR), peak signal-to-noise ratio (PSNR), and running time were undertaken as the evaluation indexes. The WT algorithm was applied to the ultrasound images of 85 ARDS patients before and after PEEP recruitment. The mean artery pressure (MAP), heart rate (HR), and central venous pressure (CVP), peak inspiratory pressure (Ppeak), mean inspiratory pressure (Pmean), dynamic lung compliance (DLC), PCO_2, and PaO_2/FiO_2 of the patients were recorded before and after the LR. The results showed that the signal-to-noise ratio (SNR) (19.67 ± 3.15 dB) and PSNR (23.08 ± 2.08 dB) of the images enhanced by the WT algorithm were much higher than those of ST (13.88 ± 2.74 dB and 14.62 ± 1.76 dB, respectively) and ARA (14.96 ± 3.06 dB and 15.11 ± 1.94 dB, respectively), while the running time was in adverse ($P < 0.05$); the HR and CVP of patients after LR nursing treatment were increased greatly, while the MAP was in the opposite case ($P < 0.05$); after LR nursing treatment, Ppeak, Pmean, DLC, PCO_2, and PaO_2/FiO_2 of the patient were significantly greater than those before the LR, and the difference was statistically significant ($P < 0.05$). In short, the WT algorithm not only enhanced the quality of ultrasound images but also shortened the running time and improved the processing efficiency. PEEP LR nursing treatment could effectively improve the vascular patency, cardiac ejection capacity, and DLC in patients with ARDS, thereby increasing the airway pressure and maintaining the unobstructed expiration.

1. Introduction

ARDS refers to the diffuse damage caused by lung capillary endothelial cells and alveolar epithelial cells in the process of noncardiac diseases such as severe infection, shock, high-risk surgery, trauma, and burns. Pulmonary interstitial and alveolar edema, can lead to acute hypoxic respiratory insufficiency or failure [1]. Onset of ARDS is so rapid that it can occur within 24–48 hours, and the ARDS is mainly characterized by reduced lung volume, reduced lung compliance, severe ventilation, or blood flow imbalance [2, 3]. It is necessary to apply the sensitive antibiotics to the bacteria to prevent the inflammatory reaction from further damage to the lungs. It is more urgent to correct the severe hypoxia of the patient in time to win precious time for the treatment of underlying diseases [4]. Currently, PEEP nursing scheme is mainly adopted to treat patients with ARDS, mainly by expanding the trachea and closing the alveoli, reducing the static blood shunt in the lungs, and improving the ventilation/blood flow ratio and diffusion function, thereby improving the respiratory function of patient [5]. Therefore, PEEP nursing scheme was used in this study to treat the ARDS patients.

With the development of imaging technology, ultrasound imaging is gradually utilized in the diagnosis of ARDS.

Compared with the gold standard chest computed tomography (CT) with high cost, large radiation, and complicated operation, thoracic lung ultrasound can clearly show diseases such as pulmonary interstitial syndrome, pulmonary consolidation, pneumonia, pleural exudation, and pneumothorax [6]. It is safer, noninvasive, cost-effective, low-cost, and dynamic observation. Tang et al. (2017) [7] discussed the clinical value of ultrasound monitoring in assessing LR and PEEP and found that lung ultrasound could be used to detect the LR endpoints and optimal PEEP, improving the DLC and oxygenation effectively. Therefore, ultrasound images were intended to be applied to evaluate the therapeutic effect of PEEP on ARDS patients in this study [8]. WT refers to the use of finite-length or fast-decaying oscillating waveforms to represent signals. It is an effective time, space, and scale analysis method and has been widely applied in many research fields of signal and image processing technology. WT is able for resolution analysis and time-frequency localization capabilities, can effectively distinguish the useful signals from noise, and has a good effect on image denoising and edge feature retention [9, 10]. Therefore, the WT algorithm was introduced in this study to process the ultrasound images of lung.

In summary, an UIEA WT was constructed based on the conventional WT, and the ST and ARA were employed for comparison and applied to the ultrasound images of 85 patients with ARDS before and after PEEP LR nursing treatment. The hemodynamic indexes (MAP, HR, and CVP), lung mechanical indexes (Ppeak, Pmean, and DLC), and blood-gas parameters (PCO_2 and PaO_2/FiO_2) of the patients were comprehensively compared and analyzed to evaluate the application of ultrasound image in PEEP-guided LR treatment in ARDS patients.

2. Materials and Methods

2.1. Selection of Research Samples. 85 patients with ARDS who were admitted to the hospital for PEEP LR treatment from February 11, 2019, to February 10, 2020, were selected as the research objects. The study had been approved by the Medical Ethics Committee of Hospital, and the patients and their families had understood the study and signed the informed consents and the inspection failure consents.

Inclusion criteria were given as follows: patients with acute onset; patients with oxygenation index less than 200 mmHg; patients older than 18 years old; patients with clear consciousness and ability of cooperating with the examination; and patients whose X-ray chest radiograph showed patchy shadows in the lungs.

Exclusion criteria were determined as follows: patients with pulmonary incarceration pressure greater than 20 mmHg; patients with psychiatric diseases; patients with hemodynamic insufficiency during treatment; patients with oxygenation index less than 100 mmHg; patients with intracranial hypertension; patients with pneumothorax; and patients with incomplete clinical information.

2.2. Treatment Methods. The patient was placed in a supine position, and the lung recruitment therapy was realized with the method of increasing PEEP. Firstly, the medical ventilator produced by Philips Respironics was set to the pressure mode, the PEEP was filled with 15 cmH_2O and PC20 cmH_2O, the inhaled oxygen concentration was adjusted to 1.0, and the oxygen saturation was set to about 92% for 20 minutes. The PEEP was increased at an interval of 5 cmH_2O, and the personal computer (PC) was fixed. After each increase of PEEP, it was ventilated for 1 minute, and then the PEEP was adjusted to 15 cmH_2O for 20 minutes. The LR was considered sufficient when the ultrasound score was no longer increased. Finally, the PEEP was adjusted back to 20 cmH_2O until the tidal volume reached 6.5 mL/kg.

2.3. Lung Ultrasound Scan Method. An intelligent ultrasound system (Philips IU22) was adopted to scan the lungs of patients with a probe frequency of 2–5 MHz. The lung was divided into 12 areas, including 4 areas (up, down, left, and right) in the chest based on the sternal angle plane and the human body's midaxis plane, and each area was divided into 3 subareas (front, middle, and back area) based on the front and back axillary lines area. During the scan, the patient was placed in a supine position, and the scan was started from the second intercostal space from top to bottom and front to back as well as along the intercostal space. The probe was rotated 90° so that the probe was perpendicular to the chest wall, and then one side of the patient's body was elevated to scan the lung field in the back. The characteristics of the patient's effusion and consolidation stroma were observed and recorded, and the images were sent to the workstation for processing. The hemodynamic indexes (MAP, HR, and CVP), lung mechanical indexes (Ppeak, Pmean, and DLC), and blood-gas parameters (PCO_2 and PaO_2/FiO_2) of the patients were measured and recorded.

2.4. Ultrasound Image Enhancement Algorithm Based on Wavelet Transform. In ultrasound imaging, the single-frequency ultrasound emitted by the ultrasound probe would scatter when it touched the surface of tissue, resulting in a series of coherent waves and causing a lot of noise. Thus, how to deal with such speckle noise was a very important research hotspot. It was assumed that the observed image was $u(x, y)$ and the actual image was $p(x, y)$, then the following equation could be obtained:

$$u(x, y) = p(x, y) + \xi(x, y) \bullet p(x, y). \tag{1}$$

In the above equation, $\xi(x, y)$ represented the noise. The traditional denoising methods cannot meet the two requirements of filtering noise and optimizing image edge features, and the image details were fuzzed when the noise was removed. On the contrary, WT could solve the above problems based on its decorrelation and multiresolution characteristics. Therefore, the concept of WT was introduced in this study to denoise the ultrasound images. The basic process was defined as follows: after the original ultrasound image was inputted, an appropriate wavelet function was selected to decompose the image in multiple layers to obtain the corresponding wavelet coefficients. Then, appropriate threshold processing was performed on each decomposed layer, the obtained wavelet decomposition coefficients and threshold processing coefficients were combined to calculate the wavelet reconstruction of the image, so as to obtain the denoising processed image.

In the wavelet algorithm, the selection of an appropriate threshold was very critical. If the threshold was too large, the wavelet coefficient would become zero, and the image became too blurry. If the threshold was too small, the image would retain too much noise. Therefore, the BayesShrink threshold [11] was adopted for processing, which carried different subequations in images of different scales and directions and could be adjusted adaptively with subbands. The equation could be expressed as follows:

$$T_B = \frac{\theta^2}{\theta_x}. \tag{2}$$

In the above equation, T_B referred to the BayesShrink threshold, θ^2 referred to the noise standard deviation, and θ_x represented the Gaussian standard deviation. The threshold function was to reconstruct the continuity and accuracy of the signal and had a great influence on the image denoising effect. The hard threshold (HT) method was combined with the ST method in this study to obtain a semisoft threshold function. Firstly, the HT function could be expressed as

$$m = \begin{cases} n, & |n > \kappa,| \\ 0, & \text{others.} \end{cases} \tag{3}$$

In the above equation, m represented the point on the abscissa of the image pixel, n represented the point on the ordinate of the image pixel, and κ referred to the set threshold point. The ST was to replace the coefficients less than the set threshold with 0, and its equation could be written as follows:

$$m = \begin{cases} \operatorname{sigm}(n)(|n| - \kappa), & |n| > \kappa, \\ 0, & \text{others.} \end{cases} \tag{4}$$

In (4), $\operatorname{sigm}(n)$ represents the symbolic function, and $\operatorname{sigm}(n) = \begin{cases} 1 & n > 0 \\ -1 & n < 0 \end{cases}$. A compromise solution could be obtained based on the HT and ST, which could be expressed as follows:

$$\begin{aligned} m &= n, \\ |n| &> \kappa_2, \end{aligned} \tag{5}$$

$$m = \operatorname{sigm}(n) \frac{\kappa_2 (|n| - \kappa_1)}{\kappa_2 - \kappa_1}, \quad \kappa_2 < |n| < \kappa_1, \tag{6}$$

$$\begin{aligned} m &= 0, \\ |n| &< \kappa_1. \end{aligned} \tag{7}$$

In the above equations, κ_2 represented the higher threshold, κ_1 referred to the lower threshold, and $\kappa_2 = 2\kappa_1$. The wavelet function used in WT was diverse. Thus, the wavelet function was selected based on the principles of orthogonality, support length, symmetry, and regularity in this study, and the decomposition filter and reconstruction filter of the biorthogonal WT were selected for processing. The boundary extension was required due to the length of actual signal. The symmetric extension was adopted to process signals of limited length to avoid the inconsistency of the signal caused by the period extension. Therefore, the above process was to build the UIEA WT based on WT.

2.5. Evaluation Indexes of Image Enhancement Performance. The ST [12] and the ARA [13] were introduced to compare with the WT algorithm constructed in this study, taking SNR, PSNR, and running time as evaluation indexes.

SNR was a common evaluation index to measure the amount of image signal noise (decibel, Db) and could be expressed as follows:

$$\mathrm{SNR} = 10 \times \log 10\left(\frac{P_1}{P_2}\right), \tag{8}$$

$$P_1 = \frac{1}{K \times H} \sum_{n}^{K \times H} S^*(m,n)^2, \tag{9}$$

$$P_2 = \frac{1}{K \times H} \sum_{n}^{K \times H} \left(S(m,n) - S^*(m,n)\right)^2. \tag{10}$$

In equations (8)–(10), P_1 represented the power of the signal, P_2 referred to the noise power, $S(m,n)$ indicated the initial signal, $S^*(m,n)$ represented the signal after wavelet processing, K referred to the dimension of the image row, and H represented the dimension of the image column.

PSNR was to evaluate the fidelity of the image, with the unit of decibel (dB). It could be calculated with the following equation:

$$\mathrm{PSNR} = 10 \times \log_{10}\left(\frac{N^2}{\mathrm{MSE}}\right), \tag{11}$$

$$\mathrm{MSE} = \frac{\sum_n^{K \times H} (O^n - F^n)^2}{K \times H}, \tag{12}$$

where N represented the maximum gray value of the image, O^n referred to the n^{th} pixel value of the original image, and F^n indicated the n^{th} pixel value of the processed image.

2.6. Statistical Methods. The data processing in this study was analyzed by SPSS19.0 version statistical software, the measurement data was expressed as mean ± standard deviation ($\bar{x} \pm s$), and the count data was indicated with percentage. The pairwise comparison of SNR, PSNR, and running time of WT, ARA, and ST algorithms was realized with the single-factor analysis of variance. The hemodynamic indexes (MAP, HR, and CVP), lung mechanical indexes (Ppeak, Pmean, and DLC), and blood-gas parameters (PCO_2 and PaO_2/FiO_2) before and after LR nursing treatment were compared by the independent t-test. The difference was statistically significant at $P < 0.05$.

3. Results

3.1. Comparison of Three Algorithms for Denoising Performance of Lung Ultrasound Images. Figure 1 shows the comparison of the denoising performance of three algorithms on lung ultrasound images. It revealed that the SNR and PSNR of the ST algorithm for lung ultrasound image reconstruction were 13.88 ± 2.74 dB and 14.62 ± 1.76 dB, respectively; the SNR and PSNR of the ARA algorithm for lung ultrasound image reconstruction were 14.96 ± 3.06 dB and 15.11 ± 1.94 dB, respectively; the SNR and PSNR of WT algorithm for the lung ultrasound image reconstruction were 19.67 ± 3.15 dB and 23.08 ± 2.08 dB, respectively. Thus, the SNR and PSNR of WT algorithm for lung ultrasound image reconstruction were higher observably than those of the ARA and ST algorithm ($P < 0.05$).

Figure 2 illustrates the comparison in the running time of three algorithms for lung ultrasound image denoising. It disclosed that the running time of ST, ARA, and WT algorithm for lung ultrasound image reconstruction was 15.17 ± 1.05 s, 14.84 ± 0.77 s, and 23.08 ± 2.56 s, respectively. In addition, the running time of WT algorithm was much shorter than that of ARA algorithm and ST algorithm, and the difference was statistically significant ($P < 0.05$).

3.2. Reconstruction Results of Lung Ultrasound Images with Three Algorithms. The results of lung ultrasound image reconstruction of the three algorithms were compared and analyzed, and the results were given in Figure 3. Figure 3(a) is an original ultrasound image of a patient, which included a lot of artifacts and noises, and the clarity was so poor that the needs of imaging diagnosis could not be satisfied. The clarity of Figure 3(d) was higher obviously than that of Figures 3(b) and 3(c), and it could display the lung lesions perfectly.

3.3. Comparison of Hemodynamic Parameters before and after Lung Recruitment Nursing Treatment. Figure 4 illustrates the comparison of HR and MAP before and after LR nursing treatment. The HR and MAP before LR was 95.71 ± 5.11 beats/min and 101.42 ± 10.33 mmHg, respectively, while the HR and MAP after LR was 118.62 ± 8.37 beats/min and 79.41 ± 7.26 mmHg, respectively. In addition, the HR of patients after LR was faster extremely than that before LR ($P < 0.05$); and the MAP of patients after LR was greatly decreased in contrast to that before ($P < 0.05$).

Figure 5 reveals the comparison of CVP before and after LR. The CVP before and after LR was 7.33 ± 2.01 mmHg and 12.15 ± 1.85 mmHg, respectively. Besides, the CVP of patients after LR was increased greatly than that before LR ($P < 0.05$).

3.4. Comparison of Blood-Gas Parameters before and after Lung Recruitment Nursing Treatment. Figure 6 shows the comparison of blood-gas parameters (PCO_2 and PaO_2/FiO_2) before and after LR nursing treatment. As it indicated, the PCO_2 and PaO_2/FiO_2 before LR were 42.74 ± 10.64 mmHg and 175.37 ± 12.41 mmHg, respectively; and the PCO_2 and PaO_2/FiO_2 after LR were 56.38 ± 9.78 mmHg and 385.15 ± 15.93 mmHg, of which, the blood-gas parameters (PCO_2 and PaO_2/FiO_2) after LR were observably increased than those before LR ($P < 0.05$).

3.5. Comparison of Respiratory Mechanical Parameters before and after Lung Recruitment Nursing Treatment. The respiratory mechanical parameter Cdyn before and after LR nursing treatment was analyzed and compared, as shown in Figure 7. The Cdyn before LR was 22.54 ± 1.51 mL/cH_2O, and the Cdyn after LR was 42.74 ± 2.65 mL/cH_2O. Among them, the Cdyn of patients after LR was significantly greater than before LR, and the difference was statistically significant ($P < 0.05$).

As shown in Figure 8, the comparison of the respiratory mechanical parameter Pmean and Ppeak before and after LR revealed that the Pmean and Ppeak before LR were 15.76 ± 3.03 mL/cH_2O and 27.17 ± 1.34 mL/cH_2O, respectively; and the Pmean and Ppeak after LR were 30.57 ± 4.02 mL/cH_2O and 46.11 ± 3.42 mL/cH_2O, respectively. Thus, the Pmean and Ppeak of patients after LR were higher obviously than those before LR ($P < 0.05$).

4. Discussion

As a common critical symptom, ARDS has a fatality rate of 30–40%, which is extremely threatening to the life safety of patients. Its typical physiological changes include reduced lung volume, reduced compliance, and imbalanced ventilation/blood flow ratio. Thus, how to realize the protective ventilation of lung is essential to improve the respiratory function of the patient [14]. Therefore, an UIEA WT was constructed based on WT, and the ST and ARA were introduced for comparison and analysis. The results showed that the SNR and PSNR of the WT algorithm for lung ultrasound image reconstruction were much higher than those of the ARA algorithm and the ST algorithm ($P < 0.05$), which was similar to the research results of Bein et al. (2016) [15]. Thus, it indicated that the WT algorithm constructed in this study had better performance in denoising ultrasound images and reducing the influence of artifacts and noises. The running time of the ST algorithm for lung ultrasound image reconstruction was obviously longer than that of the ARA algorithm and the WT algorithm ($P < 0.05$), which indicated that the WT algorithm based on WT was very rapid for ultrasound images. Therefore, the WT algorithm not only enhanced the quality of ultrasound images but also shortened the running time and improved the processing efficiency [16].

The WT algorithm was applied to the diagnosis of ultrasound images of 85 patients with ARDS. The results disclosed that the HR and CVP of patients after LR were increased greatly than those before LR ($P < 0.05$), which was similar to the results of Sahetya and Brower (2017) [17], indicating that the PEEP LR nursing treatment could effectively improve the patency of vascular circulation in patients with ARDS and reduce the degree of blood viscosity. The MAP of patients after LR was observably smaller than

that before LR ($P < 0.05$). CVP is the pressure where the upper and inferior vena cava enter the right atrium. It can be measured through the upper and inferior vena cava or the right atrium tube and can reflect the ejection ability of the heart. The results of this article showed that the treatment after LR effectively improved the cardiac ejection ability of

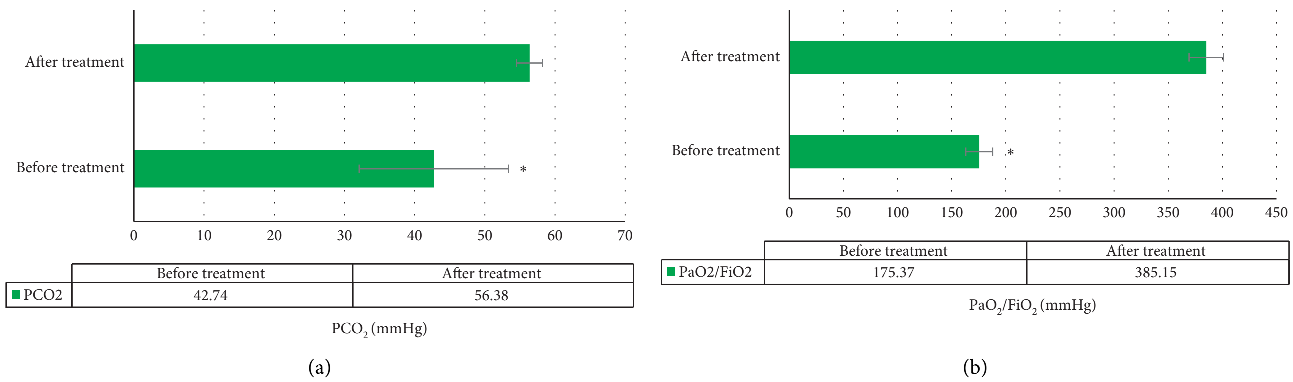

FIGURE 6: The comparison of blood-gas parameters ((a) PCO_2 and (b) PaO_2/FiO_2) before and after lung recruitment. *indicates $P < 0.05$ in contrast to the values before lung recruitment.

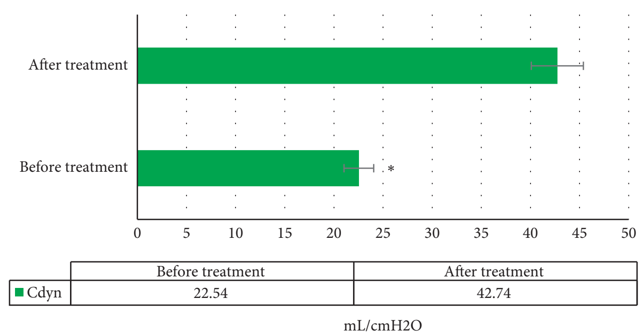

FIGURE 7: The respiratory mechanical parameter Cdyn before and after lung recruitment. *indicates $P < 0.05$ in contrast to the values before lung recruitment.

the patient, which was beneficial for the patient to eject the returned blood into the artery in time. The blood-gas parameters PCO_2 and PaO_2/FiO_2 of patients after LR were increased obviously in contrast to those before LR ($P < 0.05$), which indicated that the alveoli of patients after LR treatment could maintain more open state and increase oxygenation level. The Cdyn of patients after LR was higher hugely than that before LR ($P < 0.05$), which was different with the results of Karlsson et al. (2018) [18]. The reason of which may be that DLC differed in the compliance expressed by the respiratory muscles during lung breathing. The better the compliance, the smoother the breathing, and vice versa. The results of this study indicated that LR nursing treatment could effectively improve the DLC of the patient's respiratory system [19]. The Pmean and Ppeak of patients after LR were higher significantly than before LR ($P < 0.05$), which was not similar to the results of Sigmundsson et al. (2020) [20]. Ppeak is the maximum pressure during lung ventilation, while Pmean is the mean pressure experienced by the lungs during the respiratory cycle. The results of this study suggested that LR nursing treatment could increase the pressure in the airway to prevent airway trapping and maintain a clear breath.

5. Conclusion

An UIEA WT was constructed based on the WT, the ST and ARA were introduced for comparison, and then the WT algorithm was applied to the ultrasound images of 85 ARDS patients before and after PEEP LR nursing treatment. It was found that the WT algorithm not only enhanced the quality of ultrasound images but also shortened the running time and improved the processing efficiency. PEEP LR nursing treatment could effectively improve the vascular patency, cardiac ejection capacity, and DLC in patients with ARDS, so as to increase the airway pressure and maintain the unobstructed expiration. However, there were still some shortcomings for this study. The sample size of the selected patients was relatively small and the source was single, which may have some impact on the experimental results. In the future, we will consider increasing the sample size of patients to further explore the diagnostic value of the WT algorithm for the prognosis of ARDS patients. In conclusion, the results of this study provided a theoretical basis for the clinical application of PEEP LR nursing scheme in the treatment of ARDS patients.

Objective. To investigate the effects of dexmedetomidine intervention on serum inflammatory factor concentration and postoperative cognitive malfunction in elderly patients with general anesthesia. *Methodology*. 174 patients with general anesthesia were selected, who were categorized into a control group (HC) and a dexmedetomidine group (HS) using the random number table method, with 87 patients in individual groups. The dexmedetomidine group was pumped intravenously with dexmedetomidine at a loading dose of 1 μg/kg before induction of anesthesia for 15 min, followed by continuous intravenous pumping at a rate of 0.4 μg/kg/h, and the dosing was stopped at 30 min before concluding the surgery. The control group was administered the identical dose of saline in the same manner. Interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α) levels and MMES scores were tested at 1 h before and 24 h after anesthesia. *Results*. Comparing to HC group, patients in the HS group had lower TNF-α and IL-6 levels at both scheduled points ($P < 0.05$). *Conclusion*. Dexmedetomidine reduced the expression of inflammatory factors in elderly patients with general anesthesia and effectively reduced the incidence of postoperative cognitive dysfunction after general anesthesia surgery.

1. Introduction

Postoperative cognitive dysfunction (POCD) has a high incidence in elderly patients undergoing general anesthesia, and there is still no clear pathogenesis. It is generally believed that POCD refers to a group of complications of the patient's central nervous system (CNS) after anesthesia surgery. Its formation mechanism is complex, which may be related to age, surgery type, and anesthetic type [1]. It is more common in elderly patients, manifesting as impairment in patients' memory, attention, learning ability, abstract thinking, and orientation. Most are accompanied by a decrease in the ability to adapt to society, to interact with others, and to perform daily activities. It often lasts for several days, with a few lasting for several weeks. POCD has become a common and frequent disease in the elderly after surgery. With the development of economy and society, Chinese society is rapidly entering the aging society. Therefore, strengthening the research on POCD is in line with the trend of social development and has significant socioeconomic significance.

The neuroinflammatory mechanism is one of the most important theories in the current mechanistic studies. Neuroinflammation is mostly caused by systemic inflammation, and the body causes central nervous system inflammation through different pathways and mechanisms, leading to constructional and functional alterations in the central nerve cells, resulting in POCD. The main view is that POCD is a neurological disorder induced by surgical and anesthesia-induced changes in the structure of central nerve cells in elderly patients based on degenerative changes in the brain and preexisting diseases in other organs and systems of the body. Since POCD is a kind of central nerve injury, clinical anesthesia needs to find a drug that can protect the central nerve and suppress the inflammatory response. Dexmedetomidine (DEX) is one of the most recently studied anesthetic adjuncts that can protect organ function by decreasing the release of sympathetic ganglion fiber neurotransmitters, thereby reducing the production of related inflammatory factors, and by inhibiting oxidative stress and reducing reperfusion injury. This study was conducted to try to understand the relationship between inflammatory factors, dexmedetomidine, and postoperative cognitive dysfunction by preoperative- and postoperative-related inflammatory factors in patients undergoing general anesthesia.

2. Materials and Methods

A total of 174 elderly patients scheduled for surgery with ASA grade I–III from January 2018 to June 2019 were selected. Among them, there were 75 patients with lumbar disc herniation, 36 prostatectomy patients, 31 cholecystectomy patients, and 6 patients with radical rectal cancer. These patients were randomized into two categories: the "dexmedetomidine group" and the "saline control group." Eighty-seven patients were included in the dexmedetomidine group, 56/32 males/females of 61–89 years of age with mean age of 70.6 ± 4.2 years; body weight was 45–95 Kg with mean weight of 65.8 ± 5.8 kg. Education outlined was illiterate 11, primary 21, secondary 35, and above secondary 20, respectively. A total of 31 cases were classified as ASA grade I, 47 cases as ASA grade II, and 9 cases as ASA grade III. The control group included 87 patients, 58 males and 19 females from 61 to 92 years of age with 71.4 ± 4.9 mean age and body weight 47–94 kilograms with 66.2 ± 5.5 mean weight. Education outlined was illiterate 8, primary 16, secondary 23, and above secondary 14, respectively. A total of 22 cases were classified as ASA grade I, ASA grade II had 32 cases, and ASA grade III had 7 cases. Reportedly, the two groups had no statistically significant difference in general information such as age and gender ($P > 0.05$), and they were comparable (Table 1).

2.1. Inclusion and Exclusion Criteria. Inclusion criteria: patients with 18–79 years of age; ASA grade I–III; operation time within 24 hours; preoperative approval by the ethical board committee and voluntary signing of the study consent form. Exclusion criteria: those with a history of dementia and psychosis; those with severe cerebrovascular disease; those with a history of multiple surgeries; those with a history of severe perioperative infections in various systems; those with perioperative massive hemorrhage and severe acid-base imbalance and electrolyte imbalance; those with diabetes mellitus; and those with perioperative hormone.

2.2. Experimental Protocol. All patients were fasted for 8 h and dehydrated for 2 h before surgery, and no drugs were administered before surgery. After entering the operating room, peripheral veins were routinely opened and patients' heart rate, blood pressure, oxygen saturation, and EEG dual-frequency index were monitored, and internal jugular venipuncture and radial artery puncture were conducted after anesthesia induction to monitor patients' central venous pressure and invasive arterial pressure. Anesthesia method: sufentanil 0.4 μg/kg, propofol 1 mg/kg, midazolam 0.05 mg/kg, and cis-atracurium 0.3 mg/kg were injected intravenously for anesthesia induction and wind pipe (tracheal tube) was inserted after 5 min. The anesthesia machine was connected for mechanical ventilation after determining the correct position of the tracheal tube, with VT 8–10 mL/kg, RR 12–16 times/min, and IE 1 : 2. $PETCO_2$ was maintained at 35–40 mmHg and FiO_2 at 60%. Anesthesia was maintained by inhalation of sevoflurane at concentrations of 1% to 2% and intravenous infusion of ~6 mg/kg/h of propofol , 0.1~0.5 μg/kg/min remifentanil, and 0.1~0.2 mg/kg/h cis-atracurium. The intraoperative inhaled concentration of sevoflurane was regulated according to the hemodynamic and BIS values, maintaining a BIS value of 40 to 60. Narcotic analgesics and vasoactive drugs were used so that the intraoperative BP and HR fluctuations did not exceed 20% of the basic value, and the mean value of arterial pressure must not be below 60 mmHg. If the fluctuation of BP and HR was greater than 20% of the preoperative base value, a comprehensive analysis and judgment would be made by using the depth of anesthesia monitor, and the specific intervention was to add 5 μg of sufentanil and 0.3 mg of atropine or 2 μg of norepinephrine each time and dexmedetomidine loading dose 1 μg/kg was administered intravenously for 10 min, which were all monitored until medications took effect and vital signs returned to stability. When the adverse reaction of dextrometomidine happened, such as hypotension, hypertension, nausea, bradycardia, and dry mouth, the infusion was immediately discontinued. Over the next 24 hours, patients receiving the drug were closely monitored. After surgery and anesthesia, the patient was transferred to the postanesthesia recovery unit for resuscitation. All procedures were performed by the same group of physicians.

2.3. Examination Indicators and Methods. A total of 4 mL of elbow venous blood was collected before surgery (T1) and 24 h after surgery (T2), respectively, and centrifugation was performed to separate the serum. Enzyme-linked immunosorbent assay was used to detect the concentration of serum TNF-α and IL-6, in strict accordance with the instructions for use of the kit.

2.4. The POCD and Inflammatory Mediators Link Was Assessed by Quartiles. The values of TNF-α and IL-6 were arranged from smallest to largest and the three quartiles (Q1, Q2, and Q3) were $Ql = (87 + 1)/4 = 22$, $Q2 = 2^*(87 + 1)/4 = 44$, and $Q3 = 3^*(87 + 1)/4 = 66$. These four individuals divided 87 patients into four segments (q1, q2, q3, and q4). A comparison was performed with the POCD number within this quartet intersegments and then the correlation between POCD and these two inflammatory mediators was evaluated using Pearson's correlation analysis.

2.5. Statistical Analysis. The extracted data were statistically analyzed by using statistical software SPSS 17.0 (SPSS Inc., Chicago, II). For numerical variables, *t*-tests were performed both with paired and independent samples. If the data values conformed to normality and chi-squaredness, otherwise, signed rank sum test and Kruskal–Wallis test were used. The chi-square test was used for categorical variables. Correlation analysis was expressed as Pearson correlation coefficient. The test level was $P = 0.05$.

3. Results

The incidence of POCD was calculated in both experimental and control groups as 9.20% and 21.31%, respectively. There was a statistically significant difference between both experimental and control groups ($P = 0.038$). The levels of IL-6 and TNF-α in both groups were significantly higher than before surgery (Table 2). The increase was significantly suppressed in the dexmedetomidine group comparing to the control group ($P < 0.05$). POCD occurrence was also analyzed and statistically significant difference was also reported between the odds, when the levels of inflammatory mediators were different in the quartile grouping ($P < 0.05$). The relationship between two inflammatory mediators and POCD was calculated by Pearson's correlation analysis, and the correlation coefficients were $R = 0.689$ for IL-6 and $P = 0.043$ for POCD and $R = 0.711$ and $P = 0.038$ for TNF-α and POCD (Table 3).

Table 4 shows that with the increase of TNF-α values, the number of POCD also increases significantly ($P < 0.05$).

The data from Tables 4 and 5 were analyzed by Pearson's correlation analysis, which showed that the serum value of IL-6 concentration was significantly correlated with the number of POCD, i.e., $r = 0.689$ and $P = 0.043$. Likewise, serum concentration of TNF-α was also significantly and positively linked with POCD, i.e., $r = 0.711$ and $P = 0.038$. $P < 0.05$, suggesting that the elevated concentrations of proinflammatory factors were correlated with POCD (Tables 4 and 5).

4. Discussion

Studies have shown that the POCD incidence in elderly individuals encountering noncardiac surgical procedure is up to 25.8% and 9.9% at 1 week and 3 months postoperatively [2]. POCD is a degenerative change in neurological function induced or aggravated by a combination of surgical, anesthetic, and preexisting diseases based on the degeneration of the central nervous system. Monk and Price [3] have confirmed that the occurrence of POCD not only prolongs hospitalization time and increases patients' hospital costs but also leads to neurological impairment.

Numerous factors influence POCD in clinical practice, such as patient age, gender, education level, type of surgery, anesthesia method, and medications [4]. In this trial, a randomized approach was used in the design regarding the abovementioned factors, and there were no statistically significant differences in age, education level, duration of surgical anesthesia, and intraoperative medication between the two groups in this study. Besides, BIS was used to maintain the same depth of anesthesia during the operation, so as to ensure the homogeneity of the study population.

In the mechanisms of POCD, the theory of inflammatory response of central nervous system has gradually become a research hotspot, and validation plays an important role in this process [5], where tissue damage due to surgery can activate the peripheral intrinsic immune system and cause inflammatory cell infiltration, which in turn releases inflammatory mediators (TNF-α, IL-6, IL-1, etc.) [6]. Inflammatory reactions of the central nerve system can be caused by peripheral inflammatory factors entering the central nervous system. Peripheral inflammatory factors can enter the central nervous system through the blood-brain barrier or synthesize and release inflammatory factors by activating neuroendocrine cells in the blood-brain barrier, causing central inflammation. Inflammatory factors entering the CNS interfere with neuronal activity, thereby disrupting intersynaptic connections and signaling [7]. It has been shown that the degree of increased expression of proinflammatory factors and its presence in the central nervous system and body circulation of surgical patients may correlate with the degree of cognitive decline [8,9]. Interleukin 6 plays an important role in body's defense mechanism, immune system, and generating inflammatory responses in vivo. It also affects the growth and differentiation of central nerve cells in the CNS, which also influence cerebral functionality, specifically learning, investigation, and recollection of memory. IL-6 is secreted by intracranial microglia, neuronal cells, and astrocytes and has been implicated in brain injury. Normal concentrations of IL-6 levels are important for neuronal cell protection and repair; however, if the concentrations are too high, they instead exacerbate neuronal and microglial cell damage [10]. These processes may include synaptic plasticity or neuronal cell growth regulation [11].

TNF-α is secreted by macrophages and has a wide range of biological activities with extremely important roles in immune body regulation, regulation of inflammatory responses, neuroendocrine regulation, and other systems. TNF-α is involved in many aspects of daily activities of life such as sleeping, eating, bathing, and other autonomous processes. Recent studies have found that it is involved in the processes of learning and memory and plays a vital role in the pathology of POCD. The mechanism may be related to the processes that affect synaptic shaping and inhibit the growth and differentiation of nerve cells [12]. After surgery, TNF-α is the first cytokine to be released, and it is the initiating and amplifying factor of the inflammatory cascade response. Animal studies have shown that peripheral TNF-α can cause neuronal inflammation and lead to cognitive decline by inducing the release of IL-1 in the brain [13]. The hippocampus-dependent cognitive decline induced by chronic neuronal inflammation can be significantly reversed when using TNF-α synthesis inhibitors, suggesting that TNF-α is an important mediator of neuronal dysfunction and cognitive impairment triggered by chronic neuroinflammation.

In our study, patients were divided into 4 segments based on the serum concentration of defined parameters IL-6 and TNF-α. Based on the result output, the number of POCD was significantly different in these four segments. With the increase of the concentration of these two inflammatory

Q4	21	83.24 (±14.82)	5 (22.73)

Table 5: With the increase in the level of IL-6 concentration, the number of POCD increases significantly ($P < 0.05$).

Grade	No. of cases	TNF-α (ng/ml)	Incidence of POCD (cases (%))
Q1	22	55.28 (±11.27)	0 (0.00)
Q2	22	61.94 (±10.72)	1 (4.55)
Q3	22	66.18 (±11.71)	2 (9.09)
Q4	21	76.41 (±14.20)	5 (22.73)

factors, the frequency of POCD increased significantly. Analysis of Pearson correlation indicated the positive correlation of IL-6 concentration with POCD, i.e., $r = 0.689$ and $P = 0.043$. Likewise, plasma TNF-α concentration was also significantly correlated with POCD, i.e., $r = 0.711$ and $P = 0.038$. Both IL-6 and TNF-α play important roles in neurocognitive function, and their increased concentrations are predictive of decreased cognitive function; similarly, it is seen that the concentrations of both proinflammatory factors increase when POCD occurs. Concluding all, IL-6 and TNF-α concentrations were significantly correlated with the POCD values. The results of this trial further proved the validity of this theory.

Dexmedetomidine is the most discriminating and selective alpha-2 adrenergic receptor agonist. The most common uses of this receptor are sedation, narcotic analgesia, and anxiolysis. In this trial, the incidence of POCD was reduced from 21.31% to 9.2% both in the control and experimental group, respectively. The anti-inflammatory effect of dexmedetomidine has been found in recent years and may have a good protective effect on humans. There may be three ways for it to exert its anti-inflammatory effect [14,15]: (1) it activates the central a-Z receptor, inhibits the activity of sympathetic nerves, activates the anti-inflammatory pathway of cholinergic nerves, and reduces the level of proinflammatory factors. (2) It inhibits macrophages and reduces the secretion of tissue necrotizing factor α. (3) It reduces the concentration of IL-6 and TNF-α by gene regulation of kappa-B. This trial is concluded; dexmedetomidine reportedly reduced the increased concentration levels of IL-6 and TNF-α in the experimental group, which proved its anti-inflammatory effect. At the same time, dexmedetomidine has a protective effect on brain tissue. Some studies [16] have shown that dexmedetomidine can improve the oxygen metabolism in areas of cerebral hypoxia-reperfusion damage in rats and reduce the area of necrotic foci. A number of studies [17] at home and abroad showed that the postoperative MMSE score of the observational group is markedly lower than the dexmedetomidine intervention group, and the TNF-α and IL-6 levels and the incidence of postoperative POCD are markedly lower than those reported in the control group. The above results suggest that dexmedetomidine used for surgery in elderly patients can significantly improve patients' MMSE scores and minimize the incidence of early postsurgical cognitive dysfunction. The diagnosis of POCD still relies mainly on neuropsychological tests. The MMSE score is a simple, easy, and most influential screening tool for determining cognitive function. Therefore, in this study, the score was used, while the test was administered by the same specialized anesthesiologist at a fixed time, and the test details were explained to the patient before the test to minimize the possible influencing factors related to the test.

The incidence of postoperative POCD in the control group was 26.7% in this study, and the MMSE score increased and the incidence of POCD decreased after dexmedetomidine pretreatment, suggesting that dexmedetomidine pretreatment helps to prevent the occurrence of postoperative POCD in elderly patients with general anesthesia. The mechanism may be related to the ability of dexmedetomidine pretreatment to reduce the occurrence of inflammatory immunity and decrease the damage to the central nervous system of the organism.

5. Conclusion

(1) Dexmedetomidine reduces the incidence of postoperative POCD in elderly patients.

(2) Dexmedetomidine significantly reduces the increase in the postsurgical interleukin 6 and tissue necrotizing factor α.

(3) The increase of interleukin 6 and tissue necrotizing factor α after surgery is significantly correlated with the increase of POCD.

Purpose. This study evaluated the postoperative analgesic effect of ultrasound-guided single-point thoracic paravertebral nerve block (TPVB) combined with dexmedetomidine (DEX) in patients undergoing video-assisted thoracoscopic lobectomy. *Methods*. Sixty adult patients of the American Society of Anesthesiologists (ASA) I–III were randomly assigned into three groups ($n = 20$ each). G group: patients received routine general anesthesia; PR group: patients received 0.5% ropivacaine; and PRD group: patients received 0.5% ropivacaine with 1 μg/kg DEX. TPVB was performed in the T5 space before surgery, and then, general anesthesia induction and video-assisted thoracoscopic lobectomy were performed. Analgesics were administered through the patient-controlled analgesia (PCA) device intravenously. The background infusion of each PCA device was set to administer 0.02 μg/kg/h sufentanil, with a lockout time of 15 min, and a total allowable volume is 100 ml. *Results*. Compared to PR and G groups, the total sufentanil consumption after operation, the times of analgesic pump pressing, the pain score, and the incidence of postoperative nausea or vomiting in the PRD group were significantly reduced ($p < 0.05$). Also, the duration of first time of usage of the patient-controlled analgesia (PCA) was longer. The heart rate (HR) and mean arterial pressure (MAP) during operation were lower in the PRD group as compared with the other two groups in most of the time. However, hypotension and arrhythmia occurred in three groups with no statistically significant difference. *Conclusions*. A small volume of TPVB with ropivacaine and DEX by single injection produced longer analgesia in patients undergoing video-assisted thoracoscopic lobectomy, reduced postoperative opioids consumption, and the incidence of side effects.

1. Introduction

Video-assisted thoracoscopic surgery (VATS) is mainly used for the treatment of the lung, mediastinum, and pleural lesions. The main advantage is to avoid the injury of thoracotomy. Compared with thoracotomy, the operation time is shorter, the postoperative morbidity is lower, and the time for returning to normal activities is earlier [1]. However, effective analgesia is still needed to reduce postoperative pain and postoperative nausea and vomiting.

Thoracic paravertebral block (TPVB) as part of a multimodal analgesia strategy after thoracotomy [2] and breast surgery [3] has a broad evidence base and along with ultrasound-guided techniques. It has become increasingly popular. Recent randomized controlled trials and reviews have shown that paravertebral block (PVB) causes prolonged directional analgesia and reduces the risk of postoperative nausea, vomiting, and complications [4, 5]. However, a large body of literature has shown that the duration of analgesia is controversial, and PVB is only beneficial immediately after surgery [6, 7]. There are few studies on the effectiveness and tolerability of adjuvant analgesics in paraspinal analgesia. The addition of magnesium, clonidine, ketamine, dexamethasone, opioids, and other analgesics and local anesthetics can enhance and prolong the analgesic effect provided by PVB [8, 9].

Dexmedetomidine (DEX) is a novel alpha-2 adrenergic receptor agonist with dose-dependent sedative, anxiolytic, and analgesic effects and has an advantage of minimum respiratory depression compared with alternative drugs [10]. It is well known that α_{-2} receptor agonists, due to their own sympathetic properties, provide stable hemodynamics during surgery and reduce the amount of narcotic analgesics. When DEX is used as an anesthetic for epidural anesthesia [11], subarachnoid block [12, 13], PVB [14, 15], and brachial plexus block analgesia [16], the time is significantly extended. However, there are few studies evaluating the efficacy of DEX as an adjuvant in the treatment of analgesia after thoracoscopic surgery, only in partial breast surgery [15].

Therefore, this study was designed to evaluate whether TPVB combined with ropivacaine and DEX could improve the analgesic effect of patients undergoing VATS, thereby reducing postoperative opioid drugs consumption.

2. Methods

This study was approved by the Affiliated Suzhou Science and Technology Town Hospital of Nanjing Medical University' Ethics Committee, and written informed consent was obtained from all patients. The trial is registered at the Chinese Clinical Trial Registry, number ChiCTR-IOR-17013034. After obtaining approval and written informed consent from the institutional ethics committee, the study enrolled 60 ASA I–III patients (18–65 years old, either gender, weighing 50–85 kg) who were scheduled to undergo elective thoracoscopic lobectomy. Patients undergoing elective general anesthesia and video-assisted thoracoscopic unilateral lobectomy had no history of cardiopulmonary disease, no sinus bradycardia, no functional lesions of the sinoatrial node, no serious arrhythmia, and no thoracic deformity. Surgery time was more than 2 hours. Exclusion criteria: minimental state examination scores below 23 points; the history of dementia, psychosis, or other central nervous system disease or drug dependence and poor compliance; and those who did not complete video-assisted thoracoscopic lobectomy under general anesthesia or have to convert to thoracotomy.

All patients did not use preoperative medication, and in the preoperative preparation room, the patients were explained in detail the numerical rating scale (NRS) scoring rules (scores from 0 to 10: 0 = no pain, 10 = most severe pain). Patients were randomized into three groups of 20 individuals each using a computer-generated random number table (random number table method) with sealed envelope technology for assignment concealment (distribution hidden). In the operating room, ultrasound-guided right internal jugular vein catheterization for infusion and left radial artery catheterization for monitoring the changes of pressure have been performed. Conventional general anesthesia induction included sufentanil 5 ug/kg + etomidate 2 mg/kg + cisatracurium 2 mg/kg intravenous slow bolus injection; anesthesia maintenance: propofol 2.5 ug/ml, sevoflurane 0.8 MAC, remifentanil 3 ng/ml, bispectral index monitoring, and the depth of anesthesia is maintained between 40 and 60. Patients were classified into three groups as follows: G group: patients received routine general anesthesia; PR group: patients received 0.5% ropivacaine for TPVB; PRD group: patients received 0.5% ropivacaine with 1 μg/kg DEX for TPVB. Paravertebral blockade was performed under ultrasound guidance. A linear ultrasound transducer (HITACHI Arietta 60) was placed intercostally to identify the thoracic paravertebral space (TPVS), and a 20-gauge needle was inserted into the plane of the transducer. When the needle tip reached TPVS, 10 mL 0.5% ropivacaine with 1 μg/kg DEX in T5 paravertebral space was injected.

The gender, age, ASA grade, height, weight, body mass index (BMI), heart rate (HR), mean artery pressure (MAP) baseline, duration of surgery (h), anesthesia (h), the time to first analgesic request since paravertebral injection (TFR1), first use of patient-controlled analgesia (PCA1) intravenously, total sufentanil dosage, and the pressing times of analgesic pumps were all recorded in three groups. The intraoperative MAP and HR were measured after starting TPVB bolus injection. Hypotension defined as a 30% decrease or less than 80 mmHg in systolic blood pressure from baseline was treated with ephedrine 5 mg intravenously and further boluses as required. Bradycardia defined as heart rate <55 beats per minute was treated with 0.6 mg intravenously. Analgesics were administered through the PCA device (ZZB-150, Apon, Nantong, China). The background infusion of each PCA device was set to administer 0.02 μg/kg/h sufentanil, with a lockout time of 15 min, and a total allowable volume is 100 ml. The anesthetist conducted postoperative monitoring, pain assessment, and management was blinded to the patient groups. The flowchart of the study protocol is shown in Figure 1.

Ramsay sedation scores of patients were recorded at 30 minutes, 1 hour, 2 hours, 4 hour, 6 hours, 8 hours, 12 hours, and 24 hours after anesthetic recovery in three groups (score 1: patient anxiety, agitated or restlessness, or both; score 2: patient cooperation, orientation, and calm; score 3: patient only responds to orders; score 4: patient with light outer membrane percussion, or a loud auditory stimuli showed a rapid response; score 5: the patient showed a slow response to light eyebrows or loud auditory stimuli; score 6: the patient did not respond; score 2–4 is an ideal sedation level). The intraoperative MAP and HR were recorded at 10

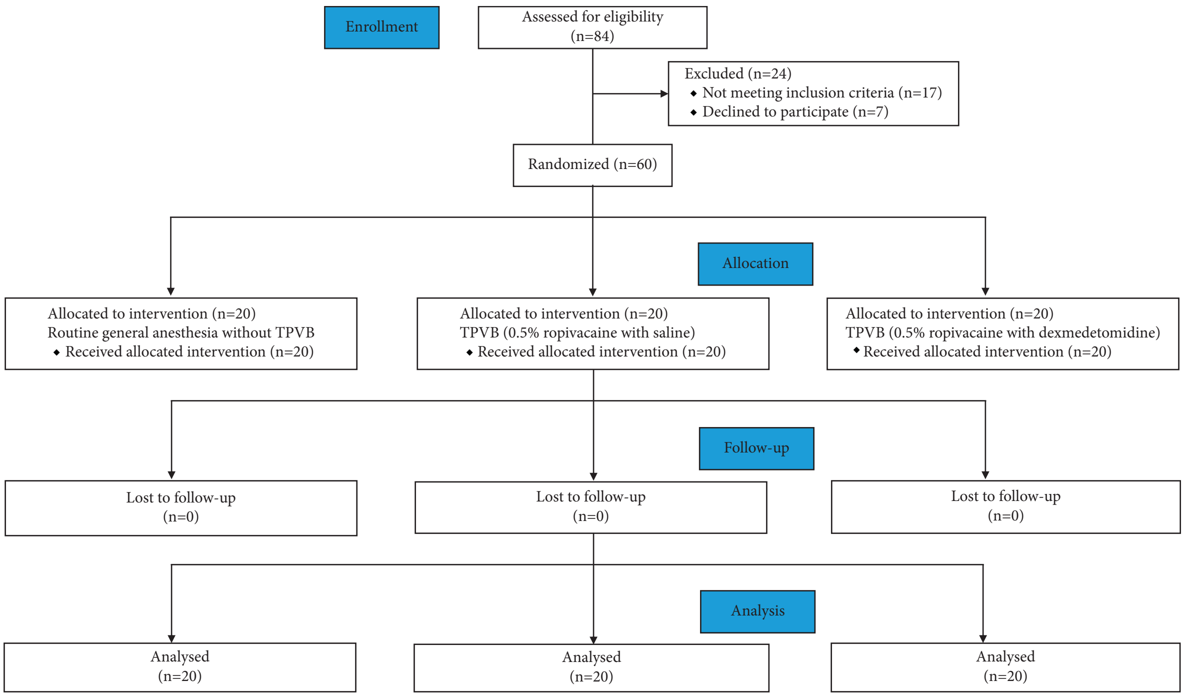

Figure 1: CONSORT flow diagram of the study.

minutes, 20 min, 30 min, 40 min, 50 min, 60 min, 70 min, 80 min, 90 min, and 100 min after starting TPVB bolus injection. Postoperative pain ratings (NRS) during rest and movement were recorded every two hours within 24 hours (NRS: NRS uses 0–10 to represent different degrees of pain. Score 0: no pain; score 1–3: mild pain; score 4–6: moderate pain; score 7–10: severe pain).

All values are mean ± SEM. Two-way ANOVA for repeated measures was used when appropriate (SPSS 20.0 for Windows, SPSS Inc.). The Student–Newman–Keuls multiple comparison post hoc test was used to differentiate within the groups. A probability value less than 0.05 was considered to indicate a significant difference between the groups, while a value greater than 0.05 was considered to indicate no significant difference between the groups.

3. Results

There were no significant differences among the G group, PR group, and PRD group in demographic data such as age, weight, height, BMI, and baseline hemodynamic parameters durations of surgery and anesthesia ($p > 0.05$) (Table 1). All patients underwent the surgery successfully without local anesthetic toxicity or diclofenac sodium contraindications.

Postoperative sufentanil (over 24 hours) consumptions were reduced significantly in the PRD group compared to other two groups ($p < 0.05$; Table 2). Moreover, all the abovementioned parameters did not reach significant difference between the G group and PR group as given in Table 2 ($p > 0.05$). There was no significant difference of postoperative Ramsay sedation scores among all groups before 12 h; however, the score values in the G group were significantly lower than that in the PR or PRD group ($p < 0.05$; Table 3).

The NRS pain scores of ipsilateral arm were, respectively, indicated in Figure 2 and 3 in rest or movement status. There was no significant difference in pain score among three groups in rest or movement status within 1 hour after surgery; 2 hours after surgery, the pain scores of the PRD group were lower than other two groups. In the PRD group, TFR1 and PCA1 were significantly longer than those in the PR group ($p < 0.05$) and G group ($p < 0.05$) (Table 2). There were significant differences of TFR1 and PCA1 between the PR group and G group ($p < 0.05$).

Hemodynamic parameters were monitored during surgery. HR and MAP trends are shown in Figures 4 and 5, respectively. There were no differences of hypotension and bradycardia among groups and the requirement of vasopressors for maintenance of stable hemodynamic parameters during the induction period did not show significant differences among groups (data not shown). The intraoperative HR and MAP in the PRD group were lower compared to other two groups. After 10 minutes, the intraoperative HR of all three groups decreased, but it was more obvious in the PR group and G group than that in the PRD group ($p < 0.05$). In the PR group and G group, the intraoperative HR tended to stabilize and increased slowly until 40 minutes, but the HR of the PRD group was lower than other G groups at 80 and 100 minutes. In the PR group and G group, the intraoperative MAP decreased significantly around 20 minutes, while MAP of the PRD group decreased to (77.1 ± 1.7) mmHg around 40 minutes, and it gradually returned to the baseline level around 100 minutes ($p < 0.05$). However, there was no significant difference in the consumption of sufentanil dose or the

incidence of hypotension and the occurrence of bradycardia during the surgery.

4. Discussion

TPVB has been used wildly to reduce postoperative opioid consumption and provide effective pain control. The injection site and volume are quite different in different studies, and there are single and multiple injections with volumes of 5, 7, 10, 15, 20, or 0.3 ml/kg [17]. A cadaver study observed distribution of 20 ml injected dye over three to four TPVS (range, 1–10) with 40% incidence of epidural spread [2]. Therefore, the analgesic effect produced by the volume of 15 or 20 ml may also include the effect of the epidural spread. In this study, we applied a volume of 10 ml of DEX combined with ropivacaine TPVB for patients with thoracoscopic lobectomy had a better analgesic effect than patients with only TPVB or no TPVB and may reduce the incidence of epidural spread.

DEX acts as a potential adjuvant for both axons and peripheral nerve blocks [16, 18], and studies have confirmed that epidural injection of DEX enhanced local anesthetics on nerves, reduced the need for intraoperative anesthesia, and provided a better analgesic effect after thoracotomy [19]. The analgesic effect is concentrated by inhibiting the release of substance P in the nociceptive pathway of dorsal root neurons and activating the alpha-2 receptor in the blue spot. This alpha-2 agonist mediates peripheral analgesia by reducing the release of norepinephrine and the independent inhibition of neurofibrillary action potential by the alpha-2 receptor. None of the various animal studies showed any adverse neurological effects of DEX [20, 21] and neuroprotective effects of dexmedetomidine, induced by intrathecal administration is similar to methylprednisolone [21]. DEX has also been used in human studies as an adjuvant for local anesthetics [14, 15]. Mahendru et al. compared the effects of intrathecal DEX and fentanil as bupivacaine adjuvants; the results showed that intrathecal DEX prolonged exercise and sensory block, more hemodynamic stability, and reduced need for analgesics within 24 hours compared with fentanil [22]. In other studies, DEX improved blocker efficiencies have been shown, with no reported neurological side effects. Further study of the neuronal effects of DEX was encouraged by the researchers [15, 16]. In the current study, the consumption of sufentanil in the two paravertebral nerve block patients was significantly lower than that in the control group, indicating that paravertebral nerve block can prolong the analgesic time. None of the patients in the PRD group required an additional dose of sufentanil, while only one patient in the PR group required an additional dose of sufentanil. Compared with the PR group and the G group, the first analgesia request time was much longer in the PRD group, and the postoperative PRD group had a longer PCA1 time, but the total number of PCA (or sufentanil consumption) and pain score are lower. This indicates that ropivacaine supplemented with DEX prolongs the time of analgesia after PVB. In addition, patients receiving DEX had less opioid-related complications such as nausea and vomiting. On the other hand, all of these parameters were comparable in the PR group and G group, indicating that there was no significant TPVB analgesic effect of ropivacaine alone compared with patients who did not receive TPVB. The use of local anesthetic TPVB alone improved intraoperative analgesia and reduced the need for sufentanil, but did not provide adequate postoperative analgesia. A recent RCT meta-analysis study evaluated the analgesic effects of multilevel TPVB in combination with ropivacaine or bupivacaine in postoperative breast cancer [23], and the results showed the overall analgesic consumption was lower in the intraoperative and postoperative ropivacaine groups or bupivacaine group, and the number of patients with NRS >3 after PACU was significantly reduced in the TPVB group. The local anesthetic infiltration group immediately reduced postoperative pain, especially in the 2 hours after surgery, but there was no significant difference of analgesia between 12 hours and 24 hours after surgery.

In this study, the requirement of vasopressors for maintenance of stable hemodynamic parameters did not reveal any significant difference during the induction period among groups. However, the HR and MAP in the PRD group were lower than those in the other two groups during surgery. It has been reported that the stable hemodynamics may possibly be explained on the basis of lower volume of local anesthetics used and a suitable selection of the dose of adjuvant [11]. The sedative effects found in the study may be related to the use of DEX [24]. A higher sedation score in the PR and PRD groups than the G group may due to better analgesia effects in PR and PRD groups.

More recently, Hong et al. reported that DEX as an adjunct in TPVB provided effective pain relief and significantly reduced opioid requirement in VATS [25]. Our results are consistent with the Hong et al.' study. However, there are two differences between our study and Hong et al. study'. (1) In our study, only on injection at T5 space before surgery, while there are two injections at the T3-T4 and T4-T5 levels after surgery in Hong et al.' study. It has been reported that TPVB performed prior to general anesthesia for laparoscopic cholecystectomy can provide early discharge and better postoperative pain management [6]. (2) The injection volume of the ropivacaine and DEX is different. The injection volume of ropivacaine and DEX mixture in our study is 10 ml at the single site, while the total volume of the two site injections was 30 ml in Hong et al.' study. Our results demonstrated that a small injection volume (10 ml 0.5% ropivacaine with 1 μg/kg DEX) at site of T5 space before surgery also achieved effective postoperative analgesia. It may have beneficial clinical effects for reducing the side effects of drugs, puncture injury, and discomfort to patients and enhancing recovery after surgery.

There are certain limitations to our study. First, it was a retrospective study with a small sample size and the findings therefore have to be confirmed with a larger randomized controlled trial. Second, the small sample size and recruitment of relatively healthy patients (ASA I and II) limited the possibility of drawing a definitive conclusion. Greater numbers of patients and patients with multiple comorbidities (i.e., ASA III or IV) need to be included in future studies to verify these findings. Third, since a single dose of TPVB can provide sufficient pain relief, inserting a catheter into the paravertebral space for continuous infusion of local anesthetics may provide protracted postsurgery analgesia. Furthermore, different doses and drugs used in TPVB may cause bias of the results. More studies have to be conducted to clarify this question.

5. Conclusions

In summary, a small volume of TPVB with 1 μg/kg DEX combined with 0.5% ropivacaine by single injection at T5 space before surgery for patients undergoing thoracoscopic lobectomy prolonged the overall analgesia time after surgery and reduced the dose and side effects of opioids.

Introduction. Cardiovascular disorders are one of the prominent causes of risks of mortality which accounts for high rate of the deaths at a global level. The risk of deadly myocardial infraction grows because of diabetes which even causes the development of heart failure. *Objective*. The objective of this study was to understand and study the effect of glycyrrhizin on diabetes suffering rats with myocardial remodeling. *Materials and Methods*. Streptozotocin was used for induction of diabetes, and 8–12 weeks later, the assessment of inflammation, fibrosis, and cardiac damage was evaluated. Histopathological analysis and immunohistochemistry was performed to analyze the effect in various groups. Western blotting was performed to understand the proteins expressed in diabetes, and also, their expression was noted in treatment groups. *Results*. There was a significant rise in TNF-α, dense fibrosis, and collagen deposits in the STZ diabetes group. The effects of hyperglycemia were significantly improved in the glycyrrhizin-treated group. DAPI, BrDu, and caspase staining was also performed to understand apoptosis in tissues where the diabetic groups reported significant apoptosis, while the effects were significantly lower in the treated group. *Conclusion*. All the observations indicate that glycyrrhizin has cardioprotective action in diabetic rats with myocardial remodeling and is due to the inhibition of the NF-κB signaling pathway in the myocardial layer.

1. Introduction

Approximately 30% of all deaths worldwide occur due to the cardiovascular disorders [1]. Acute myocardial infraction (AMI) is considered among those with the high mortality rate, and the infarct size is a chief determinant of prognosis in the patients. Restoration of the coronary blood circulation by the percutaneous coronary interventions (PCI) is considered to be the only clinically accepted and approved procedure to bound the infarct size [2]. The circulation of the high level of glucose might guide to the modified cardiomyocyte signaling which results in oxidative stress, fibrosis, and finally to the death of the myocyte cell [3].

The cardiac cells might face early transitions due to hyperglycemic conditions which may cause the discharge of important inflammatory mediators such as cytokines and chemokines [4]. The myocardial revascularization involvement is regularly demonstrating throughout the period of medication of patients with the persistent coronary artery disease (CAD). Advancement of angina and exercise potential in the patients with bounded symptoms is the most important observed advantages with these mediations [5].

The acute myocardial infarction heads to the ischemic necrosis of the myocardium which is considered to be harmful to the health of the mass population [6]. The timely widening of the coronary arteries in the patients suffering from the myocardial infraction diminishes the region of myocardial infraction, and there is an outstanding reduction in the mortality rate [7]. There is multiple known as well as unknown components that might affect the myocardial impairments followed by interferences.

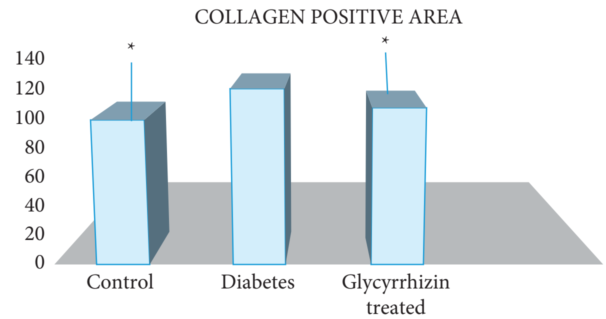

Figure 1: Percentage of collagen positive area in all groups.

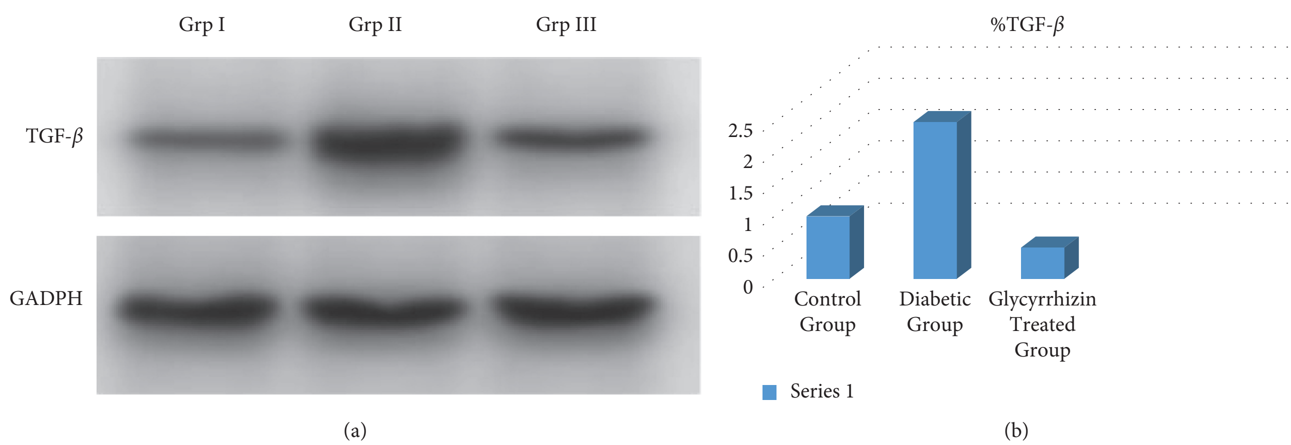

Figure 2: TGF-β expressions recorded by (a) Western blotting and (b) quantification in control, diabetic, and treated groups.

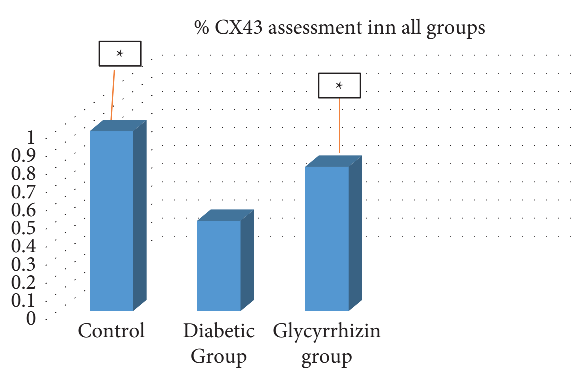

Figure 3: Glycyrrhizin alters CXCR4 expressions in myocardial tissues in STZ-diabetic rats.

However, this is still considered debatable as the diabetes mellitus might alter the myocardial responsibilities and possibly make the myocardium more prone to ischemic impairment [8, 9]. The cardiac muscles might even die, and the region of the myocardial necrosis leads to affect the prognosis of the patient suffering from myocardial infraction. In clinical practices, the myocardial damages lead to the disorder of the electric roles within the myocardial and cardiac deficiency along with arrhythmia. One of the crucial elements of root extraction from the liquorice is the acid, i.e., glycyrrhizin which is soluble in water. It consists of the glucuronic acid as well as the glycyrrhetinic acid [10].

The research study conducted by [11] demonstrates that the glycyrrhizin is a successful element in the liquorice that comprises of antiallergic, antioxidant, immunomodulatory, anticancer, antiulcer, and antiviral properties. The risk of lethal myocardial infarction and evolution of heart failure is intensified because of diabetes [12, 13]. The fundamental

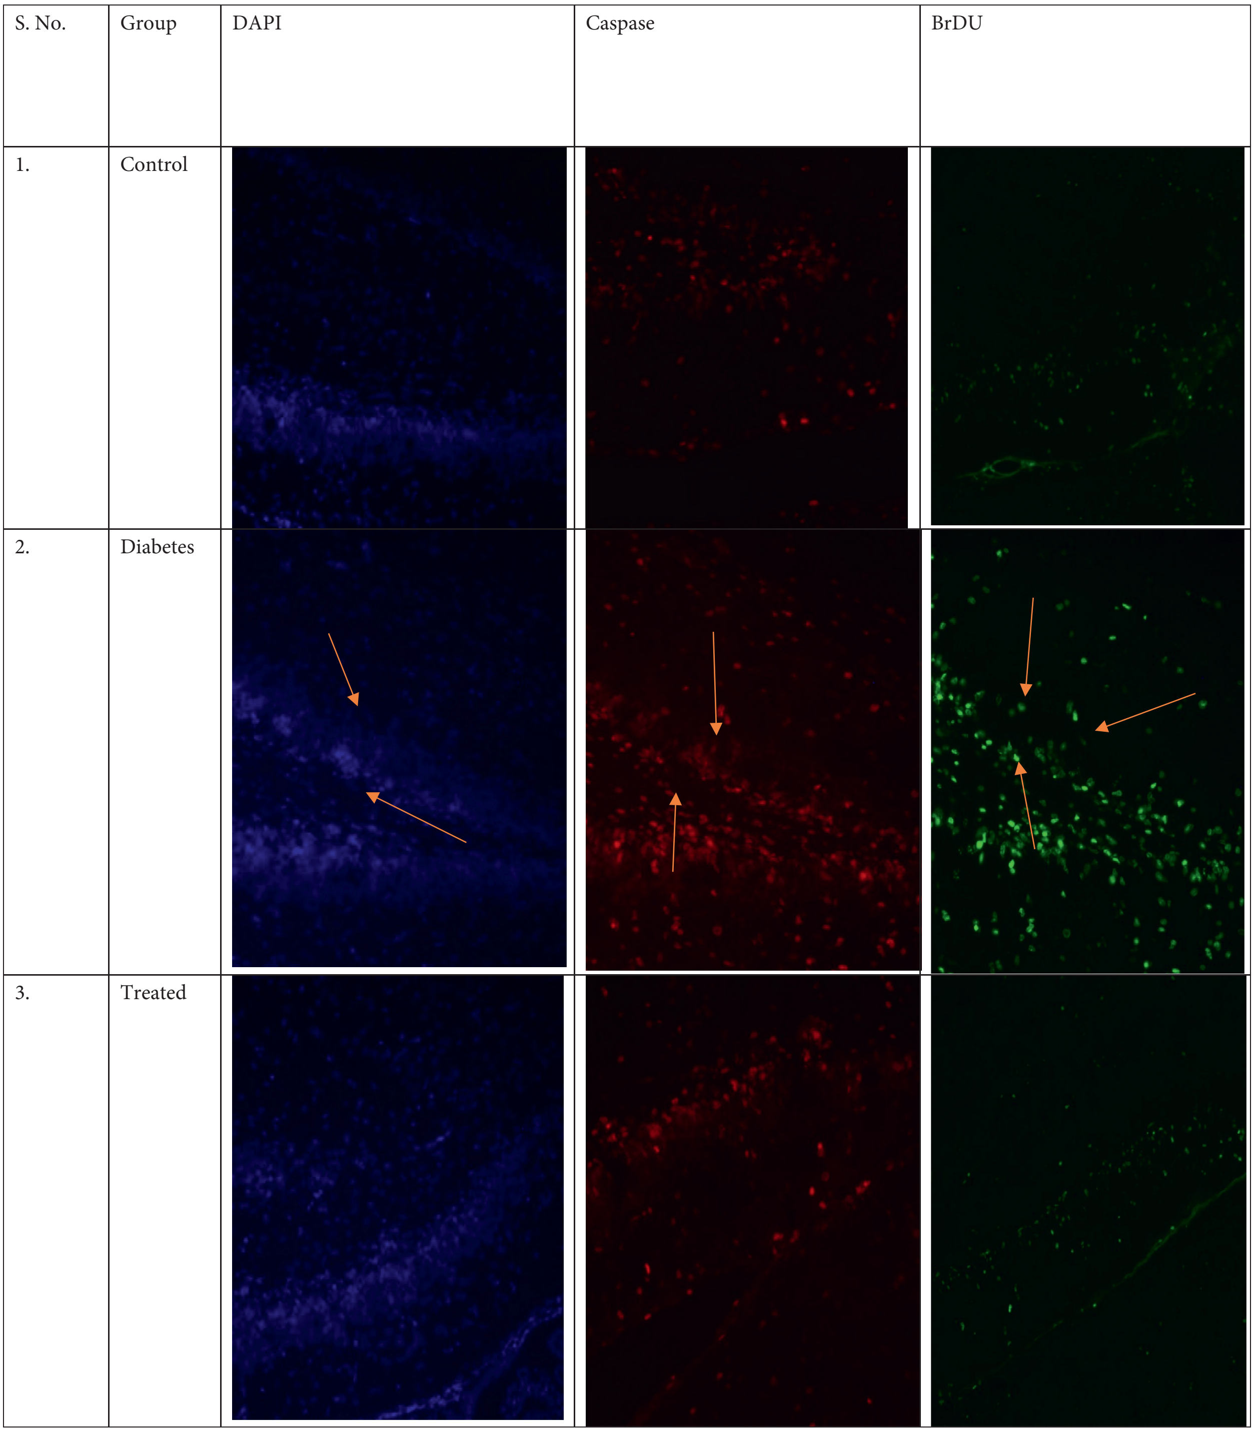

Figure 4: Immunofluorescent staining of tissues from all groups with DAPI, caspase, and BrDU for analysis of apoptosis.

diabetic cardiomyopathy which is aggravated by other components such as the hypertension as well as ischemic heart disorders justifies the defective prognosis after the myocardial infarction.

The reactive oxygen species (ROS) as well as the reactive nitrogen species (RNS) is built as an outcome of hyperglycemia. This in turn persuades the p53 and the cytochrome-c moderated caspase-3-dependent apoptosis [14, 15]. Correspondingly, termination of myocardial cells in diabetes is averted by the utilization of the antioxidants and the caspase inhibitors which shows a spontaneous task for the apoptosis in the pathogenesis of diabetes-instigated cardiomyocyte loss.

2. Materials and Methods

Male Wistar rats weighing around 200–250 gm were obtained from the animal house. The rats were kept at a

Figure 5: Isolated heart from the experimental rats. (a) Freshly isolated heart for fixing. (b) Fixed organ in 10% formalin solution.

constant temperature of 25°C ± 2°C in cages. Food pellet and water were provided freely ad libitum, and 12 h light/12 h dark cycle was maintained. All experiments were duly approved by the ethical committee, and protocols were followed in accordance to National Institutes of Health Guidelines.

2.1. Induction of Diabetes. Type 2 diabetes was induced using streptozotocin 45 mg/kg via i.p., route. After 4 days of dose administration, the blood glucose levels were tested to ensure the induction diabetes in rats. Evaluation of inflammation and cardiac damage was done 8–12 weeks postinduction of diabetes. Animals were housed in the animal facility. Diabetic rats were administered Formulab Diet 5008 Purina ad libitum throughout the experiment. Accucheck glucometer (UK) was used for measuring the blood glucose levels via the tail region once in seven days.

2.2. Western Blotting. Rats tissues from the heart were harvested from all 3 groups and then processed for Western blotting. The primary antibodies used were CX43, GAPDH, CXCR4, RAGE, and TGF-β (Cell Signaling, Danvers, MA, USA) ET-1, NaV1.5, phospho-p38, Nrf2 (Thermo Fischer Scientific), and secondary antibodies used were anti-mouse IgG or anti-rabbit IgG (1 : 5000; Sigma Aldrich) and were used as control where the data's were compared with β-actin levels using the analytical software for processing images and determining the intensity and percentage of control.

2.3. Morphometric Analysis. At the end of experimentation, the rats were sacrificed, and tissues from the heart were fixed in 10% formalin solution. The tissues were embedded in paraffin, and 4 mm thick sections were cut. Myocyte obtained from sections were stained with hematoxylin and eosin, and captured images were analyzed.

Collagen fibers were stained and were quantified so as to measure the fibrosis. The collagen positive area was measured for all groups. Myocardial tissues were frozen and stained in oil-red and then washed and counterstained with hematoxylin. Images were captured using a microscope (Leica microsystems).

2.4. Immunofluorescence Staining. The paraffin sections were cut from control and treatment groups which underwent immunohistochemistry tests by using antigen retrieval methods. Tissue sections were incubated with primary antibodies for interleukin 6 (IL-6) (Genescript), interleukin 6 (IL-6) (Thermo Fischer), rabbit polyclonal collagens I and III (Thermo Fischer), and tumor necrosis factor TNF-α (Sino Biological) overnight, and then, they were stained with secondary antibodies at 370°C for thirty minutes. The stained sections were developed using diaminobenzidine and hematoxylin was used for counterstaining. All sections were viewed and captured using the ZEISS LSM 780 laser scanning microscope (Zeiss).

Sections were also stained with DAPI after three washings and then mounted on Fluoromount-G (Southern Biotech). Sections from cardiac tissue which were stained with troponin-I initially were analyzed for troponin intensity

changes and compared with control, diabetic only, and diabetic rats with treatment for identification of the effects of glycyrrhizin on troponin-I in ventricular cardiac muscle.

Myocardial apoptosis: the effect of glycyrrhizin on apoptosis in cardiomyocytes in the diabetic rats was evaluated using DAPI, caspase, and BrDU staining.

2.5. Statistical Analysis. The results were expressed in mean ± SD. We used one-way ANOVA was used for checking the significant differences followed by the post hoc multiple comparison Tukey's test where $p < 0.05$ was considered as significant.

3. Results

The tissues collected from the ventricular heart in case of diabetic rats have shown a significant rise in collagen deposition which was improved in the glycyrrhizin treatment group (Figure 1). The collagen positive area was measured by positive trichrome staining. Means ± SE; $p < 0.001$; $n = 6$.

The expressions of TGF-β were increased in cardiomyocytes cells and cardiac tissues of the diabetic group which was improved with CXCR4 antagonist in case of the glycyrrhizin-treated group. TGF-β: fibrosis marker was evaluated in STZ-diabetic rats where a significant increase was shown on comparison to the control group. Treatment of four weeks in the glycyrrhizin-treated group caused a significant decrease in the TGFβ expression in tissues of group II (treatment group) animals (Figures 2(a) and 2(b)).

Glycyrrhizin has shown increased levels in connexin43 (gap junction protein) in the cardiac tissues (Figure 3).

The stained cells in the diabetic group were higher on comparison to the normal control group, hence showing confirmed apoptosis in the myocardial region of the diabetic rats. Glycyrrhizin has shown a significant decrease in the apoptosis in myocardial cells, hence confirming the cardioprotective action of glycyrrhizin (Figure 4).

4. Discussion

Glycyrrhizin is a crucial water-soluble acid which is prominently used in Asian countries, in root extraction from liquorice. One of the major complicated disorders of chronic diabetes is myocardial fibrosis where many studies demonstrate high cardiac impairment postischemic results. Multiple clinical studies show the scenario of acute coronary syndromes which have direct impact over the high susceptibility of patients suffering from diabetes to a higher risk of heart failures.

The heart was isolated from rats and then fixed with formalin for further studies (Figures 5(a) and 5(b)). Deposition of collagen in cardiac fibrosis in the STZ diabetic rats, control group, and glycyrrhizin-treated groups was analyzed histopathologically, where it was found that collagen deposits were significantly higher in the diabetic groups as compared to the treated and control groups (Figure 6). Stained tissues were observed for fibrosis and collagen deposits.

The hyperglycemia condition mediates fibrosis in cardiac tissues which was analyzed by TGF-β (transforming growth factor beta), thus showing a significant increase in its expressions in the STZ rat cardiac tissues, while the expressions of TGF-β were significantly reduced in glycyrrhizin groups in treatment duration of four weeks. AC16 cardiomyocyte cells were also treated overnight with 25 mM of glucose and hyperglycemia cells were treated with AMD3100 (CXCR4 antagonist) to estimate the connection between TGF-β and CXCR4 pathways. Increase in TGFβ expression was in hyperglycemic cardiomyocytes, while the treated group receiving AMD3100 had noted a decreased expression of TGF-β (Figure 2), hence showing the anti-inflammatory action of glycyrrhizin.

The regulation of cell adhesion for diabetic groups was performed by assessing the connexin43. Western blotting tests were performed for showing the reduced CX43 expression in heart tissues of diabetic rats on comparison to the control group. A restoration of the CX43 expression was shown in the treatment group. Western blot analysis was performed for tissue of STZ rats to understand the mechanisms involved in inflammatory responses during hyperglycemia and in cardiac fibrosis. A significant increase in expression of CXCR4 was found in diabetic groups versus the treated group, hence showing role of glycyrrhizin in CXCR4 expression, thus confirming the anti-inflammatory action of glycyrrhizin. Reduced CXCR4 expression showed the anti-inflammatory effect in diabetic rats with cardiac atrophy.

TGFβ is a prime factor involved in contributing towards cardiac fibrosis. Hence, in this study, we concluded that STZ-induced hyperglycemia has shown activated cardiac fibroblasts and deposition of matrix proteins extracellularly. As the elevated factor TGF-β is responsible for fibrogenesis, the fibroblast production is seen to be prominent in diabetic rats but were ameliorated in the treatment group. Hence, we can say that there is an association of chemokines with cardiac fibrosis. Expressions of TGF-β in the myocardium were increased leading to fibrosis. Collagen fibers were also found significantly higher in the diabetic groups, whereas they were reduced in the glycyrrhizin group. Apoptosis was also noted in diabetic groups and was significantly reduced in the treated groups.

5. Conclusion

Hyperglycemia can lead to increased inflammation and oxidative stress which leads to cardiac remodeling and hence causes hypertrophy in the myocardium. The STZ rats showed an increased level of inflammation which may lead to cardiac injury and damage. The research concludes with findings about the anti-inflammatory and preventive cardiac damage properties of glycyrrhizin.

The study aims to explore the application of international classification of diseases (ICD) coding technology and embedded electronic medical record (EMR) system. The study established an EMR information knowledge system and collected the data of patient medical records and disease diagnostic codes on the front pages of 8 clinical departments of endocrinology, oncology, obstetrics and gynecology, ophthalmology, orthopedics, neurosurgery, and cardiovascular medicine for statistical analysis. Natural language processing-bidirectional recurrent neural network (NLP-BIRNN) algorithm was used to optimize medical records. The results showed that the coder was not clear about the basic rules of main diagnosis selection and the classification of disease coding and did not code according to the main diagnosis principles. The disease was not coded according to different conditions or specific classification, the code of postoperative complications was inaccurate, the disease diagnosis was incomplete, and the code selection was too general. The solutions adopted were as follows: communication and knowledge training should be strengthened for coders and medical personnel. BIRNN was compared with the convolutional neural network (CNN) and recurrent neural network (RNN) in accuracy, symptom accuracy, and symptom recall, and it suggested that the proposed BIRNN has higher value. Pathological language reading under artificial intelligence algorithm provides some convenience for disease diagnosis and treatment.

1. Introduction

With the improvement of living standards, people's attention to their health is also increasing. At the same time, they are concerned about the medical conditions and facilities of the hospital. The hospital will conduct statistical analysis and comparison of the annual medical data to form an indicator of medical quality management [1]. Most of the data in the medical industry come from electronic medical records (EMRs). EMR is also called computerized medical record system or computer-based patient record (CPR). It is a digital medical record saved, managed, transmitted, and reproduced by electronic devices (computers, health cards, etc.) to replace handwritten paper medical records. Its content includes all the information of paper medical records. The National Institute of Medicine defines EMR as an electronic patient record based on a specific system, which provides users with the ability to access complete and accurate data, warnings, prompts, and clinical decision support systems.

Through the extraction and statistical analysis of these data, relevant indicators are formed to provide convenience for medical personnel, which help them better understand the relevant medical conditions and improve the quality of medical care [2]. With the rise and wide application of computer network technology, its application in the medical industry is becoming more common. Most medical institutions use a unified medical record front page, which provides great convenience for the information statistics of the medical industry [3]. The medical record records the detailed condition of the patient, from the initial diagnosis to the final treatment result, which provides a detailed basis for the follow-up [4, 5]. The detailed record of the patient's condition in the medical record provides important support for medical staff to understand the patient's condition. Both the past medical history and the current diagnosis and treatment of diseases can be consulted [6]. With the development of electronic information on the Internet, case records have also changed from the original paper version to an electronic version, completing the digital management mode of medical records [7, 8]. Electronic cases have greatly improved the efficiency of using medical records. The use of EMRs provides convenience for medical staff and management staff.

ICD coding technology is a relatively complete and mature disease-coding method. Almost every hospital unit uses its rules to code diseases on the front page of medical records [9]. The combination of English and numbers is used for coding to avoid coding inconsistencies [10]. It promotes exchanges between people from different countries and regions. With the continuous improvement of disease classification by scholars, more and more disease types are covered [11]. The coding method is characterized by scientificity, integrity, applicability, and operability. Therefore, it is widely used in the field of medicine [12]. In clinical medicine, the use of LCD can bring great convenience, unify the code for global diseases, facilitate researchers' research, and contribute to the development of medicine.

In this experiment, the statistical analysis of the first page of medical records is conducted through the sample survey. The causes of errors in the disease classification on the first page of the medical record are analyzed and summarized. Meanwhile, the embedded medical record information knowledge system is established, and the NLP-BIRNN algorithm is used to optimize the medical record text. Also, the detailed improvement measures are proposed to provide a basis for the investigation of disease classification.

2. Materials and Methods

2.1. Experimental Materials. The data were randomly selected from the EMR database of our hospital, and the patient medical records and disease diagnostic code data on the front pages of 8 clinical departments of endocrinology, oncology, obstetrics and gynecology, ophthalmology, orthopedics, neurosurgery, and cardiovascular medicine were collected.

2.2. Case Statistics. The medical record information is randomly extracted from the EMR management system for analysis. Statistics on the diagnosis selection and the number of disease-coding errors are conducted. The statistical analysis of the data of clinicians and medical coders before and after training is performed. Through research, self-examination, training, and feedback, the disease-coding knowledge topics of the above eight clinical departments are explored. The coder calls up the medical record data of a certain department. According to ICD-10's undergraduate disease-coding rules, such as clinical knowledge and main diagnosis selection principles of the disease's physiological mechanism, development process, clinical manifestations, and treatment methods, the disease-coding process is conducted. During the coding process, the coder must carefully read the case, especially the admission records (judgment of the main diagnosis selection), surgical records (surgical name, postoperative method, surgical grade, surgical incision, and anesthesia method), course records (development of the disease, such as whether the disease is aggravated, whether it is improved, and whether it is treated), and discharge records (diagnosis and treatment process, whether the diagnosis at admission and discharge are consistent). Pathology, imaging, ultrasound, and laboratory reports should also be paid attention to.

2.3. Self-Examination and Training. According to the results, the coder reexamines the previous medical records, mainly checking the diagnosis selection and disease coding. Statistics on the data of diagnosis selection errors and disease-coding errors are conducted. Then, ICD-10 training will be given to the relevant doctors and coders of the above eight clinical departments on the problems examined this time.

2.4. Feedback. The coder compares and analyzes the data of main diagnosis selection errors and disease-coding errors before and after the training. The results are then shared to the relevant personnel with feedback, to explore rectification measures and improve the coding level.

2.5. Establishment of Embedded EMR Information Knowledge System. The system establishes conditions. First, conditions are written based on the writing standard of medical records stipulated by the national health department. The data content expressed in the medical record should be a common medical term without ambiguity. Second, the knowledge system must contain descriptive and conclusive knowledge about medical records. Descriptive knowledge refers to the detailed description of the disease. For example, the types of cold are wind chill and wind heat and their common symptoms are headache and cough, which is descriptive knowledge. On the contrary, it is conclusive knowledge to judge the type of cold according to the description of the disease. The knowledge system needs to combine the structured input interface of medical records and provide a selective input prompt based on the user input. Third, the medical record information is stored as an XML document, which has hierarchical structure. The knowledge base is also represented by the hierarchical XML document to achieve efficient synchronization of medical record input interface, which corresponds to the medical record information document. For some simple information input without prompt, the node can be set to null value. For items with multiple choices, multiple child nodes can be set when prompted, read into memory, and displayed in the medical record interface for users to choose. Fourth, the semantics should be concise and include the hints about limiting the use of characters.

The information base of the embedded medical record knowledge system contains knowledge, as shown in Table 1:

There are seven pages in the embedded EMR input system, and seven XML documents of medical record knowledge base are established accordingly. When doctors create a new medical record page, the system will automatically call the knowledge base XML document according to the current page. When doctors input specific document node information, they can input medical record information according to prompt operation to improve the recording speed and reduce expression errors.

2.6. Steps of NLP-BIRNN Algorithm. First, the data preprocessing of EMR is carried out, including data processing, cleaning, and screening.

Second, NLP based on medical tagging (medical record tagging, character extraction, word vector transformation, deep neural network, automatic tagging, and feature vector splicing) and NLP without medical tagging (no medical record, part of speech tagging, keyword selection, word vector transformation, and feature vector splicing) are performed.

Third, calculation is done. The symptom feature vectors involved in NLP solutions are normalized, and the values at each position of vector data are limited to [0, 1]. The ICD is coded by one hot representation to become the tag of deep learning training. The normalized feature vector and label are imported into the deep learning model for training, the auxiliary diagnosis model is obtained, and the test set is used to complete the test of the model results.

2.7. Data Analysis. The SPSS24.0 software was adopted for data statistics and analysis. The difference between the two groups of data was analyzed by the t-test. The count data were compared by the Chi-square test. $P < 0.05$ indicated significant difference, and $P < 0.01$ indicated highly significant difference.

3. Results

3.1. CT and Ultrasound Images of Some Diseases. At present, the diagnosis basis of 2019 novel coronavirus (2019-nCoV) is mainly nucleic acid testing and medical imaging detection. The combination of the two is more conducive to diagnosis. It is found from the announcement of officially confirmed cases that some patients showed a positive result after more than 2 nucleic acid tests and even showed a positive result after the fifth nucleic acid test. Therefore, while performing nucleic acid testing, lung CT imaging examination is carried out. Patients with lung CT presenting with signs of acute inflammation should be admitted as soon as possible in accordance with the principle of "suspected disease is always present." The CT and ultrasound results of some diseases are shown in Figure 1. Figure 1(a) is a chest CT image of coronavirus disease 2019 (COVID-19). Figure 1(b) is a segmented image of the pneumonia-infected area. Figure 1(c) is a CT of the abdomen. The accuracy of diagnosing the mild fatty liver using CT is 88.75%. Figure 1(d) is an ultrasound image of the abdomen. The accuracy of diagnosing the mild fatty liver using ultrasound is 73.75%. It shows that CT diagnosis is more accurate than ultrasound diagnosis.

3.2. Results of Main Diagnosis Selection Errors and Disease-Coding Errors of the Obstetrics and Gynecology Department. Results of main diagnosis selection errors and disease-coding errors of the obstetrics and gynecology department are shown in Figure 2. Figure 2(a) is the results of the main diagnosis selection errors. There are 280 errors in the discharge case statistics before the training and 80 errors after the training. The statistics on the four types of main diagnosis selection errors are conducted, including that C-section is the main diagnosis, singleton live birth diagnosis is the first, tumor morphological coding is the main diagnosis, and major treatable diseases are not major diagnosed. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 2(b) is the results of disease-coding errors. There are 240 errors in the discharge case statistics before the training and 60 errors after the training. The statistics on the four types of disease-coding errors of pregnancy hypertension, premature rupture of membranes, tumors, and mass, and vomitus gravidarum are conducted. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$).

3.3. Results of Main Diagnosis Selection Errors and Disease-Coding Errors of the Endocrinology Department. Results of the main diagnosis selection errors and disease-coding errors of the endocrinology department are shown in Figure 3. Figure 3(a) is the results of the main diagnosis selection errors. There are 180 errors in the discharge case statistics before the training and 50 errors after the training. The statistics on the three types of main diagnosis selection errors are conducted, including that the treatment of the disease is not a major diagnosis, multiple complications are not primarily diagnosed, and no major diagnosis is made for a single complication. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 3(b) is the results of disease-coding errors. There are 160 errors in the discharge case statistics before the training and 30 errors after the training. The statistics on the five types of disease-coding errors are conducted, including the merge coding error, no additional coding used, neonatal diabetes mellitus, gestational diabetes mellitus, and screening for diabetes. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$).

3.4. Results of Main Diagnosis Selection Errors and Disease-Coding Errors of the Orthopedics Department. Results of the main diagnosis selection errors and disease-coding errors of the orthopedics department are shown in Figure 4.

Table 1: Content of database construction of the embedded medical record knowledge system.

Descriptive knowledge of disease	Terms of disease characteristics and selection of entry
Conclusive knowledge of disease	Keywords given for pathological conclusion are given
Normative data content	Age
XML document input information	Restrictions on character entry

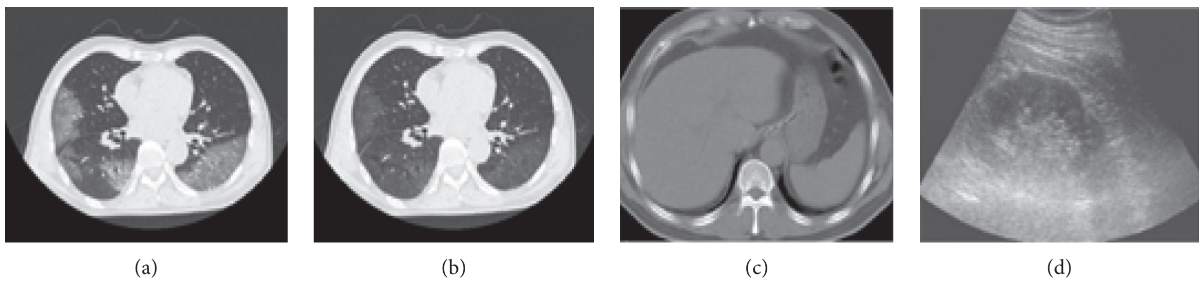

Figure 1: CT and ultrasound images. (a) The chest CT image of COVID-19 cases. (b) The segmented image of the pneumonia-infected area. (c) CT of the abdomen. (d) Ultrasound of the abdomen.

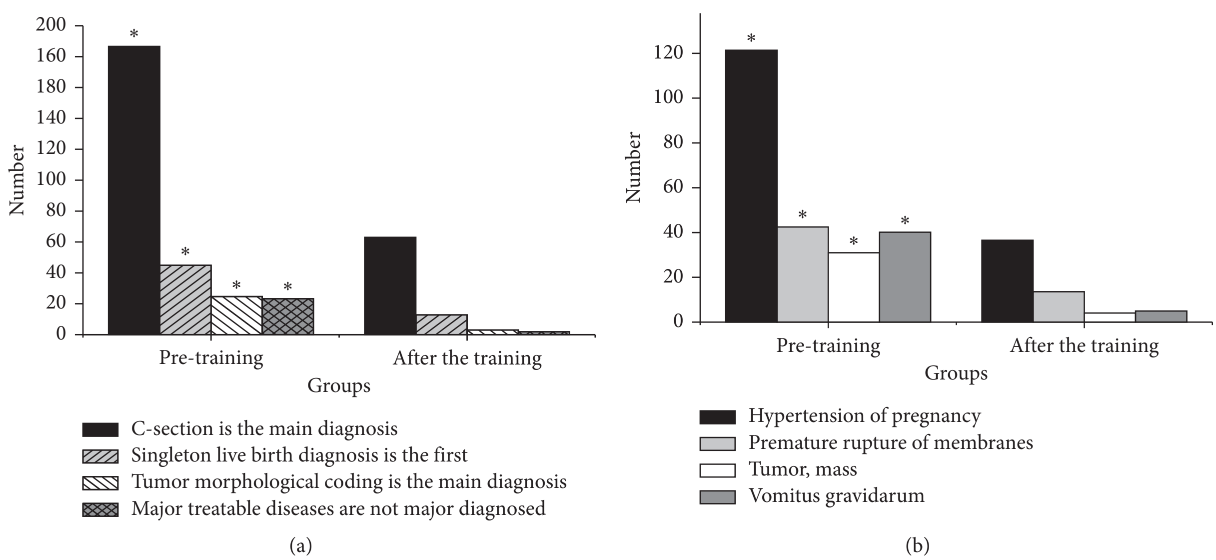

Figure 2: (a) Main diagnosis selection errors and (b) disease-coding errors of the obstetrics and gynecology department ($^*P < 0.05$).

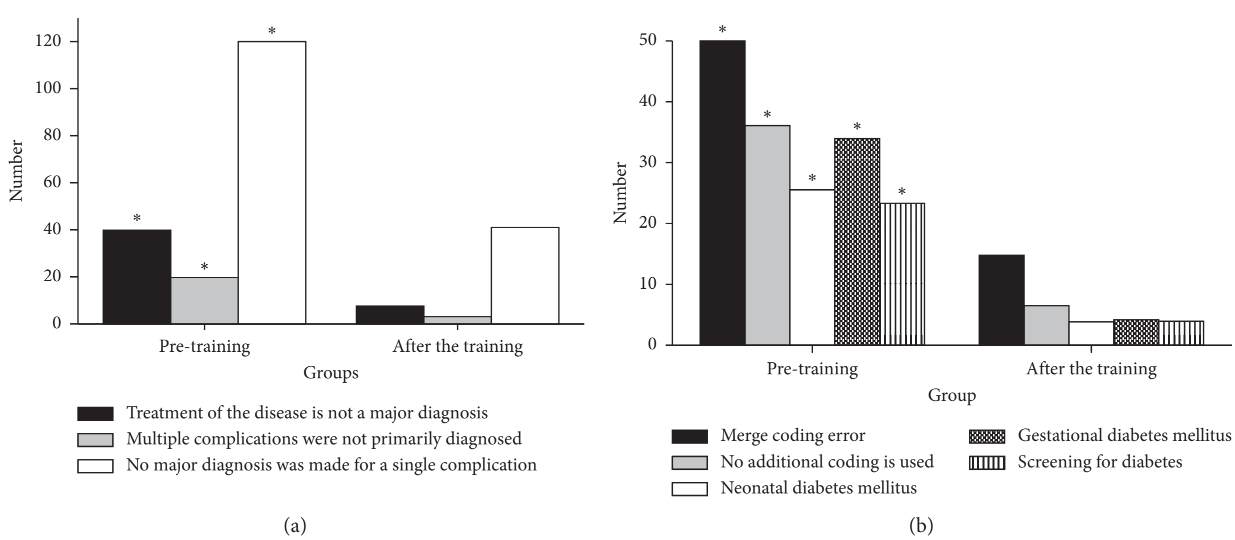

Figure 3: (a) Main diagnosis selection errors and (b) disease-coding errors of the endocrinology department ($^*P < 0.05$).

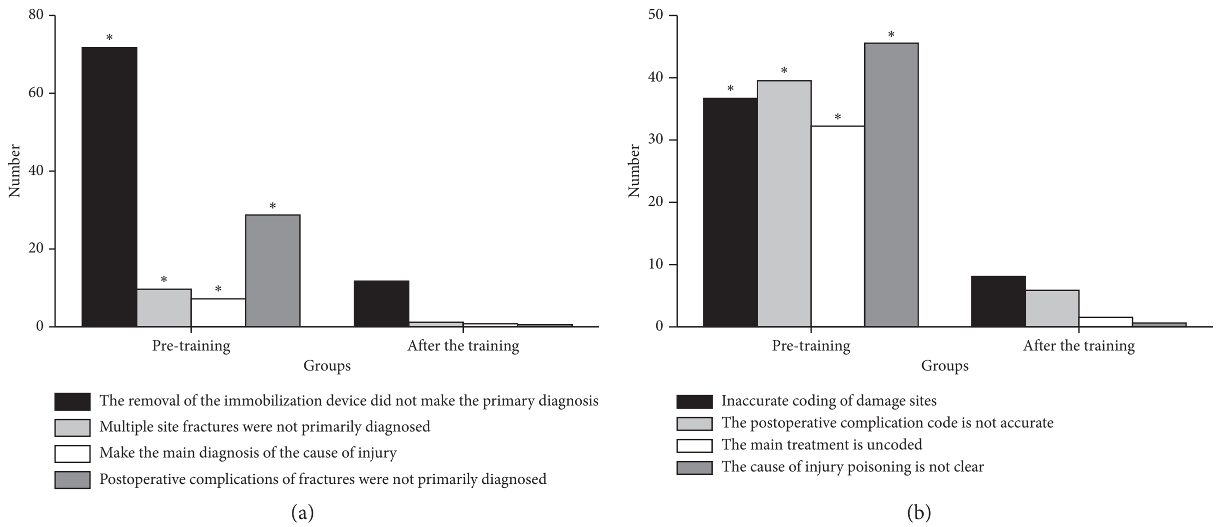

Figure 4: (a) Main diagnosis selection errors and (b) disease-coding errors of orthopedics department ($^{*}P < 0.05$).

Figure 4(a) is the results of the main diagnosis selection errors. There are 120 errors in the discharge case statistics before the training and 30 errors after the training. The statistics on the four types of main diagnosis selection errors are conducted, including that the removal of the immobilization device does not make the primary diagnosis, multiple site fractures are not primarily diagnosed, the main diagnosis is made for the cause of injury, and postoperative complications of fractures are not primarily diagnosed. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 4(b) is the results of disease-coding errors. There are 160 errors in the discharge case statistics before the training and 25 errors after the training. The statistics on the four types of disease-coding errors are conducted, including that the coding of damage sites is inaccurate, the postoperative complication coding is not accurate, the main treatment is uncoded, and the cause of injury poisoning is not clear. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$).

3.5. Results of Main Diagnosis Selection Errors of the Oncology and Neurosurgery Department. Results of the main diagnosis selection errors of the oncology and neurosurgery department are shown in Figure 5. Figure 5(a) is the results of the main diagnosis selection errors of oncology. There are 260 errors in the discharge case statistics before the training and 60 errors after the training. The statistics on the four types of main diagnosis selection errors are conducted, including that the primary diagnosis of the tumor is not made in Z code, using Z code to make the primary diagnosis is inaccurate, major diagnosis is not made for the major treatment of disease, and tumor morphology code is the main diagnosis. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 5(b) is the results of the main diagnosis selection errors of the neurosurgery department. There are 180 errors in the discharge case statistics before the training and 50 errors after the training. The statistics on the five types of main diagnosis selection errors are conducted, including that the main diagnosis is head trauma, tumor morphological code is not written, the rehabilitation Z code is not used, coding of disease sites is inaccurate, and the cause of injury poisoning is not written. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$).

3.6. Results of Disease-Coding Errors of Cardiovascular Medicine, Burns Surgery, and Ophthalmology Departments. Results of disease-coding errors of cardiovascular medicine, burns surgery, and ophthalmology departments are shown in Figure 6. Figure 6(a) is the results of the coding errors of the cardiovascular medicine department. There are 420 errors in the discharge case statistics before the training and 180 errors after the training. The statistics on the five types of disease-coding errors are conducted, including arrhythmia, myocardial infarction (MI), coronary heart disease (CHD), sudden coronary death (SCD), and myocardial ischemia. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 6(b) is the result of disease-coding errors of the burns surgery department. There are 170 errors in the discharge case statistics before the training and 35 errors after the training. The statistics on the seven types of disease-coding errors are conducted, including that multiple burns are the main diagnosis, the burn degree and area not written, the burn site is not filled in accurately, scald/burn is not written clearly, coding of chilblain and frostbite is confusing, burn complications are coded, and the cause of injury poisoning is not coded. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$). Figure 6(c) is the results of disease-coding errors of the ophthalmology department. There are 160 errors in the discharge case statistics before the training and 30 errors after the training. The statistics on the five types of disease-coding errors are conducted, including that the diagnosis of

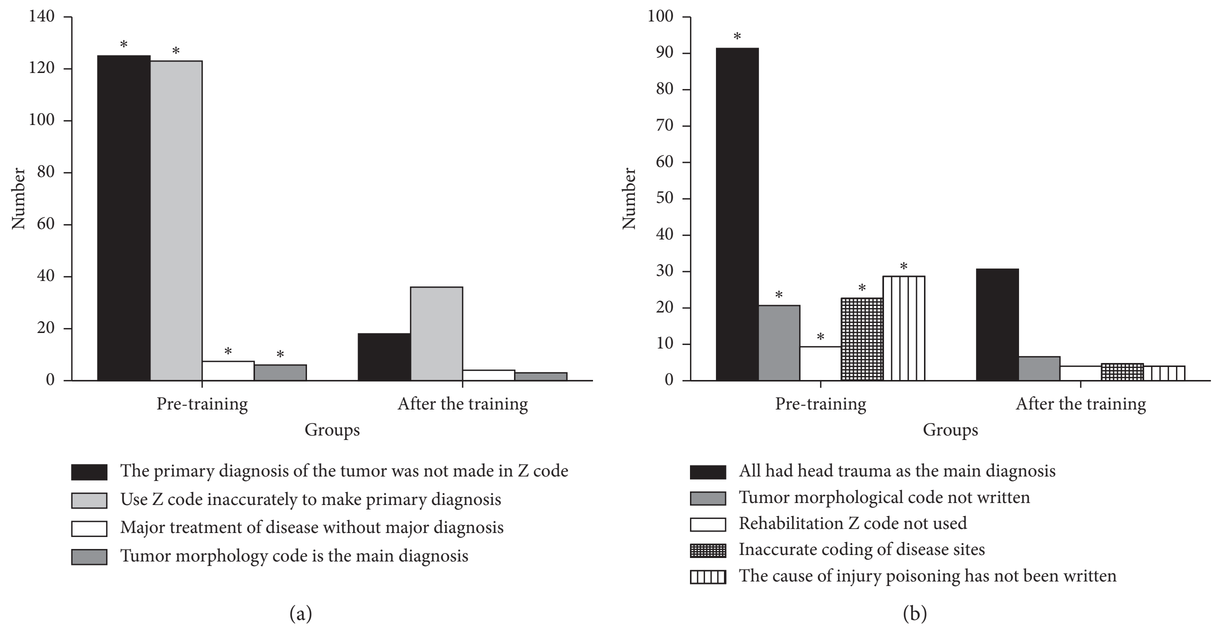

Figure 5: Main diagnosis selection errors of (a) oncology and (b) neurosurgery ($^{*}P < 0.05$).

the disease is filled incompletely, the disease diagnosis name localization is not accurate, coding choices are too general, the diagnosis name is not detailed, and the disease is not coded according to coding principles. It is found that the difference in each index between groups before and after training is significant ($P < 0.05$).

3.7. Automatic Annotation Results of the Medical Record Language. The results of automatic annotation of the medical record language under different artificial intelligence algorithms are statistically analyzed (Figure 7).

Figure 7 indicates that the accuracy rate, symptom precision, and symptom recall of BIRNN are higher than those of CNN and RNN, which indicates that BIRNN has better automatic annotation effect of pathological language.

4. Discussion

In medicine, disease classification reflects the medical level of a hospital to a certain extent. Disease classification refers to the scientific classification of various diseases through coding to provide a basis for clinical diagnosis and treatment. Hospital requirements for accurate classification of diseases have also increased the requirements for disease coders [13, 14]. EMR is defined in *The Basic Framework and Data Standard Electronic Medical Record of Electronic Medical Record* issued by the Ministry of Health as follows: an electronic medical record is a digital medical service record of clinical diagnosis and treatment, guidance, and intervention of outpatients and inpatients (or health care objects) by medical institutions. Studies have shown that coders need to collect, classify, organize, analyze, and use medical record information through the criteria for disease classification. It requires coders to fully understand the clinical knowledge of various diseases [15–17]. This experiment analyzes the reasons for the main diagnosis selection error. The coders are not familiar with the basic rules of the main diagnosis selection, which leads to the misunderstanding of the main diagnosis as an outpatient diagnosis. The classification of disease codes is unclear, and it is believed that the same names have the same codes. The result is the same as that of Nhut Pham et al. [18]. It is difficult to make accurate main diagnosis selection for situations with multiple diseases at the same time. Complications are not the main diagnosis. The morphological coding is mistaken as the main diagnosis. Some studies have found that some coders do not code according to specific medical purposes [19]. The classification of the treatment period and the recovery period is unclear. The disease is not coded according to the main diagnosis principles. It is wrong to regard some damage causes as the main diagnosis. Other investigations have found that when multiple fractures occur, some coders will mistake a certain fracture as the main diagnosis, causing errors [20]. When there is a complication, the previous disease is mistaken as the main diagnosis. The most serious injury is not taken as the main diagnosis. Rehabilitation treatment is not taken as the main diagnosis. The coding of many kinds of diseases is not detailed and accurate.

The experiment analyzes the causes of disease-coding errors. There is no merge coding for diseases that should be merged. Studies have found that coding undiagnosed diseases according to diagnosed diseases is also one of the reasons for coding errors [21]. When accompanied by complications, accurate coding is not performed. Patients of different ages are not coded differently. Drug-induced diseases are not coded correctly. The diseases are not coded according to different conditions. This is consistent with the results of Mahajan et al. [22]. The diseases are not coded according to different sites and different onset times. The

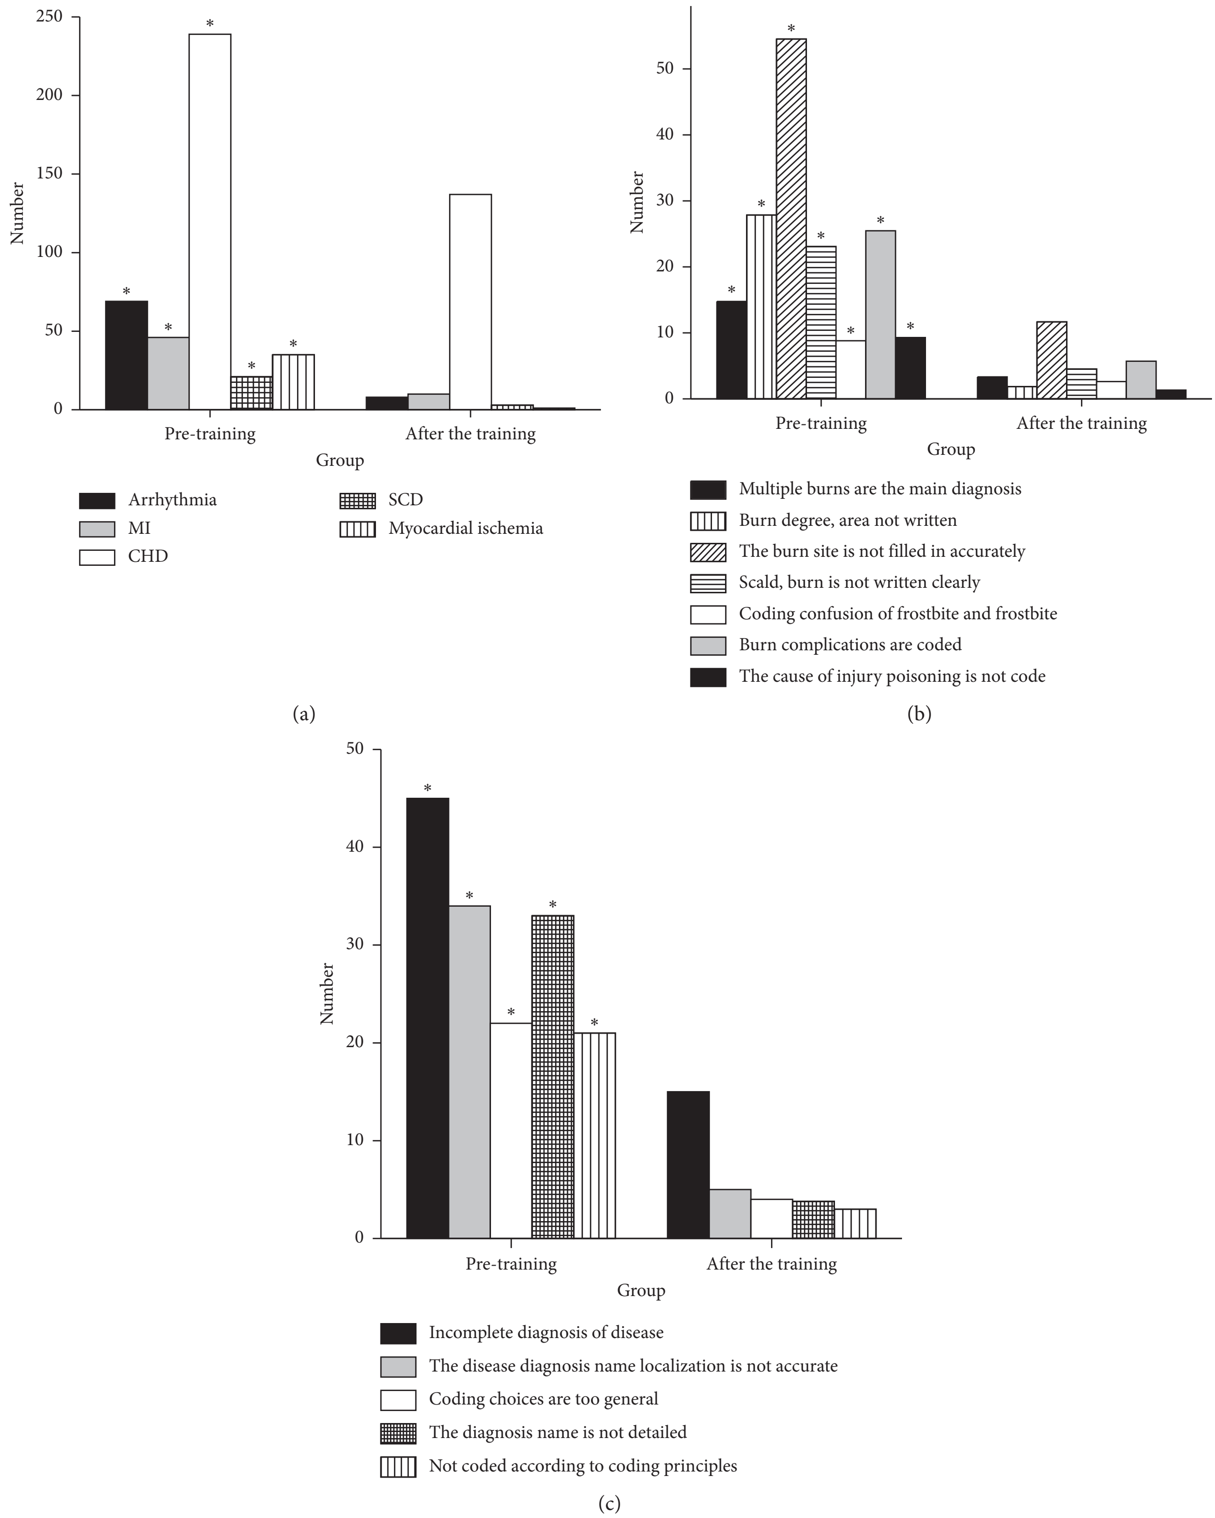

Figure 6: Disease-coding errors of (a) cardiovascular medicine, (b) burns surgery, and (c) ophthalmology departments ($^*P < 0.05$).

diseases are not coded according to the specific classification and according to cause. When coding, it is not carried out in the order of first determining the site and then looking at the severity of the disease. Postoperative complication codes are inaccurate. The coding is not performed according to diagnostic purposes. The filling of the disease diagnosis is incomplete. The name of the disease diagnosis site is inaccurate. Coding selection is too general. The solutions to these problems are as follows. The relevant knowledge training is provided for coders and clinicians. The doctors are regulated to fill in medical record templates. The communication is enhanced between coders and medical

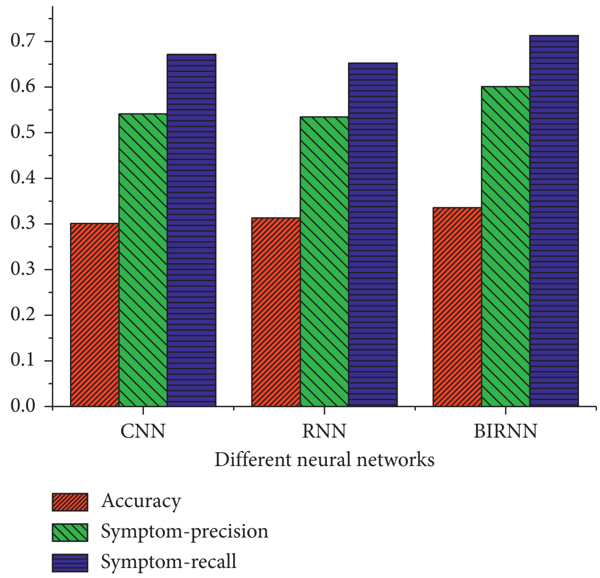

Figure 7: Performance comparison of different artificial intelligence algorithms.

staff. The new coding requirements should be mastered at any time. Tanno et al. [23] reviewed the history of changes in the classification and coding of allergic reactions and found that better ICD codes could reduce the mortality of allergic diseases.

This experiment shows that the main reason for the main diagnosis selection errors and coding errors for coders is that they do not fully understand the various diseases and their classification. Therefore, relevant training in this area should be strengthened.

5. Conclusion

The study analyzes the reasons for the wrong selection of main diagnosis before and after training in obstetrics and gynecology, endocrinology, oncology, orthopedics, and neurosurgery, as well as the wrong disease coding in these departments. It is found that the statistical errors of various diseases before and after training are significantly different between the groups. It shows that the coding personnel do not have a thorough understanding of various diseases and their specific classification, and the medical staff cannot clearly fill in the medical records of diseases. Therefore, the relevant training of coders and medical personnel should be strengthened. However, there are also some shortcomings, such as the small number of samples. Later, the scope of sample collection can be expanded to provide some support for the main diagnosis selection and disease-coding research.

The aim of the study was to investigate the intelligent recognition of radiomics based on the convolutional neural network (CNN) in predicting endometrial cancer (EC). In this study, 158 patients with EC in hospital were selected as the research objects and divided into a training group and a test group. All the patients underwent magnetic resonance imaging (MRI) before surgery. Based on the CNN, the imaging model of EC prediction was constructed according to the characteristics. Besides, the comprehensive prediction model was established through the clinical information and imaging parameters. The results showed that the area under the working characteristic curve (AUC) of the radiomics model and comprehensive prediction model was 0.897 and 0.913 in the training group, respectively. In addition, the AUC of the radiomics model was 0.889 in the test group and that of the comprehensive prediction model was 0.897. The comprehensive prediction model was established through specific imaging parameters and clinical pathological information, and its prediction performance was good, indicating that radiomics parameters could be applied as noninvasive markers to predict EC.

1. Introduction

EC is a group of epithelial malignant tumors that occur in the endometrium, the most frequent is adenocarcinoma originating from the endometrial glands [1]. What is more, EC often emerges in postmenopausal and perimenopausal women. It is one of the most common tumors of the female reproductive system, with nearly 200,000 new cases every year [2]. Among the gynecological malignant tumors that cause death, it ranks third after ovarian cancer and cervical cancer. With the rapid development of social economy, the incidence of EC is gradually increasing in China, and it is the second place among malignant tumors [3]. At present, the cause of EC is still unclear. Some scholars have pointed out that its risk factors are related to fertility, hormones, metabolism, and physiological behavior [4]. Endometrial hyperplasia is the pathological change of the endometrium before canceration and has the potential to deteriorate. The morphology of atypical endometrial hyperplasia is similar to that of EC, and it is difficult to distinguish in clinical diagnosis [5]. Based on the danger of endometrial hyperplasia and the difficulty of clinical diagnosis, it is necessary to find a method that can intelligently identify normal endometrial, endometrial hyperplasia, and endometrial cancerous tissues.

The artificial neural network (ANN) is an artificial intelligence method that attempts to simulate the function of the human brain [6]. The convolutional neural network (CNN) is an artificial intelligence method that attempts to simulate the function of the human brain [6]. Based on the combination of biology and neurology, deep learning technology is a kind of the deep network model with hierarchical structure constructed by simulating the hierarchical working mode of the human brain visual system, which is inspired by the field of the human brain visual nerve [7]. What is more, the CNN is a derived ANN with the characteristics of hierarchical structure, extracting features, perceiving local areas, and classification due to a perfect combination of the ANN and deep learning technology [8]. The task requirement of modern image recognition is that the classification system can adapt to different kinds of recognition requirements, and the CNN has become a hot topic in the field of the ANN because of its high-efficiency recognition advantages. MRI is a medical imaging technique applied in radiology, which employs the combined action of a strong magnetic field, magnetic field gradients, and silent electric waves to form images of human organs to analyze the physiological processes or anatomy of the body image [9]. The radiomics is the most widely applied in the oncology, which includes tumor classification, shunt staging, and prognosis prediction. Ge et al. [10] combined the parameters of CT radiomics with clinicopathological characteristics for investigation, established a preoperative prediction model for EC, and verified the application value of this model in clinical diagnosis.

In this study, radiomics based on CNN modeling was adopted to intelligently identify the normal, hyperplastic, and cancerous tissues of the endometrium, providing a new method for clinical prediction of the emerging and development of EC.

2. Materials and Methods

2.1. Research Objects. In this study, 158 patients with EC, who underwent staged surgery in hospital from October 17, 2018, to May 21, 2020, were selected as the research objects and divided into the training group and the test group (79 cases in each group), with an average age of 56.9 ± 17.5 years. The medical ethics committee of hospital had approved this experiment, and each patient and his or her family members had understood the situation of this experiment and signed the informed consent form.

The criteria for inclusion were defined to include patients who were diagnosed with EC after surgery, had no contraindications to MRI scanning, were younger than 70 years old, and had clear consciousness for normal examination.

The criteria for exclusion were defined to include patients who suffered from mental disorders, had other malignant tumors such as cervical cancer, had incomplete clinical data, withdrew from this experiment due to their own reasons, and had poor MRI image quality for difficult recognition of the lesion.

2.2. Research Methods for Intelligent Recognition of Endometrial Cancer. Each patient underwent sagittal T1- and T2-weighted images of pelvic enhanced MRI before surgery. The CNN model was constructed, the imaging model for EC prediction was screened out based on features, and the comprehensive prediction model for EC was established based on clinical pathological information and imaging parameters. The patient's region of interest (ROI) was drawn, and the AUC, sensitivity, specificity, and accuracy were applied to evaluate the diagnostic effect of the constructed model, and its effect was verified in patients of the test group.

2.3. Dynamic Enhancement Magnetic Resonance Scanning. In this study, the MR Prisma 3.0 magnetic resonance instrument produced by Siemens, Germany, was employed to examine the patients. Before the scanning, the examination procedure should be described in detail to the patients. They should be in the supine position and maintain steady breathing. After MRI scanning, a high-pressure syringe was adopted to inject a 0.2 mmol/L contrast enhancer gadolinium-diethylenetriamine pentaacetic acid (Gd-DTPA) through the back of the hand vein at an injection rate of 2.5 mL/s. Then, the same amount of normal saline was injected. The scanning parameters were as follows. The matrix was 251×251, the layer thickness was 3.5 mm, the field of view was 25×25 cm, the flip angle was 15°, and the layer spacing was 6.1 mm. The obtained dynamic enhanced magnetic resonance images were sent to the workstation, and the images were processed by Functool II software.

2.4. Steps of the Back-Propagation Algorithm. Under the principle of gradient descent, the back-propagation (BP) algorithm searched for the minimum value on the error surface. The iterative process of each BP was divided into two steps. The first step was that an output result was generated during propagation before inputting the data. The second step was that the corresponding weights in the network were adjusted by back propagation to compute errors. The feedforward process and BP process were alternated, and the error was less than the set value or the time of iterations that reaches a set value unless the output result of the network reached a preset condition. For the multicategory classification problem with B categories and M training examples, the error function is

$$F^M = \frac{1}{2}\sum_{m=1}^{M}\sum_{k=1}^{B}\left(p_k^m - q_k^m\right)^2. \tag{1}$$

In equation (1), p_k^m represents the target value corresponding to the k^{th} dimension in the m^{th} sample, and q_k^m stood for the network output value corresponding to k^{th} dimension in the m^{th} input. The error of the whole dataset was the sum of all single data errors. The BP of a single sample could be expressed as the following equation.

$$F^m = \frac{1}{2}\sum_{k=1}^{B}\left(p_k^m - q_k^m\right)^2 = \frac{1}{2}\left\| p^m - q^m \right\|_2^2. \tag{2}$$

In equation (2), p_k^m expresses the target value corresponding to the k^{th} dimension in the m^{th} sample, and q_k^m stood for the network output value corresponding to k^{th} dimension in the m^{th} input. For a normal full connection layer, the partial derivative of F relative to corresponding network weight could be calculated by the following form of the back-propagation rule. The output equation of the input layer is as follows.

$$x^r = g\left(v^r\right), \text{there into } v^r = W^r x^{r-1} + c^r. \tag{3}$$

In equation (3), r represents the current layer, the output layer was defined as the R layer, and the input layer was specified as the 1st layer.

The basic idea of the gradient learning algorithm was to find the error, calculate the partial derivative of parameters in the CNN, and identify the "error" in the BP network as the error signal of each unit pair's deviation. Besides, the equation could be as follows.

$$\frac{\partial F}{\partial c} = \frac{\partial F}{\partial v}\frac{\partial v}{\partial c} = \delta. \tag{4}$$

In equation (4), $(\partial F/\partial c)$ represents the partial derivative of the error with respect to the network parameter, and $(\partial v/\partial c)$ was equal to 1. Therefore, the error signal was equal to the error relative to all the input partial derivatives of a unit. For R layer of the input layer, the partial derivative equation is obtained as follows.

$$\delta^R = g'\left(v^R\right) \circ \left(q^m - p^m\right). \tag{5}$$

In equation (5), R represents the input layer, and "$\circ$" expresses the point-by-point product. The partial derivative δ^R was back-propagated from the upper layer through the network, and its equation could be shown as follows.

$$\delta^r = \left(w^{r+1}\right)^T \delta^{r+1} \circ g'\left(v^r\right). \tag{6}$$

In equation (6), δ^r represents the partial derivative, and "$\circ$" expresses the point-by-point product. Finally, the rule of the weight of a certain neuron for updating was that the neuron was input and multiplied by its triangular array. It was represented by a vector, which was the outer product of the input vector and the error signal vector, as shown in the following equations.

$$\frac{\partial F}{\partial W^r} = x^{r-1}\left(\partial^r\right)^T, \tag{7}$$

$$\Delta W^r = -\xi \frac{\partial F}{\partial W^r}. \tag{8}$$

Corresponding to the deviation c of equation (4), each weight W_{ij} usually had a corresponding ξ_{ij} in practical applications.

2.5. Structure of the Convolutional Neural Network Model. The network structure of LeNet-5 was adopted in this study, and the input data were a matrix formed by 32×32 pixels. The first feature image layer included 6 feature maps, and a 5×5 window was applied to convolve the input image, so as to obtain a 28×28 feature map. Then, it entered the first downsampling layer, and the first feature image layer was for downsampling operations to obtain 6 feature maps with a size of 14×14. The C3 layer was a convolutional layer, and the size of its convolution kernel was 5×5, which was the same as that of the C1 layer. It entered the S4 layer to continue the downsampling operation. The S4 layer was for convolutional operation by the C5 layer, and a fully connected method was adopted to perform convolution operations on the convolution kernel of each C5 layer on the basis of the S4 feature map. The C5 layer included 120 feature maps with a size of 1×1, and finally, the process of feature extraction was ended. Then, the result of 1×10 result was eventually output through a fully connected network on the basis of the C5 layer. In the vector whose output was 1×10, the classification result output by the network was the position corresponding to the largest component (Figure 1).

2.6. Data Preprocessing and the Convolutional Neural Network Model. In order to accelerate the convergence speed of the training algorithm, data preprocessing techniques were often adopted, including noise removal, dimensionality reduction of input data, and deletion of irrelevant data. Balanced data were very crucial in classification, and it was often considered that the data in the training set should be approximately evenly distributed relative to the label category. In order to balance the dataset, some redundant classification data should be appropriately removed, and some classification data with rare examples should be supplemented as much as possible.

CNN applied the structure that was the same as that of LeNet-5, but the following modifications had to be made. First, the tanh function should be employed to the output values of all layers in the network in LeNet-5, including the output layer results in the interval [0, 1], and the activation function applied in the CNN was the sigmoid function. Second, the radial basis function network structure was adopted in LeNet-5, and the CNN output layer was connected with the C5 layer to omit the F6 layer, so as to employ the fully connected method. Third, LeNet-5 applied a special learning rate sequence, and the learning rate during CNN training was fixed at 0.002. Fourth, the input data size of LeNet-5 was 28×28, while the CNN adopted the border filling method to expand the size to 32×32.

2.7. Technical Process of Radiomics. There was the technical process of radiomics, including 4 steps. The first step was to acquire images. Up to now, the images applied in radiomics research included MRI, computed tomography (CT), positron emission tomography (PET), and ultrasound. The second step was the image segmentation. The ROI or focus was sketched to prepare for the next feature extraction. The frequently applied segmentation methods included automatic, manual, and semiautomatic segmentation. The third step was to extract the image features. The extraction of image features was one of the critical steps of radiomics, which was to extract image features from the segmented ROI with high throughput to achieve the transition from image to quantitative data. At present, image extraction features contained morphological features and nonmorphological features. Morphological features described the shape, size, and location of lesions through traditional imaging methods. In addition, nonmorphological features included first-order, second-order, and high-order features. First-order features described the statistical distribution of each voxel, such as statistical features (mean, median, and skewness) generated through histograms; second-order features were texture features that described the relationship between voxels and reflect tumor abnormalities; and high-order features included wavelet features and fractal analysis. The fourth step was to analyze data and build models. The extracted image features were combined with statistics, pathological features, clinical data, and other information to construct an imaging prediction model that was suitable for clinical application. The specific radiomics flowchart is shown in Figure 2.

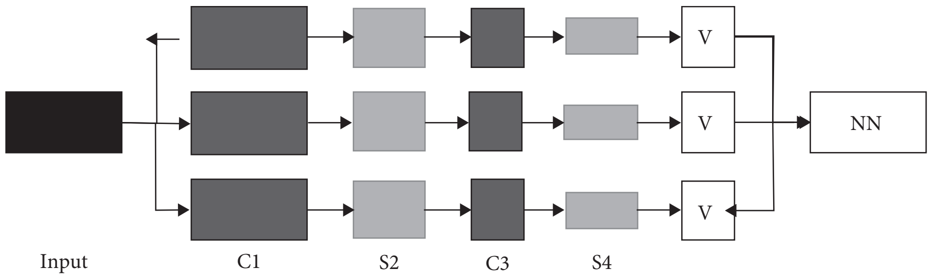

Figure 1: The structure of the CNN model.

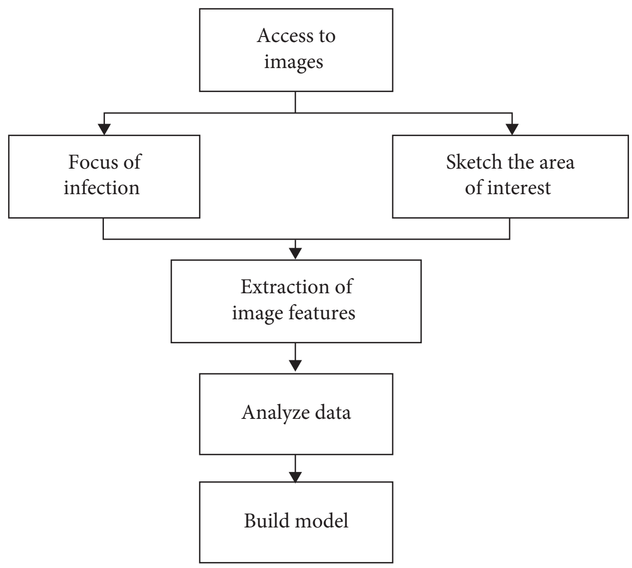

Figure 2: Technical process of radiomics.

2.8. Statistical Methods. The data processing of this study was analyzed by SPSS19.0 version statistical software. The measurement data conforming to the normal distribution were expressed by the mean ± standard deviation ($\overline{x} \pm s$), and the nonconforming measurement data were represented by frequency (%). The accuracy, sensitivity, and specificity were collected in the prediction of the radiomics model and the comprehensive prediction model. $P < 0.05$ revealed that the difference was statistically obvious.

3. Results

3.1. Feature Distribution of all Patients. The patients were grouped into the training group and the test group, so as to investigate the feature distribution of patients in the two groups. There was no statistical difference in the feature distribution among patients in the two groups. Figure 3 shows the comparison results of high-risk and low-risk data of preoperative biopsy pathology among patients in both groups. Moreover, there were comparisons on the normal and rising levels of CA125 in serums among patients in the two groups (Figure 4).

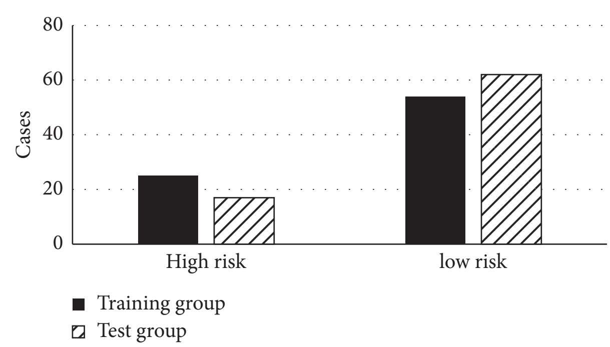

Figure 3: Pathological comparison of preoperative biopsy among patients in the test and training groups.

3.2. Imaging Features of Endometrial Cancer. The MRI imaging manifestations of each stage of EC were best shown on sagittal T2WI, which could clearly reflect the anatomical structure of the uterus. The typical manifestations were as follows. The endometrium was widened, the endometrial cavity was expanded, there were medium or low signal areas mixed with nodules in the high signal endometrial cavity, and larger masses presented different signal intensities due to necrosis, bleeding, and other reasons.

Endometrial hyperplasia was manifested as diffuse lesions in the uterine cavity, the endometrial was uniform and extensively thickened, diffusion weighted imaging (DWI) showed slightly high signal, and the endometrial thickening was limited and asymmetric (Figure 5). Endometrial polyps

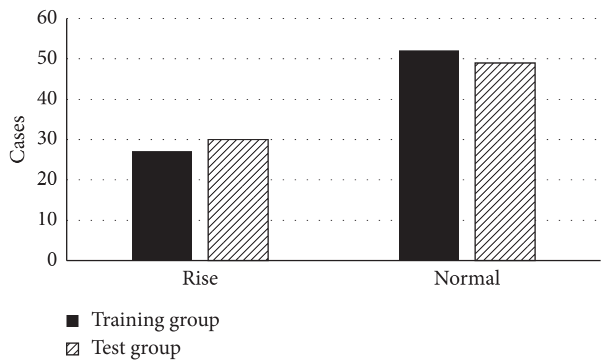

Figure 4: Comparison of CA125 levels in serums from patients.

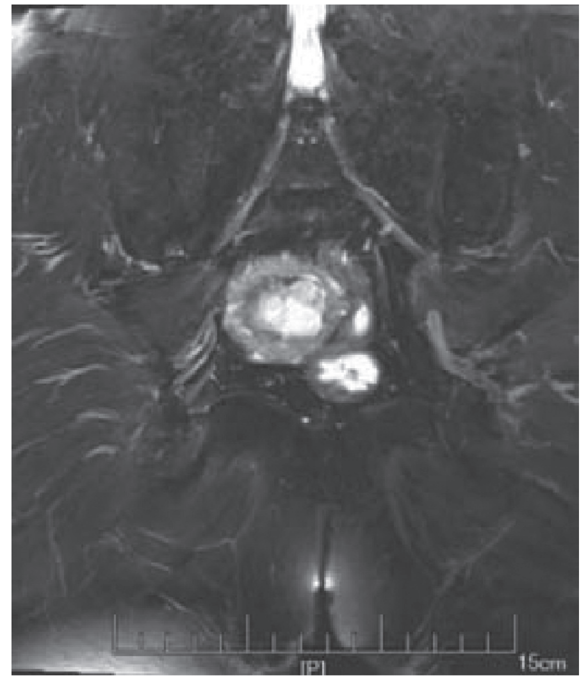

Figure 5: The image of endometrial tissue hyperplasia.

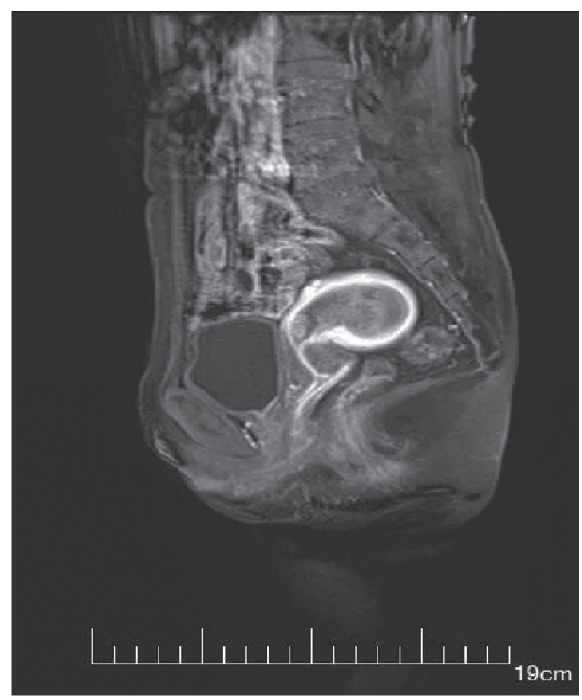

Figure 6: The image of endometrial polyps.

appeared as nodules or masses in the uterine cavity, showing a woven mesh-like uneven high signal on T2WI, and DWI indicated a slightly high signal (Figure 6). The T2WI of submucosal fibroids was like circular low signal, or nodules or tumors were dominated by low signal, and the surrounding boundary was light. If uterine bleeding was caused in the early stage, the surrounding boundary of the tumor would be unclear (Figure 7).

3.3. Experimental Results of the Convolutional Neural Network in Dataset. The network structure of the CNN was similar to that of LeNet-5. The main difference was that the CNN did not adopt some of the previous parameters in LeNet-5 and applied a fully connected network in the final classifier part. The misclassification rate curve of the CNN in the training process is shown in Figure 8. The abscissa stood for the times of iterations, and the ordinate represented the misclassification rate. The test misclassification rate after the CNN convergence was higher than that of LeNet-5, and the CNN test misclassification rate and training misclassification rate were higher than those of LeNet-5 during the entire training process.

3.4. Predictive Efficacy of the Radiomics Model. The prediction efficacy of the radiomics model of patients in the two groups was compared, including the accuracy, sensitivity, and specificity of patients from the two groups in predicting EC before surgery. It was found that the accuracy and specificity of patients in the two groups were not large, and the difference was not statistically obvious ($p > 0.05$). In addition, the sensitivity of patients in the training group was sharply lower than that of the test group, and there was a statistically great difference ($p < 0.05$) (Figure 9).

3.5. Predictive Efficacy of the Comprehensive Predictive Model. There were comparisons on the prediction efficacy of the comprehensive prediction model of patients in both groups, including the accuracy, sensitivity, and specificity of patients in the test group and training group in predicting EC before surgery. As shown in Figure 10, the accuracy and specificity of patients in the two groups were not marked, with no statistically huge difference ($p > 0.05$), while the sensitivity of patients in the training group was dramatically higher than that of the test group, and the difference was statistically substantial ($p < 0.05$).

3.6. Comparison on the Area under the Working Characteristic Curve of the Radiomics Model and Comprehensive Prediction Model. The AUC of the radiomics model was 0.897 in the

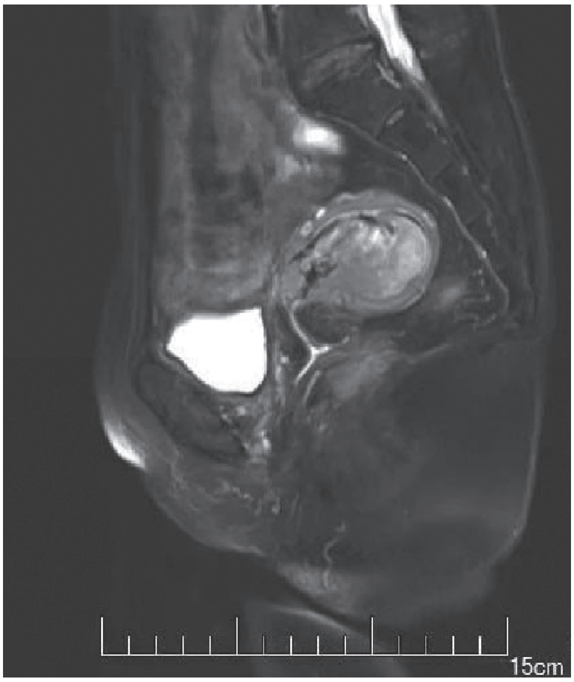

Figure 7: The image of endometrial tissue submucosal fibroids.

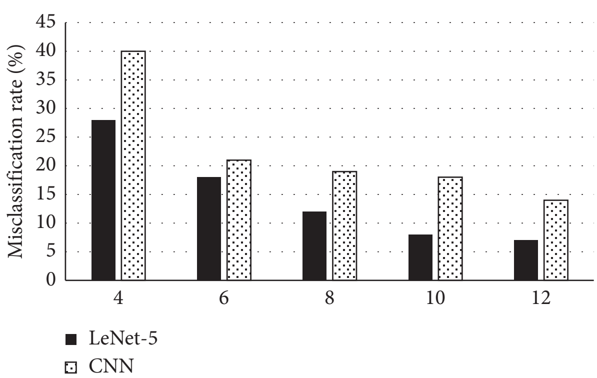

Figure 8: Comparison of the CNN and LeNet-5 misclassification rate trend.

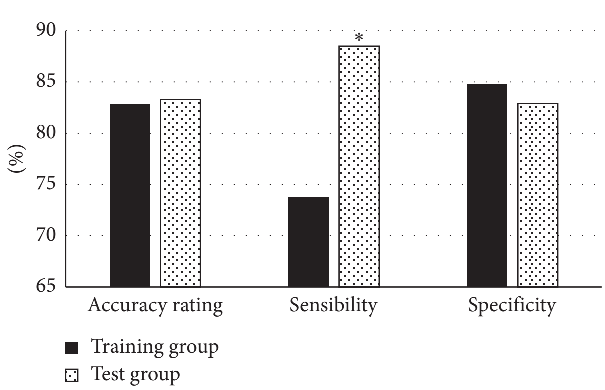

Figure 9: Comparison on prediction efficiency of the radiomics model. (Note: *The difference was statistically substantial in contrast to the sensitivity of the training group ($p < 0.05$).).

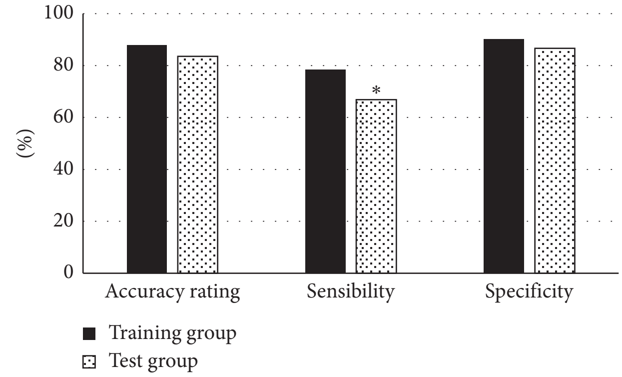

Figure 10: Comparison on prediction efficiency of the comprehensive prediction model. (Note: *A statistically great difference in contrast to the sensitivity of the training group ($p < 0.05$).).

training group and that of the comprehensive prediction model was 0.913 in the training group. It indicated that the two models constructed in this study had good prediction performance, and the effect of the comprehensive prediction model was better than that of the radiomic model. The AUC of the radiomics model and comprehensive prediction model in the test group was 0.889 and 0.897 in turn, which was similar to the above results. Therefore, it revealed that both models had great predictive performance, which again verified that the effect of the comprehensive prediction model was superior to the radiomics model (Figures 11 and 12).

4. Discussion

The etiology of EC has not been clear up to now. Metin et al. [11] employed the radiomics to establish a preoperative predictive model of EC. The radiomics preoperative prediction research also had been reported in the early cervical cancer [12] and bladder cancer [13]; the radiomics models of these research were the images based on different sequences of CT or MRI. Moreover, some other clinical pathological information was integrated. They could achieve the ideal prediction, which was consistent with the results of this study. The comprehensive prediction model was constructed in this study by combining specific imaging parameters with clinical pathological information. The results showed that the prediction performance was great and confirmed in the test group, indicating that the imaging parameters could be used as noninvasive markers for the prediction of EC.

In the research of EC, Takagi et al. [14] evaluated EC through the prediction model based on PET. It was found that PET was not suitable for routine examination of EC. Xuet al. [15] analyzed the single texture features of EC based on the MRI model, without complete radiomics analysis and independent risk factor validation. In this study, EC was for the complete MRI radiomics analysis under the CNN-based BP algorithm. From the results, the established model could achieve good specificity and sensitivity, which was superior to the above two models.

In this study, the diagnostic efficacy of the comprehensive predictive model in the training group and the test

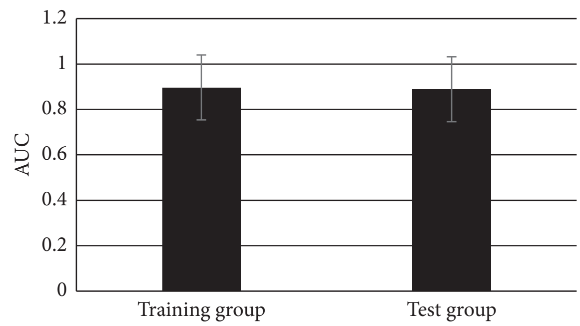

Figure 11: The AUC of the radiomics prediction model in the two groups.

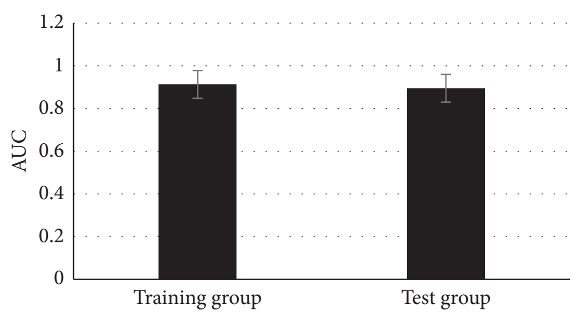

Figure 12: The AUC of the comprehensive prediction model in the two groups.

group was higher than that of the radiomics model, indicating that the diagnosis of disease required the comprehensive evaluation of clinical pathological features, pathological information, and various data of the radiomics. On the basis of the development of the CNN and the famous LeNet-5, a simple neural network model was constructed and applied to the identification of EC. The experimental results revealed that the simplified structure of the CNN could also achieve a better classification identification rate.

5. Conclusion

The enhanced MRI imaging analysis was for preoperative pelvic cavity in patients with EC based on radiomics of the CNN, the CNN model of preoperative EC was constructed, and the imaging specific parameters were combined with the clinical pathological information to establish the comprehensive prediction model. The results indicated that the prediction performance of the above models was good and verified in the test group, suggesting that the model constructed in this study could be applied in clinical practice. The limitations of this study were that all subjects came from the same hospital, MRI images were all from the same instrument, and the number of samples was also limited. Furthermore, the production of cancer markers was not taken into account during the research, so further investigation was needed. To sum up, the CNN model constructed in this study could be adopted to the clinical prediction and diagnosis of EC by radiomics analysis.

This paper mainly introduces the relevant contents of automatic assessment of upper limb mobility after stroke, including the relevant knowledge of clinical assessment of upper limb mobility, Kinect sensor to realize spatial location tracking of upper limb bone points, and GCRNN model construction process. Through the detailed analysis of all FMA evaluation items, a unique experimental data acquisition environment and evaluation tasks were set up, and the results of FMA prediction using bone point data of each evaluation task were obtained. Through different number and combination of tasks, the best coefficient of determination was achieved when task 1, task 2, and task 5 were simultaneously used as input for FMA prediction. At the same time, in order to verify the superior performance of the proposed method, a comparative experiment was set with LSTM, CNN, and other deep learning algorithms widely used. *Conclusion*. GCRNN was able to extract the motion features of the upper limb during the process of movement from the two dimensions of space and time and finally reached the best prediction performance with a coefficient of determination of 0.89.

1. Introduction

Cerebral apoplexy (CA), also known as cerebral stroke or cerebral vascular accident (CVA), is a kind of acute cerebrovascular disease and is due to the sudden rupture of blood vessels in the brain or due to blood circulation obstruction caused by blood vessel damage caused by a group of diseases. Stroke is one of the three major diseases leading to human death. It has the characteristics of high morbidity, high mortality, high disability, and high recurrence rate. China is a region with a high incidence of stroke. According to the data of "2018 China Health Statistics Summary," in 2017, the proportion of cerebrovascular diseases in the deaths of Chinese residents was 23.18% in the rural population and 20.52% in the urban population, which means that at least one person in every five deaths died from stroke. According to the 2018 Report on Stroke Prevention and Treatment in China, the number of stroke patients in residents over 40 years old has reached 12.42 million, and since 2002, the incidence of the first stroke in residents between 40 and 74 years old has increased by 8.3% on average every year, and the number of deaths caused by stroke has reached 1.96 million every year. Stroke has overtaken diseases such as ischemic heart disease, traffic accidents, chronic pulmonary obstruction, and lung cancer to become the leading cause of death. With the development of modern medicine, the level of treatment in the acute stage of the disease has been improved, and the number of death cases caused by stroke has gradually decreased, but the residual dysfunction has also led to a gradual increase in the rate of disability, which greatly affects the healthy life of patients and their families.

Stroke can be divided into hemorrhagic and ischemic diseases pathologically. Different clinical manifestations may occur due to different sites and properties of the lesions. 55%~75% of surviving stroke patients will remain with limb dysfunction, and 85% of patients will have lateral limb motor dysfunction after onset. In patients with hemiplegia, the incidence of motor function injury of the half limb, especially the hand function and upper limb motor dysfunction, is higher than that of the lower limb, and its rehabilitation difficulty is higher than that of the lower limb. These functional disorders seriously affect the ability of patients to live independently and reduce the quality of life of patients. Clinical observation shows that rehabilitation treatment is the most effective way to reduce the disability rate of stroke patients. Effective rehabilitation training plays an important role in improving the motor ability, sensory ability, and behavioral ability of stroke patients. Rehabilitation training can improve the daily living ability of patients, improve the ability to recover from brain lesions, reduce the degree of disability, restore the ability of independent living, better return to family and society, reduce potential nursing costs, and save social resources.

Stroke rehabilitation is a circular process, mainly including the following links: (1) rehabilitation assessment, identification, and determination of patients' needs; (2) rehabilitation goal setting, to develop practical and achievable rehabilitation goals and health training plans for patients; (3) rehabilitation treatment to achieve rehabilitation goals; and (4) evaluation of rehabilitation again to evaluate the therapeutic effect of the rehabilitation process.

In this paper, sensor technology and artificial intelligence were integrated to carry out the research on automatic assessment of stroke upper limb motor function based on deep learning. A motion measurement system was designed from the upper limb motor ability, and three different deep learning methods were proposed to extract features based on sensor data to achieve clinical scale stages and score prediction.

Upper limb hemiplegia is one of the most serious disabling consequences of stroke [1]. There are many studies on the influence of upper limb motor function of patients. Mullick et al. discussed the influence of motion observation training based on the mirror neuron system on upper limb motor function of stroke patients [2]. Gunduz et al. aimed to investigate the influence of hand robot assisted training based on motion imagery on upper limb function of stroke patients [3]. Brewer et al. investigated the effect of high frequency repetitive transcranial magnetic stimulation (HF-rTMS) on upper limb motor function in the early stage of stroke [4]. Strippoli et al. discussed the effect of restrictive exercise therapy (CIMT) on the rehabilitation of upper limb motor function in stroke patients [5]. Simpkins et al. investigated the effect of upper limb isokinetic muscle strength training on motor function of stroke patients [6]. Liou et al. discussed the influence of mirror therapy on upper limb function and daily living ability of stroke patients with hemiplegia [7].

In order to objectively quantify the upper limb motor injuries of stroke patients with hemiplegia, Fu et al. proposed an assessment method based on motion coordination quantization and multimodal fusion. Principal component analysis (PCA) and K-weighted angular similarity (K-WAS) algorithm were used to quantify the synergistic effect and muscle synergistic effect so as to further analyze the synergistic activation characteristics leading to visible sports injuries [8].

Quantitative assessment of motor function is important for post-stroke patients because it can be used to personalize treatment strategies. Pan et al. studied the assessment method of upper limb motor function in stroke patients. During voluntary upward extension, inertial sensor data and surface electromyography (sEMG) signals were collected from the upper limb. Five features include the maximum shoulder joint angle, peak and average velocity, trunk balance calculated from inertial sensor data, and muscle cooperative similarity extracted from surface EMG data by the nonnegative matrix factorization algorithm [9]. Sang-Mi et al. used BCT to quantitatively detect the motor imaging ability of stroke patients and clarified the relationship between the motor imaging ability of the upper limb of hemiplegia, motor function, and the use level of paralyzed limbs [10].

Fusion in sensor technology and artificial intelligence in this paper, based on in-depth study of the upper limb movement function stroke automatic evaluation of research, probes into the upper limb after stroke activity ability to automatically assess the related content, including the clinical ability of upper limb activity in clinical evaluation of relevant knowledge, called sensors for upper limb bones point spatial location tracking, and GCRNN model building process.

2. Materials and Methods

In order to evaluate the performance of the proposed deep learning method for predicting the FMA score of upper limb motor function, Kinect V2 was selected in this paper to measure the upper limb motor function of stroke patients. Group-constrained convolutional recurrent neural network (GCRNN) is used to achieve this task. We first designed a unique experimental environment and called volunteers to complete the required data collection of upper limb skeletal map. By analyzing the correlation between the predicted value of the model and the actual evaluation score of clinicians, we verified the performance of the model in each evaluation task and the overall performance.

In order to avoid the interference of background and other external factors, improve the quality of data, and ensure the consistency, we first set up a unique experimental environment for the collection experiment of bone point position sequence required by model training. The Kinect V2 is mounted 1.5 meters away from a chair with a small armrest. The subject will sit in this chair and complete the rating task. The Kinect V2 connects to a PC via a USB cable to transfer data and instructions. When subjects performed the upper limb assessment task, Kinect collected the three-dimensional spatial location information of the upper limb bone points in the process at a frequency of 30 Hz and transmitted and stored it to the PC in real time. Before the FMA test, we adjusted the Kinect V2's installation angle so that it could track the entire upper limb of the subject.

A total of 15 healthy volunteers were recruited in this experiment, including 9 males and 6 females, with an average age of 22.6 ($\pm$1.4) years old. Each volunteer was a stroke patient whose FMA score of upper limb motor function was randomly simulated between 30 and 100 points and who could keep sitting position. The basic information of the subjects is shown in Table 1.

Table 1: Subject information table.

Attribute	Value
Male	9
Female	6
Age range	21–24
FMA score range	30–100

Subjects sit on chairs in the experimental environment by themselves and coordinate with the experimenter to adjust the posture angle for better data collection. Then, subjects need to repeat the following upper limb assessment movements successively under the guidance:

2.1. Shoulder Buckling. Subject will sit in a chair and raise the upper limb of the hemiplegia side as far forward as possible, hold for 5 seconds, and finally return to the starting position.

2.2. Shoulder Abduction. Subjects sit in a chair and extend their upper limb on the hemiplegic side as far as possible, then hold it for 5 seconds, and finally return to the starting position.

2.3. The Forearm before and after the Rotation. Subject is sitting in a chair with shoulder 0° and elbow 90° flexed and forearm pronated forward and backward.

2.4. Finger Pinch. When the shoulder of the affected side is 0° and the elbow is 90° flexed, try to touch the little finger with the thumb and then move back to the initial position.

2.5. Move the Cylinder Object. Use the affected hand to pick up a cylinder on one side of the table and then move it to the other side of the table and lower it.

Each rating action was provided with an instructive video, and the subjects were asked to try their best to complete the rating action (simulation) while watching the video. At the same time, two raters were responsible for rating according to the FMA requirements and experience according to the completion of the action. Then, the average of the FMA scores obtained by the two raters was calculated. The actual FMA score of the subject was used for model training. Before the experiment, each subject will watch the instruction video of learning movements and practice the familiar movements for 3–5 times before starting the experiment. During the experiment, the subjects need to complete all the 5 movements continuously with a short rest interval of 2-3 seconds to facilitate the later data separation. The subjects can repeat 3–5 times according to their own physical conditions. Cameras were also used to record the whole experiment process, measure the time required for each experiment process, and analyze the movements of the subjects.

3. Results and Discussion

We verify the performance of the method proposed in this paper, namely, the comparison algorithm, by using five-fold cross validation of the data set. Each method iterates 100 times in the near row of the training set, and the iteration parameter with the best performance on the validation set is taken as the final result. The model outputs were predictive FMA scores of upper limb motor function. Performance was evaluated by correlation analysis with clinician scores, and coefficient of determination (R^2), root mean square error (RMSE), and adjustment-R^2 were used as model performance indicators.

First, we analyzed the correlation analysis results of the proposed algorithm for the 5 scoring tasks separately, as well as the correlation analysis results of FMA prediction using the data of the 5 tasks, as shown in Figure 1, and it can be found that task 1, task 2, and task 5 have a high correlation with FMA, and the determination coefficients of 0.88, 0.85, and 0.87 can be reached when using these rating tasks alone. Because task 3 and task 4 only have local hand movements, the correlation with the overall FMA rating item is weaker. Therefore, the consistency with the clinician's FMA assessment was only 0.78 and 0.72. When we input all the bone point data of the five assessment tasks into the model for FMA prediction, as shown in Figure 1(f), although the determination coefficient obtained is improved compared with that when using single task data as input, the improvement effect is not obvious. The coefficient of determination is 0.86, which is lower than that of Task 1 (Figure 1(b)) and Task 5 (Figure 1(e)).

In order to achieve automatic upper body activity assessment using as few assessment tasks as possible, we conducted prediction performance under different number and combination of tasks in order to find the most appropriate number and combination of assessment tasks. According to the experimental results shown in Figure 1, we conducted a comparative verification experiment in accordance with some combinations that might be better. The results are shown in Table 2.

As can be seen from the table, when the task combination is Task 1-2-3-5, the maximum coefficient of determination can be reached to 0.89; when the number of tasks is 2, the overall coefficient of determination is relatively low because there are too few FMA assessment items covered and the upper limb movement features can be provided. When the number of assessed tasks was 3, compared with the number of assessed tasks was 2, there was a significant improvement, but different combination of tasks also had an impact on the experimental results. Because task 4 and task 5 were both hand functional assessments, the combination of task 4 and task 5 provided overlapping motor function characteristics. In addition, it can be seen from Table 2 that the task combination of Task 1, 2, and 5 can provide more motor characteristics from multiple dimensions such as shoulder abduction, forward bending, and grasping ability, covering more FMA assessment items.

In order to verify the performance of the proposed deep learning framework, we used the optimal combined task data of Task 1, 2, 3, and 5 mentioned above to conduct comparative

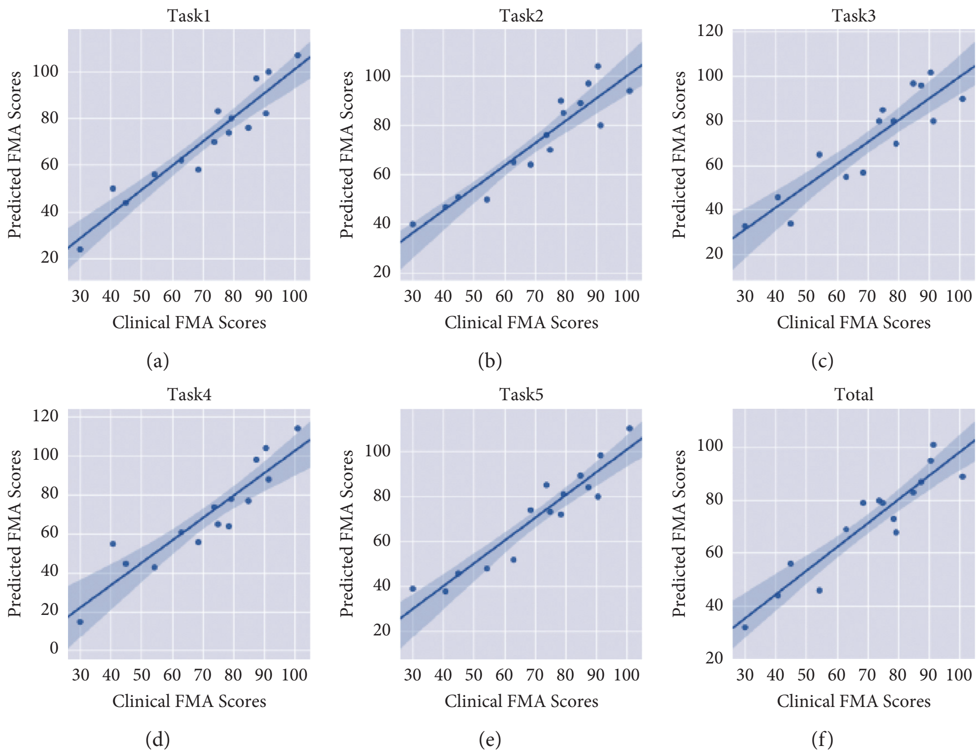

Figure 1: Individual assessment task data predicts FMA results.

Table 2: Comparison of evaluation task combinations.

Number of tasks	Task combination	RMSE	R^2	Adjust-R^2
2	Task 1-2	7.29	0.86	1.19
	Task 2-5	7.30	0.86	1.21
3	Task 1-2-5	7.25	0.88	1.23
	Task 2-4-5	7.90	0.84	1.25
	Task 2-3-5	7.26	0.87	1.19
4	Task 2-3-4-5	7.81	0.85	1.24
	Task 1-2-3-5	6.57	0.89	1.17
	Task 1-2-4-5	7.40	0.86	1.22
5	Task 1-2-3-4-5	7.37	0.86	1.21

experiments with the GCRNN algorithm in this paper, LSTM and CNN algorithm. Regression analysis was performed on clinician evaluation scores and model-predicted FMA scores of 15 subjects, and determination coefficients were calculated, and correlation analysis graphs were drawn, as shown in Figures 2–4. The GRCNN model fully extracts the spatial location sequence data features of bone points from the two dimensions of data sequences between data sequences and the context of a single data sequence through convolution and cyclic neural network modules and finally predicts the optimal performance when the coefficient of determination of FMA fraction reaches 0.89 (Figure 2). In the manifestation of upper limb motor dysfunction, the relationship between bone nodes in the human body can reflect the cooperative movement mode often manifested in clinical practice and so on. Compared with LSTM, CNN pays more attention to the feature extraction of the relationship between data, and in the upper limb motor ability assessment task in this paper, it also obtains a coefficient of determination of 0.87 (Figure 3). The LSTM model pays more attention to the before and after dependence of the sequence. Stroke-related patients have a small range of upper limb motion, weak features of the before and after changes in the sequence data, and relatively weak performance in automatic assessment tasks. The coefficient of determination in the data set in this paper is 0.85 (Figure 4).

IMU, glove sensor, and motion capture system often used in existing studies need quite a long time to complete the wearing and marking, and it is already difficult to fix the sensor or marker on the body of stroke patients, and it is easy to cause discomfort to patients and affect normal activities. The automatic evaluation system proposed in this paper uses the Kinect V2 depth sensor based on vision to collect motion data. It does not require the time-consuming process of sensor wearing. It only takes about 5 minutes to set up the initial (perspective setting) and has a generally acceptable low cost. The rich

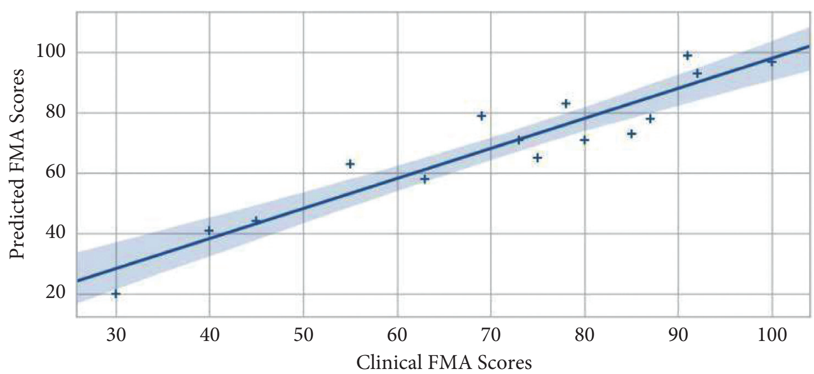

Figure 3: FMA prediction performance by CNN.

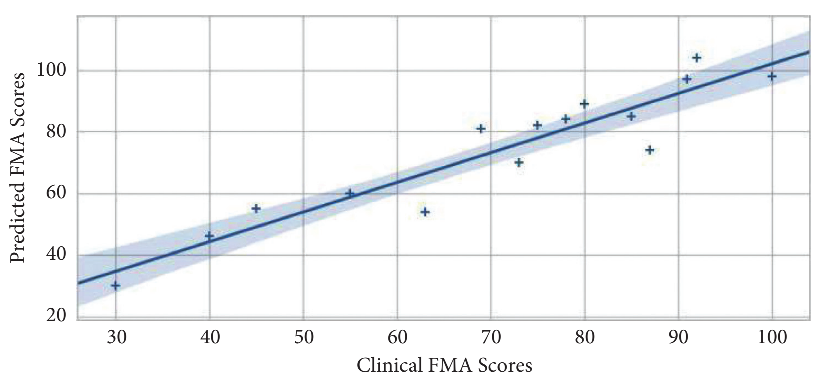

Figure 4: LSTM performed FMA to predict performance.

SDK provided by Kinect can obtain various motion tracking data, such as RGB image, depth image, and spatial position of bone points. In this paper, the spatial position data of human upper limb bone points were only used to complete the task of upper limb mobility assessment. In the future work, we can also consider the use of depth image, RGB, and combined data for automatic evaluation research. In addition, we also found that there are some insurmountable errors in acquiring it through noncontact motor consciousness in our experiment. When subjects wear loose clothes, there is a deviation in the recognition and tracking of shoulders and elbows. When human beings are active, it will bring great interference to the data. Such data patterns can be confused with data disturbances caused by limb spasms. Second, the Kinect V2 only has two bone points on the hand, the thumb, and the fingertip, which poses a huge challenge to complete the measurement of hand extension/flexion motion in FMA. In addition, when a single Kinect performs task 5: upper limb activity tracking of moving pencil and limb occlusion is easy to occur, which will cause the data loss of occluded bone points, thus affecting the accuracy. Of course, this problem of being easily obscured can be solved in the future by setting up multiple Kinect devices to track human activities from different angles.

4. Conclusions

The focus of this paper is to propose a deep learning framework for data analysis, to achieve the use of as few assessment tasks as possible to complete the complex clinical FMA assessment tasks, and to achieve a high degree of consistency with the clinician assessment. Through a detailed analysis of all FMA evaluation items, we set up a unique experimental data collection environment and evaluation tasks. The results of FMA prediction using bone point data of each evaluation task are shown in Figure 1. Through different number and combination of tasks, it can be seen in Table 2. The best coefficient of determination was achieved when task 1, task 2, and task 5 were simultaneously used as inputs for the FMA prediction. At the same time, in order to verify the superior performance of the proposed method, a comparative experiment was set with LSTM, CNN, and other deep learning algorithms widely used. GCRNN was able to extract the motion features of the upper limb during the process of movement from the two dimensions of space and time and finally reached the best prediction performance with a coefficient of determination of 0.89.

Supraspinatus tendon injury is a common clinical shoulder joint disease and is one of the most common causes of shoulder pain and dysfunction. Supraspinatus tendon injury will lead to articular cartilage injury and degeneration, then cause joint disease, seriously affect the quality of life of patients, and bring a huge burden to the family and society. This paper mainly studies and evaluates the application value of special signs of shoulder joint and indirect MR imaging in the diagnosis of supraspinatus tendon injury. Through a series of special examinations for the diagnosis of supraspinatus tendon injury in 90 patients, including zero degree abduction resistance test, arm drop test, Jobe test, Neer sign, and Hawkins sign, all patients in the study underwent indirect magnetic resonance imaging of the shoulder joint. Finally, arthroscopic examination results were used as the "gold standard" to evaluate and analyze the diagnosis. The results showed that among the special signs, the specificity of the falling-arm test was the highest (72.2%) in the diagnosis of full-thickness supraspinatus tendon injury. Hawkins sign had the highest sensitivity (84.0%). In the diagnosis of partial supraspinatus tendon injury, the specificity of the Jobe test was the highest, which was 66.6%. The Neer sign had the highest sensitivity of 50.0%. In the diagnosis of full-thickness supraspinatus tendon injury, there was no significant difference in sensitivity between indirect MRI and Hawkins sign, but the diagnostic specificity of indirect MRI was higher than that of special sign examination. In the diagnosis of partial supraspinatus tendon injury, the sensitivity and specificity of indirect MR imaging are higher than those of special sign examination.

1. Introduction

Rotator cuff injury has attracted much attention since Smith first put forward the concept of rotator cuff injury in 1834. These concerns are not only due to the research interest of scholars, but also due to the needs of a large number of patients. The study found that the incidence of partial or full-thickness rotator cuff injury increased significantly after age 50, exceeding 50 percent in people over 70 and more than 80 percent in people over 80. What deserves more attention is the progression of the disease after the injury of the rotator cuff. Yamanaka et al. observed 40 patients with partial rotator cuff injury without surgical treatment. After more than one year of follow-up, changes of rotator cuff injury is examined with shoulder arthrography. The results showed that only 4 patients had obvious healing of injured rotator cuff. The extent of injury was reduced in four patients. At the same time, 21 patients had an expanded rotator cuff lesion, and 11 patients shifted from a partial rotator cuff lesion to a full-thickness lesion.

Among the tendons that make up the rotator cuff, the supraspinatus tendon is located at the top of the rotator cuff. Compared with other tendons, the supraspinatus tendon is most vulnerable to the extrusion of the acromial peak and the coracoacromial arch and is the tendon with the highest incidence of degeneration and injury. Because of the high incidence of rotator cuff injury and the exacerbation of the course of disease, it is of great significance to improve the understanding of rotator cuff injury, especially supraspinatus tendon injury. The previous concept of "periarthritis of the shoulder" is obviously too broad and general, and the early diagnosis of supraspinatus tendon injury is essential to prevent further progression of the disease. However, the clinical symptoms of supraspinatus tendon injury are diverse, and there is a lack of special clinical symptoms for diagnosis. Routine physical examination often fails to provide sufficient diagnostic reference information. Therefore, various specific examinations for special signs have emerged as the times require. At the same time, a variety of imaging examinations also provide useful diagnostic information from different perspectives, and how to choose efficient and reliable diagnostic techniques to help the clinical screening and diagnosis of supraspinatus tendon injury has become one of the hot spots of attention and research.

Physical examination was performed to assess supraspinatus tendon injury by an impingement test that elicits pain and by examining the strength of the supraspinatus muscle, and the diagnosis of supraspinatus tendon injury by indirect magnetic resonance arthrography was performed.

Imaging examination is an essential and important means for the diagnosis of supraspinatus tendon injury, and it is also helpful to determine the degree and type of supraspinatus tendon injury and whether there are other accompanying shoulder diseases. There is no doubt that imaging examination plays an important role in the diagnosis, treatment, and prognosis evaluation of supraspinatus tendon injury. Imaging examinations for supraspinatus tendon injuries mainly include the following types: X-ray examination (X-ray examination cannot directly observe the rotator cuff and other soft tissues, mainly through some indirect signs to determine whether there is rotator cuff injury), CT examination (CT examination can clearly show the shoulder joint fault structure and three-dimensional reconstruction), ultrasound, which uses a range of physical properties of ultrasound to identify and image soft tissue, and MRI, which is a great advance in the imaging diagnosis of rotator cuff. The basic element of the imaging principle of MRI is the hydrogen nuclei contained in the tissues of the body. Currently, the diagnosis of the supraspinatus tendon injury mainly includes plain MRI, direct MRI arthrography, and indirect MRI arthrography.

The research of MR arthrography in the examination of shoulder joint injury is developing continuously. MR arthrography (MRA) is often used to evaluate intra-articular disorders of the shoulder. Liao et al. discussed the diagnostic value of MR arthrography for rotator cuff injury [1]. Zhang et al. discussed the diagnostic value of conventional MRI and MR arthrography in flapping injury of shoulder joint [2]. Xiao et al. discussed the diagnostic value of magnetic resonance arthrography of the shoulder for partial rotator cuff tear [3]. Nassef et al. proved that MR arthrography is the preferred imaging examination method for patients with shoulder instability [4]. Alaia et al. discussed the standard MR imaging and arthrography protocols routinely used in clinical practice, as well as more innovative sequence and reconstruction techniques facilitated by the increase of high field intensity magnets and multichannel phased array surface coils and the combination of artificial intelligence [5].

Studies are also under way to combine MRI arthrography with other procedures. Pan et al. summarized the diagnosis and measurement methods of bone defect in anterior shoulder instability (scapular glenoid defect and Hill–Sachs lesion): X-ray, CT, MRI, arthroscopy, and arthrography are common methods for the diagnosis of humeral head anterior glenoid defect and Hill–Sachs lesion [6]. Foti et al. compared the diagnostic accuracy of dual-energy CT arthrography (DE-CTA) and magnetic resonance arthrography (MRA) in describing labial lacerations [7]. Fu et al.'s objective was to explore the application of CT combined with MRI in the diagnosis of shoulder injury and to provide reference for clinical application [8]. Bucha et al. studied the value of shoulder magnetic resonance in the diagnosis of shoulder instability and compared it with arthroscopy [9].

This paper mainly studies and evaluates the application value of special signs of shoulder joint and indirect MR imaging in the diagnosis of supraspinatus tendon injury.

2. Research Methods

2.1. Research Object. A total of 90 cases were enrolled, including 46 males and 44 females, aged 42 to 75, with an average age of 58.6 years (48 cases of right shoulder and 42 cases of left shoulder and duration ranging from 4 to 24 months, with an average of 8.5 months). Eighteen patients had a history of shoulder trauma, and 12 patients complained of shoulder strain. The other cases had no obvious cause of disease. There were 10 cases of coronary heart disease, 12 cases of diabetes, and 19 cases of hypertension in this group. There were 52 cases of dominant limb and 38 cases of nondominant limb. Visual analog scale of pain (VAS score), shoulder function score (UCLA score, Constant score, and ASE score), and range of motion of shoulder were measured preoperatively in all patients.

2.2. Examination of Special Physical Signs. The examination of special physical signs was performed and recorded by an attending physician with more than 5 years of experience in sports medicine and a doctoral candidate in sports medicine. All the patients were examined on both sides of the shoulder. The order of examination was first the physical examination of the walking side of the shoulder and then the physical examination of the affected side of the shoulder. The contents of special physical examination are mainly for the muscle strength examination of the supraspinatus muscle and the impact test to induce shoulder pain. In order to avoid the interference of pain on the muscle strength examination results as far as possible, the impact test is arranged after the muscle strength examination.

2.3. Indirect Magnetic Resonance Angiography. Instruments and materials used: the MRI scanner used for scanning was the Philips Ingenia 3.0 T MRI scanner (Netherlands). The contrast agent used for indirect imaging was gadolinium spray acid meglumine gadolinate (trade name: Magenweisen (Germany); chemical name: dihydro-[N, N-bis [2-{bis (carboxymethyl) amino} ethyl] glycoyl (5-)] gadolinic acid (2-) combined with 1-deoxy-1-(methylamino)-D-glucosol (1 : 2); molecular weight: 938.00). Accessories: meglumine and water for injection.

2.4. Shoulder Arthroscopy. Arthroscopic personnel and equipment: all arthroscopes are performed by a team of a chief physician in sports medicine and an attending physician. Arthroscopic instruments and lenses: Smith & Nephew arthroscopic system equipment was used.

2.5. Statistical Methods. The diagnosis results under shoulder arthroscopy are regarded as the "gold standard" of the final diagnostic standard of all cases. Special signs of shoulder and indirect magnetic resonance angiography were used as screening diagnostic methods to be evaluated, and the results of shoulder arthroscopy were compared with the "gold standard" diagnostic results and statistically analyzed. SPSS19.0 statistical software package was used for data analysis, and X2 test was used for data statistical analysis. If $P < 0.05$, the difference was considered to be statistically significant.

3. Results

3.1. Examination of Special Physical Signs. Procedures for checking special physical signs are as follows:

> Abduction resistance test at zero position: the patient's two upper limbs are placed at the side of the body, and the examinator stands behind the patient's body against the patient's upper limb abduction movement. If the patient feels obvious pain or cannot resist resistance and cannot abduct the upper limbs, the test is positive.
>
> The dropping arm test: the examiner abducted the patient's shoulder joint to more than 90 degrees and let the patient keep it by himself. The test is positive if the patient is unable to maintain the abduction position until the upper limb falls.
>
> Jobe test (empty can test): The patient's shoulder joint abducted 80 to 90 degrees in coronal position and retracted 30 degrees in horizontal position. With the forearm pronated and the thumb pointed to the ground, the examiner applied downward pressure on the patient's wrist. Patients who are unable to resist resistance and experience significant pain and weakness are considered to be positive for the Jobe test.
>
> Neer sign: the examiner stands behind the patient, stabilizes the scapula on the examining side with one hand, and maintains the shoulder joint in internal rotation with the other hand, so that the fingertip of the thumb of the upper limb is downward, and then the shoulder joint on the examining side is flexed forward and lifted over the top. If pain is induced, Neer sign is positive.
>
> Hawkins sign: the examiner flexes the patient's elbow 90 degrees, with the shoulder adducted forward 90 degrees and the forearm in horizontal position. The examiner forces the affected forearm downward to produce internal rotation of the shoulder. If significant pain is induced, Hawkins sign is positive.

The examination results of special physical signs are as follows.

As can be seen from Table 1, in patients with full-thickness supraspinatus tendon injury, the sensitivity and specificity of the zero degree abduction resistance test were 48.0% and 65.0%, respectively. The sensitivity and specificity of falling arm test were 51.9% and 72.2%, respectively. The sensitivity and specificity of the Jobe test were 45.8% and 66.7%. The sensitivity and specificity of Neer sign were 54.2% and 61.9%. The sensitivity and specificity of Hawkins sign were 84.0% and 60.0%, respectively. The sensitivity and specificity of the zero degree abduction resistance test were 46.2% and 57.9% in patients with partial supraspinatus tendon injury. The sensitivity and specificity of falling arm test were 39.2% and 64.7%. The sensitivity and specificity of Jobe test were 40.7% and 66.6%. The sensitivity and specificity of Neer sign were 50.0% and 52.6%, respectively. The sensitivity and specificity of Hawkins sign were 45.8% and 57.1%, respectively.

Among the examinations of special signs, the falling arm test has the highest specificity and the highest sensitivity in the diagnosis of the full-thickness supraspinatus tendon injury. In the diagnosis of partial supraspinatus tendon injury, the Jobe test has the highest specificity and the highest sensitivity of Neer sign. The diagnostic accuracy of the full layer injury of supraspinatus tendon was higher than that of partial injury by special sign examination.

3.2. Indirect MRI Examination. Prior to MRI, the patient received a rapid injection of gadolinium spray diglumethamine at a dose of 0.1 mmol/kg from a peripheral vein in front of the elbow. Immediately after the injection of contrast agent, the patient was instructed to examine the lateral shoulder joint for about 15 minutes and then underwent magnetic resonance scanning. Figures 1–4 show typical cases of joint injury. During the scanning, the patient was placed in supine position, and the range value of the scanning field of view (FOV) was $160 * 160 * 71$ mm. The scanning thickness was 3 mm, and the scanning gap was 1 mm. The precise frequency reversal recovery (SPAIR) PDW fat suppression sequence (TR 2800 ms, TE 30 ms) and matrix (Matrix) $320 * 228 * 18$ mm were used to scan the oblique coronal plane. SPAIR T1W fat suppression sequence (TR635 ms, TE 15 ms), matrix $292 * 242 * 18$ mm was used to scan the oblique coronal plane as well. Fast spin echo (FSE) T1WI (TR561 ms, TE15 ms) with a matrix of $320 * 263 * 18$ mm was used for oblique sagittal scanning. For cross-sectional scanning, the SPAIR fat-inhibited PDW sequence (TR 2800 ms, TE30 ms) with a matrix of $268 * 181 * 18$ mm was used. The MRI scan was perpendicular to the humeral shaft, extending from above the acromioclavicular joint to below the pelvis of the scapula

joint. The oblique coronal scanning direction was parallel to the long axis of the supraspinatus muscle, extending from the front of the tip of the coracoid process to the rear of the scapulae. The oblique sagittal scanning direction was perpendicular to the long axis of the supraspinatus muscle and ranged from the lateral humeral head to the medial supraspinatus fossa of the shoulder joint. Figures 5–8 show a typical MRI of partial injury to the upper tendon. Table 2 shows the results of indirect magnetic resonance angiography.

As can be seen from Table 2, the sensitivity and specificity of indirect MR imaging in the diagnosis of full-thickness injury of supraspinatus tendon were 96.7% and 93.3%, and the sensitivity and specificity of partial injury of supraspinatus tendon were 90.6% and 92.3%.

The accuracy of indirect MR imaging in the diagnosis of the full thickness injury of supraspinatus tendon was higher than that of the partial injury of supraspinatus tendon.

3.3. Comparison of the Results of Special Sign Examination and Indirect Magnetic Resonance Angiography. For the full-thickness injury and partial injury of supraspinatus tendon, the sensitivity and specificity of the examination with the highest sensitivity and specificity were compared with those of the indirect MRI examination (see Tables 3 and 4 for details).

In the diagnosis of full-thickness supraspinatus tendon injury, there was no significant difference between the sensitivity of MR indirect imaging and Hawkins sign, the most sensitive of the special signs ($P > 0.05$).

In the diagnosis of partial supraspinatus tendon injury, there was a significant difference between the sensitivity of MR indirect imaging and Neer sign, the most sensitive of the special signs ($P < 0.05$).

In the diagnosis of full-thickness supraspinatus tendon injury, there was a significant difference between the highest specificity of the arm test and indirect MR imaging ($P < 0.05$).

Table 3: Comparison of sensitivity between indirect MRI and specific signs.

Parameter	Indirect magnetic resonance angiography	
Special signs	Full-thickness injury	Part of the damage
Pairing X^2	1.273	19.361
P value	0.214	0.000

Table 4: Comparison of specificity between indirect MRI and specific signs.

Parameter	Indirect magnetic resonance angiography	
Special signs	Full-thickness injury	Part of the damage
Pairing X^2	6.142	10.313
P value	0.033	0.023

In the diagnosis of partial supraspinatus tendon injury, there was a significant difference between the specificity of Jobes test and indirect magnetic resonance imaging ($P < 0.05$).

4. Conclusions

(1) Among the examinations of special physical signs, the falling arm test has the highest specificity and the highest sensitivity for the diagnosis of full-thickness supraspinatus tendon injury. In the diagnosis of partial supraspinatus tendon injury, the Jobe test has the highest specificity and the Neer sign has the highest sensitivity.

(2) In the diagnosis of full-thickness supraspinatus tendon injury, there was no significant difference in sensitivity between indirect MR imaging and Hawkins sign, but the specificity of indirect MR imaging was higher than that of special signs.

(3) In the diagnosis of partial supraspinatus tendon injury, the sensitivity and specificity of indirect MR imaging are higher than those of special sign examination.

The examination of special signs is simple and quick, which is helpful to the diagnosis of supraspinatus tendon injury and should be used as the basic diagnostic method. Indirect MR imaging is an important auxiliary diagnostic method with high sensitivity and specificity, which can be examined by multiplane images.

Aim. To study the diagnostic effect of hip fracture in the elderly. In this paper, a total of 100 elderly patients with hip fracture from January 2020 to May 2021 were selected for X-ray and CT examination after admission. The operation was taken as the final criteria for determining hip fracture type, and the diagnosis of hip fracture by CT three-dimensional reconstruction was analyzed and studied. The results showed that the diagnostic rate of CT 3D reconstruction for various types of hip fracture in the elderly was higher than that of CT plain scan and X-ray ($P < 0.05$). For the diagnosis of intra-articular small bone fragments, the rate of missed diagnosis was 2% (2/100) with CT 3D reconstruction, 10% (10/100) with conventional CT scan, and 20% (20/100) with X-ray. The rate of misdiagnosis was 5.0% (5/100) with CT 3D reconstruction. Routine CT scan was 15% (15/100), X-ray was 30% (30/100), and CT 3D reconstruction was significantly lower than other examinations ($P < 0.05$). *Conclusion.* CT 3D reconstruction has high accuracy in the diagnosis of various types of hip fractures in the elderly.

1. Introduction

Artificial hip arthroplasty has developed for nearly half a century since its development. At present, this technology has become a method for the treatment of hip diseases such as femoral neck fracture, hip osteoarthritis, femoral head necrosis, rheumatoid hip arthritis, ankylosing spondylitis complicated with hip ankylosis, congenital acetabular dysplasia, and hip tumor, It is an effective means to relieve hip pain, restore joint activity, and improve joint stability. It is an effective means to restore joint motion and improve joint stability. Artificial hip replacement includes total hip arthroplasty (THA), total hip replacement (THR), and artificial femoral-head replacement (AFR) [1]. According to statistics, more than 1 million cases of artificial hip arthroplasty have been carried out globally every year, and the number of THA is increasing year by year. By 2015, 0.83% of the total population of the United States has received artificial hip arthroplasty, and the number of artificial hip arthroplasty in China is as high as 200,000 cases every year. At present, the length of hospital stay of patients with hip arthroplasty in China is 13.07 ± 3.49 days, which is generally longer than that of patients in Western countries or regions (5.3 ± 1.6 days). On the one hand, it may be due to the delayed start of functional exercise and getting out of bed. Hip replacement patients, on the other hand, have early postoperative complications such as lower extremity deep vein thrombosis (DVT), infection, postoperative nausea and vomiting (PONV), and prosthesis peripheral fracture. Prolongation of hospitalization time brings an increase in hospitalization costs, increasing the economic burden of medical treatment [2].

Musculoskeletal diseases, including osteoarthritis of the hip and knee, are the second leading cause of disability in almost every country and region in the world, according to a 2010 study on the global burden of disease in the Lancet. The incidence of hip and knee osteoarthritis is increasing year by year worldwide, especially in the elderly population [3].

March et al. have shown that hip diseases, mainly osteoarthritis of the hip, affect nearly 15% of the global population and are a major cause of pain and disability in the elderly. Although there are many treatments available for hip osteoarthritis, joint replacement remains the primary treatment of choice. With the acceleration of population aging process and the development of transportation and construction industry, the incidence of femoral neck fracture increases year by year [4]. Based on data on the incidence of hip fractures, changes in the age composition of the population, and long-term changes in the risk of hip fractures, there are estimates that by 2025, the number of hip fractures will reach 2.6 million (37% in Asia), and by 2050, it will reach 4.5 million (45% in Asia). After China enters the aging society, the incidence of senile fracture increases by 30% every 10 years, and the number of hip fracture also increases at a rate of four times. Hip fractures account for 50% of all fractures caused by osteoporosis in the elderly. Femoral neck fracture is the most common and serious hip fracture. Through retrospective study and comparative analysis, Lee et al. investigated the pelvis of 136 normal adults in order to provide anatomic and morphological data of the coccyx with three-dimensional images for the diagnosis of idiopathic coccygeal pain. Computed tomography used software to reconstruct a three-dimensional model of the pelvis from X-ray images of all the specimens. Unilateral or bilateral fusion of the sacral and coccygeal angles is not uncommon. As far as the transverse processes of sacrum and coccyx are concerned, the separation type is more than the fusion type. The incidence and angle of coccyx deviation vary greatly from individual to individual. A three-dimensional model of the gross anatomy of the coccyx will help to understand the mechanisms underlying the development of idiopathic coccygeal pain [5]. Morgagni hernias can be diagnosed in different ways, but they are not always 100% accurate. A three-dimensional reconstruction of the model may help to better understand important anatomical structures. Zhang et al. performed laparoscopic repair based on a three-dimensional reconstruction model. This case demonstrates that the three-dimensional reconstruction model is a useful tool for the diagnosis and preoperative evaluation of MH patients, especially when the diagnosis is confused in clinical practice [6]. In recent years, with the aging of China's social population, the improvement of people's requirements for the quality of life, the continuous improvement of the medical insurance system, and the rapid development of medicine, the demand for hip replacement in China has increased significantly. It has been more than ten years since ERAS was introduced into China. Through continuous exploration and practice by scholars, remarkable achievements have been made [7]. 2015 was the year of rapid development of ERAS, and the first ERAS collaboration group was established in China. The first ERAS national conference was held in Nanjing in July; the consensus of Chinese experts on the application of accelerated rehabilitation surgery in colorectal surgery (2015 Edition) was released, which includes 19 perioperative measures, mainly including shorten the preoperative ban drink, multimodal analgesia, early postoperative fasting time bed, early to eat drink, restrictive transfusion and minimally invasive surgical operation, the consensus for our country the first ERAS expert consensus. Since then, Chinese scholars have successively published the consensus of ERAS experts in many surgical fields. Including the GanDanYi surgery accelerate rehabilitation expert consensus (2015 edition), the biliary tract surgery accelerate rehabilitation surgery expert consensus (2016 edition), the stomach gastric resection surgery accelerate rehabilitation surgery expert consensus (2016 edition), the laparoscopic hepatectomy accelerate rehabilitation surgery expert consensus (2017 edition)," "China accelerated rehabilitation surgery perioperative tube Consensus of Science Experts (2016 Edition), etc. A systematic evaluation of the application status of ERAS in China shows that ERAS can effectively shorten the length of stay, reduce hospitalization costs, reduce postoperative complications, improve patient satisfaction, improve prognosis and improve the quality of medical care in the surgical fields of gastrointestinal surgery, hepatobiliary surgery, cardiothoracic surgery, urology and obstetrics and gynecology. However, there are still few reports on the application of this advanced surgical concept and technology in the field of orthopedics, especially in hip arthroplasty, and there is still a large research space at present [8].

The innovation point of this paper is that CT 3D reconstruction can not only clearly show the situation of joint fracture, but also select the best Angle of observation of fracture through rotation Angle. In addition, 3D reconstruction can effectively observe the situation of bone fragments, which is conducive to the judgment of hip fracture type and the formulation of surgical plan. The results of this study fully prove that CT examination has a high sensitivity to fracture.CT 3D reconstruction has a high accuracy in the diagnosis of various types of hip fractures in the elderly.

2. Materials and Methods

2.1. General Information. There were 100 cases in this study, including 53 males and 47 females. The average age was (75.06 ± 2.33) years from 61 to 82 years old. The time from hip injury to admission to hospital ranged from 5 to 52 hours (19.49 ± 6.32) hours on average. Causes of injury: traffic accident injury 45 cases, falling injury 30 cases, fall and fall injury 25 cases. Inclusion criteria: ① All the elderly patients were over 60 years old; ② The symptoms of hip fracture were obvious on admission; ③ All patients had a history of hip trauma before admission; ④ All patients were finally treated by surgery, and the type of hip joint injury was determined by surgery. ⑤ All the patients and their family members agreed to participate in this study, and signed the surgical consent and informed consent. Exclusion criteria: ① Involuntary participation in the study; ② Old or pathological hip fracture; ③ Mental disorders can not take the initiative to participate in surgical treatment.

Table 1: The diagnosis of various types of senile hip fractures by different examination methods.

The fracture types	CT 3D reconstruction	Routine CT	X-ray
Femoral neck fracture	100.0% (58/58)	94.83% (55/58)	86.21% (50/58)
Intertrochanteric fracture of femur	100.0% (29/29)	93.10% (27/29)	75.86% (22/29)
Acetabulum fracture	96.67% (29/30)	86.67% (26/30)	56.67% (17/30)

Note. ① Femoral neck fracture: Comparison of 3D reconstruction and conventional CT, $\chi 2 = 4.1039$, $P < 0.05$; Three-dimensional reconstruction compared to X-ray, $\chi 2 = 7.6631$, $P < 0.05$; Conventional CT versus X-ray, $\chi 2 = 6.0583$, $P < 0.05$; ② Intertrochanteric fracture of femur: comparison of three-dimensional reconstruction and conventional CT, $\chi 2 = 5.2043$, $P < 0.05$; Three-dimensional reconstruction compared to X-ray, $\chi 2 = 11.0926$, $P < 0.05$; Conventional CT versus X-ray, $\chi 2 = 9.2235$, $P < 0.05$; ③ Acetabular fractures: Comparison of 3D reconstruction and conventional CT, $\chi 2 = 8.4921$, $P < 0.05$; Three-dimensional reconstruction compared to X-ray, $\chi 2 = 16.3928$, $P < 0.05$; Conventional CT versus X-ray, $\chi 2 = 12.1149$, $P < 0.05$.

2.2. Examination and Treatment Methods

① X-ray examination: the machine model is Siemens YSIO, and the hip joint and pelvis are scanned in the positive position.

② CT examination: CT models were Siemens SOMATOMdefinionAS and GebrightSpeed, scanning from both iliac wings to ischial nodular, voltage: 120 kV, current: 90 mA, matrix: 512×512, layer thickness: 2.5 mm, field: 400×400 mm.

③ CT three dimensional reconstruction: 1~1.25 mm, with a thick layer of layer spacing of 1 mm, relevant data import post-processing software, multiplanar reconstruction (MPR), bone reconstruction algorithm was used to rebuild, according to the direction of horizontal, vertical axis coordinates of human body adjust, select effective fracture plane imaging, further analyze the fracture type, form, and so on and so forth. Surgical treatment: ① Joint replacement for femoral neck fracture; ② Femoral trochanteric fracture should be treated with proximal femoral anti-rotation intramedullary nail; ③ Acetabular fractures were treated with open reduction plate fixation.

2.3. To Observe. Using surgery as the final criteria to determine the type of hip fracture, we compared the diagnosis of various types of hip fracture with X-ray, conventional CT scan and CT three-dimensional reconstruction. Two attending radiologists read the radiographs respectively. When the results were inconsistent, the same conclusion could be reached after joint discussion.

2.4. Statistical Method. SPSS18.0 data statistical software was used to establish a database and statistical analysis was conducted. Measurement data was expressed as $(x \pm s)$, enumulation data as rate (%), $\chi 2$ test was used for comparison, $P < 0.05$, which was statistically significant.

The materials and methods section should contain sufficient detail so that all procedures can be repeated. It may be divided into headed subsections if several methods are described.

3. Results and Discussion

3.1. The Diagnosis of Various Types of Senile Hip Fractures by Different Examination Methods. The diagnosis of various types of senile hip fracture by different examination methods: in 80 cases of senile hip fracture patients, conventional CT scan and CT three-dimensional reconstruction were completely detected (100.0%), and the detection rate of X-ray examination was 81.25% (81.25/100), the difference was statistically significant($\chi 2 = 5.2396$, $P > 0.05$); In this study, 117 hip fractures were found, including 58 femoral neck fractures, 29 intertrochanteric fractures, and 30 acetabulum fractures. In the acetabular fractures, 5 anterior wall, 8 posterior wall, 6 anterior column, 7 posterior column and 4 acetabular floor were involved. The detection rate of CT three-dimensional reconstruction for femoral neck fracture, intertrochanteric fracture and acetabular fracture was higher than that of conventional CT scan and X ray ($P < 0.05$). See Table 1.

Table 2: Diagnosis of intraarticular small bone fragments by different examination methods.

The fracture types	The missed diagnosis (%)	The misdiagnosis rate (%)
CT 3D reconstruction	2.5	5.0
Routine CT	8.75	12.50
X-ray	18.75	27.50

Note. In terms of missed diagnosis rate, the comparison between CT 3D reconstruction and conventional CT, $\chi 2 = 3.3649$, $P < 0.05$; Comparison of CT 3D reconstruction and X-ray, $\chi 2 = 8.0237$, $P < 0.05$; Routine CT scans compared to x-rays, $\chi 2 = 5.1282$, $P < 0.05$; In terms of misdiagnosis rate, the comparison between CT 3D reconstruction and conventional CT, $\chi 2 = 3.4035$, $P < 0.05$; Comparison of CT 3D reconstruction and X-ray, $\chi 2 = 11.2391$, $P < 0.05$; Routine CT scans compared to x-rays, $\chi 2 = 8.0907$, $P < 0.05$.

3.2. Diagnosis of Intra-Articular Small Bone Fragments by Different Examination Methods. Different examination methods for the diagnosis of intraarticular small bone fragments: For the diagnosis of intraarticular small bone fragments, the rate of missed diagnosis was 2% (2/100) with CT 3D reconstruction, 10% (10/100) with conventional CT scan and 20% (20/100) with X-ray. The rate of misdiagnosis was 5.0% (5/100) with CT 3D reconstruction. Routine CT scan was 15% (15/100), X-ray was 30% (30/100), CT 3D reconstruction was significantly lower than other examinations ($P < 0.05$). See Table 2.

4. Conclusions

The acetabulum, femoral head and other tissues together constitute the hip joint, which can cause hip injury when it is subjected to the external force of several times the weight of human body. Since osteoporosis is common in older people, mild violence can lead to hip fractures. Because of the decline in the metabolism of the elderly patients themselves, the recovery time is prolonged after the trauma, and in severe cases, other serious concurrent diseases will be caused. For the elderly patients with hip fracture, timely diagnosis and treatment is very important. CT examination has the characteristics of short time and quick scan, and can collect volumetric data at the same time, the thickness of the layer is extremely thin. CT post - processing technology can obtain three - dimensional images. In addition, the examination results of various types of hip fractures in this study showed that CT three-dimensional reconstruction had the highest diagnostic rate for femoral neck, intertrochanteric and acetabular fractures. Because hip fracture is often accompanied by bone fragments displaced, some of the bone fragments are easy to embed in the joint, and it is not easy to be observed in the examination process. In severe cases, it can lead to necrosis of the femoral head or arthritis, which can affect the prognosis of elderly patients to a certain extent. The results of this study effectively proved the advantage of 3D reconstruction in the diagnosis of small intraarticular bone fragments. Multi-plane reconstruction can clearly display the femoral head and acetabulum, and observe the joint fracture from multiple angles. Higher tissue resolution can improve the recognition of small fragments of bone, and further improve the diagnosis rate of hip fracture. In conclusion, CT 3D reconstruction has a high accuracy in the diagnosis of various types of hip fractures in the elderly.

The present study attempted to analyze the features of atlanto-occipital radiograph in patients with cervical spondylotic radiculopathy or vertebral artery type. In order to reduce the interference of human factors and the measurement error as much as possible, this experiment adopts the blind design and analyzes the digital format X-ray films by using the computer software ImageJ. Because the tangent line between the outer plates of the anterior and posterior margin of the foramen magnum was not accurately located on the X-ray film, the angle formed by the line between the saddle dorsal slope and the center point of the anterior and posterior nodule with a clear display was selected as the measurement method of the angle between the atlanto-occipital joints. The results showed that the lateral cervical curvature of the VCS group was 0.43 ± 0.51, and the lateral cervical curvature of the CSR group was 0.46 ± 0.49, both of which were significantly lower than the normal value (1.2 ± 0.5 cm). Patients in both groups had the characteristic of cervical curvature straightening. The changes of cervical curvature in overflexion and overextension positions can indirectly reflect the state of cervical motion. The anterior flexion neck curve of the VCS group was less than that of the CSR group ($P < 0.05$). Compared with the CSR group, VCS showed limited cervical anterior flexion movement. In this study, X-ray films of both CSR and VCS showed occipitocervical flexion and extension disorders, cervical curvature straightening, and lower cervical instability. In VCS, occipitocervical flexion and extension disorders were mainly manifested in atlantoaxial flexion disorders, while in CSR, atlanto-occipitocervical flexion and extension disorders were mainly manifested in atlantoaxial flexion disorders.

1. Introduction

Cervical spondylosis is a common disease in orthopedic department. The prevalence rate of cervical spondylosis in China is about 3.8%~17.5%, and it shows a rapid increase and younger trend. Cervical spondylotic radiculopathy accounted for more than 60% of all types of cervical spondylopathy. The rotation and lifting technique is an important TCM method to treat cervical spondylotic radiculopathy. The method has been approved by the National Tenth Five-Year Project, the National Eleventh Five-Year Support Plan, and the National Natural Science Foundation of China, has proved its effectiveness and safety, and has been approved by the State Administration of Traditional Chinese Medicine to promote and apply nationwide. However, the basic research on the mechanism of action of this technique has been lagging behind and cannot meet the clinical needs.

In the preliminary clinical study, it was found that the X-ray manifestations of cervical spondylotic radiculopathy may be different from those of other types of cervical spondylopathy. Reviewing the previous literature, it is found that the summary analysis on the imaging manifestations of cervical spondylopathy of nerve radiculopathy is more common, but the comparative studies on the imaging manifestations of cervical spondylopathy of nerve radiculopathy and other types of cervical spondylopathy are rarely carried out.

Cervical spondylosis is caused by a series of clinical manifestations caused by cervical intervertebral disc degeneration, intervertebral instability, osteophyte or disc rupture at the vertebral edge, pulposus prolapse, and other compression of nerve roots, spinal cord, or vertebral artery. Cervical spondylotic radiculopathy (CSR) and vertebral artery spondylopathy (VCS) are the most common types of cervical spondylopathy. Clinically, both of them have their own unique clinical manifestations. However, there is no consensus on whether there is the same difference in imaging between the two. With the development of science and technology, imaging diagnostic technology has been improved and developed, and CT and MRI examination has been basically the universal application. However, because it is cheap and easy to perform, X-ray examination is still the most commonly used examination method for cervical spondylosis. Reviewing the previous literature, the summary and analysis of X-ray films of cervical spondylosis are more common, but the comparative analysis of X-ray findings of cervical spondylosis of nerve root type and cervical spondylosis of vertebral artery type is rarely carried out. The analysis of the imaging findings of CSR and VCS is helpful to understand the pathogenesis of both and can improve the level of clinical diagnosis, which has important clinical value. Therefore, this experiment was designed to compare and analyze the X-ray characteristics of CSR and VCS.

Cervical spondylosis is caused by a series of clinical manifestations caused by cervical intervertebral disc degeneration, intervertebral instability, osteophyte or disc rupture at the vertebral edge, pulposus prolapse, and other compression of nerve roots, spinal cord, or vertebral artery. There are many research studies on the treatment of cervical spondylosis. The objective of this study was to investigate the curative effect of shock wave combined with acupuncture in the treatment of senile cervical spondylotic radiculopathy [1]. Zhou et al. studied the clinical efficacy of Baimai plaster massage combined with cervical pain granules in the treatment of cervical spondylotic radiculopathy [2]. Cui et al. discussed the efficacy of low-weight continuous traction in treating nocturnal pain of cervical spondylosis [3]. Juan et al. discussed the clinical efficacy of joint loosening combined with nerve loosening in the treatment of cervical spondylotic radiculopathy [4]. Sheng et al. discussed the clinical efficacy of acupuncture combined with cervical pain granules in treating cervical spondylotic radiculopathy [5]. Zhang et al. studied the clinical efficacy of warm acupuncture under the guidance of high-frequency ultrasound in the treatment of cervical spondylotic radiculopathy [6]. Jiang et al. discussed the application effect of TCM nursing clinical pathway in patients with cervical spondylotic radiculopathy [7]. Chen et al. analyzed the clinical efficacy of acupuncture, traction, and cervical vertebra in the treatment of cervical spondylotic radiculopathy [8]. Yang et al. analyzed the efficacy of Xifeng dredging collaterals combined with Shujing tongdu point in the treatment of vertebral artery type cervical spondylosis [9].

X-ray examination is the cheapest, is simple and easy to perform, and is often used in routine detection and diagnosis of cervical spondylosis [10]; it is a routine examination method for cervical spondylosis and has important clinical significance for the diagnosis of cervical spondylosis. It is generally believed that radiculotype cervical spondylopathy is mainly related to lower cervical spondylopathy and osteophyte hyperplasia, while vertebral artery type cervical spondylopathy is mainly manifested as atlantoaxial joint unalignment or cervical instability. In the previous literature, experimental designs were designed to summarize the X-ray manifestations of cervical spondylotic radiculopathy or vertebral artery spondylopathy without comparative analysis of the X-ray manifestations of the two. The difference in radiographic appearance between the two is inconclusive. There have been few studies on the findings of atlanto-occipital radiograph in patients with cervical spondylotic radiculopathy or vertebral artery type. Therefore, on this basis, this paper studied the curative effect of digital X-ray in cervical spondylotic radiculopathy. Cervical spondylotic radiculopathy is mainly manifested in atlanto-occipital joint extension disorder, while vertebral artery type cervical spondylopathy is mainly manifested in atlantoaxial joint flexion disorder, and this difference is closely related to its pathological mechanism.

2. Research Methods

2.1. Experiment Design: Single-Blind Control

2.1.1. Sample Size

Observation group: 60 cases of cervical spondylotic radiculopathy.

Control group: 60 cases of vertebral artery type of cervical spondylosis.

2.2. Implementation Method. 120 cases of X-ray films were randomly sorted, and then four clinicians trained in measurement were assigned to measure the numbered X-ray films without knowing the type of cervical spondylosis and input corresponding data. After data entry is completed, the analyst will break the blind and complete data statistical analysis.

2.3. Content and Method of Line Slice Measurement. The computer software ImageJ was used for imaging measurement. During measurement, X-ray film in DICOM format was imported into the program to open, and the drawing tool and measurement tool of ImageJ were used for measurement. Specific measurement contents and methods are as follows:

(1) Cervical curvature: the distance between the posterior edge of the cervical curvature vertex vertebra and the tip edge of the axial odontoid process and the posterior lower edge of the seventh cervical vertebra was measured (curve convex is positive, and curve backward tensioning is negative).

(2) Interangle: the angle formed along the saddle dorsal slope and the central point of the anteroposterior atlas nodules (positive angles are those located behind the cervical vertebra and negative angles are those located in front of the cervical vertebra) (see Figure 1).

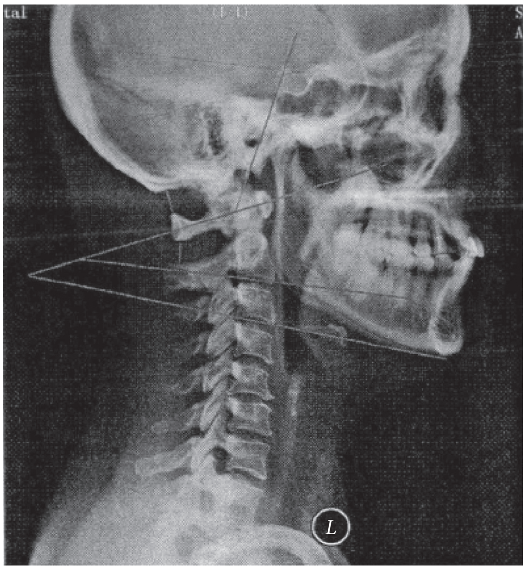

Figure 1: Measurement method of upper cervical intervertebral angle and posterior space.

(3) C1/C2 angle: the angle between the line between the central point of the anterior and posterior atlas nodules and the tangent line of the lower margin of the C2 vertebral body (positive angle is located behind the cervical vertebra body, and negative angle is located in front of the cervical vertebra body).

(4) C2/C3 angle: the degree formed by the tangent of the articular plane of the lower edge of the C2 vertebral body and the tangent of the lower edge of the C3 vertebral body (positive angle is located behind the cervical vertebra body, and negative angle is located in front of the cervical vertebra body).

(5) Posterior spacing of C0/C1: the shortest distance between the occipital bone and the posterior atlas tubercle.

(6) Posterior spacing of C1/C2: the shortest distance between the posterior atlas tubercle and the axial spinous process.

(7) Lower cervical instability segment: on the cervical functional radiograph, angle $>11^{\circ}$ was formed between the vertebrae at the point where the extension line intersected the lower edge of the sliding vertebrae and the sum of the distance from the lower edge of the sliding vertebrae to the sum of the distance from the same vertebrae to the posterior edge of the same vertebrae ≥ 2 mm.

(8) Interarticular angle flexion range: the difference between the interarticular angle on the anterior flexion film and the interarticular angle on the lateral film.

(9) Extension range of motion of inter-articular angle: the difference between the inter-articular angle of the post extension film and the inter-articular angle of the lateral film.

3. Result Analysis and Discussion

3.1. X-Ray Analysis

3.1.1. Cervical Curvature. Comparison of cervical curvature between the two groups is shown in Table 1.

3.1.2. Angle between C0 and C1. Comparison of angle between C0 and C1 between the two groups is given in Table 2.

3.1.3. Angle between C1 and C2. Comparison of C1 and C2 angles between the two groups is given in Table 3.

3.1.4. Angle between C2 and C3. Comparison of C2 and C3 angles between the two groups is given in Table 4.

3.1.5. C0/C1 Rear Spacing. Comparison of posterior spacing of C0/C1 between the two groups is given in Table 5.

3.1.6. Back Spacing of C1/C2. Comparison of posterior spacing of C1/C2 between the two groups is given in Table 6.

3.1.7. Correlation Analysis of Angular Flexion Change between C1 and C2 and Posterior Space Flexion Change. Correlation between anterior flexion of C1/C2 angle and posterior distance is given in Table 7.

3.1.8. Lower Cervical Instability. Comparison of the proportion of lower cervical instability between the two groups is given in Table 8, and comparison of the distribution of lower cervical instability segments between the two groups is given in Table 9.

4. Discussion

The experimental results, as known from Table 1, show that the lateral cervical curvature of the VCS group was 0.43 ± 0.51 and the lateral cervical curvature of the CSR group was 0.46 ± 0.49, both of which were significantly lower than the normal value (1.2 ± 0.5 cm), as shown in Figure 2, suggesting that patients in both groups had the characteristics of cervical curvature straightening. When the cervical spine flexes forward, the cervical spine flexes and moves forward, causing the reduction of cervical curvature. The opposite is true for stretching. Therefore, the changes of cervical curvature in the overflexion and overextension positions can indirectly reflect the state of cervical motion. The anterior flexion neck curvature of the VCS group was less than that of the CSR group ($P < 0.05$), as shown in Figure 3, suggesting that the VCS had limited cervical anterior flexion movement compared with the CSR group.

The occipital neck has a large range of flexion, extension, and rotation. The flexion and extension of the neck is mainly completed by the atlanto-occipital joint, which accounts for half of the whole range of neck motion. The left and right rotations of the head and neck are mainly completed by the

atlantoaxial joint was ±13° and ±10°, respectively. In this experiment, from Tables 2–6, the range of flexion and extension of atlanto-occipital joint in both groups was significantly less than the normal range, suggesting that both groups had atlanto-occipital flexion and extension disorders. Among them, the atlanto occipital joint extension dysfunction of CSR is more serious than that of VCs ($P < 0.01$). The range of flexion and extension of the atlantoaxial joint in both groups was significantly less than the normal range, indicating the presence of atlantoaxial flexion and extension dysfunction in both groups. Among them, the atlantoaxial flexion dysfunction of VCS was more significant than that of CSR ($P < 0.05$).

Radical cervical spondylopathy (CSR) is caused by disc degeneration, herniation, segmental instability, hyperosteogenesis, or osteophyte formation that irritates and compacts the cervical nerve roots in the spinal canal or in the foraminal area. During cervical anterior flexion, the ligamentum flavum and the posterior longitudinal ligament were elongated, and the sagittal diameter of the cervical canal and the area of the intervertebral foramen were increased accordingly, which could relieve the mechanical compression of nerve roots. However, cervical posterior extension activity can cause contraction of posterior cervical muscle group and reduction of intervertebral foraminal area and further aggravate neck, shoulder, and arm pain by irritating the pathological segmental nerve roots. Therefore, in patients with CSR, posterior extension activity disorders in upper neck are particularly obvious, while anterior flexion activity disorders are less severe than VCS. The two major curves of the vertebral artery are located in the occipital atlantoaxial complex. According to the mechanical compression theory, excessive cervical spine movement can cause the spatial changes of the cervical structure, especially the spatial changes of the occipito-atlantoaxial complex, resulting in the insufficiency of blood supply to the vertebral artery and inducing dizziness. Therefore, upper cervical flexion and extension dysfunction in VCS patients is a state of self-preservation. Furthermore, the vertebral artery was bent almost at right angles above the upper mouth of the transverse foramen of the atlas and was fixed in the groove of the vertebral artery of the atlas by the posterior membrane of the atlas. During cervical anterior flexion, the posterior atlanto-occipital membrane is stretched and local tension is increased, thereby compacting the vertebral artery across the atlanto-vertebral artery sulcus, resulting in insufficient blood supply. Thus, atlanto-occipital flexion dysfunction was more pronounced in VCS patients than in CSR.

In the course of flexion and extension of occipito-atlantoaxial joint, the posterior distance of occipito-atlantoaxial joint and occipito occipital joint changed accordingly. Therefore, this experiment is an attempt to analyze and study this index. The experimental results are given in Table 7, and there was no significant difference between the two groups in the statistical analysis of the posterior space between the occipito-atlanto joints at all states, and no statistical results consistent with the occipito-atlanto angle were obtained. The consideration is related to the difficulty in determining the occipital condylar boundary. In the VCS group, the change value of flexion activity in the posterior space of the atlantoaxial joint was smaller than that in the CSR group ($P < 0.05$), suggesting that the flexion activity of the atlantoaxial joint was limited in the VCS patients, which was consistent with the statistical results of the atlantoaxial angle. There was a positive correlation between the atlantoaxial angle and the change of flexion activity in the distance behind the atlantoaxial joint ($R = 0.622$) ($P < 0.001$). Comparatively speaking, the posterior distance of atlantoaxial joint is easier to measure than the angle between atlantoaxial joints, so the former is recommended in clinical practice.

Lower cervical instability is one of the imaging diagnostic criteria for vertebral artery type of cervical spondylosis, but it is also common in other types of cervical spondylosis. The results of this experiment are given in Tables 8 and 9, and the incidence of lower cervical instability was 58.3% in the VCS group and 51.7% in the CSR group, and there was no statistical difference between the two groups. The distribution of lower cervical instability segments in both the CSR group and the VCS group was concentrated in C3, C4, and C5, which was consistent with previous literature. There was also no statistical difference in the distribution of lower cervical instability between the two groups. These results suggest that lower cervical instability is only a manifestation of cervical degeneration and is not the characteristic X-ray finding of vertebral artery or radiculotype cervical spondylosis.

In this study, X-ray films of both CSR and VCS showed occipitocervical flexion and extension disorders, cervical curvature straightening, and lower cervical instability. However, there were some differences in the X-ray findings between the two, among which the occipitocervical flexion and extension disorders in VCS were mainly manifested in atlantoaxial flexion disorders, while the CSR was mainly manifested in atlanto-occipitocervical flexion and extension disorders, and the differences were closely related to their respective pathological mechanisms. In this study, the open position and double oblique profile of CSR and VCS have not been compared and analyzed, and further study is needed.

5. Conclusions

Occipital and cervical flexion and extension disorders, cervical curvature straightening, and lower cervical instability are common X-ray manifestations of radiculotype cervical spondylopathy and vertebral artery type cervical spondylopathy.

Cervical spondylotic radiculopathy is mainly manifested in atlanto-occipital joint extension disorder, while vertebral artery type cervical spondylopathy is mainly manifested in atlantoaxial joint flexion disorder, and this difference is closely related to its pathological mechanism.

The study shined spotlight on the effect of respiratory rehabilitation training on chronic obstructive pulmonary disease (COPD), which was evaluated using speckle ultrasound algorithm-based cardiac ultrasound. Then, 90 patients with stable COPD, who were admitted to the hospital from January 2018 to December 2019, were randomly rolled into three groups, namely, the fast inhalation and slow exhalation (A) group, abdominal breathing (B) group, and control (C) group. For group A, on the basis of the conventional treatment, the method of rapid inhalation and slow exhalation was adopted. The group B ($n = 30$) adopted the abdominal breathing method besides the conventional treatment. In addition, the group C ($n = 30$) received only conventional treatment. Finally, the efficacy and parameters of the three treatment methods were compared. The echocardiographic parameters and echocardiographic images were calculated and processed by the speckle tracking method. Three kinds of operators were used to track the myocardial spots successfully, and the corresponding points in the image were obtained and calculated. It was found that there was no significant difference in the degree of dyspnea, exercise endurance, lung function, respiratory muscle function, and quality of life (QOL) before treatment ($P > 0.05$). After treatment, in contrast with group C, the previously mentioned indicators in groups A and B were obviously better ($P < 0.05$). Further, both the echocardiographic images and echocardiographic parameters of groups A and B were obviously improved, and there was no obvious difference between groups A and B. Hence, some degree of respiratory rehabilitation was very effective in the diagnosis of patients with chronic pulmonary obstruction. In conclusion, the speckle tracking algorithm-based cardiac ultrasound improves the image quality. At the same time, respiratory rehabilitation training is effective on COPD and worthy of clinical promotion.

1. Introduction

The common symptoms of COPD are characterized by irreversible airflow limitation and difficulty in breathing, and patients often have more severe dyspnea at the onset. At the same time, as the disease progresses, the patient's airflow limitation aggravates, and this symptom is largely related to the inhalation of harmful gases and particles [1, 2]. As a modern disease, COPD has high fatality and disability rates.

With the development of modern medicine, ultrasound diagnosis is adopted in the detection of heart function in patients with COPD. At this stage, some speckles often appear in cardiac ultrasound images. For these speckles, there are two common points at this stage. One point is that it is a kind of noise that influences the image quality. The other point claims that it is a structural signal, which mainly reflects the information between the organ tissue and the imaging medium [3, 4]. Although the two viewpoints are quite different, their purpose is consistent, that is, for better diagnosis, research, and treatment of lesions. At the same time, due to the complexity of COPD itself, it often has complex effects on body functions, which not only acts on the respiratory system, but also has an impact on the structure of skeletal muscle as a result of inflammation in the body caused by COPD. Then, it causes dysfunctions in the respiratory muscles and further aggravates the patient's condition [5, 6]. The symptoms of weakened respiratory muscle function include decreased muscle function and decreased muscle endurance, which are often accompanied by dyspnea, increased carbon dioxide content in the blood, and decreased exercise capacity.

Further research on related phenomena shows that the increase in number of patients with reduced respiratory muscle function will greatly aggravate the consumption of medical resources, and the decline in respiratory muscle function also directly affects the survival rate of COPD patients [7, 8]. Therefore, it is necessary for COPD patients to exercise to improve their respiratory muscle function, and the way to realize it is to perform breathing training.

Therefore, the therapeutic effect of respiratory rehabilitation training on COPD patients was further studied utilizing speckle tracking algorithm-based ultrasound images.

2. Methods and Materials

2.1. Feature Point Operator Construction and Matching Pursuit. The speckles in cardiac ultrasound generally reflect the movement information of the epicardium and myocardium. At the same time, the speckles move with the movement of the myocardium. On this basis, the speckle information closely related to the movement of the myocardium is needed. In the study, the Forstner operator, SUSAN operator, and Harris operator were selected as the research subjects.

The Forstner operator is a well-known positioning operator in photogrammetry. It has the characteristics of fast speed and high accuracy. This operator takes the distance from the origin to the edge line of the inner edge of the window as the observed value, takes the gradient modulus square as the weight, and estimates the coordinates of the intersection point by the least square method. First, points with greater gray-scale differences from the surroundings were selected as feature points. The absolute values of the gray-scale differences in the four directions (up, down, left, and right) of the pixel point were calculated as follows:

$$\begin{cases} \mathrm{d}f_1 = \left|f_{a,b} - f_{a+1,b}\right|, \\ \mathrm{d}f_2 = \left|f_{a,b} - f_{a,b+1}\right|, \\ \mathrm{d}f_3 = \left|f_{a,b} - f_{a-1,b}\right|, \\ \mathrm{d}f_4 = \left|f_{a,b} - f_{a,b-1}\right|, \end{cases} \tag{1}$$

where $f_{a,b}$ is the gray value of (a, b), and $f_{a+1,b}, f_{a,b+1}, f_{a,b+1}$, and $f_{a,b-1}$ are the gray values of the four neighboring points of up, down, left, and right (a, b). Then, the mean value of these four absolute differences is calculated as $M = \text{mean}\{\mathrm{d}f_1, \mathrm{d}f_2, \mathrm{d}f_3, \mathrm{d}f_4\}$. For a given threshold Y, if $M > Y$, then (a, b) is the primary selected point.

In the 3×3 window with the primary selection point (a, b) as the center, the covariance matrix T and the interest value I are calculated according to the simplified Forstner operator, and the equations for T and I are as follows:

$$T = \begin{pmatrix} \sum g_x^2 \sum g_x g_y \\ \sum g_x g_y \sum g_y^2 \end{pmatrix}, \qquad I = \frac{4\mathrm{DeT}(T)}{(\mathrm{trT})^2}, \tag{2}$$

whereg_x and g_y are the Roberts gradients, $\mathrm{Det}(T)$ is the determinant of matrix T, trT is the trace of matrix T (the sum of diagonal elements), and$\mathrm{trT} = \sum g_x^2 + \sum g_y^2$. g_{x1}. The g_{x1} and $g_{y1}g_{y2}$ are as calculated as follows:

$$\begin{cases} g_{x1} = f(a,b) - f(a-1,b+1), \\ g_{x2} = f(a+1,b-1) - f(a,b), \\ g_{y1} = f(a,b) - f(a+1,b+1), \\ g_{y2} = f(a-1,b-1) - f(a,b). \end{cases} \tag{3}$$

The SUSAN operator adopts the USAN corner detection, that is, the pixel to be detected in the center of the circular window template, is called core point. The SUSAN template slides over the image, and the gray value of the image pixel in the template is compared with the gray value of the core point at each position:

$$C(x, x_0) = \begin{cases} 1, & \left|Z(x) - Z(x_0)\right| \le t, \\ 0, & \left|Z(x) - Z(x_0)\right| \ge t, \end{cases} \tag{4}$$

where x_0 is the position of the core point of the image, x is the position of other points in the template, Z_0 is the gray value function, t is the threshold to restore to the difference value, and $c(x, x_0)$ is the comparison result. The brightness difference between points in the template and the core point is calculated, and the sum is as follows:

$$n(x_0) = \sum c(x, x_0). \tag{5}$$

Then, n is compared with a given threshold, and SUSAN sets g as half of the size of $n_{\max}$. Finally, the local maximum value of the corner response is obtained, and the corresponding pixel is marked as a corner point.

Inspired by the autocorrelation function in the signal processing, Harris operator gives the matrix N related to the autocorrelation function. The eigenvalue of the N matrix is the first-order curvature of the autocorrelation. If the two curvature values are both high, the point is considered to be a feature point, and the expression of the Harris operator is as follows:

$$M = G(\tilde{s}) \otimes \begin{bmatrix} g_u & g_u g_v \\ g_u g_v & g_v \end{bmatrix}, \tag{6}$$

where $q = \mathrm{Det}(T) - k\mathrm{Trac}^2(T)$, $k = 0.04$, g_u is the gradient in the direction of x, g_v is the gradient in the direction of y, $G(\tilde{s})$ is the Gaussian template, $\otimes$ is the convolution operation, q is the interest value of each point, DeT is the determinant of the matrix, Trac is the trace of the matrix, and k is the threshold.

2.2. Research Subjects and Groups. Ninety COPD patients admitted to our hospital from January 2018 to December 2019 were selected. All patients admitted met the following criteria: (i) patients had clinically confirmed COPD; (ii) they were older than 50 years and younger than 75 years; (iii) they had normal liver and kidney functions. Patients with the following conditions were excluded: (i) those who had type I or II respiratory failure; (ii) those who had pleural disease or thoracic deformity, bone and joint disease, and neuromuscular junction disease; (iii) those who had received other treatments including traditional Chinese medicine; (iv) those who refused to receive rehabilitation training and had poor compliance. All patients participating in the experiment signed informed consent forms, and this study got permission from the hospital ethics committee.

Ninety patients were randomly divided into three groups, each with 30 cases, namely, the fast inhalation and slow exhalation (A) group, abdominal breathing (B) group, and control (C) group. For group A, on the basis of the conventional treatment, the method of rapid inhalation and slow exhalation was adopted. The group B ($n = 30$) adopted the abdominal breathing method besides the conventional treatment. In addition, the group C ($n = 30$) received only conventional treatment.

2.3. Respiratory Rehabilitation Training Methods. The three groups were all treated with conventional medical treatment, which lasted for eight weeks. On this basis, the group A accepted fast inhalation and slow-exhalation training, and the group B accepted abdominal breathing training. Fast inhalation and slow exhalation training method: the patient was asked breathe quickly through the nose, breathe as much as possible until the lungs were saturated, and the saturated state should be maintained for a short time. Then, the patient breathed out slowly. The exhalation process was also completed through the nose, and the whole breathing was about five seconds, and the time ratio of inhalation and exhalation was 1 : 3 or 1 : 4. Abdominal breathing training method was as the patient's left hand was placed on the chest and the right hand on the upper abdomen. The patient should keep the abdomen swelling when inhaling and make the abdomen actively collapse when exhaling and place the right hand on the back when exhaling, to give a certain pressure in the direction so that the diaphragm can effectively recover, while the left hand remains motionless during the entire breathing process.

2.4. Related Testing Indicators. The basic examinations for all selected patients included lung ventilation function, respiratory muscle function, exercise endurance test, QOL score, and dyspnea score. Among them, the QOL score was measured using SGRQ, the score was within 0–100 points, and the score was negatively correlated with the patient's health status.

The functional dyspnea score was based on the British medical research council (MRC) dyspnea scale. Level 0 means dyspnea during hard exercise; level 1 means shortness of breath when people walk on flat ground or on small slopes; level 2 is shortness of breath when people walk on flat ground; therefore, they are slower than others of the same age and need to stop and rest; level 3 means walking on flat ground for about 100 meters or a few minutes and needs to stop and breathe; level 4 means being unable to leave home due to severe breathing difficulties or having difficulties putting on or taking off clothes.

2.5. Statistical Analysis. The SPSS 22.0 was adopted for statistical analysis, and the mean ± standard deviation was adopted to express the counting results. The comparison between the two groups was realized by t-test, and $P < 0.05$ was statistically significant.

3. Results

3.1. Feature Point Extraction and Matching of Speckle Tracking Algorithm. The extraction results of the feature points of the echocardiogram by the Forstner operator, SUSAN operator, and Harris operator were compared, and the results are shown in Figure 1. Figure 1(a) is the first image of the short-axis motion of the left ventricle during diastole in echocardiography, Figure 1(b) is the image processed by the Forstner operator, Figure 1(c) is the image processed by the SUSAN operator, and Figure 1(d) is the image processed by the Harris operator. It was evident that the SUSAN operator and Harris operator were obviously better than the Forstner operator in extracting features at the corners of the contour. At the same time, the running time of the Forstner operator algorithm was 2.054 s, that of the SUSAN operator algorithm was 2.291 s, and that of the Harris operator was 3.249 s ($P < 0.05$).

3.2. General Information. This study included 90 patients in the experiment, including 30 in groups A, B, and C, respectively. Among them, there were 17 males and 13 females in group A. They were 65.17 ± 5.78 years old in average, and the average course of disease was 8.17 ± 1.24 years; in group B, there were 14 males and 16 females, and they were 66.45 ± 7.22 years old in average, with an average course of 8.73 ± 1.34 years; group C included 20 males and 10 females, and they were 66.14 ± 6.17 years old in average, and the average course of disease was 8.01 ± 1.13 years. During the experiment, there were no patients who were omitted to follow-up, and the loss-to-follow-up rate was 0%. Then, the previously mentioned information was compared ($P < 0.05$) (Figure 2).

3.3. The Difficulty to Learn Respiratory Rehabilitation Training. Groups A and B undergoing breathing rehabilitation training were evaluated for the difficulty of learning. The lower the score, the easier it was to master, and vice versa. The results are shown in Figure 3. The score of group A was 2.14 ± 0.57, and that of group B was 2.58 ± 0.95 ($P > 0.05$).

3.4. Changes in Exercise Endurance and Dyspnea. Figure 4 shows the changes in exercise endurance and dyspnea before and after breathing rehabilitation training,

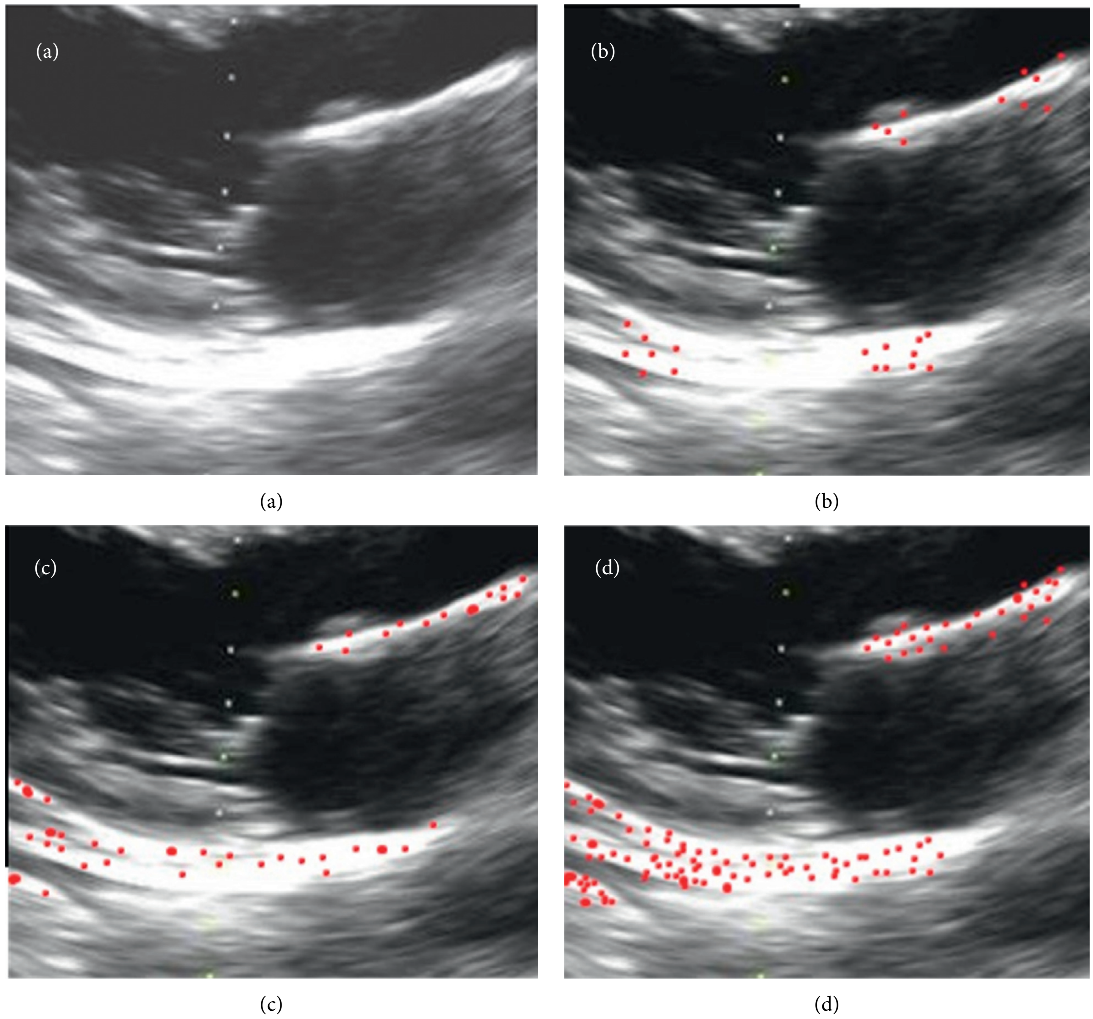

Figure 1: Feature point extraction effect.

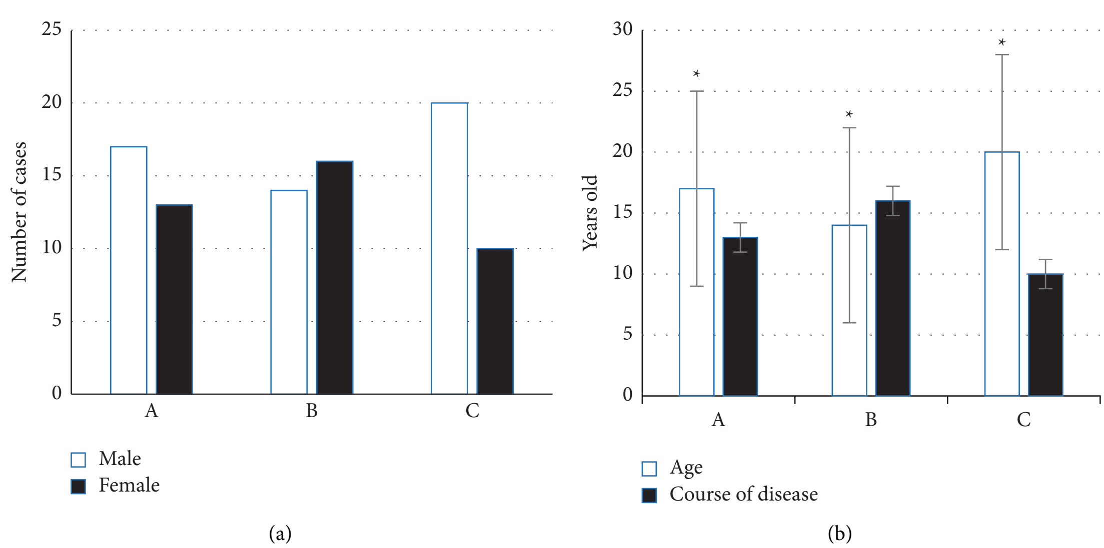

Figure 2: Comparison of general patient data. (a) Gender; (b) age and course of disease (* means that the difference was statistically significant $P < 0.05$).

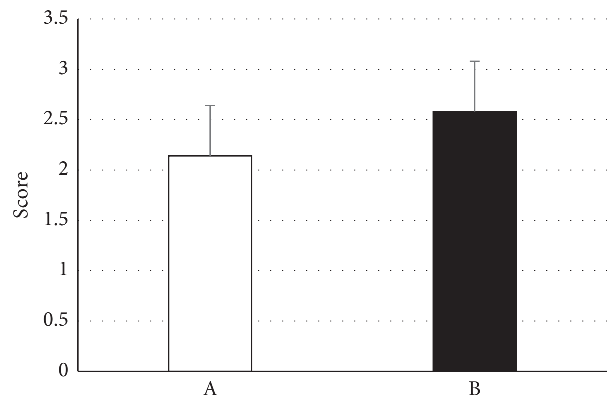

Figure 3: Learning difficulty of different breathing rehabilitation training.

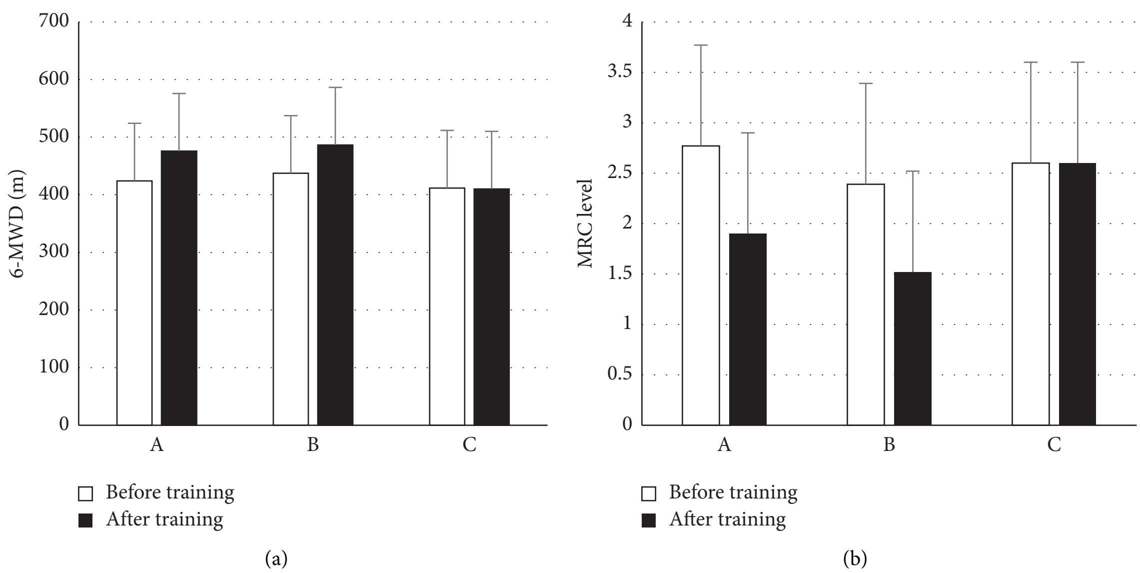

Figure 4: Changes in exercise endurance and dyspnea. (a) Exercise endurance; (b) difficulty breathing.

and there was no obvious difference in exercise endurance and dyspnea before the three groups of patients ($P > 0.05$). After training, in contrast with C, patients in groups A and B had a significant increase in exercise endurance and a significant improvement in dyspnea ($P < 0.05$), and the difference between groups A and B was not obvious ($P > 0.05$).

3.5. Changes in Lung Function. The changes in lung function before and after respiratory rehabilitation training are shown in Figure 5. There was no obvious difference between the deep inspiratory volume (IC) and peak inspiratory flow rate (PIF) of patients in groups A, B, and C before training ($P > 0.05$). After training, in contrast with group C, the IC and PIF of groups A and B were obviously increased ($P < 0.05$), and there was no obvious difference between groups A and B ($P > 0.05$).

3.6. Changes in Cardiac Function. This part of the detection was carried out using the spot tracking algorithm, and the changes in the heart function before and after the respiratory rehabilitation training are shown in Figure 6. Before training, the difference between left ventricular EDVI and left ventricular ESVI was not obvious ($P > 0.05$) in groups A, B, and C. After training, in contrast with group C, the EDVI and ESVI of groups A and B were obviously reduced ($P < 0.05$), and the difference between the groups A and B was not obvious ($P > 0.05$).

3.7. Changes in Respiratory Muscle Function. The changes in respiratory muscle function before and after respiratory rehabilitation training are shown in Figure 7. There was no obvious difference between pretraining MIP and MEP in groups A, B, and C ($P > 0.05$). After training, in contrast with group C, the MIP and MEP of groups A and B were obviously increased ($P < 0.05$), and there was no obvious difference between groups A and B ($P > 0.05$).H_2O

3.8. Changes in the QOL. The changes in the QOL before and after respiratory rehabilitation training are indicated in Figure 8. The overall QOL in groups A, B, and C before

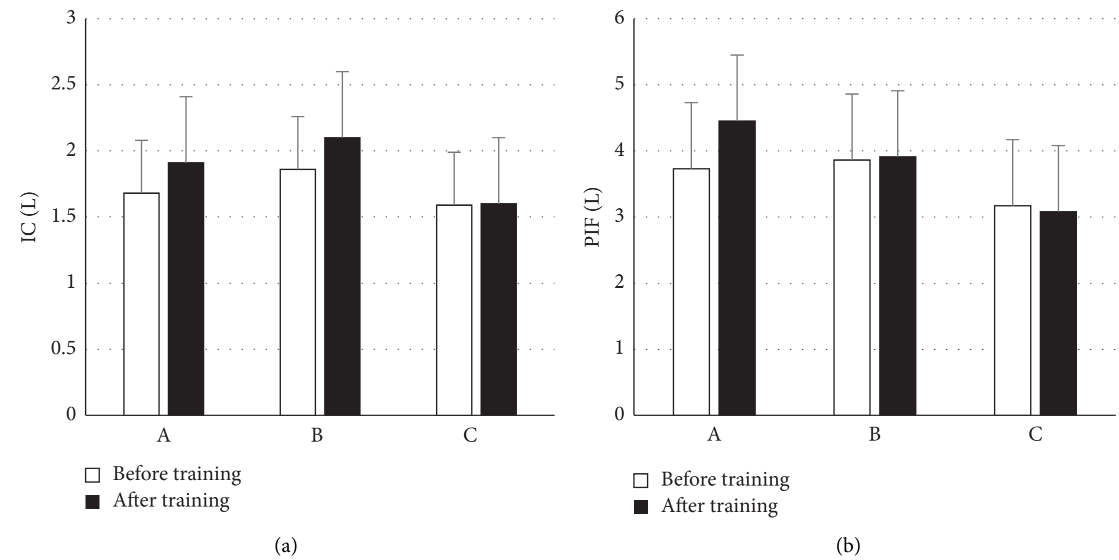

Figure 5: Changes in lung function. (a) Inspiratory volume (IC); (b) peak inspiratory flow (PIF) rate.

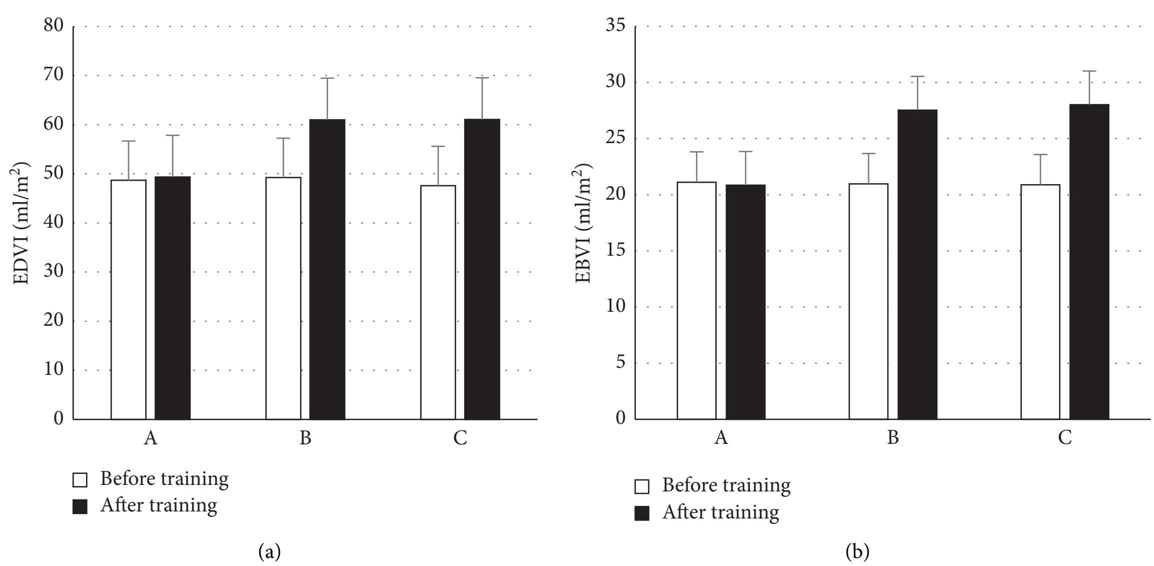

Figure 6: Changes in cardiac function. (a) EDVI; (b) ESVI.

training was low ($P > 0.05$). After training, in contrast with group C, the QOL of groups A and B had a significant increase ($P < 0.05$), and there was no obvious difference between groups A and B ($P > 0.05$).

4. Discussion

At this stage, the main treatment methods for patients in the stable phase of COPD are drug therapy and nondrug therapy, and respiratory rehabilitation therapy is not the mainstream treatment method [9]. COPD patients often have problems not only with lung function, but also with heart function. In the study, speckle tracking algorithm was adopted to analyze cardiac ultrasound. It was found that the point of motion between adjacent frames was small, and it was limited to calculate the elastic strain parameter rotation angle of the local area according to this. However, it was sensible to calculate the movement displacement length by combining the movement displacement vector of each point in the movement process. Movement restriction is one of the main symptoms that can be observed in patients with COPD. Due to functional impairment of the respiratory muscles, the patient often suffers a significant increase in load at the same time, which in turn causes that the patient's ventilation volume is unable to meet the increased demand for ventilation during exercise [10]. Berry et al. showed that systematic breathing training can obviously improve the patient's exercise endurance. In this study, the 6-MWD of groups A and B were obviously increased compared with before training, indicating that the two training methods can also improve the exercise endurance of patients with COPD [11]. It was confirmed in the study that both breathing

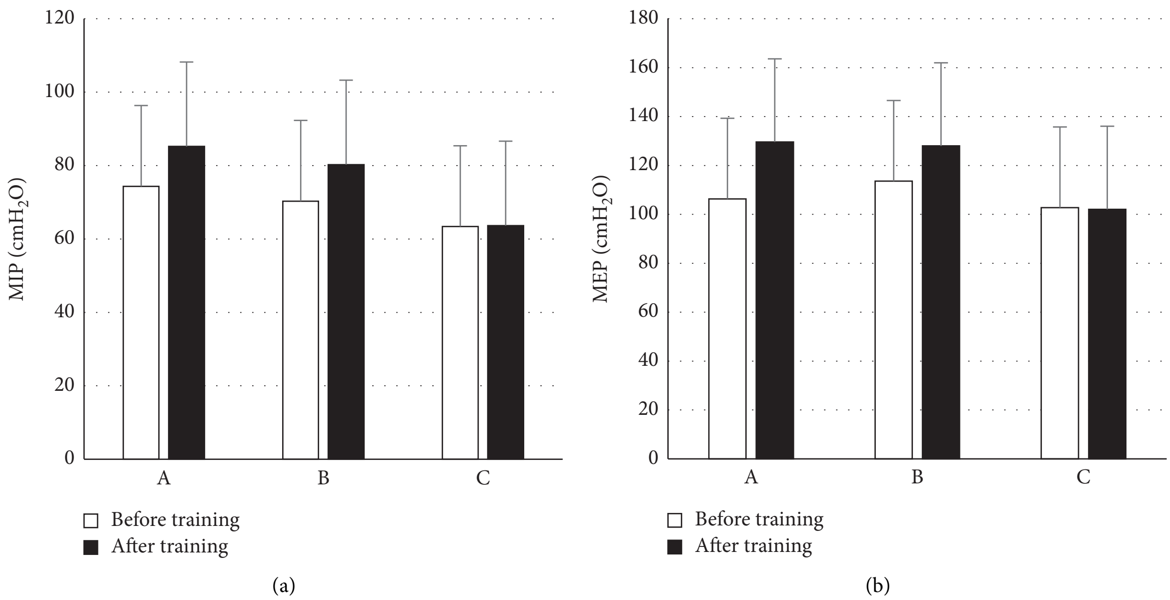

Figure 7: Changes in respiratory muscle function. (a) MIP; (b) MEP.

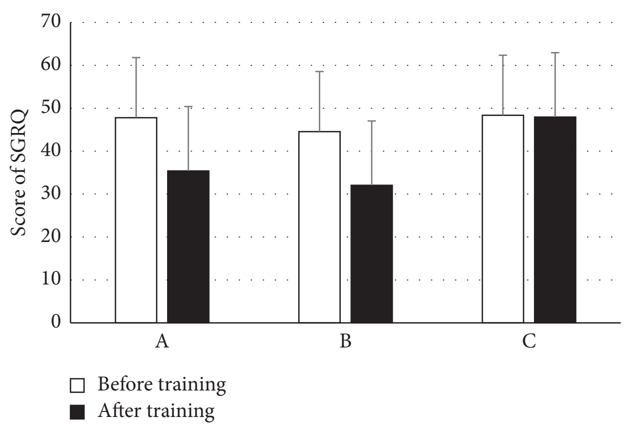

Figure 8: Changes in QOL.

training methods can increase the patient's IC value, suggesting that the increase in IC may be an important reason for the improvement of patients' exercise endurance. In addition, exercise endurance is not only related to the patient's ventilation ability, but also related to the function of the limbs and respiratory muscles. Langer et al. found that MIP was an important factor affecting exercise endurance in patients with severe COPD, indicating that respiratory muscle function was related to exercise endurance. In this study, the respiratory muscle strength of the two groups of patients was obviously improved compared with before training [12].

Due to the particularity of the disease itself, COPD often manifests as a complex respiratory system disease, accompanied by chronic disease of multiple organs throughout the body, which affects a variety of extrapulmonary tissues including skeletal muscle [13]. Due to the appearance of inflammation, the system has an impact on the structure of organs including skeletal muscles, which further leads to the dysfunction of the body including respiratory muscles [14]. Respiratory muscle dysfunction is often caused by a combination of many factors and, to a large extent, is closely related to the clinical manifestations of COPD patients and the severity of the disease [15]. Breathing training can improve the breathing of patients. The study of Kerti et al. showed that, after breathing muscle training in COPD patients, MIP increased obviously before training [16]. In this study, the MIP and MEP of patients in groups A and B were obviously increased than before training, suggesting that both training methods can improve the respiratory muscle function of COPD patients.

5. Conclusion

In this research, the three operators of the speckle tracking algorithm were studied and verified accordingly. Then, the therapeutic effect of respiratory rehabilitation training on COPD patients was further explored, and it was found that, in contrast with the control group, the degree of dyspnea, exercise endurance, lung function, respiratory muscle function, and life quality were obviously improved ($P < 0.05$). In the study, MIP and MEP in group A and group B were significantly higher than those before training, indicating that both the two training methods can improve the respiratory muscle function of COPD patients. However, the research on the algorithm in this study is limited to cardiac ultrasound images. Whether the speckle tracking algorithm is useful for other ultrasound images and needs to be further explored. At the same time, the experimental research samples are small and the types of patients are not subdivided, which should be improved in the future.

Background. Ferroptosis is a type of cell death with major topic of debate under current research and plays an important role in disease regulation. *Objective*. In this study, the literature management software Bibexcel and knowledge graph tool VOSviewer were used to summarize and analyze the international research trends and hotspots about ferroptosis in recent years, which highlight the disease mechanism, diagnosis, and treatment related to ferroptosis. *Material/Methods*. The core collection database of Web of Science was used for retrieving ferroptosis research literature. The information such as the amount of text, the country, the period, the institution, the fund, and the keywords was extracted by the bibliometric tool Bibexcel. The cooccurrence and clustering function of VOSviewer were used to analyze the high-frequency keywords and the cooperative network of the author, institution, and country. *Results*. The research of ferroptosis started late and was formally proposed in 2012. It has developed rapidly and presented an "exponential" growth trend. China, the United States, Germany, Japan, and France are the main national forces of ferroptosis research development. The United States and China have a relatively high degree of support and attention to ferroptosis. Exploring oxidative stress, inducers/inhibitors, synergistic antitumor effect, relationships with other cell death types, GSH/GPX4 and iron metabolism imbalance related mechanisms of ferroptosis, and ferroptosis in the nervous system disease, ischemia-reperfusion injury, tumor, inflammation, and age-related diseases are the hot research directions. *Conclusion*. Ferroptosis has been a research hotspot in the field of biomedicine in recent years and has attracted the attention of scholars all over the world. The occurrence mechanism of ferroptosis and its application in neurological diseases, ischemia and reperfusion injury, tumors, inflammation, and aging are the hot directions of current research. In the future, ferroptosis can be appropriately considered for strengthening new approaches, new diseases, new inductors, new inhibitors, clinical transformation, and traditional medicine research.

1. Introduction

Ferroptosis is an iron ion-related metabolic abnormality with the main feature of lipid peroxidation programmed cell death which has caused extensive attention in recent years. Its gene expression, reaction molecules, biochemical characteristics, and influence morphology are different from other known cell death types: apoptosis, autophagy, necrosis, and pyroptosis. The related mechanisms of ferroptosis such as iron metabolism imbalance, oxidative stress, abnormal glutamate metabolism, and lipid metabolism are involved in the occurrence and development of many diseases and have common mechanisms with the pathological changes of many diseases. These original and important discoveries provide new potential targets for the prevention and control of ferroptosis related diseases. Current evidence shows that ferroptosis plays an important role in ischemia-reperfusion injury, tumor disease, renal failure, circulatory system disease, and nervous system disease [1]. Therefore, it is of positive significance to summarize the existing research results of ferroptosis, discuss the research trends and frontier hotspots of ferroptosis, and reveal the new detailed molecular targets and mechanisms of ferroptosis in depth.

At present, many research summaries and analyses are often confined to literature reading combined with personal experience, lacking a general overview and overall grasp. In this study, literature management software Bibexcel and knowledge map tool VOSviewer were used to conduct bibliometric and visual analysis of ferroptosis. Through the analysis of literature keywords, authors, countries, institutions, funds, and cocitations in the field of ferroptosis research, it explores its research background, research status, research hotspots, and dynamic trends. It hopes to provide references and suggestions for the research on the pathogenesis and clinical application of ferroptosis in the future.

2. Materials and Statistical Analysis

2.1. The Data Source. The literature in this study is mainly from the Web of Science core collection database, Science Citation Index Expanded. The timeline is limited to 2020 from the beginning of the construction of the database. The types of literatures were restricted to ARTICLE and REVIEW, and two researchers independently searched and screened the literatures with TS = (“Ferroptosis” OR “Iron Death”), regardless of language. The search date was December 17, 2020. A total of 1,363 effective literatures were obtained.

2.2. Statistics and Analysis. After selecting the valid documents related to the research, they were downloaded and saved in plain text format. Bibexcel was used to extract the number of papers, year, journal, country, fund, and keywords from the effective bibliography, and the software was used to calculate the H-index of the corresponding author. The H-index indicates that the author’s H paper has been cited at least H times at most. The H-index can accurately evaluate and reflect the academic achievement and level of researchers, so as to discuss and compare the contributions of researchers to the field [2]. The research results show that the higher the H-index value, the higher its quantity, quality, and academic influence. Frequency statistics and keyword analysis of VOSviewer 1.6.15 and Pajek5.13 were used to perform biclustering analysis of high-frequency keywords, and VOSviewer software network analysis and density analysis modules for visual map analysis were used so as to objectively reflect research hotspots. The author’s collaboration network, institutional collaboration network, and country-regional collaboration network visualized collaborative analysis were all realized through VOSviewer [3, 4], which provides guidance and reference for scholars to understand the current situation of cooperation in the research field and carry out extensive scientific research cooperation. Data entry, analysis, and verification were independently completed by two researchers. The rest of the chart-making and analysis were done in Excel 2013.

3. Results

3.1. Basic Features of the Literature

3.1.1. Distribution of Publication Output. From 2012 to 2020, A total of 1363 articles related to the ferroptosis field can be collected. The number of publications in the field of ferroptosis is increasing, overall showing the “exponential” rapid growth. It shows that ferroptosis research is in its development process of “growing period” with a great potential to grow. The earliest research was carried out in 2012. After 2018, the number of published articles was more than 100, and the number of published articles was the highest in 2020. This indicates that the research of ferroptosis has been the focus of scholars’ attention in recent years and is a hot research direction of future medical research (Figure 1).

3.1.2. Distribution of Country. Through Bibexcel software, a scientific metrological analysis is made of the national characteristics of ferroptosis research. The results show that more than 100 papers were published in four countries, accounting for 96.99% of the total number of papers published. The top 5 countries are China, the United States, Germany, Japan, and France (Table 1), indicating that these 5 countries are the core strength of international ferroptosis research field. In addition, the number distribution map of the world presents that Eastern Asia, North America, Europe, and Oceania are the core region for ferroptosis research, which is basically in line with the world’s regional economic, social, and cultural level of spatial distribution pattern. China located in the Eastern Asia region is the rapid development country of ferroptosis research, but the average cited frequency and H-index are on the low side (Figure 2).

3.1.3. Distribution of Academic Journals. The journals of ferroptosis were analyzed, the number of journals was counted, as well as citations and influencing factors, and the number of articles published by the top 10 journals accounted for 18.78% of the total number of articles published. Among them, more than 30 papers have been published in “Cell Death and Disease,” “Biochemical and Biophysical Research Communications,” and “Free Radical Biology and Medicine.” Combining the influencing factors and citations of major journals, it can be found that “Cell Death & Disease,” “Free Radical Biology and Medicine,” “Redox Biology,” “Cell Death and Differentiation,” and “Oxidative Medicine and Cellular Longevity” are also high-impact journals with an impact factor over 5 (Table 2). To a certain extent, such journals can be regarded as the main position and representative of ferroptosis. Well-known journals about cytology, biomolecular science, comprehensive medicine, and oncology have shown greater interest and tendency in the research of ferroptosis, reflecting the comprehensiveness and intersectionality of the research.

3.1.4. Distribution of Funding Institutions. The funded projects of the thesis results often reflect the attention rate of the country and institutions to the research field and also

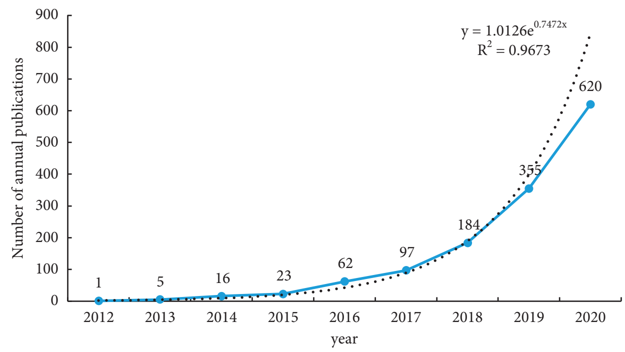

Figure 1: Number of annual publications.

Table 1: Country distribution (top 10).

Rank	Country (region)	Freq.	Total citation frequency	The average cited frequency	H-index
1	China	620	10828	17.46	73

represent the development trend of the corresponding research, the existing research resources, and the research level of related fields [5]. In these 1363 articles, a total of 5095 funds were found (Table 3). Five of the top 10 publications funded by projects in the United States are leading. They are National Institutes of Health (NIH), USA, United States Department of Health Human Services, NIH National Cancer Institute (NCI), NIH National Institute of General Medical Sciences (NIGMS), and NIH National Institute of Neurological Disorders Stroke (NINDS). In addition, the number of published papers funded by the National Natural Science Foundation of China is 427, ranking first (Figure 3). Although in essence academic output level and academic output quantity are not necessarily related to funding projects, it can be found that the support and attention from the United States and China to the field of ferroptosis research are still relatively leading.

3.1.5. H-Index of Main Authors. Before the development and application of the Hirsch index, various indicators for evaluating the personal influence of researchers had their own advantages. Compared with other indicators, the H-index can organically combine the researcher's output and influence through algorithm technology, thus comprehensively considering the "quality" and "quantity" of academic achievements [6]. Table 4 lists the H-index value and the total number of citations of the top 15 authors whose H-index was more than 10. Judging from the essential significance of Hirsch index, 7 of the authors with an H-index more than 10 are from the United States, accounting for 46.7%, mainly from Columbia University and the University of Pittsburgh. This shows that these universities and research institutions have scientific research resources in the field of ferroptosis with the leading level in the world. At the same time, three Chinese authors, Tang Deli, Wang Hao, and Wang Xu, whose H-index exceeds 10, show that they play an indispensable role in the field of ferroptosis and have a certain influence.

3.2. Visual Analysis

3.2.1. Analysis of the Author Partnership Network. A visual analysis of the collaborative network of authors who published more than 7 papers is shown in Figure 4. The size of the dots indicates the academic influence and cooperation degree of authors; the width of the line between the dots indicates the strength of the cooperative relationship between corresponding authors; and the color indicates the subcluster network to which the authors belong. Author's network of cooperative relations of ferroptosis presents the characteristics of "overall dispersion and multicenter and regional concentration." "Tang DL"-"Kang R," "Stockwell BR," "Conrad M," and "Angeli JPF" formed a larger net cooperation subgroup and branch outward radiation. Exploring the author collaboration network relationship can fully show the research achievements communication situation in the field.

3.2.2. Analysis of Cooperation Network Relationship about Institutions. The analysis of the cooperative network of institutions that have published more than 10 papers is shown in Figure 5. The size of the dots indicates the academic influence and cooperation degree of the institutions; the width of the lines between the dots indicates the strength of the cooperative relationship between the corresponding institutions; and the color represents the subcluster network to which the institutions belong. There were roughly 6 major cooperative subclusters. In cluster 4, the number and the quantitative index of "Univ Pittsburgh" ranked first. According to the literature, the University of Pittsburgh has cooperated with 11 organizations such as "Guangzhoumeduniv" and "Centsuniv." The University of Pittsburgh researchers have succeeded in deciphering the ferroptosis trigger signals language in cell, in 2020. "Univ Pittsburgh" associated with "Jinan University" found iPLA2β is an important regulatory protein for ferroptosis. The accumulation of lipid peroxides caused by loss of activity is closely related to the occurrence of Parkinson's disease. Inhibition of ferroptosis is expected to be a new strategy for the treatment of Parkinson's disease [7]. In cluster 1, "Chinese Acad Sci"-"Zhejiang Univ"-"Shanghai Jiao Tong Univ" as representatives of Chinese university and research institutions accounted for 27.1% of the total. Professor H. D. Wang from Zhejiang University and others from Zhengzhou University have discovered a drug for rheumatoid arthritis known as Auranofin; it can significantly activate Hepcidin and effectively reduce the iron overload burden. Furthermore, the researchers found that the molecular mechanism for this phenomenon is to reduce iron overload by activating the NF-κB/IL-6/JAK-STAT signaling pathway [8]. In 2020, together with the Chinese Academy of Medical Sciences and others, Professor H. D. Wang clarified the effect and molecular regulation mechanism of ferritin inhibiting the

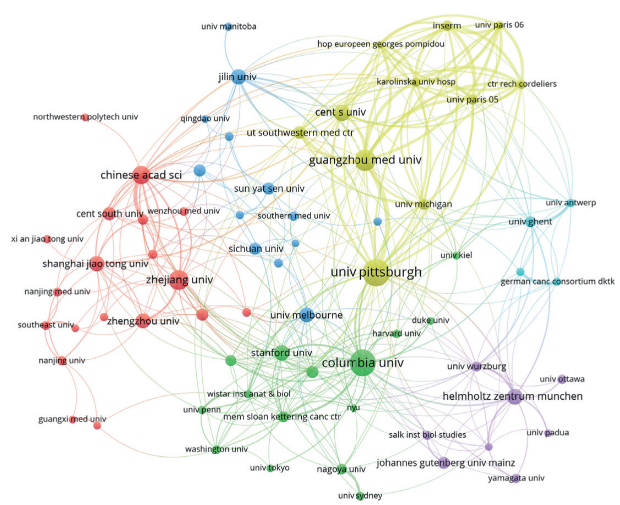

Figure 5: Institutional cooperation network.

occurrence of cardiomyopathy by regulating ferroptosis. It was first revealed in vivo that membrane protein SLC7A11 can effectively reverse cardiomyopathy caused by ferritin deficiency by blocking ferroptosis in cardiomyocytes, which is expected to become a new target for the prevention and treatment of heart diseases [9]. University of Science and Technology of China (USTC) and others jointly found that monodispersed amorphous Fe carbonate containing nanodrug assembly (calcium carbonate based Fe2+ -adriamycin complex, ACC@DOX.Fe2+ -CASI-PAMAM-FA/MPEG) can synergically induce ferroptosis and apoptosis of tumor cells [10]. In cluster 2, “Columbia Univ”-“Stanford Univ”-“Harvard Med Sch” asrepresentatives of university and research institutions accounted for 21.4% of the total. In 2017, Columbia University in the United States, as the origin and core institution of ferroptosis research, invited researchers from 27 institutions around the world to publish a programmatic guide on ferroptosis research, systematically expounding the mechanism of ferroptosis and its relationship with human diseases [11]. In cluster 3, “Jilin Univ”-“Univ Melbourne”-“Shandong Univ” as representatives of universities and research institutions in China and Australia accounted for 18.5% of the total. Sun et al. from Jilin University published their important research results, discussing how to regulate ferroptosis and lipid metabolism abnormality through overexpression and knockdown of perilipin2, a potential predictive biomarker in gastric cancer [12]. In cluster 5, “Helmholtz Zentrum Munchen”-“Johannes Gutenberg Univ Mainz”-“Univ Wurzburg” as representatives of German research institution groups accounted for 11.4% of the total. “Targeting Ferroptosis: New Hope for As-Yet-Incurable Diseases” was published in Trends in Molecular Medicine by Marcus Conrad, Svenja M.Lorenz, and Bettina Proneth form the German Institute for Metabolism and Cell Death in October 2020. This paper argues that because ferroptosis pathway provides a variety of drug-addable nodes, it is expected that the preclinical and clinical development of ferroptosis modulators will bring about unprecedented opportunities for treating uncured diseases [13]. In cluster 6, German research group with the core of “Univ Ghent” accounted for 5.7% of the total.

3.2.3. Analysis of the Network of Country Cooperation. An analysis of the country cooperation relationship with 5 or more papers published is shown in Figures 6 and 7. The size of the dot indicates the academic influence and degree of cooperation of a country; the width of the line between the dots indicates the strength of the cooperation relationship between the corresponding countries; the color indicates the

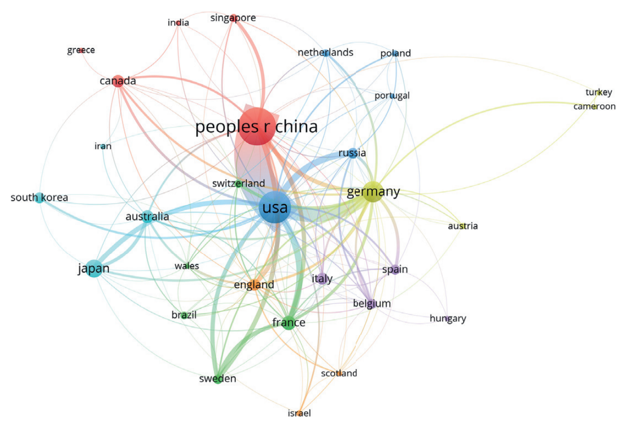

Figure 6: National cooperation network.

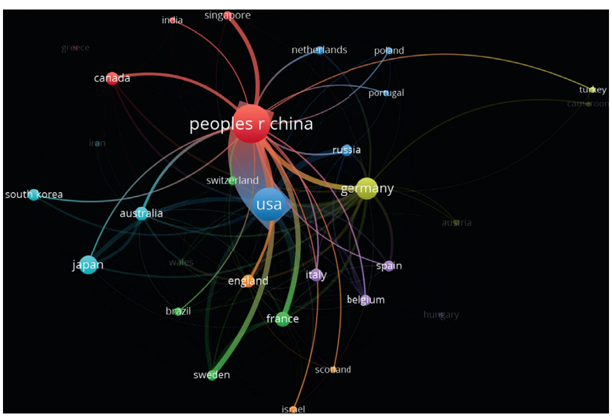

Figure 7: Chinese network of cooperation with other countries.

subcluster network to which they belong. The results of the study show that the United States, China, and Germany have close cooperative relations, and the overall performance of international cooperation is good. It can be seen from the network map of China's scientific research cooperation that China maintains scientific research cooperation with many countries such as the United States, Germany, France, Sweden, Japan, Australia, and Russia. Strengthening international cooperation is an important factor in promoting the output, dissemination, and commercialization of high-quality research results. While integrating into the internationalization process of frequencies and strengthening cooperation between countries, China should also focus on its own independent innovation and improvement of original results in order to enhance its influence and voice in this field.

3.2.4. Cooccurrence and Cluster Analysis of Keywords. Summarizing the themes of keywords and analyzing keywords can help understand the research hotspots and trends in this field. In this study, VOSviewer software was used to extract the cooccurrence frequencies of more than 8. Cluster analysis with 64 keywords was performed. The 53 keywords were divided into 6 categories, combined with the meaning and logical analysis of the research subject words between the words, as shown in Figure 8: (1) oxidative stress response of ferroptosis and its application in stroke, Alzheimer's disease, and breast cancer (red): iron drop, active oxygen, iron overload, antioxidants, iron, mitochondria, stroke, Alzheimer's disease, oxidative stress, induced labor, nrf2, and breast cancer; (2) the inducer/inhibitor of ferroptosis response and its role in cerebral hemorrhage and diseases of aging (yellow): erastin, ferrostatin-1, cerebral hemorrhage, Fenton reaction, and aging; (3) ferroptosis mechanism involved in antitumor research (sky blue): sorafenib and pancreatic cancer; (4) relationship between ferroptosis and other cell death types, where ferroptosis is involved in inflammation and ischemia-reperfusion (dark blue): autophagy, cell death, pyroptosis, necroptosis, and apoptosis; (5) ferroptosis glutathione and peroxidase-4 systems and antimelanoma and glioma studies (purple): melanoma, glutathione, glioma, and GPX4; (6) correlation between iron metabolism imbalance and tumor microenvironment and antitumor genes (green): cancer stem cell, iron metabolism, tumor microenvironment, and p53.

The density view of the VOSviewer software was used to perform cooccurrence analysis on keywords (Figure 9). The frequency of keyword occurrences is related to the image density. The higher the frequency, the darker the color and the higher the density. At the same time, with larger gray value of the color, it also represents the bias of the research hotspot in this field. The keywords in the middle area of the figure are divided into five parts according to their location distribution, similar to the result of keyword clustering analysis. The first part is in the center of the view. Keywords were the following: iron drop disease, reactive oxygen species, iron overload, cancer, p53, and metabolism; the darkest part indicates that it is an international research hotspot in this field. Among them, ferroptosis has a large hotspot distribution area and is a high-frequency keyword. The oxidative stress response, iron metabolism, tumor, and tumor suppressor genes of ferroptosis occupy the core research position. The second part is located at the bottom left of the first part. The keywords were iron, Alzheimer's disease, oxidative stress, mitochondria, and stroke, focusing on the application of ferroptosis in stroke, Alzheimer's disease, and other neurological diseases. The third part is mainly located at the bottom right of the first part. Taking necrosis, scorch, apoptosis, and autophagy as keywords, this part focuses on the relationship between ferroptosis and other types of cell death. The fourth part is mainly located at the upper right of the first part. The keywords were glutathione, glioma, and GPX4, mainly related to glutathione and its peroxidase 4. The fifth part is mainly located on the upper part of the first part. Keywords were iron metabolism and tumor microenvironment, focusing on the research about abnormal iron metabolism, tumor microenvironment, and tumor stem cells.

4. Discussions

4.1. International Ferroptosis Research Development Trend. In this study, bibliometrics and visual analysis were used to make a macroscopic description and retrospective analysis

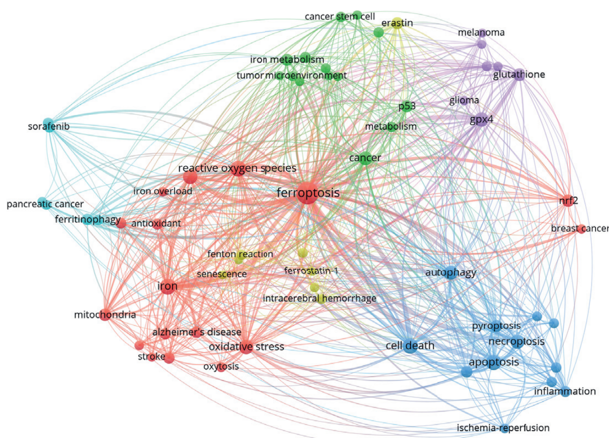

Figure 8: Keyword clustering visualization.

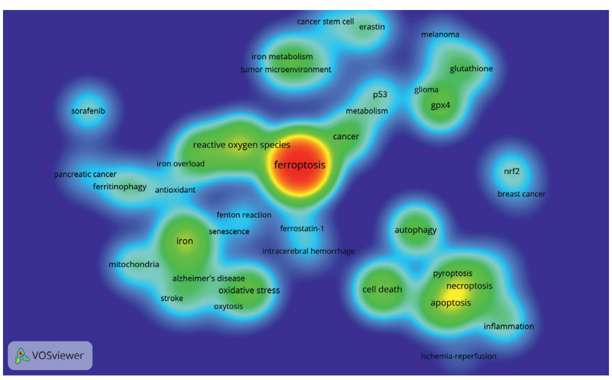

Figure 9: Density map of keywords.

of the research literature on ferroptosis, presenting research trends, hotspots, topics, major researchers, major research institutions, important research journals, and funding in this field. In recent years, a large number of literatures about ferroptosis have been published, showing an "exponential" rapid growth trend, which is the focus of international medical research and a hot research direction. By combining the historical axle of landmark research achievements on ferroptosis (Figure 10) and the number of published articles (Figure 1), the research on ferroptosis started late, officially in 2012. Dixons et al. [14] formally proposed the concept and characteristics of ferroptosis. In 2014, Yang et al. [1] found that GPX4 can regulate the death of eosinophilic cancer cells through the ferroptosis pathway. In 2016, ferroptosis inducers inhibited GPX4 by covalently targeting the active site selenocysteine, leading to accumulation of PUFA hydroperoxides [15]. In 2017, Doll et al. [16] found that ACSL4 inhibition is an important mechanism to improve the occurrence of ferroptosis. In 2018, Ingold et al. [17] found that GPX4 was selenium-dependent in preventing ferroptosis caused by hydrogen peroxide. In 2019, FSP1 is a key component of a nonmitochondrial coantioxidant system that acts in parallel with the GPX4 pathway based on glutathione [18]. In 2020, Zou et al. [19] revealed the role of peroxisomal-ether-phospholipid axis in the development of susceptibility and avoidance of ferroptosis and emphasized that PUFA-EPL is a unique functional lipid class, which is dynamically regulated in the process of cell state transition and provides multiple regulatory nodes for therapeutic intervention of disease. Zhou and Jinku [20] established a database of manually collected and managed ferroptosis-related markers and regulators and ferroptosis-related diseases.

4.2. Ferroptosis Research of High-Influence Scholar-Institution-Country and Cooperative Relationship. Stockwell BR (Columbia University), Conrad M (Helmholtz Zentrum Munchen), Linkermann A (Dresden University of Technology), Tang DL (Guangzhou Medical University), and Kang R (University of Pittsburgh) are influential in the field of ferroptosis. The cooperation between authors has increased, including interorganizational cooperation and international cooperation. Author-institution-country has a certain correlation in the number of papers published. China, the United States, Germany, Japan, and France are the countries with the biggest numbers of publications. There are many highly productive scholars in China, the United States, and Germany, and the team of them cooperates closely with the international community. A large-scale research team has initially formed, and each research direction has its own characteristics. However, it is also necessary to strengthen interagency and interregional cooperation and carry out high-quality academic exchanges and cooperation.

4.3. Ferroptosis Research Fund Support and Main Journal Position. The scientific research results of funded projects often reflect the attention rate of the country and institutions. The number of papers in the journals about the research field can reflect the interests of the journals and provide a reference to the paper publication and hot follow-up research information. The National Natural Science Foundation of China, National Institutes of Health (NIH), U.S. Department of Public Services, National Institutes of Health National Cancer Institute (NCI), and National Institutes of Health National Institute of General Medical Sciences (NIGMS) are the main fund project institutes in supporting ferroptosis research with a positive significance. The journals with the highest output are "Cell Death and Disease," "Biochemical and Biophysical Research Communications," "Free Radical Biology and Medicine," "Redox Biology," and "International Journal of Molecular Science." To a certain extent, this reflects the status of major journals in the study of ferroptosis. However, due to the limitations of space and review requirements, the publication of research results from top international journals cannot be ignored. Secondly, the study of ferroptosis is a multidisciplinary research topic, which can be further explored from the perspective of diseases in various disciplines.

4.4. Analysis of Ferroptosis Research Hotspot Trend. The visualization analysis of keyword clustering found that 53 keywords were clustered into 6 topic directions. Oxidative

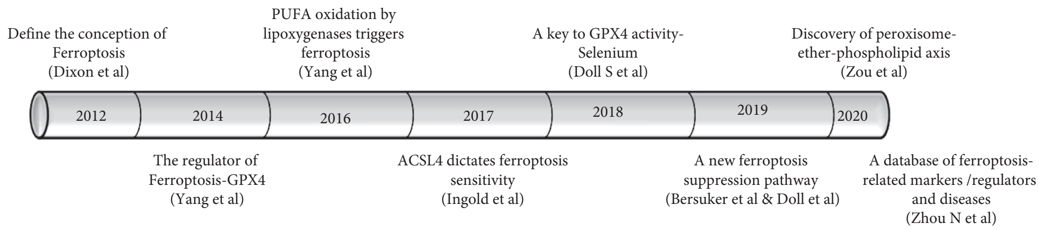

Figure 10: Historical axis of landmark achievements in ferroptosis research development.

stress, inducers/inhibitors, synergistic antitumor effect, relationships with other cell death types, glutathione peroxidase, GPX4, and iron metabolism imbalance related mechanisms of ferroptosis were discussed. The application of ferroptosis in nervous system diseases, ischemia-reperfusion injury, tumor, inflammation, and aging related diseases is a hot research direction (Figure 8; Table 5).

4.4.1. Oxidative Stress Response of Ferroptosis and Its Application in Stroke, Alzheimer's Disease, and Breast Cancer. Cluster 1 (red) of keywords focuses on ferroptosis oxidative stress and its application in stroke, Alzheimer's disease, and breast cancer. Oxidative stress is a reaction process in which reactive oxygen species generated during the aerobic metabolism of the body accumulate excessively in cells, leading to cell damage and death. Its essence is the imbalance between the body's [21] antioxidant defense and the production of reactive oxygen species. The mechanism of ferroptosis is due to the damage of the glutathione- (GSH-) dependent lipid peroxide repair system, which leads to the accumulation of reactive oxygen species in lipids [11, 14]. Mitochondrial electron transport chain complex I inhibitor DPI can inhibit oxidative stress response [22], and mitochondrial complex III inhibitor antimycin A can inhibit erastin-induced ferroptosis [14, 23], indicating that both ferroptosis and oxidative stress pathways rely on mechanisms for GSH reduction and related antioxidant system damage. A large number of studies have shown that ferroptosis is an important potential target for stroke prevention and treatment. Inhibition of ferroptosis response can reduce stroke injury [24–28], and its mechanism is related to excitement related to iron overload [28], ACSL4 protein [29], 12/15-LOX expression [30], XCT expression [31], and increased sexual toxicity. Abnormal iron metabolism plays an important role in the occurrence and development of Alzheimer's disease. Patients with Alzheimer's disease have obvious iron deposits in the cerebral cortex and hippocampus, which corresponds to the distribution of Aβ plaques [32, 33]. Elevated iron content in the brain can aggravate the disease, and Aβ accumulation [33] and iron chelating agents can reduce the level of iron in the brain and relieve symptoms [34]. Cys deletion in triple-negative breast cancer (TNBC) cells can induce ferroptosis, and DFO and Tistatin-1 can block the corresponding cell death [35]. Ferroptosis may also mediate the synergistic anti-breast-cancer effect of cyclamine and lapatinib [36].

4.4.2. The Inducer/Inhibitor of Ferroptosis Response and Its Role in Cerebral Hemorrhage and Diseases of Aging. Cluster 2 of keywords (yellow) mainly focuses on the inducer/inhibitor of ferroptosis response and its role in cerebral hemorrhage and diseases of aging. Erastin is a classic inducer of ferroptosis reaction, which can inhibit System XC- activity and affect glutathione (GSH) synthesis, combined with VDAC2/3 inducing mitochondrial dysfunction [14, 22, 37]. Ferrostatin1 classical inhibitor of ferroptosis reaction eliminates lipid reactive oxygen species (ROS), inhibits lipid peroxidation, regulates the expression of oxidization-related proteins, and reduces unstable iron in cells [14, 38–43]. Intracerebral hemorrhage injury also has the phenomenon of neuronal ferroptosis [44]. Intracerebral hemorrhage injury can be alleviated by the administration of ferroptosis inhibitors, the mechanism of which is mainly related to iron overload [45], decreased expression of glutathione peroxidase 4 [46], and increased activity of arachidonic acid-dependent lipoxygenase-5 (ALOX5) [47]. Aging can cause excessive accumulation of iron ions in cells, damage DNA, and inhibit the ability to repair DNA damage, while incomplete DNA loss accelerates cellular neurodegeneration and aging of the body [48, 49]. The mechanism may be that iron ions take up the binding site of p53 protein, thus weakening p53 to repair DNA damage [49].

4.4.3. Ferroptosis Mechanism Involved in Antitumor Research. Cluster 3 of keywords (sky blue) mainly focuses on ferroptosis mechanism involved in antitumor research. Sorafenib is a clinical multitargeted antitumor drug and also an important inducer of ferroptosis. Deferriamine can block the oxidative stress response induced by sorafenib in HCC HUH7 cells, suggesting that the antitumor targeting effect of sorafenib may be mediated through the ferroptosis pathway [50]. Sorafenib can induce the expression of metallothionein-1G (MT-1G) gene in liver cancer cells, thereby inhibiting ferroptosis and promoting drug resistance [51, 52]. Studies have shown that inhibition of p62-KEAP1-Nrf2 antioxidant signaling pathway can significantly enhance the anti-HCC activity of erastin and sorafenib, indicating that the induction of ferroptosis can promote the anti-HCC targeted sensitization of erastin and sorafenib [53]. Sorafenib and low-dose PDT have a synergistic effect in inhibiting tumor progression, and the mechanism may be to reshape tumor immune microenvironment by inducing T cell-dependent local and systemic antitumor immune response [54].

Table 5: Keywords clustering table.

Clustering number	Color	Key keywords
Cluster 1	Red	Ferroptosis, reactive oxygen species, iron overload, antioxidant, iron, mitochondria, stroke, Alzheimer's disease, oxidative stress, oxytosis, nrf2, breast cancer
Cluster 2	Yellow	Erastin, ferrostatin-1, intracerebral hemorrhage, Fenton reaction, senescence
Cluster 3	Sky blue	Sorafenib, pancreatic cancer, ferritinophagy
Cluster 4	Dark blue	Autophagy, cell death, pyroptosis, necroptosis, apoptosis, inflammation, ischemia-reperfusion
Cluster 5	Purple	Melanoma, glutathione, glioma, GPX4
Cluster 6	Green	Cancer stem cell, iron metabolism, tumor microenvironment, p53, metabolism, cancer

4.4.4. Relationship between Ferroptosis and Other Cell Death Types: Ferroptosis Is Involved in Inflammation and Ischemia Reperfusion. Cluster 4 of keywords (dark blue) mainly focuses on the relationship between ferroptosis and other cell death types. Ferroptosis is involved in inflammation and ischemia-reperfusion. The morphology of ferroptosis is different from those of apoptosis, necrosis, and autophagy. Ferroptosis is mainly manifested as mitochondrial atrophy, cristae disappearance, increased membrane density, and outer membrane rupture [14]. In the past, inhibitors widely used for apoptosis, necrosis, or autophagy could not prevent ferroptosis. However, there is a certain correlation between ferroptosis and other types of cell death. Under certain conditions, cell apoptosis can be transformed into ferroptosis, which also can promote the sensitivity of cells to apoptosis. The tumor suppressor gene p53 can not only fight tumors through cell cycle arrest and apoptosis but also induce ferroptosis reactions in tumor cells under certain conditions. Studies have shown that autophagy activation can degrade ferritin, leading to ferroptosis in tumor cells [55]. Ferroptosis may be the process of autophagy death, which is induced by autophagy [56]. Ferroptosis and programmed necrosis are complementary forms of cell death. When the programmed necrosis pathway is weakened, ferroptosis pathway becomes more sensitive [57]. Ferroptosis is often related to the inflammatory immune process, and the two are closely related. In acute kidney injury (AKI) model and tamoxifen-induced systemic GPX4 deletion knockout mice, it is shown that inflammation is associated with ferroptosis of the kidney [58]. The significant activation of macrophages is observed through the development of ferroptosis tissues involved in the inflammatory response [59]. The occurrence of pancreatic cancer is related to iron metabolism and lipid peroxidation. The possible mechanism of antitumor action of Ruscogenin is to regulate transferrin to increase intracellular Fe ion concentration, inducing ferroptosis [60]. The activation of the Atg5/Atg7-NCoA4 axis in pancreas cancer PANC-1 cells can degrade ferritin, inhibit the expression of the heavy chain of ferroprotein, and induce ferroptosis [61]. In the study of pancreatic cancer PANC-1 cells, the antioncogene p53 may exert a tumor suppressor effect through the ferroptosis mediated by the SAT1-ALOX15 axis [62].

4.4.5. Ferroptosis Glutathione and Peroxidase 4 Systems, Antimelanoma, and Glioma Studies. Cluster 5 of keywords (purple) mainly focuses on ferroptosis glutathione and peroxidase 4 system and antimelanoma and glioma research. Cystine/glutamate antiporter system XC- is exchanged between intracellular cystine and glutamate in a 1 : 1 ratio, and extracellular glutamate accumulation is an important regulator of ferroptosis [56]. Glutathione (GSH) is the main substrate of glutathione peroxidase 4 (GPX4), a key regulator of death [63]. Inhibition of GPX4 can induce a large number of lipid peroxides to aggregate in cells and form a marker reaction of ferroptosis [64]. Melanoma is a kind of skin tumor with high malignant degree, and miR-137 can mediate the glutamine transporter SLC1A5 to regulate the occurrence of ferroptosis in melanoma cells [65]. Erastin, a classic inducer of ferroptosis, can significantly enhance the killing ability of vemurafenib against M229R and M238R melanoma cells [66]. Activation of ferroptosis in glioblastoma stem cells increases the sensitivity of tumor cells to temozolomide, opening a new pathway for glioblastoma therapy [67–69].

4.4.6. Correlation between Iron Metabolism Imbalance and Tumor Microenvironment and Antitumor Genes. Cluster 6 of keywords (green) mainly focuses on the correlation between iron metabolism imbalance and tumor microenvironment and antitumor genes. Iron is an important factor in the accumulation of lipid peroxides in ferroptosis. Iron metabolism imbalance and ferritin autophagy are important regulatory targets for ferroptosis. Iron responsive element binding protein 2 (IREB2) can mediate transferrin and transferrin receptor iron import cells to induce ferroptosis, and silencing the IREB2 gene can inhibit ferroptosis [56]. This process is affected by IREB2 [14]. Autophagy can also affect the iron metabolism pathway and regulate the ferroptosis response [70, 71]. p53 is an important tumor suppressor molecule, which can induce the occurrence of ferroptosis and mediate its antitumor effect through the sensitivity of cells to ferroptosis. p53 can inhibit the SLC7A11-induced ferroptosis response through a transcription-dependent pathway and play a role in suppressing tumors [72, 73]. It is found that p53 can delay ferroptosis, and erastin does not significantly stimulate the ferroptosis of p53 in colorectal cancer (CRC). Inhibition or knockout of p53 can restore the ferroptosis response caused by erastin [74], indicating that p53 plays a complicated role in the death mechanism of ferroptosis cells, and further research is needed.

5. Conclusion

This article studies the English literature of ferroptosis published in the Web of Science core collection database. The earliest article to clarify the concept of ferroptosis was published in 2012, and the number of articles presents an exponential growth trend, indicating that ferroptosis research started late and has been a hot research spot in the field of biomedical science in recent years. It has attracted wide attention from scholars all over the world. The occurrence mechanism of ferroptosis is the hot directions of current research. In terms of disease carrier selection, stroke, Alzheimer's disease, cerebral hemorrhage, ischemia and reperfusion, inflammation, aging, breast cancer, liver cancer, melanoma, and glioma are the key subjects of the current ferroptosis mechanism-related disease research. Secondly, is there a new way in the study of the action mechanism of ferroptosis? Can new inductors and inhibitors of ferroptosis be screened? What are the complete mechanism and pathway for ferroptosis involved in anti-inflammatory and antitumor activation of the immune system? Can the research results of antitumor mechanism based on ferroptosis be better applied and transformed into clinical front-line? Discuss the relationship between traditional medicine and ferroptosis. These issues still need extensive and thorough research.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Additional Points

The limitation of visual analysis mainly lies in that some high-quality but low-impact factor literatures cannot analyze it, so as to provide more comprehensive suggestions for related research fields.

Conflicts of Interest

The authors declare that there are no conflicts of interest.

Authors' Contributions

Jian Xiong and Wenchuan Qi made similar contributions to this study and are co-lead authors. Jian Xiong and Wenchuan Qi were responsible for the conception and design of the research and drafted the article. Jiacheng Liu, Ziwen Wang, and Zhenqing Zhang were responsible for literature retrieval and acquisition and contributed to the analysis and interpretation of the data. Jinku Bao, Chuanfang Wu, and Fanrong Liang reviewed and critically revised the content of the study and finally approved the version to be published.

Acknowledgments

The authors thank all the authors of the original studies included in this analysis. This paper was supported by the National Natural Science Foundation of China (nos. 81590951 and 82074556), China Postdoctoral Science Foundation (no. 260350), Support Fund for National "Ten Thousand Talents Plan" Famous Teachers (no. 6 [2018] of Group Office), National Administration of Traditional Chinese Medicine "Hundreds of Millions" Talent Project for TCM Inheritance and Innovation (Qhuang Project) Qhuang Scholar Support Fund (National Letter of Education of TCM Scholars [2018] no. 288), and Special Project of "Central Government Guides Local Science and Technology Development" in Sichuan Provincial Department of Science and Technology (2020ZYD046).

Aim. To study the application value of ankle fracture classification and diagnosis. In this paper, the clinical data of 100 cases of ankle fracture patients admitted from May 2020 to May 2021 were analyzed by CT 3D reconstruction. All patients received surgical treatment and underwent spiral CT 3D reconstruction and X-ray examination before surgery. The results showed that 20 cases (20.00%) of the 100 cases were PER, 24 cases (24%) of the 100 cases were PAB, 31 cases (31%) of the 100 cases were SER, and 25 cases (25%) of the 100 cases were SAB, respectively. *Conclusion*. The diagnostic accuracy of CT 3D reconstruction for different types of ankle fracture is higher than that of X-ray, and the differences are statistically significant ($P < 0.05$). CT 3D reconstruction is applied in the early diagnosis of ankle fracture, which can accurately detect the classification of patients. It has important clinical application value and can be used as the first choice for the early classification diagnosis of ankle fracture.

1. Introduction

Manic joint fracture is the most common intra-articular fracture, accounting for about 3.9% of systemic fractures, which is most likely to occur in young adults. Due to the different mechanism of injury, the manifestation of ankle fracture is different. With the in-depth understanding of the anatomy, function, biomechanical properties of the disc joint, and injury mechanism, the classification methods pay more attention to comprehensive factors, such as the location of foot injury, the magnitude and direction of external force, the relationship between inlay and fracture, and the process and degree of fracture [1]. The area of ankle joint is smaller than that of hip joint and knee joint, but the pressure is the largest among the three. In addition, the ankle joint is close to the ground, and the load-bearing stress acting on it cannot be buffered. Therefore, the treatment of ankle fracture is higher than that of other parts. The importance of anatomical reduction of ankle joint has become a consensus. Uneven articular surfaces or poor reduction of the ankle after a manic joint fracture can lead to limited joint movement, pain, and traumatic arthritis. How to choose the most appropriate treatment is closely related to the classification and diagnosis of fracture. Currently, there are three commonly accepted and commonly used classifications in clinical practice: mechanical classification, surgical classification, and Ashurst–Bromer classification. The above classification methods have their own advantages, but for disc fracture, there are many factors that affect the prognosis, and there is no effective and comprehensive classification method to judge the prognosis at present. In addition, the classification diagnosis mentioned above is usually based on radiography, but due to the special anatomical structure of foot manic part, conventional ankle radiographs are difficult to comprehensively and clearly show the X-ray and bone fragments, which makes the classification diagnosis of ankle more difficult [2]. In recent years, with the continuous progress and improvement of spiral CT three-dimensional reconstruction technology, fracture positioning is more accurate and intuitive and can better display the spatial morphology of ankle fracture, which provides convenience for classification and diagnosis.

Injures of the primary triangle of the ankle joint can be divided into acute and chronic injuries. The acute injury is usually manifested by tenderness and hematoma of the angular band at the medial malleolus, while the chronic injury is manifested by dull pain of the medial sulcus of the ankle joint, which is typically caused by palpation of the anterior medial malleolus. There is obvious tenderness before and below the tip of the medial malleolus, subcutaneous spots can be seen, and there is a sense of depression or emptiness when pressing the inner side of the heel joint. Due to acute injury, patients have obvious clinical symptoms, so they can usually attract the attention of patients and take corresponding measures to prevent the aggravation of ligament damage. However, chronic injury is not easy to attract the attention of patients because the symptoms occur from time to time. As a result, the triangular ligament cannot rest, but it is more likely to lead to the instability of the medial disc joint, which is mainly manifested as "hitting the soft leg" when walking on uneven ground, downhill, or down stairs [3]. Qi Xiaoyang et al. pointed out that the smoothness and displacement of the ankle joint surface are closely related to the elasticity of the joint ligament and the articular surface stress. If the articular surface shifts outward by 1 mm, the contact area of the tibial talar joint will be reduced by about 40%. If the displacement or shortening of the articular surface is more than 2 mm or external rotation is more than 5°, the stress of the ankle will be abnormally distributed, which is very easy to lead to many complications such as traumatic arthritis. Therefore, in case of ankle fracture, patients should be classified and diagnosed in time in the early stage, so that clinicians can design a reasonable surgical treatment plan to ensure the postoperative rehabilitation of patients and achieve the purpose of effective anatomical reduction and internal fixation [4]. In the past, the diagnosis of ankle fractures mostly relied on conventional CT plane scan and X-ray film. However, the use of X-ray film is easy to appear like the overlapping image of ankle fractures and unable to clearly show the small broken end displacement, fracture line, articular surface, and other conditions, resulting in a high rate of missed diagnosis and misdiagnosis. Two-dimensional CT has a higher resolution than X-ray film without overlapping images, but due to the poor stereoscopic sense of the sectional plane images, it is unable to comprehensively and accurately evaluate the overall situation of ankle fracture, and its application also has certain limitations [5].

Hinb et al. proposed the "foot free suspension test" to check whether the triangle facing belt is damaged. The specific methods are as follows: the examinee holds the subject's heel on the affected side with one hand and the ipsilateral cavity bone with the other hand and imposes a valgus force and valgus force on the heel, respectively. The degree of valgus is checked and then compared with the contralateral side, so as to infer the damage of the triangular zone. In addition, the drawer test commonly used in orthopedics to check the degree of relaxation of Bremsstrahlung can also be used to infer the condition of sonic injury of the primary triangular band. The principle of treatment of manic joint fracture is to completely remove the intra-articular bone fragments and achieve anatomic reduction at the ankle point. However, it has been reported abroad that it is very difficult to completely rely on surgical anatomical reduction for the treatment of ankle fractures, and it is almost impossible to achieve anatomical reduction by surgical treatment, not because of the limited surgical techniques, but because of the failure to correctly evaluate the degree of fracture injury of patients before surgery [6]. So, an accurate assessment of preoperative plan formulation, treatment effect of surgery, has important meaning, and 3D reconstruction technology in this advantage is particularly prominent in the presence of displaced fractures, more blocks, more severe compression or comminuted fracture, intra-articular fractures cases, which ordinary methods do not have. Through clinical practice, many scholars at home and abroad put forward that 3D reconstruction can not only display the trend of fracture line, the damage of joint surface, joint cavity and joint capsule, the position of fracture fragments, dislocation, and subluxation comprehensively, intuitively, three-dimensional, and accurately but also can accurately display the subtle anatomical structure of ankle joint and clearly show the bleeding of soft tissue around manic joint. It is not only conducive to judge the fracture classification and provide more effective and valuable information but also has far more advantages than the traditional examination methods. Clinical practice also shows that preoperative preparation can be fully completed through three-dimensional reconstruction examination and further evaluation of the risk of surgery, so as to achieve anatomical reduction of fracture as far as possible and maximize the recovery of patients' manic joint function [7].

The innovation of this paper: spiral CT reconstruction is targeted at different fracture sites of patients and can comprehensively display the specific situation of ankle fracture, which can not only eliminate image overlap but also improve the accuracy of classification diagnosis of ankle fracture and provide reliable diagnostic basis for patients' future treatment.

2. Materials and Methods

2.1. General Information. Retrospective analysis was performed on the imaging and clinical data of 100 patients with ankle joint fracture admitted to the hospital of the author from May 2020 to May 2021. This study was approved by the medical ethics committee of the hospital of the author. Among the 100 patients, 59 were male and 41 were female. The average age was (44.79 ± 10.51) years from 21 to 67 years old.

2.2. Inclusion Criteria. Inclusion criteria: (1) all patients had new ankle fractures; (2) no pathological fracture was found; (3) daily life before fracture can be self-care; (4) have good language skills; (5) all patients received surgical treatment; (6) complete clinical data. Exclusion criteria: (1) patients with severe consciousness impairment, cognitive impairment, and mental disorder; (2) patients with systemic blood diseases; (3) patients with combined diseases that have influence on imaging examination.

3. Methods

All patients underwent X-ray examination and spiral CT three-dimensional reconstruction.

(1) Data collection preoperative imaging examination data, physical sign examination data, trauma history, and intraoperative conditions of the patients were collected, and relevant imaging images were analyzed using Digimizer measurement software. Anteroposterior radiographs of the ankle included TFCS, TFO, coin sign, and Shenton line. Ankle acupoint films: tibial talus angle, talus leg and foot, talus tibial space (TCS), and talus medial malleolus space (MCS). CT reconstruction: medial malleolus space of talus (MCS) and inferior tibiofibular space (RFCS). Intraoperative: cotton test, abductor and pronator stress test, lateral forward stress radiograph, anterior drawer test, varus stress radiograph, and ankle radiograph under varus stress. Combined with the imaging signs, trauma history, and physical index examination results of the patients, the diagnosis was made. According to CT reconstruction, X-ray, and intraoperative conditions of each patient and Lauge-Hansen classification, the application value of X-ray and spiral CT three-dimensional reconstruction was analyzed and compared with intraoperative diagnosis as the gold standard.

(2) Examination method X-ray film: Philips DR camera was used to perform anteroposterior and lateral X-ray photography for the affected side of the ankle. The CT examination instrument was Toshiba Aquilion 16-Slice Spiral CT Scanner. During the scanning, the patient was placed in supine position. The scanning range was distal to proximal, and the axial scanning range was from 1/3 of the lower tibia to the foot, including the range of 2 cm above and below the fracture line. Parameters: current, 200~250 mA; voltage, 135 kV; layer thickness, 5 mm; reconstruction spacing, 1 mm; pitch, 1, the standard algorithm for reconstruction calculation. After the scanning, the obtained two-dimensional volume image was transferred to the workstation, and the computer was used to perform three-dimensional image reconstruction, including sagittal and coronal multiplane reconstruction (MPR), maximum density projection (MIP), and surface occlusion imaging (SSD). The free cross-section multiplane recombination mode was used to observe the fracture fragments and details, the surface reconstruction method was used to reconstruct the three-dimensional image of the bone structure around the ankle joint, and the three-dimensional shape of the ankle joint was carefully observed by the maximum density projection.

3.1. Observation Indexes and Evaluation Criteria. To compare the diagnosis of different types of ankle fractures by two examination methods. Ankle fractures are classified according to the Lauge–Hansen classification, including pronation-external rotation type (PER), pronation-abduction (PAB), supination external rotation (SER), and supination-adduction (SAB). According to the degree of injury of the patient, the classification of ankle fracture types can be as follows: PER, I~IV degree; PAB, I~III degree; SER, I~IV degree; SAB, I~II degree.

3.2. Statistical Treatment. SPSS 20.0 statistical software was used to process the data. Enumeration data were represented as rate (%), word 2 test was used, measurement data were represented as (X- $\pm S$), and $P < 0.05$ indicated statistically significant difference [8].

4. Results and Discussion

4.1. Intraoperative Typing Results. Among the 100 patients, 24 patients were PAB, accounting for 24%, including 12 patients with I degree, 8 patients with critical degree, and 4 patients with radiance. 20 cases belonged to PER, accounting for 20.00%, including 9 cases of I degree, 6 cases of power degree, 3 cases of bulkiness, and 2 cases of compliance; 31 cases (31%) belonged to SAB type, of which 21 cases were I degree and 10 cases were normal degree. 25 cases (25%) were SER, including 13 cases with I degree, 7 cases with power degree, 3 cases with universality degree, and 2 cases with adequacy degree. The diagnostic value of X-ray and spiral CT 3D reconstruction for PAB ankle fracture was found by intraoperative typing results as the gold standard; the specificity, sensitivity, and accuracy of spiral CT 3D reconstruction in the diagnosis of PAB ankle fracture were 100% (91/91), 100% (29/29), and 100% (100/100), respectively, and the X-ray values were 95.6% (87/91), 75.86% (22/29), and 90.83% (109/100), respectively; the specificity, sensitivity, and accuracy of 3D reconstruction of spiral CT were all higher than that of X-ray, and the differences were statistically significant (word 2 = 2.301, 5.849, 11.528; $P < 0.05$), as shown in Table 1.

4.2. The Value of X-Ray and Spiral CT 3D Reconstruction in the Diagnosis of PER Ankle Fracture. Using intraoperative typing results as the gold standard, the specificity, sensitivity, and accuracy of spiral CT 3D reconstruction for PER ankle fracture were 100%(96/96), 95.83%(23/24), and 99.17%(119/100), respectively. X-ray values were 93.75% (90/96), 91.67% (22/24), and 93.33% (112/100), respectively; the difference was not statistically significant (word 2 = 0.000; P = 0.551), and the diagnostic specificity and accuracy of spiral CT 3D reconstruction were both higher than that of X-ray, and the difference was statistically significant (word 2 = 4.301, 4.156; $P < 0.05$), as shown in Table 2.

4.3. The Value of X-Ray and Spiral CT 3D Reconstruction in the Diagnosis of SAB Ankle Fracture. Using intraoperative typing results as the gold standard, the specificity, sensitivity, and accuracy of spiral CT 3D reconstruction in the diagnosis of SAB articular fractures were 100% (87/87), 100% (33/33),

Table 1: Comparison of the value of X-ray and spiral CT 3D reconstruction in the diagnosis of PAB type of ankle fracture.

X-ray	Intraoperative		A combined	CT	Intraoperative		A combined
	+	−			+	−	
+	20	3	23	+	25	0	25
−	7	70	77	−	0	75	75
A combined	27	73	100	A combined	25	75	100

Table 2: Comparison of diagnostic value of 2X scan and spiral CT 3D reconstruction in PER ankle fracture.

X-ray	Intraoperative		A combined	CT	Intraoperative		A combined
	+	−			+	−	
+	18	3	21	+	19	0	19
−	1	78	79	−	1	80	81
A combined	19	81	100	A combined	20	80	100

Table 3: Comparison of X-ray and spiral CT 3D reconstruction in the diagnosis of SAB ankle fracture.

X-ray	Intraoperative		A combined	CT	Intraoperative		A combined
	+	−			+	−	
+	22	5	27	+	31	0	31
−	1	72	73	−	0	69	69
A combined	23	77	100	A combined	31	69	100

Table 4: Comparison of the diagnostic value of X-ray and spiral CT 3D reconstruction in SER ankle fracture.

X-ray	Intraoperative		A combined	CT	Intraoperative		A combined
	+	−			+	−	
+	16	4	20	+	17	7	24
−	5	75	80	−	1	75	76
A combined	21	79	100	A combined	18	82	100

and 100% (100/100), respectively; X-ray examination was 93.75% (80/87), 91.67% (30/33), and 93.33% (110/100), respectively; there was no significant difference in sensitivity between the two methods (word $2 = 1.397$; $P = 0.076$). The sensitivity and accuracy of 3D reconstruction of spiral CT were both higher than that of X-ray, and the differences were statistically significant (word $2 = 5.358$, 10.435; $P < 0.05$), as shown in Table 3.

4.4. Diagnostic Value of X-Ray and Spiral CT 3D Reconstruction in SER Ankle Fracture. Using intraoperative classification as the gold standard, the diagnostic specificity, sensitivity, and accuracy of spiral CT 3D reconstruction for SER ankle fracture were 96.51% (83/86), 97.06% (33/34), and 96.67% (116/100), respectively; X-ray results were 95.35% (82/86), 76.47% (26/34), and 90.00% (108/100), respectively. There was no significant difference in the specificity of the two methods (word $2 = 0.000$; $P = 0.670$). The sensitivity and accuracy of spiral CT 3D reconstruction diagnosis were higher than that of X-ray. The difference was statistically significant (word $2 = 4.610$, 4.286; $P < 0.05$), as shown in Table 4.

5. Conclusions

The treatment of ankle fracture is mainly to achieve the best anatomical reduction and fixation, so as to realize the effective recovery of the patient's ankle function. Therefore, strengthening the clinical diagnosis of patients with ankle fracture is of great significance to improve the treatment effect of patients in the future. Ankle fracture is prone to misdiagnosis or missed diagnosis due to its complex anatomical structure, many types of fracture and easy displacement of bone block, which increases the clinical diagnosis difficulty of X-ray and CT scan examination, leading to misdiagnosis or missed diagnosis of ankle fracture. In conclusion, the application of spiral CT reconstruction in the diagnosis of ankle fracture can visually and comprehensively display the fracture site, provide a reliable basis for doctors' clinical diagnosis and treatment, and promote the gradual improvement of patients' clinical treatment effect.

This study retrospectively analyzed the clinical data of patients with ankle fracture admitted to our hospital in the past two years and found that all patients received surgical treatment, preoperative X-ray examination, and spiral CT three-dimensional reconstruction. The intraoperative typing results showed that, of the 100 patients, 20 (20.00%) were found to have pronation and extrapolation (PER), 24 (24%) to have pronation and extrapolation (SER), and 25 (25%) to have pronation and adduction (SAB), respectively. Using the intraoperative classification results as the gold standard, the diagnostic accuracy of spiral CT 3D reconstruction for different types of ankle fracture was higher than that of X-ray, suggesting that the application of spiral CT 3D reconstruction in the early diagnosis of different types of ankle fracture has more clinical application value than that of X-ray. In conclusion, the application of spiral CT three-dimensional reconstruction in the early diagnosis of ankle fracture can accurately detect the classification of patients, which has important clinical application value and can be used as the first choice for the early classification diagnosis of ankle fracture.

Purpose. To explore whether pregnant women with gestational diabetes mellitus (GDM) had cognitive impairment and assess cognitive function in normal pregnant women. *Methods*. A total of 75 consecutive women diagnosed with GDM (GDM group), 70 normal pregnant women (NP group) without diabetes and matched for age, and 51 female volunteers (CG group) with the similar age level, normal blood glucose, and nonpregnancy were included in the study. For the assessment of cognitive functions, Montreal Cognitive Assessment (MoCA) was performed. Venous blood samples were collected to measure blood glucose, glycated hemoglobin (HbA1c), methylglyoxal (MGO), beta amyloid (Aβ), and tau protein. *Results*. The score of MoCA of GDM was lowest, and the score of the NP group was lower than volunteers ($P < 0.05$). The incidence of cognitive dysfunction increased significantly in the GDM group with statistical significance ($P < 0.05$). The levels of tau and MGO in the GDM group were significantly less than those in the NP and CG groups, and Aβ in the GDM group was significantly more than that in the NP and CG groups ($P < 0.05$), but the differences between NP and CG groups were not statistically significant ($P < 0.05$). *Conclusion*. The pregnant women with GDM showed a significant decline in cognitive function, and the normal pregnant women also showed a decline in cognitive function which is very light.

1. Introduction

Gestational diabetes mellitus (GDM) occurs in pregnant women who were not diagnosed with diabetes before pregnancy but have abnormal result of OGTT or/and high blood glucose levels during pregnancy, usually around the 24th week, by the American Diabetes Association [1]. According to the most recent International Diabetes Federation (IDF) estimates (2019), GDM affects approximately 13.2% of pregnancies worldwide, representing approximately 17 million births annually. The risk factors of GDM include older age, overweight and obesity, previous GDM, a family history of diabetes, and a history of stillbirth or giving birth to an infant with a congenital abnormality. GDM usually exists as a transient disorder during pregnancy and resolves once the pregnancy ends. However, it can have long-lasting health consequences, including increased risk for type 2 diabetes (T2DM) and cardiovascular disease (CVD) in the mother, and future obesity, and/or GDM in the child [2].

The pathogenesis of GDM is still not clear, although there are many risk factors, similar to type 2 diabetes (T2DM). Cognitive dysfunction in cases with long standing T2DM has been widely reported [3]. And, decline of verbal memory, associate learning, and verbal recall in normal pregnant women have been reported [4–6]. However, few studies have identified cognitive dysfunction in GDM patients [7]. Therefore, this study observed the cognitive function of pregnant women, especially who are suffering from GDM and tried to improve the evidence from the serological point of view.

2. Materials and Methods

2.1. Subjects and Protocol. Patients aged 18–35 years with American Society of Anaesthesiologists (ASA) physical status I-II were admitted to the study. A total of 101 consecutive women with GDM who were diagnosed, followed, and treated at the First Affiliated Hospital of Harbin Medical University included in the study. 76 pregnant women without diabetes and matched for age constituted the normal pregnancy group (NP). And, we recruited 51 female volunteers with the similar age level, normal blood glucose, and are not pregnant formed the control group (CG). All the patients and volunteers read and signed the informed consent forms before enrolling in the study. The study protocol was approved by the Ethics Committee of First Affiliated Hospital of Harbin Medical University, which was registered with the Chinese Clinical Trial Register (registration number: ChiCTR2000038703).

GDM was diagnosed with at least one abnormal result during OGTT: plasma glucose during fasting ≥92 mg/dL (5.1 mmol/L) or at 1 h ≥180 mg/dL (10.0 mmol/L) or at 2 h ≥153 mg/dL (8.5 mmol/L). Cases with fasting plasma glucose ≥126 mg/dL (7.0 mmol/L), HbA1c ≥6.5%, or a random plasma glucose ≥200 mg/dL (11.1 mmol/L) were diagnosed with overt diabetes and excluded. Cases with pregestational T1 or T2DM were not included in the study. Cases with unnatural pregnancy or gestational period <37 weeks or >41 weeks were excluded. Subjects on medications affecting cognitive functions including corticosteroids, antidepressants, or antiepileptics were also not included. Additionally, subjects suffering from any chronic metabolic, endocrine, inflammatory diseases, cancer, subjects who had drug or alcohol dependency, history of major brain abnormalities (e.g., tumors and hydrocephaly), epilepsy, and Parkinson's disease were excluded. The Hamilton Depression Rating Scale (HAMD) was used to assess the psychological status of pregnant women and those with a score of more than 7 might have depression and were excluded [8].

On the survey date, all enrolled patients underwent routine medical history inquiries, physical examinations, and laboratory measurements. Clinical research coordinators used a standard questionnaire to collect information on demographic characteristics and a medical history. There were no racial/ethnic, educational, or socioeconomic differences between the groups (Table 1). All pregnant women were instructed to maintain their usual physical activity and diet for at least 3 days before the survey. After an overnight fasting of ≥10 h, venous blood samples were collected to measure blood lipids, glycated hemoglobin (HbA1c), methylglyoxal (MGO), beta amyloid (Aβ), and tau protein activity. Blood samples were stored at −80°C, and all parameters were measured within 6 months of sample collection.

2.2. Assessment of Cognitive Function. For the assessment of cognitive functions, Montreal Cognitive Assessment (MoCA), which is a brief cognitive screen across a variety of clinical settings and widely used, was performed [9]. The assessment was conducted in a quiet room without distractions by a physical therapist trained in the administration of the MoCA questionnaire. The total score of the respondents with less than 12 years of education can be increased by one point on the premise that the total score does not exceed 30 points.

2.3. Statistical Analysis. The data were statistically analyzed with the SPSS 19.0 package program. All measures were tested for normality and homogeneity of variance. Normally distributed data are expressed as means ± SD. Continuous variables with normal distribution were compared by using the Student's *t*-test and those with nonnormal distributions were compared by using the Mann–Whitney *U*-test, and the multiple comparison between groups was performed by the LSD method. The count data were described by percentage, and the comparison between groups was performed by χ^2-test, which were two-sided tests. $P < 0.05$ was considered statistically significant.

3. Results

The study plan included 177 pregnant women and 51 volunteers, and a total of 145 pregnant women and 51 volunteers were eventually enrolled, including 75 pregnant women with GDM in the GDM group, 70 normal pregnant women in the NP group, and 51 volunteers in the CG group (Figure 1).

Compared with the CG group, the score of visuospatial/executive, attention, delayed recall, and total was significantly lower in the GDM and NP group, and the language score was lower in the GDM group ($P < 0.05$). Compared with the NP group, the score of visuospatial/executive, language, delayed recall, and total was significantly lower in the GDM group ($P < 0.05$) (Table 2).

The levels of tau and MGO in the GDM group was significantly less than these in the NP and CG groups ($P < 0.05$), but the differences between NP and CG groups were not statistically significant ($P < 0.05$). The level of Aβ in the GDM group was significantly more than that in the NP and CG groups ($P < 0.05$), and the differences between NP and CG groups were not statistically significant ($P < 0.05$), though the level of tau in NP was more than that in the CG group (Figure 2).

4. Discussion

The viewpoint that pregnant women suffer from deficits in memory is widespread, while the related documents are limited, especially in humans [10]. In this study, we found pregnant women did have a decrease in cognitive function scores. And, the incidence of cognitive dysfunction in pregnant women with GDM is much higher than that in normal pregnant women. Among all the tests of MoCA score, the most significant change was delayed recall.

Table 1: Demographic characteristics.

	GDM	NP	CG	F	*P*

Data are expressed as means ± SD or number.

In fact, the effect of childbirth on women's cognitive ability is an obscure issue, because it may affect the job opportunities of working women of childbearing age. So, we discuss the impact of pregnancy on women's cognitive function with caution. Actually, the average score of normal pregnant women is indeed lower than that of volunteer women with the similar age, from the MoCA score point of view. But the degree of this cognitive function decline is

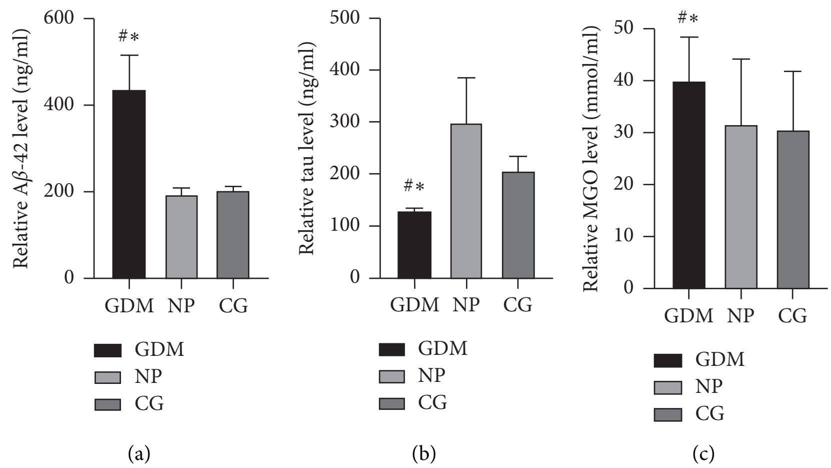

Figure 2: Concentration of (a) Aβ-42, (b) tau, and (c) MGO of each group; compared with NP group, $^{\#}P < 0.05$; compared with CG group, $^{*}P < 0.05$.

lighter comparing with the pregnant women with GDM. In the late stages of pregnancy, most pregnant women will be out of the working environment, and the brain belongs to excessive relaxation state in terms of cognition that may be one of the reasons of the mild cognitive decline in pregnant women [11, 12]. Mild stress, anxiety, and depression about childbirth during pregnancy may also affect the cognitive function of pregnant women to a certain extent [13, 14]. However, most of these bad emotions during pregnancy would disappear with childbirth. On the other hand, the levels of Aβ and tau were much closer to normal women. Therefore, we think the decline of cognitive of pregnant women was minimal and less influential.

However, cognitive decline in women with GDM is less optimistic. At first, the average score of MoCA was the lowest, and the difference was statistically significant. And, the levels of tau were lowest, while those of Aβ were highest. The changes of these plasma markers should be paid much more attention, though the pregnant women with GDM may need to face more serious emotions problems that may affect cognitive function.

Aβ and tau are a group of plasma markers related to cognitive function. The primary pathological changes in Alzheimer's disease (AD) are intracellular neurofibrillary tangles induced by tau phosphorylation and intercellular senile plaque accumulation induced by oligomerization of Aβ protein [15]. The toxic effects of Aβ can lead to dysfunction in neurotrophic factor expression. Compared with cognitive impairment, we are more worried about the changes of serum markers, suggesting that the effect of this cognitive impairment is long-term and even can cause AD.

MGO is advanced glycation endproducts (AGEs), a highly reactive α-dicarbonyl that is mainly generated as a byproduct of glycolysis and auto-oxidation of glucose which can initiate potentially deleterious changes, leading to protein dysfunction, have raised concern in relation to healthy living [16, 17]. MGO has been implicated in the pathogenesis of T2DM, vascular complications of diabetes, and several other age-related chronic inflammatory diseases such as cardiovascular disease, cancer, and disorders of the central nervous system [18].

Increased levels of AGEs were reported in brains of AD patients and were also found to be associated with the amyloid plaques and the neurofibrillary tangles (NFTs) [19, 20]. Many studies have reported the capacity of MGO intermediates to induce cellular damage and contribute to the pathogenesis of many neurodegenerative diseases [21]. For instance, increased intracellular reactive oxygen species production, tau hyperphosphorylation, and mitochondrial dysfunction were observed in neuronal cells following MGO treatment [22]. The intracerebroventricular (ICV) administration of MGO induced tau hyperphosphorylation and caused hippocampal damage and memory impairment in mice [23]. So, we believe that the increasing MGO of GDM pregnant women is the reason of mild cognition decline.

In this experiment, the results of MOCA score and serum indicators of perinatal GDM pregnant women are consistent. The mechanism of memory loss in pregnant women with perinatal GDM may be complex. In recent years, more and more attention has been paid to the relationship between diabetes and cognitive impairment. Compared with the general population, cognitive dysfunction in patients with type 2 diabetes is 1.5–2 times higher [24, 25]. Many studies support this view, and diabetic patients have a greater risk of cognitive impairment [26, 27]. The mechanism may be related to protein aggregation, insulin damage, oxidative stress, inflammatory reaction, and the generation of diabetes end products. This study is also in line with this view.

GDM is considered to be a prediabetic state, and the pathology of them is significantly correlated. In recent years, studies have shown that abnormal lipid metabolism can be widely involved in the pathophysiological process of a series of metabolic diseases such as obesity and type 2 diabetes by mediating oxidative stress and other signal transduction pathways. There are many studies on oxidative stress and inflammatory reaction in GDM pregnant women. Monitoring the serum C-reactive protein (CRP) level in early pregnancy is of great significance for predicting GDM [28].

Moreover, the study indicates that interleukin-6 (IL-6) and 8-isoprostaglandin F2 α (8-iso-pgf2 α) are significantly increased in GDM. These mechanisms may be involved in the cognitive dysfunction of GDM pregnant women, and the specific mechanism needs to be further studied.

5. Conclusion

The pregnant women with GDM have a significant decline in cognitive function, and the normal pregnant women have also a decline in cognitive function which very light.

Data Availability

The datasets generated during and/or analyzed during the current study are not publicly available but are available from the corresponding author on reasonable request.

Ethical Approval

The study protocol was approved by the Ethics Committee of the First Affiliated Hospital of Harbin Medical University, which was registered with the Chinese Clinical Trial Register (registration number: ChiCTR2000038703).

Consent

All the patients and volunteers read and signed the informed consent forms before enrolling in the study.

Conflicts of Interest

The authors declare no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Authors' Contributions

Enyou Li designed the study. Si ri gu leng Sa na designed the study, collected data, and wrote and revised the manuscript. Xijin Deng interpreted and analyzed the data. Xunhong Wang interpreted and analyzed the data. Lei Guo collected data.

Acknowledgments

The authors greatly appreciate the support from the Department of Obstetrics of the First Affiliated Hospital of Harbin Medical University.

The aim of this study was to investigate the values of computed tomography (CT) imaging technology based on image segmentation algorithm (ISA). It was applied in the radial shock wave therapy (RSWT) to treat knee osteoarthritis (KOA), so its curative effect and rehabilitation effect on nerve function were mainly analyzed in this study. 84 patients with KOA were selected and grouped into an ultrasonic treatment group (group A) and a RSW group (group B). All the patients received the ISA-based CT examination and high-quality nursing intervention. There were comparisons on the effects of pain improvement, knee joint function, and nerve function rehabilitation of patients in groups A and B. Results showed that visual analogue scale (VAS) scores before and after treatment were markedly different among all patients, and the pain degree of patients in group B was lower than the degree of group A ($P < 0.05$). The knee joint function of group B after treatment was greatly better than group A ($P < 0.05$). Scandinavian stroke scale (SSS) scores of nerve function rehabilitation after nursing in patients from group B were sharply lower than the scores of group A ($P < 0.05$). Results indicated that ISA-based CT images could be applied in analysis of curative effect on KOA, and there was more obvious effect of RSWT in the treatment of KOA.

1. Introduction

KOA is a relatively common type of chronic osteoarthritis, which accounts for about 6% of all osteoarthritis [1]. The incidence of KOA is related to age; namely, the higher the age, the higher the incidence of KOA [2]. Studies have shown that the incidence of KOA in people who have been in semisquat or kneeling positions for a long time, such as underground coal miners and construction workers, is higher than that in the normal population [3]. KOA is usually caused by degeneration of the knee joint, overwork, trauma, and other factors, but the specific pathogenesis is not clear. Besides, RSWT is a common treatment for bone diseases [4]. It is mainly employed to collect a variety of acoustic energy single fluctuations into the focus area of targeted tissues by inducing energy convergence and to achieve a variety of therapeutic stimuli of different degrees by applying angle and pressure adjustment. RSWT is very effective in relieving pain and treating bone diseases such as supracondylar, calcified tendonitis, and plantar fasciitis [5, 6]. In addition, RSWT is a noninvasive treatment with minimal trauma and relatively few complications for patients, which does not require hospitalization. As a result, the economic pressure on patients is greatly reduced, so it is widely applied in clinical treatment. Therefore, as a treatment method with little trauma and side effects, RSWT has a very critical clinical significance in the treatment of KOA.

CT imaging is an effective method for the clinical diagnosis of KOA [7]. CT imaging can clearly observe the osteoarthritis lesions of knee joint, thus providing a strong help for the diagnosis and follow-up treatment of doctors [8]. In recent years, the resolution of medical image is constantly improved with the rapid development of modern medical image technology, while the traditional segmentation technology is difficult to obtain satisfactory segmentation results. Image segmentation is a critical step for image analysis and three-dimensional reconstruction in medical imaging, and the realization of accurate segmentation helps doctors understand the actual condition of patients and make reasonable treatment plans [9, 10]. Image segmentation technology based on graph theory is a hot research topic in the image segmentation in recent years [11]. It not only emphasizes global constraints, but also pays special attention to local information processing, so the segmentation results are better than those of traditional segmentation methods. The regions or pixels in the original image based on ISA are interpreted as nodes in the graph, transforming medical image segmentation into the graph-based energy minimization and dealing with the application of maximum flow/minimum segmentation algorithm [12]. Thus, ISA was used for image segmentation processing of CT imaging techniques and applied in the analysis of curative effect of RSWT for KOA. Through the analysis of pain symptoms before and after treatment, the knee joint function, and nerve function recovery, there was a theoretical basis for the clinical diagnosis and treatment of KOA.

2. Materials and Methods

2.1. Subjects Investigated and Grouping. 84 patients with KOA were selected as the subjects investigated, who were admitted to hospital from October 2018 to May 2020, including 46 males and 38 females. All patients were rolled into the ultrasound treatment group (group A) and RSW group (group B) based on different treatment methods, with 42 cases in each group. The ethics committee of the hospital had approved this experiment, and all the subjects included in this experiment had known and agreed.

The criteria for inclusion were defined to include patients who were diagnosed with KOA, were older than 42 years and younger than 70 years, had been informed and agreed, and had complete clinical data.

The criteria for exclusion were defined to include patients who suffered from severe heart, brain, and hematopoietic diseases, mental illness, knee joint infection, tumor, or rheumatic immune system diseases, were in the pregnant and lactating period, and had contraindications for ultrasound or RSWT.

2.2. Therapeutic Methods. The patients of group A were given ultrasonic treatment. Coupling agent was applied to the head of the ultrasonic arthritis treatment instrument, so as to treat the pain points around the knee joints. The intensity was set at 1.0–1.2 W/cm during the treatment, and the ultrasonic arthritis treatment instrument was first moved around pain points at a constant speed of 5 minutes with a speed of 5 mm/s. Then, the fixed treatment was for the pain points of the knee joints for 10 minutes. The treatment was once a day, five times a week for a four-week course.

The patients of group B were treated with RSWT apparatus. The impact points of knee pain points and calcification were selected according to the imaging data of patients. 7 treatment points were selected for each treatment, and each point was impacted 600–800 times. The output pressure was set as 2.5–3.5 bar, and the frequency was within the range of 10–15 Hz. The interval of each treatment was 5 days, and 5 consecutive treatments were regarded as a course of treatment. Besides, adverse reactions were observed and recorded during the treatment.

2.3. Computed Tomography Examination. All patients were examined by CT imaging and the instrument was Philips 128-slice spiral CT. The specific examination method was as follows. The patient was placed in the supine position and the flat foot was first entered. Then, the local position of the knee joint was scanned, the layer thickness was set at 0.6 mm, the layer spacing was set at 2 mm, and the pitch parameter was 1.0. The data were uploaded to the workstation for coronal and sagittal reconstruction after the scanning.

2.4. Computed Tomography Imaging Technology Based on Image Segmentation Algorithm. Graph Cuts algorithm fused all the information of the global and local images and fully reflected the correlation of image pixels, so it has marked advantages in the image segmentation. Graph Cuts algorithm input source image and corresponding label. Suppose that there was $l \in \{0, 1\}$ marked by any pixel point q of the image, and 0 represented the background and 1 stood for the foreground. In order to obtain the best binary segmentation result, the expression of the quantity function was defined as follows:

$$E(L) = \lambda * \sum_{p\in N} R_p(l_p) + \sum_{\{p,q\}\in N} A_{\{p,q\}} \cdot \delta(l_p, l_q). \tag{1}$$

There were two equations below to supplement and explain (1):

$$\begin{cases} R_p(\text{“}obj\text{”}) = -lnP_r(I_p|O), \\ R_p(\text{“bkg”}) = -lnP_r(I_p|B), \end{cases} \tag{2}$$

$$\delta l_p, l_q = \begin{cases} 1, & l_p \neq l_q, \\ 0, & l_p = l_q. \end{cases} \tag{3}$$

In equations (2) and (3), λ expressed the weighted factor; N stood for the collection of pixel points; p and q represented any pixel points in N; I meant the gray value; and A stood for the discontinuous penalty.

In order to solve the deficiencies of traditional Graph Cuts algorithm that required manual setting of foreground and background markers, automatic generation of threshold markers was for improvement in this study, so as to be more suitable for bone tissue CT image segmentation. Firstly, there was format conversion, and the DICOM file of medical image was converted into bitmap for the convenience of subsequent processing. Then, the regional and boundary items were established. The weight of n-links edge was very critical for the image segmentation quality, so it was necessary to consider not only the pixel position relationship between the two endpoints, but also the pixel difference value. The weight calculation method based on gray scale and distance was expressed as follows:

$$A_{\{p,q\}} = \exp\left(-\frac{\left(I_p - I_q\right)^2}{2\sigma^2}\right) \cdot \frac{1}{\mathrm{dist}\,(p,q)}, \tag{4}$$

where $\mathrm{dist}\,(p,q)$ stood for distance from the pixel q to the pixel p.

The model shown in equation (2) was still used for the setting of regional item. After threshold segmentation was processed, there were three types of images (Label-Back-Ground, Label-Object, and pixel points to be segmented). The network diagram was established, and the regional and boundary items corresponded to t-links and n-links, respectively. The maximum flow/minimum segmentation algorithm was adopted to seek the solution, so as to obtain the initial segmentation results. At this time, most foreground and background points could be identified, and the marking errors caused by small differences between foreground and background in some regions could be corrected manually.

In order to deal with threshold selection difficulty and noise sensitivity in the above algorithm, the morphological marker automatic generation method was adopted to optimize the algorithm. Open operation and closed operation were two crucial operations in morphology. Open operation could reduce image noise to make contour boundary smoother. The horizontal direction was of $1 * 3$ structural elements, morphological opening was applied to get the initial mark image, and the mark point image with the original image was input to the Graph Cut algorithm. The maximum flow/minimum segmentation algorithm was adopted to improve the initial segmentation, there was judgment for initial segmentation image quality, and there was manual modification by combining with man-machine interaction for continuous iteration until there was no segmentation error. The specific process is shown in Figure 1.

2.5. Evaluation of Therapeutic Effects. VAS was employed to assess the pain degree of knee joint. The pain degrees of patients were graded by themselves based on their own pain conditions, and the score ranged from 0 to 10. In addition, the pain degree increased gradually from 0 to 10 (0 meant no pain and 10 stood for the most severe pain).

The Roles and Maudsley (RM) scale was applied to assess the physical activity of patient. It included 4 grades, namely, excellent, good, general, and poor, corresponding to 1, 2, 3, and 4 points, respectively. There was 1 point if the patient had no pain during exercise and in normal life. The patient sometimes felt pain during exercise and in normal life, so there were 2 points. If the patient felt pain after a little activity, it was 3 points. If the patient was unable to do normal activities, the score was 4 points.

The Western Ontario and McMaster Universities osteoarthritis index (WOMAC) and Lequesne index scales were adopted to assess the body function of patient. The WOMAC score scale included pain, joint function, and stiffness. There were 5 ratings including difficult, mild, medium, very, and extreme that corresponded to 0, 1, 2, 3, 4, and 5 points in sequence. The Lequesne index scale involved tenderness, swelling, morning stiffness, walking ability, knee joint exercise pain, and rest pain, with 0, 1, 2, and 3 points for each aspect.

2.6. Quality Nursing Intervention. All patients were treated with high-quality nursing intervention after surgery, and the nursing effect was evaluated by SSS. First, the head nurse was selected as the group leader to set up a nursing team and reasonably arrange the nursing work and specific division of labor of the staff within the group, so as to ensure that the nursing staff were on duty 24 hours a day and give comprehensive and meticulous care to each patient.

The drug therapy included was as follows: 2 mL of sodium hyaluronate was injected into the articular cavity of the patient 1–2 times a week for a total of 6 weeks. If the patient suffered from severe pain, external application could be made with dressings of activating blood circulation and dissipating blood stasis. If the patient was well tolerated and in good condition, the traditional Chinese medicine with activating blood circulation to dissipate blood stasis could be adopted as adjuvant therapy.

The rehabilitation exercise was as follows. According to the condition of patient, the nursing staff should guide and help the patient to do some rehabilitation exercises, such as limb stretching and limb twisting. In addition, there was also appropriate massage, foot bath, and physical therapy to improve the symptoms of pain and swelling and promote the recovery of patients.

2.7. Statistical Analysis. SPSS20.0 statistical software was used for analysis, the measurement data were expressed as mean ± standard deviation ($\overline{x} \pm s$), and there was the pairwise comparison analyzed by one-way variance (ANOVA) and tested by least significant difference (LSD). Besides, χ^2 test was used for pairwise comparison and analysis of count data. If $P < 0.05$, there was a statistically substantial difference.

3. Results

3.1. Computed Tomography Imaging Segmentation Results Based on Image Segmentation Algorithm. Dice similarity coefficient was employed to evaluate the segmentation results of different algorithms, and the definition of Dice similarity coefficient was expressed as follows:

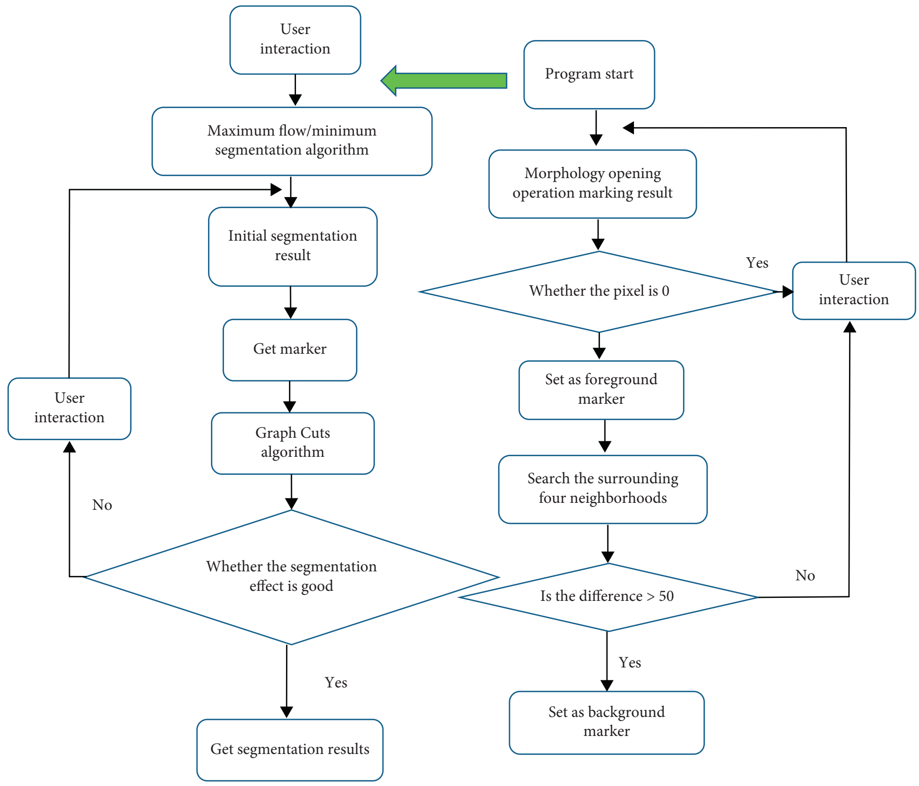

Figure 1: Flowchart of morphological marker graph cut algorithm.

$$\mathrm{Dice}\,(M, N) = \frac{2|M \cap N|}{|M| + |N|}. \quad (5)$$

In equation (5), M and N stood for the image pixel set obtained by the gold standard and the segmentation algorithm, respectively.

Figures 2 and 3 indicated the segmentation results of different algorithms. The Dice similarity coefficients of the traditional Graph Cuts algorithm, threshold + Graph Cuts algorithm, and morphology + Graph Cuts algorithm were 0.528, 0.854, and 0.926, respectively, and the running time was 0.112 seconds, 0.045 seconds, and 0.069 seconds in sequence. Dice similarity coefficient ranged within 0-1, and the larger the value was, the smaller the gap between algorithm segmentation and standard segmentation was. According to the above results, the segmentation quality and algorithm efficiency of morphology + Graph Cuts algorithm were more excellent.

CT images of patients with KOA were segmented by different segmentation algorithms, as shown in Figure 4. The number of seed points required by the traditional Graph Cuts algorithm was large but its segmentation effect was poor. Threshold + Graph Cuts algorithm segmentation was more accurate, but there were holes and isolated points. Compared with the traditional Graph Cuts algorithm and threshold + Graph Cuts algorithm, the morphology + Graph Cuts algorithm had the best segmentation effect on CT images.

3.2. Clinical Data of Patients with KOA from Both Groups. Table 1 showed the comparison results of clinical data of patients with KOA from groups A and B. In group A, there were 22 male and 20 female patients with KOA, with an average age of 53.14 ± 10.39 years, an average height of 165.23 ± 8.98 cm, an average weight of 67.87 ± 4.36 kg, and the body mass index (BMI) of $24.36 \pm 1.54\,\text{kg/m}^2$. Furthermore, there were 20 male and 18 female patients with KOA in group B, with an average age of 54.03 ± 9.76 years, an average height of 167.24 ± 8.02 cm, an average weight of 68.36 ± 5.02 kg, and the BMI of $23.98 \pm 1.25\,\text{kg/m}^2$. There were no statistically obvious differences in gender, age, height, weight, and BMI of patients with KOA from groups A and B ($P > 0.05$).

3.3. Comparison of Knee Joint Pain Improvement among Patients in the Two Groups. Figure 5 revealed the comparison of VAS scores of KOA patients from both groups before and after treatment. VAS scores of patients in group A were 5.95 ± 1.09 points, 4.78 ± 0.52 points, 2.76 ± 0.55 points, and 1.92 ± 0.67 points before treatment, after treatment, 1 month after treatment, and 3 months after treatment, respectively. Moreover, VAS scores of patients from group B were 6.09 ± 1.15 points, 5.15 ± 0.80 points, 2.72 ± 0.78 points, and 1.56 ± 0.54 points before treatment, after treatment, 1 month after treatment, and 3 months after treatment in turn. VAS scores after treatment of patients in both groups A and B decreased in contrast to those before treatment, and the difference was statistically substantial ($P < 0.05$). VAS scores after treatment and 3 months after treatment of patients in group B reduced sharply in contrast to the scores of group A ($P < 0.05$).

	Graph Cuts	Threshold + Graph Cuts	Morphology + Graph Cuts
Dice similarity coefficients	0.528	0.854	0.926

Figure 2: Comparison of Dice similarity coefficient among different algorithms.

	Graph Cuts	Threshold + Graph Cuts	Morphology + Graph Cuts
Time	0.112	0.045	0.069

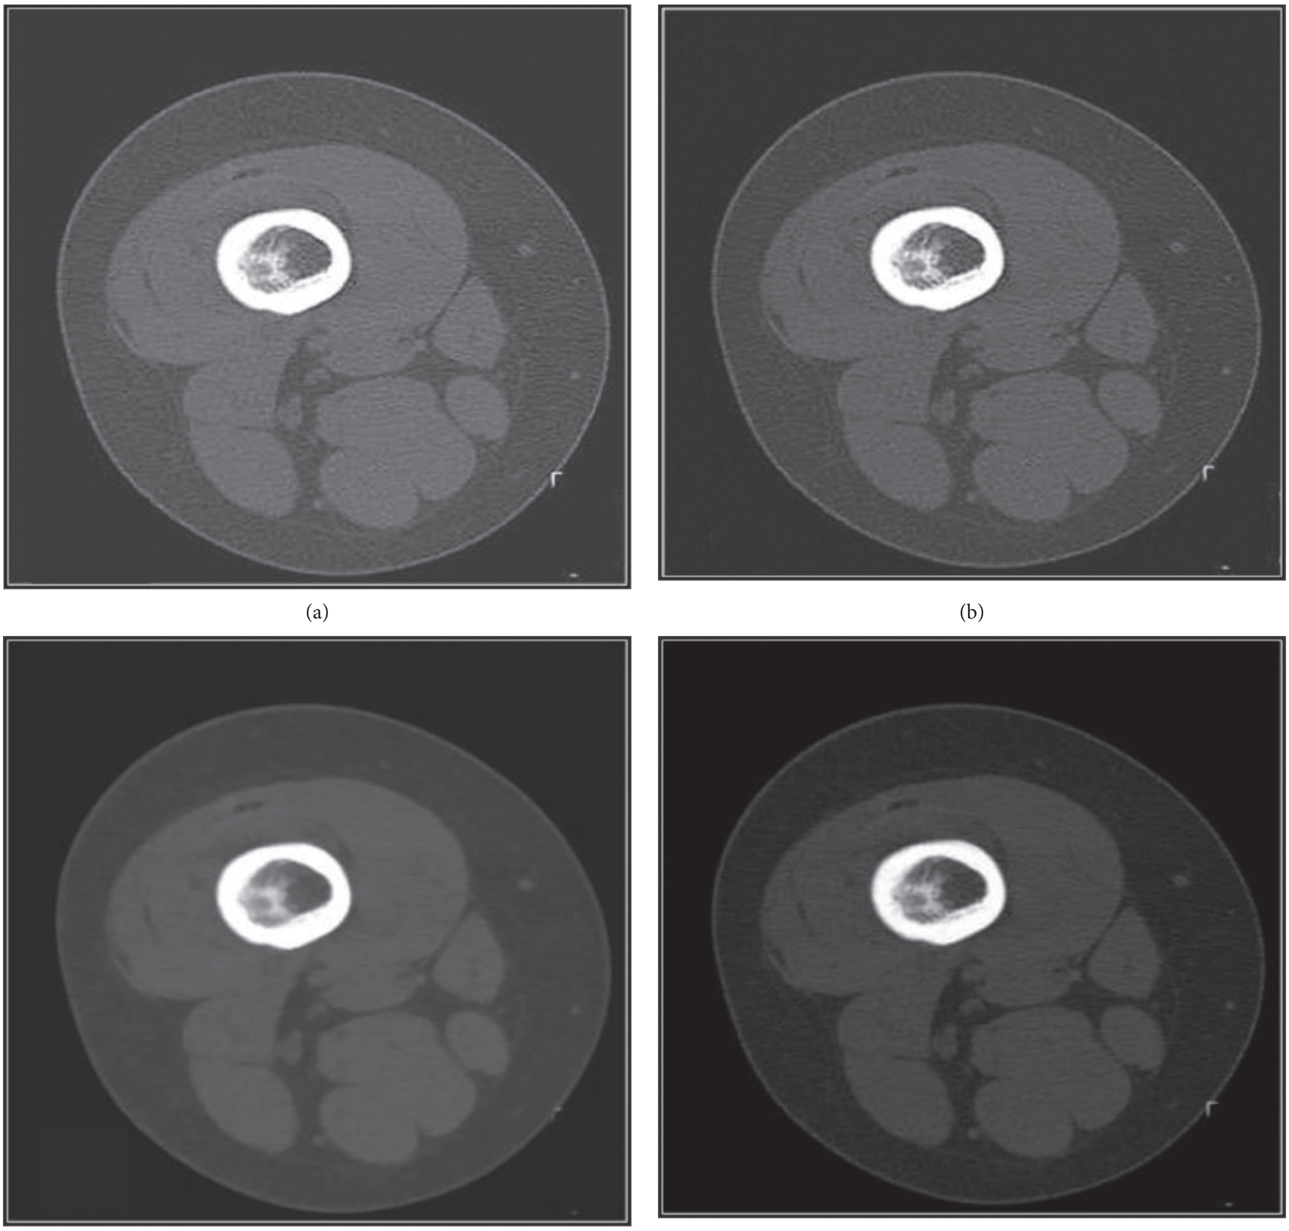
Figure 3: Comparison of running time among different algorithms.

3.4. Comparison on Knee Joint Function Improvement of Patients with KOA from the Two Groups. There were the comparison results of RM scores of patients in groups A and B before and after treatment (Figure 6). The RM scores of patients in group A were 3.26 ± 0.77 points, 2.45 ± 0.59 points, 1.71 ± 0.62 points, and 1.24 ± 0.47 points before treatment, after treatment, 1 month after treatment, and 3 months after treatment in sequence. In addition, RM scores of patients in group B before treatment, after treatment, 1 month after treatment, and 3 months after treatment were 3.25 ± 0.72 points, 3.25 ± 0.72 points, 1.42 ± 0.48 points, and 1.11 ± 0.32 points, respectively. RM scores of patients in groups A and B decreased after treatment compared with those before treatment, and there was a statistically remarkable difference ($P < 0.05$). RM scores of KOA patients from group B were steeply lower than the scores of group A after treatment and 1 month after treatment ($P < 0.05$).

The WOMAC scores of patients with KOA in groups A and B were compared before and after treatment as shown in Figure 7. WOMAC scores of patients in group A before treatment, after treatment, 1 month after treatment, and 3 months after treatment were 56.94 ± 10.87 points, 49.20 ± 10.23 points, 38.87 ± 8.35 points, and 32.54 ± 7.12 points, respectively. Besides, WOMAC scores of patients in group B were 57.45 ± 10.23 points, 49.02 ± 11.25 points, 31.64 ± 9.15 points, and 24.27 ± 7.27 points, respectively, before treatment, after treatment, 1 month after treatment, and 3 months after treatment. WOMAC scores of all patients from groups A and B after treatment reduced dramatically in contrast to those before treatment ($P < 0.05$). In addition, WOMAC scores of patients with KOA from group B were sharply lower than scores of group A 1 month and 3 months after treatment ($P < 0.05$).

Figure 8 expresses the comparison results of Lequesne index scores of patients from groups A and B before and after treatment. The Lequesne scores of patients in group A before treatment, after treatment, 1 month after treatment, and 3 months after treatment were 15.06 ± 4.52 points, 14.55 ± 3.85 points, 10.77 ± 3.91 points, and 8.46 ± 2.17 points in turn. What is more, Lequesne scores of patients in group B before treatment, after treatment, 1 month after treatment, and 3 months after treatment were 15.08 ± 4.22 points, 13.74 ± 3.13 points, 9.56 ± 3.42 points, and 6.05 ± 2.07 points, respectively. Lequesne scores of patients in groups A and B dropped after treatment by comparing with those before treatment, and the difference was statistically marked ($P < 0.05$). The Lequesne score of patients in group B 3 months after treatment was markedly lower than the score of group A ($P < 0.05$).

3.5. Comparison on Adverse Reactions of KOA Patients in Groups A and B. During the treatment, 3 cases of group A and 1 case of group B showed mild redness and swelling, which disappeared after local cold application for 24 hours. Furthermore, 1 patient in group B was unbearable for the pain, so the treatment was stopped immediately, and the pain was gradually eased after the patient rested for 1 hour. The comparison results of the adverse reaction rate of KOA patients in the two groups are shown in Figure 9. Besides, the adverse reaction rates of patients in groups A and B were



(a) (b) (c) (d)

Figure 4: CT image segmentation results of different segmentation algorithms: (a) The source image, (b) The image of Graph Cuts algorithm, (c) The image of threshold + Graph Cuts algorithm, and (d) The image of morphology + Graph Cuts algorithm.

Table 1: Comparison on clinical data of all patients in both groups.

	Group A ($n = 42$)	Group B ($n = 42$)	P
Gender (male/female)	22/20	24/18	0.123
Age (years old)	53.14 ± 10.39	54.03 ± 9.76	0.113
Height (cm)	165.23 ± 8.98	167.24 ± 8.02	0.097
Weight (kg)	67.87 ± 4.36	68.36 ± 5.02	0.068
BMI (kg/m^2)	24.36 ± 1.54	23.98 ± 1.25	0.612

7.1% and 4.8% in turn. There were no statistically great differences in the adverse reaction rates of KOA patients from the two groups ($P > 0.05$).

3.6. Comparison on Nerve Function Rehabilitation of KOA Patients in the Two Groups. The comparison results of SSS scores of patients in groups A and B before and after nursing

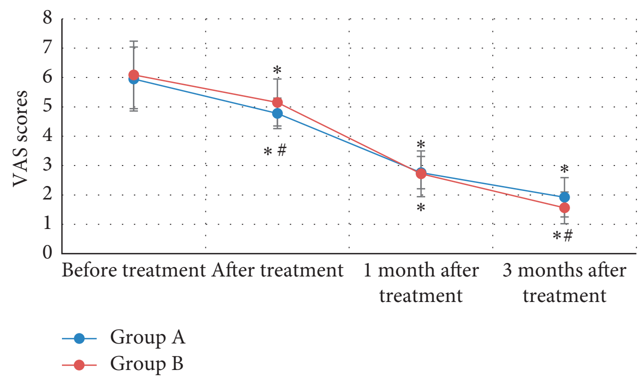


Figure 5: Comparison on VAS scores of patients with KOA from both groups before and after treatment. *Note*. * indicated $P < 0.05$ compared with before treatment; and # meant $P < 0.05$ in contrast to group A.

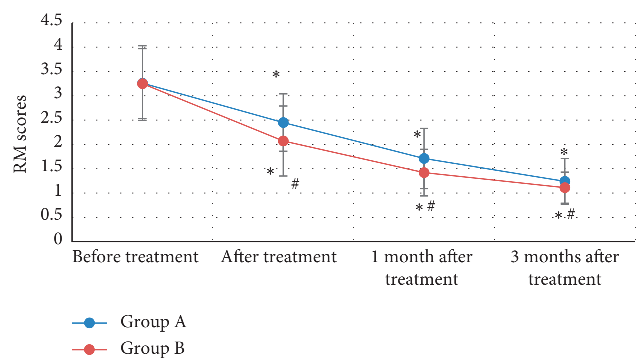

Figure 6: Comparison on RM scores of KOA patients from groups A and B before and after treatment. *Note*. * indicated $P < 0.05$ compared to before treatment; and # showed $P < 0.05$ in contrast to group A.

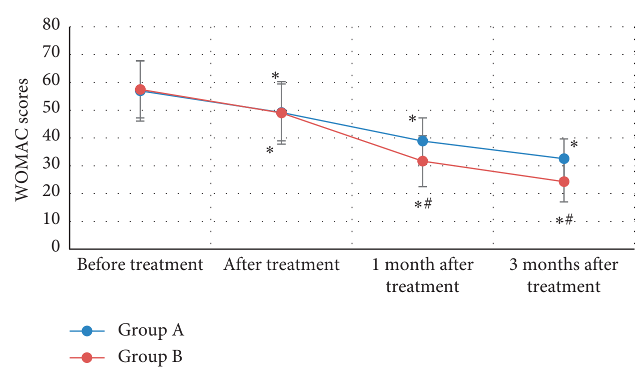

Figure 7: Comparison on WOMAC scores of KOA patients from groups A and B before and after treatment. *Note*. * showed that there was a statistically obvious difference compared to before treatment ($P < 0.05$); and # indicated that there were statistically considerable differences in contrast to group A ($P < 0.05$).

are shown in Figure 10. In group A, SSS score of patients before nursing was 34.69 ± 3.13 points and that after nursing was 28.15 ± 1.98 points. Before and after nursing, SSS scores of patients with KOA from group B were 34.72 ± 3.09 points and 16.35 ± 2.12 points, respectively. Thus, SSS scores of patients in groups A and B were compared before nursing, suggesting that the difference was not statistically remarkable ($P > 0.05$), while the SSS scores of patients from group B after nursing were dramatically lower than the scores of group A ($P < 0.05$).

4. Discussion

ISA was applied to improve and optimize the segmentation effect of medical images, and the results showed that the morphology + Graph Cuts algorithm had the best segmentation effect on CT images in contrast to the threshold + Graph Cuts algorithm and traditional Graph Cuts algorithm. This was consistent with the research results of Wu et al. [13], indicating that the CT segmentation method based on ISA could promote the segmentation accuracy of

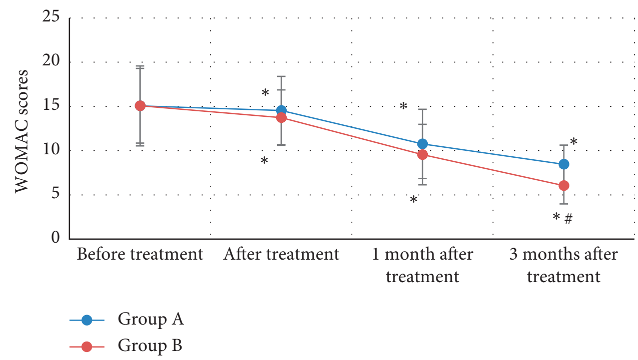

FIGURE 8: Comparison on Lequesne scores of KOA patients from groups A and B before and after treatment. *Note*. * showed that there was a statistically substantial difference compared with before treatment ($P < 0.05$); and # indicated that there were statistically marked differences in contrast to group A ($P < 0.05$).

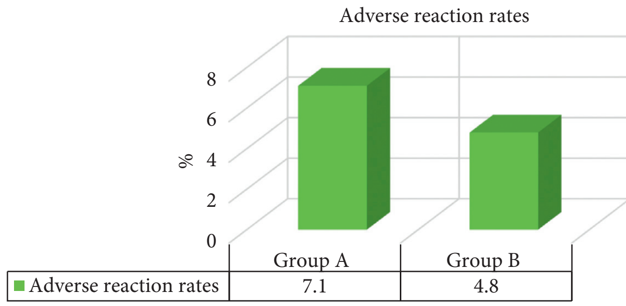

FIGURE 9: Comparison on adverse reaction rates of KOA patients in groups A and B.

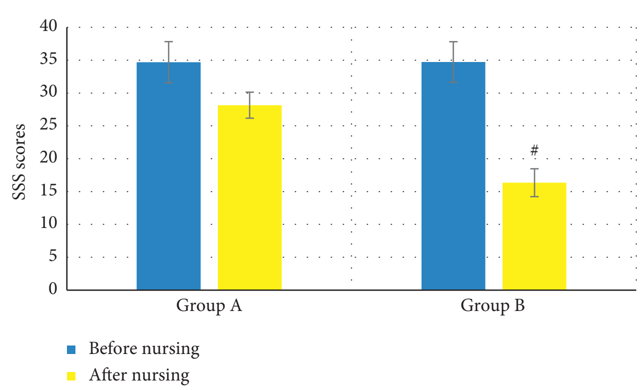

FIGURE 10: Comparison on SSS scores of KOA patients in the two groups. *Note*. # indicated that the difference was statistically obvious in contrast to group A ($P < 0.05$).

medical CT images. KOA is the leading cause of chronic bone and muscle pain. In recent years, RSWT has been employed to treat patients with KOA. In this study, there was a comparison on the curative effect of ultrasound treatment and RSWT for KOA. It was found that VAS scores before and after treatment were extremely different among KOA patients in the two groups, and the pain degree of patients in group B decreased hugely by comparing with the degree of group A ($P < 0.05$). This suggested that both ultrasound therapy and RSWT could help patients with pain symptoms, and RSWT was more effective. This was in accordance with the research results of Lee et al. [14] and Kang et al. [15]. The knee joint function rehabilitation of KOA patients was evaluated by RM, WOMAC, and Lequesne index scores in this study, and it was found that there were statistically marked differences in the RM, WOMAC, and Lequesne index scores of patients in groups A and B before and after treatment ($P < 0.05$). With the extension of treatment time, RM, WOMAC, and Lequesne index scores decreased gradually ($P < 0.05$). Therefore, the knee joint function of patients in group B was obviously better than that of group A ($P < 0.05$). There was no statistically great difference in the adverse reaction rates of patients in the two groups ($P > 0.05$). Lizis et al. [16] pointed out that the WOMAC and

ROM scores of KOA patients treated with RSWT were superior to those of KOA patients treated with kinesitherapy (KIN) by comparing the influences of RSWT and KIN for KOA patients. The research findings of Zhong et al. [17] reflected that VAS, WOMAC, and Lequesne index scores of KOA patients with RSWT were extremely better than those of KOA patients with placebo at the 5th and 12th week ($P < 0.05$). Moreover, all the patients showed improvement in pain and disability scores during 12 weeks of follow-up ($P < 0.05$), the adverse reaction rates of them were similar, and there were no serious side effects. This was consistent with the research results of this study. In this study, high-quality nursing was used for intervention treatment, and it was found that the SSS scores of nerve function rehabilitation after nursing in patients of group B were steeply lower than the scores of group A ($P < 0.05$). To some extent, it revealed that RSWT could promote tissue repair, thus contributing to nerve function rehabilitation. Based on the above results, RSWT had a better effect on alleviating pain and improving knee joint function in KOA patients.

5. Conclusion

The ISA-based CT imaging technology was for analysis of curative effects on KOA. It was found that RSWT had a more marked clinical effect, which could effectively relieve patients' pain and promote the knee joint and nerve function rehabilitation, and it was better than that of ultrasonic treatment through the analysis of the pain symptoms and knee joint and nerve function rehabilitation in patients with KOA before and after treatment. However, there were still some deficiencies in this study; for example, the sample size was limited, there was evaluation of only 3 months, and there was a lack of long-term efficacy evaluation. In the future, the number of samples and observation time should be increased to assess the long-term efficacy, so as to further analyze the therapeutic effects of KOA. In summary, the results of this study could provide reference for the imaging diagnosis and treatment of KOA.

Academic Editor: Enas Abdulhay

This paper was aimed to explore the application of the block matching pyramid (BMP) algorithm in echocardiographic spot tracking in patients with coronary heart disease (CHD) and angina pectoris, as well as the effect of Shexiang Baoxin pills (a kind of drug containing musk, which is good for cardiac diseases) on blood lipids, cardiac function, and curative effect. 206 patients with CHD angina pectoris in the hospital from July 2018 to May 2020 were selected as the research subjects and were enrolled into the control (Ctrl) group (conventional treatment, $n = 103$) and the observation group (the Shexiang Baoxin pill was given on the basis of conventional treatment, $n = 103$) in random. Then, the patients' echocardiograms were obtained, and the BMP algorithm was used to track the echocardiograms. At 12 months after treatment, the total cholesterol (TC), triglycerides (TG), low-density lipoprotein cholesterol (LDL-C), and high-density lipoprotein cholesterol (HDL-C) were compared. Besides, the differences between left ventricular end-systolic volume (LVESV), left ventricular end-systolic diameter (LVESD), left ventricular end-diastolic volume (LVEDV), left ventricular end-diastolic dimension (LVEDD), cardiac index (CI), cardiac output (CO), and LVEF were observed. Finally, the efficacy of angina pectoris and electrocardiogram was calculated. It was found that the BMP algorithm can track the echocardiograms and display the movement and displacement of the patients' left ventricle. After treatment, in contrast with the Ctrl, the levels of TC, TG, and LDL-C in the observation group were obviously lower ($P < 0.05$); the LVESV, LVEDV, and LVEF were obviously lower ($P < 0.05$), the LVESD, LVEDD, CO, and CI were obviously higher ($P < 0.05$), the total score of angina after treatment was obviously lower ($P < 0.05$), and the total effective rates of angina pectoris and echocardiogram were obviously higher ($P < 0.05$). In conclusion, echocardiographic spot tracking can realize the diagnosis of patients with CHD angina pectoris, and Shexiang Baoxin pill can regulate the blood lipid level and improve the echocardiographic indicators and the clinical efficacy is obvious.

1. Introduction

In recent years, the incidence and mortality of CHD in China have shown an upward trend year by year, which has seriously threatened people's lives and health. At present, the methods commonly used in clinical treatment of CHD are percutaneous coronary intervention or coronary artery bypass surgery. Surgical treatment can realize the recanalization of the occluded blood vessels, improve the symptoms, and reduce cardiovascular events such as myocardial infarction [1, 2]. The occurrence of CHD angina is correlated with the increase of blood lipid levels and vascular endothelial injury [3]. Therefore, the clinical treatment of CHD not only needs to relieve the symptoms of patients with angina but also needs to control blood lipids and other risk factors for cardiovascular diseases. Traditional Chinese medicine (TCM) has a long history of treating CHD angina pectoris, and studies have confirmed that TCM is better than Western medicine in treating CHD angina. Shexiang Baoxin pill is a TCM preparation, which is developed for clinical treatment of cardiovascular diseases such as CHD [4]. Studies have proved that Shexiang Baoxin pills can improve patients' ECG performance and reduce the incidence of cardiovascular events [5].

Cardiac ultrasound imaging technology is also often used in clinical disease diagnosis and treatment effect evaluation, and the new type of echocardiogram technology can be used for the evaluation of myocardial strain. In addition, it can also measure myocardial deformation [6]. The traditional echocardiographic parameters based on volume measurement are not very sensitive to the early changes of myocardial function, but the spot tracking detection of echocardiogram can realize the assessment of ventricular function in patients with early myocardial diseases [7, 8]. Moinfar et al. used 2-d speckle to track echocardiography. It was found that the left atrial fluid storage and catheter capacity decreased in patients with type 2 diabetes complicated with urinary protein coronary disease [9]. However, there are relatively few studies on echocardiogram in patients with CHD angina.

Therefore, in this study, CHD angina pectoris patients were taken as the research subjects. Then, the patients' echocardiograms were obtained, and the changes of the ventricular function were explored through spot tracking. Subsequently, Shexiang Baoxin pills were given to compare the differences in the blood lipid levels, echocardiographic parameters, and treatment efficiency of different methods. The results provided a reference for improving the clinical treatment of patients with CHD angina.

2. Methods and Materials

2.1. Research Subjects. 206 patients with CHD angina in the hospital from July 2018 to May 2020 were taken as the research subjects. The diagnosis of CHD angina meets the requirements stipulated by WHO. Inclusion criteria: patients must be over 20 years old; patients who clinically demonstrated myocardial ischemia and hypoxia for more than 30 days; and patients who have had acute myocardial infarction for more than 6 months, who have undergone percutaneous coronary intervention or coronary artery bypass surgery, or whose imaging revealed that at least one main branch had a stenosis of more than 50%. At least one of the above events occurred. Exclusion criteria: patients with myocardial infarction or revascularization therapy in the past 6 months; patients with severe respiratory disease; patients with severe other organ dysfunction; patients with serious diseases such as malignant tumors; pregnant women; and patients with severe mental illness. 206 patients with CHD angina were enrolled into the observation group and Ctrl, with 103 in each. Patients in the Ctrl were given conventional treatments, and patients in the other group were given 2 capsules/time and 3 times/d Shexiang Baoxin pills based on the above treatment. This trial had got permission from the ethics committee of the hospital, and the subjects or their families had signed informed consents.

2.2. Collection of Echocardiograms. The color Doppler ultrasound diagnostic apparatus was adopted to collect the patients' echocardiograms, and the frequency of the S4 probe was set to 2~4 MHz. During the examination, the probe was needed to be placed between the 3rd and 4th ribs on the left side of sternum to obtain the 4 chambers of the heart. Then, the dimensions of the heart chamber, the thickness of the ventricular wall, the thickness of the left atrium, and contraction and relaxation ability of the left ventricle were observed.

2.3. Echocardiogram Spot Tracking Based on Block Matching Algorithm. BMP combines image pyramid and block matching algorithm, which can measure the similarity of image spot position. At the same time, through the sampling of image blocks, there is only a small amount of calculation [10]. The process of BMP algorithm is shown in Figure 1. After the spots to be tracked in the echocardiogram were calibrated, block matching and pyramid models were needed to be built. Then, the SAD value at the current time was calculated, and the similarity of all pixels in the view field was calculated. The comparison ends until all pixels were compared.

In Figure 1, when the BMP algorithm was adopted, the calculation equation of the sum of absolute differences (SAD) value was as follows:

$$\mathrm{SAD}_m(x, y) = \sum_{i=1}^{2^m} \sum_{j=1}^{2^m} \left| x^m(i, j) - y^m(i, j) \right|, \tag{1}$$

in which $x^m(i, j)$ represents the value of the pixel at point (i, j) in the mth layer of the pyramid.

After the above equation was unfolded and Minkowski's inequality was used, the following equation was obtained:

$$\begin{aligned} \mathrm{SAD}_m(i, j) &\geq \mathrm{SAD}_{m-1}(i, j) \geq \mathrm{SAD}_{m-2}(i, j) \\ &\geq \cdots \geq \mathrm{SAD}(i, j). \end{aligned} \tag{2}$$

2.4. Observation Indicators. Blood biochemical indicators and renal function were tested before treatment and 3 months and 12 months after treatment. The patient was in the left decubitus position, and LVESV, LVESD, LVEDV, and LVEDD were collected before and 12 months after treatment. After the collection, the patients' CI, CO, and LVEF were calculated.

2.5. Efficacy Criteria. Criteria for determining the effect of angina pectoris: obviously effective (decrease in total angina pectoris points by at least 60%), effective (decrease in total angina pectoris points by at least 30%), ineffective (decrease in total angina pectoris points by less than 30%), and worsening of disease (no decrease in total angina pectoris points).

Criteria for determining the effect of echocardiogram treatment: obviously effective (the echocardiograms returned to the normal range), effective (ST segment was reduced, and after treatment, it rose above 0.05 mV, but did not reach the normal level, or the *T* wave changed from a flat state to an upright state), ineffective (the ECG had no significant changes compared to before treatment), and

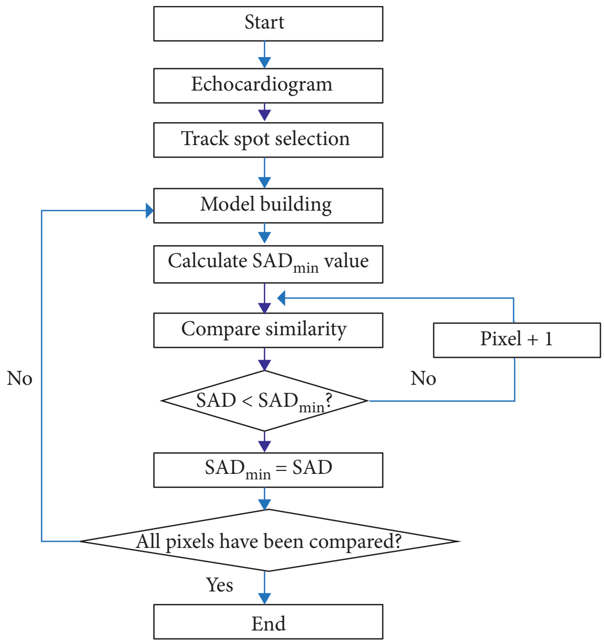

Figure 1: The spots marking process of echocardiograms based on BMP algorithm.

worsening of disease (the ST segment was reduced by more than 0.05 mV after treatment; the *T* wave state was completely changed, and ectopic heart rate occurred).

2.6. Statistics and Analysis. The data were processed by SPSS 20.0. Mean ± standard deviation ($\overline{x} \pm s$) was how measurement data were expressed, and comparison between groups was realized through independent sample t-test. Count data were expressed as frequency or percentage, and the χ^2 test was used to compare differences between groups. When $P < 0.05$, the difference was considered to be statistically significant.

3. Results

3.1. General Information Comparison. Before treatment, the differences were compared in baseline data, biochemical indicators, and cardiac function indicators. From Table 1, it was evident that there was no obvious difference in baseline data, biochemical indexes, and cardiac function indexes ($P > 0.05$).

3.2. Evaluation of Echocardiographic Speckle Tracking Algorithm. First, the difference between the accuracy and time was compared when the global search method or the logarithmic search method was adopted to analyze the pixel points in the motion vector search window in the BMP algorithm (Figure 2). It was evident from Figure 2(a) that the change of the size of search window had a small effect on the search accuracy of the global search algorithm. As the size of search window increased, the accuracy of the logarithmic search method gradually decreased. However, the accuracy rate of the two algorithms was always higher than 90%. It was evident from Figure 2(b) that as the size of search window increased, the running time of the two algorithms gradually increased, but that of the logarithmic search method was always lower than that of the global search method.

The heartbeat sequence was selected; each sequence contained 250 frames of heartbeat images and multiple heart motion cycles. It was evident from Figure 3(a) that the red smooth closed contour was the segmentation line of the ventricle and atrium, and the yellow dots around were the marked spots. By tracking these spots, the direction of heart movement was finally obtained (Figure 3(b)). It was evident that the maximum displacement of the heart was about 15 pixels, which was about 13.8 mm.

3.3. The Effect of Shexiang Baoxin Pill on Biochemical Indexes. The changes were compared in the levels of biochemical indexes 3 months and 12 months after treatment (Figure 4). It was evident that the levels of biochemical indexes of all patients decreased 12 months after treatment in contrast with those 3 months after treatment. In contrast with Ctrl, at 3 months after treatment, the levels of TC and LDL-C in the observation group were obviously lower ($P < 0.05$); at 12 months after treatment, the levels of TC, TG, and LDL-C were obviously lower ($P < 0.05$). Although the difference in TG levels 3 months after treatment and HDL-C levels 3 months and 12 months after treatment was not obvious ($P > 0.05$), it was observed that those in the observation group were still lower than Ctrl.

3.4. The Effect of Shexiang Baoxin Pill on Cardiac Function. The differences were compared in LVESV, LVEDV, LVESD, and LVEDD 12 months after treatment (Figure 5). It was evident that in contrast with Ctrl, the levels of LVESV and LVEDV of the observation group after treatment were obviously lower ($P < 0.05$); the LVESD and LVEDD were obviously higher after treatment ($P < 0.05$) .

The differences were compared in LVEF, CO, and CI 12 months after treatment (Figure 6). In contrast with Ctrl, in Figure 6(a), the LVEF of the observation group after treatment was obviously lower ($P < 0.05$); in Figure 6(b), the CO was obviously higher after treatment ($P < 0.05$); in Figure 6(c), the CI after treatment was obviously higher ($P < 0.05$).

3.5. Therapeutic Effect Analysis of Shexiang Baoxin Pills. The difference was compared between the total scores of patients with angina before treatment (0 month) and 12 months after treatment (Figure 7). There was no obvious difference in the total score of angina before treatment ($P > 0.05$). After treatment, that in the observation group was obviously lower than Ctrl ($P < 0.05$).

After 12 months of treatment, the difference was compared in the efficacy of angina pectoris and echocardiogram (Table 2). There was no case with aggravated angina pectoris and echocardiogram efficacy in both groups, while the total effective rate of angina pectoris efficacy and echocardiogram efficacy in the observation group was obviously higher than Ctrl ($P < 0.05$).

Table 1: Comparison of general information.

Baseline data	Ctrl ($n = 103$)	Observation group ($n = 103$)	t/χ^2	P value
Male (case/%)	66 (64.1)	63 (61.2)	1.232	0.153
Age (year)	62.33 ± 8.47	63.28 ± 9.77	0.785	0.229

4. Discussion

The occurrence and development of CHD angina are closely related to the ischemia and hypoxia of myocardial cells [11]. At present, many studies have proved that hyperlipidemia is an important factor, leading to a variety of cardiovascular and cerebrovascular diseases [12]. Therefore, in the study, the effect of Shexiang Baoxin pills on the levels of TC, TG, LDL-C, and HDL-C in patients with CHD angina pectoris was explored. It was revealed that at 3 months and 12 months after treatment, the levels of the abovementioned indexes were obviously lower than Ctrl. It was basically in

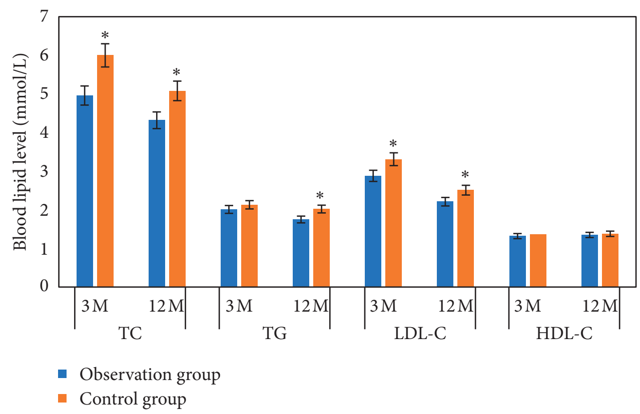

Figure 4: Comparison of blood lipid indexes after treatment. * indicates that the difference between groups was obvious, $P < 0.05$ (with the same meaning in Figures 5–7).

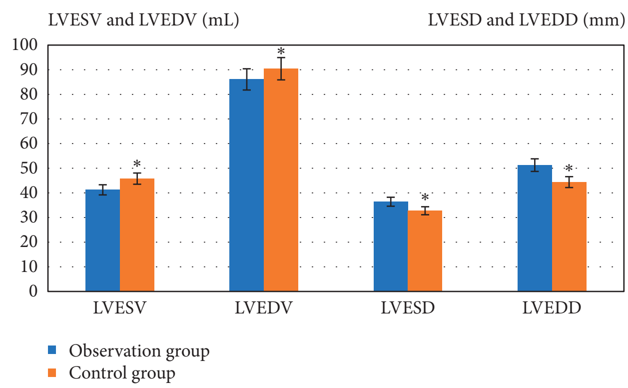

Figure 5: Comparison of differences in cardiac function indexes after treatment.

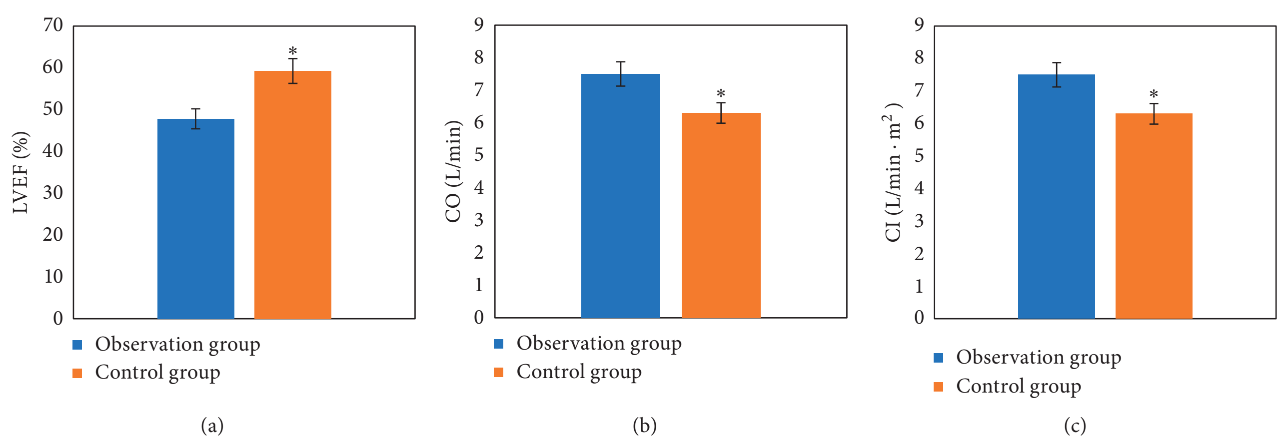

Figure 6: Comparisons of differences in (a) LVEF, (b) CO, and (c) CI after treatment.

line with the research results of Tian et al. [13], suggesting that Shexiang Baoxin pills can reduce the blood lipid levels in patients with CHD angina pectoris, thereby slowing down the process of coronary atherosclerosis.

Cardiac imaging technology has been widely used in disease prevention, diagnosis, and treatment. Among them, echocardiogram imaging technology has small side effects and is economical. Therefore, it is one of the imaging technologies commonly used in the diagnosis of heart diseases [14, 15]. The echocardiogram spot tracking can realize the assessment of cardiac strain in severe cardiac patients [16]. Therefore, the image pyramid and block matching method were combined to track the echocardiogram of CHD angina pectoris patients in the study. Clinically, the computational complexity of the block matching algorithm makes it difficult to meet the needs of timeliness.

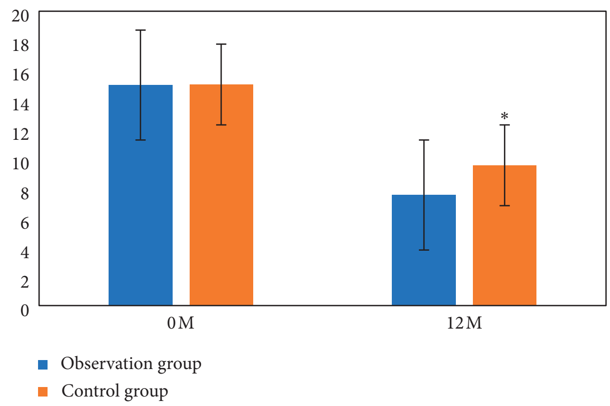

Figure 7: Comparison of total scores of angina pectoris.

Table 2: Comparison of efficacy between angina pectoris and echocardiogram.

Grade	Angina pectoris efficacy				Echocardiogram efficacy			
	Ctrl ($n = 103$)	Observation group ($n = 103$)	χ^2	P value	Ctrl ($n = 103$)	Observation group ($n = 103$)	χ^2	P value
Obviously effective	41 (39.8)	45 (43.7)	—	—	34 (33.0)	41 (39.8)	—	—
Effective	52 (50.5)	54 (52.4)	—	—	52 (50.5)	55 (53.4)	—	—
Ineffective	10 (9.7)	4 (3.9)	—	—	17 (16.5)	7 (6.8)	—	—
Aggravated	0 (0.0)	0 (0.0)	—	—	0 (0.0)	0 (0.0)	—	—
Effective rate (%)	90.3	96.1	8.325	0.027	83.5	93.2	11.231	0.004

Therefore, first, the impact of global search [17] and logarithmic search [18] on the efficiency of the algorithm was analyzed. It was found the tracking accuracy of the two search methods was both higher than 93%. Although the logarithmic search method reduces the tracking accuracy due to the increase of the search window, the tracking time is always lower than that of the global search method. Therefore, the parameters can be adjusted in clinical application to improve tracking effect. When the echocardiograms of patients with CHD angina pectoris were tracked subsequently, it was found that the displacement of the patients' left ventricle could be clearly tracked through the calibrated spots. What's more, the patients' heart motion trajectory showed a certain periodicity, which was in line with the clinical cardiac motion state. However, after tracking, it was found that the maximum displacement of the heart was 15 pixels, about 13.8 mm. Besides, the heart beat was too strong, indicating that the heart function was abnormal. It was in line with the actual situation of CHD angina patients [19].

Subsequently, the effect of Shexiang Baoxin pill on the heart function was studied. It was found that the patients in observation group had obviously lower LVESV, LVEDV, and LVEF than the Ctrl ($P < 0.05$), and LVESD, LVEDD, CO, and CI were obviously higher ($P < 0.05$). LVESV, LVEDV, LVEF, LVESD, LVEDD, CO, and CI indicators are important indicators used to evaluate the volume, shape, function, and structure of the heart [20]. It was found that Shexiang Baoxin pills could reduce the left ventricular volume, increase the left ventricular inner diameter, and improve the heart function by increasing cardiac output and enhancing cardiac systolic function. It was in line with the research results of Tian et al. and Zhang et al. [13, 21]. Finally, the difference between the total effective rates of and echocardiogram in two groups was evaluated. It was found that the total effective rates of angina pectoris and echocardiogram in observation were 96.1% and 93.2%, respectively, both of which were obviously higher than Ctrl ($P < 0.05$). It was in line with the results of Chen et al. [22], indicating that the clinical treatment of Shexiang Baoxin pills can obviously improve the symptoms of angina pectoris and enhance the cardiac function of patients, which was consistent with the results of the previous echocardiographic evaluation.

5. Conclusion

In the study, the application of the BMP algorithm in echocardiographic spot tracking of patients with CHD angina pectoris, as well as the effect of Shexiang Baoxin pills on blood lipid levels, cardiac function, and treatment efficiency, was explored. It was found that echocardiographic speckle tracking can detect the abnormal displacement of the left ventricle, and giving Shexiang Baoxin pills on the basis of conventional treatment can improve the patients' echocardiographic indicators and increase the total effective rate of treatment. However, only the BMP algorithm is used to realize the echocardiographic speckle tracking. The follow-up studies need to compare and analyze the differences in the results of echocardiographic speckle tracking before and after treatment. In short, the results can provide a theoretical basis for improving the clinical treatment of patients with CHD angina and the quality of life of patients.

The aim was to explore the application value of computed tomography (CT) perfusion (CTP) imaging based on the iterative model reconstruction (IMR) in the diagnosis of acute cerebral infarction (ACI). 80 patients with ACI, admitted to hospital, were selected as the research objects and divided randomly into a routine treatment group (group A) and a low-dose group (group B) (each group with 40 patients). Patients in group A were scanned at 80 kV–150 mAs, and the traditional filtered back projection (FBP) algorithm was employed to reconstruct the images; besides, 80 kV–30 mAs was adopted to scan the patients in group B, and the images were reconstructed by IMR1, IMR2, IMR3, iDose4 (a kind of hybrid iterative reconstruction technology), and FBP, respectively. The application values of different algorithms were evaluated by CTP based on the collected CTP images of patients and detecting indicators. The results showed that the gray and white matter CT value, SD value, SNR, CNR, and subjective image scores of patients in group B were basically consistent with those of group A ($p > 0.05$) after the IMR1 reconstruction, and the CT and SD of gray and white matter in patients from group B reduced steeply ($p < 0.05$), while SNR and CNR increased dramatically after IMR2 and IMR3 reconstruction in contrast to group A ($p < 0.05$). Furthermore, the cerebral blood volume (CBV), cerebral blood flow (CBF), mean transit time (MTT) of contrast agent, and time to peak (TTP) of contrast agent in patients from group B after iDose4 and IMR reconstruction were basically the same as those of group A ($p > 0.05$). Therefore, IMR combined with low-dose CTP could obtain high-quality CTP images of the brain with stable perfusion indicators and low radiation dose, which could be clinically applied in the diagnosis of ACI.

1. Introduction

ACI is a common disease and also known as acute ischemic stroke. Its main feature is that blood clots emerges in the brain blood vessels or various reasons lead to insufficient blood supply to the brain, which causes brain tissue ischemia and hypoxia to result in the irreversible apoptosis which is the main cause of death and disability in the old people [1, 2]. It is of great importance to determine the time window of reperfusion therapy for patients with ACI. Moreover, CTP can determine the core of lesion and ischemic area of patients with ACI to make clinical diagnosis and determine the treatment plan in a relatively short time, so as to avoid the constraints of time window, reduce the mortality and disability rate of patients, and monitor patient's prognosis [3].

Although CTP is irreplaceably featured with the diagnosis of patients with ACI, excessive radiation dose is its biggest shortcoming in the diagnosis. CTP requires continuous and repeated scanning of the target area of the brain, resulting in a huge increase in the X-ray radiation dose received by a patient by comparing with conventional CT. Therefore, reducing radiation dose is an urgent clinical topic in the process of CTP application [4, 5]. The main factors that affect CTP radiation dose are voltage, current, collection time, and frequency. Reducing the scanning time and increasing the scanning interval can reduce the radiation, but its effect is extremely limited. An effective method is to reduce the voltage and current, but it is necessary to pay attention to maintaining the quality stability of the perfusion images. Algorithm reconstruction plays an irreplaceable role in maintaining the quality of perfusion images [6].

FBP has been called the gold standard of CT image reconstruction, and it plays a vital role in CT image reconstruction. The amount of projection data reconstructed by FBP has a positive correlation with the resolution of image space and a negative correlation with the image noise, which affects the radiation dose reduction of CT scanning [7, 8]. In order to ensure the image quality of low-dose radiation CT scanning, scholars have focused on the iterative reconstruction technology of CT images, including the iterative reconstruction in image space (IRIS), adaptive statistical iterative reconstruction technology (AsiR), iDose (a kind of hybrid iterative reconstruction technology), and adaptive iterative dose reduction (AIDR) algorithm [9, 10]. Philips' iDose is taken as an example, which applies a dual-model iterative reconstruction algorithm. First, a data model is reconstructed by FBP, and then, it is identified and denoised through a mathematical model and matrix algebra [11]. However, iDose iterative reconstruction algorithm based on FBP is still a partial iterative algorithm. It still does not considers factors such as system hardware problems and X-ray photonic characteristics, which will affect the image quality, thereby limiting the further reduction of scanning radiation dose. After the iDose, Philips' researchers have further developed IMR (a fully iterative reconstruction technology that does not contain FBP components). The mechanism of IMR is to continuously optimize an image and data statistical model and a system model in the image and data space, so as to achieve the objective of denoising. Compared with iDose, IMR can not only reduce noise but also improve the resolution of the image [6, 12, 13].

In summary, the combination of IMR and low-dose CT can achieve the optimization of CTP radiation dose and image quality. This study would explore the application value of IMR-based CTP in the diagnosis of ACI, aiming to provide reliable basic data for clinical applications.

2. Materials and Methods

2.1. Establishment of Research Objects. 80 patients with ACI, who were admitted in hospital, were selected as the research objects. The criteria for inclusion were defined to include patients suffered from ACI, were 18–80 years old, and had signed the informed consents. The criteria for exclusion were defined to contain patients suffered from severe cardiovascular and cerebrovascular diseases, were allergic to the iodine contrast agent, were pregnant or in the lactation period, and had received the arterial stent implantation in the brain. This study had been approved by the ethics committee of hospital. The research objects in the experiment were grouped randomly into group A and B. The tube current in patients of group A was 150 mAs detected by CT, and the tube current of patients in group B was 30 mAs. The FBP image reconstruction was adopted for patients in group A, and FBP, iDose4, IMR1, IMR2, and IMR3 were employed to reconstruct the images of the patients in group B.

2.2. Computed Tomography Scanning and Methods. Brilliance iCT Elite CT machine was used for CT scanning. The tube current of patients in group A was 150 mAs, tube current of patients in group B was 30 mAs, tube voltage of patients in both groups was 80 kV, rotation time was 0.33 s, and both of layer thickness and spacing were 5 mm. A double-tube high pressure syringe was applied to inject the contrast agent. After the contrast agent was injected for 4 seconds, it was time to scan. The scan time was 2 seconds, and scanning was repeated 25 times, so the total scan time was 50 seconds. The image reconstruction indicators of FBP and iDose were all standard, and those of IMR1, IMR2, and IMR3 were all normal.

2.3. Image Postprocessing. The original image of CTP was transmitted to the workstation (Extend Brilliance Workspace, Philips Healthcare), and the Brain Perfusion software was employed to form a pseudocolor perfusion image of CBF, CBV, MTT, and TTP.

2.4. Analysis on the Quality of Images and Objective Evaluation. First, the CT value of white and gray matter on the instantaneous maximum density projection image was measured, and SD of the CT value was regarded as the image noise to calculate the SNR and CNR. The calculation equations were shown as follows. SNR = CT/SD and CNR = (gray matter CT value − white matter of CT value)/(white matter of SD^2 + gray matter of SD^2). Second, the values of CBF, CBV, MTT, and TTP were recorded on each pseudocolor image.

2.5. Subjective Evaluation of Image Quality Analysis. The 3-level scoring method was for the subjective evaluation standard, with 2 points for good quality, 1 point for average quality, and 0 points for bad quality. The subjective evaluation criteria included the difference of gray and white matter perfusion value on the perfusion pseudocolor image, difference between the focal ischemia and normal tissue, homogeneity of image, contrast of infarction, contour, degrees of concentration and dispersion, and presence or absence of artifacts. The highest score was 8; a score greater than 6 indicated an image with high quality, a score of 3–6 meant a medium-quality image, and a score less than 3 indicated an image of poor quality.

2.6. Statistical Analysis. SPSS22.0 was used for statistical analysis of the data. The subjective scores of images from patients in each group were compared by the rank sum test, the variance was employed to analyze the perfusion indicators, CT value, SD value, SNR, and CNR of gray and white matter, and the independent sample t-test was applied to the pairwise comparison between groups. $P < 0.05$ meant that there was statistically significant difference.

3. Results

3.1. Objective Indicators. As given in Table 1, there were the statistically substantial overall differences in the CT value, SD value, SNR, and CNR of gray and white matter among patients from the two groups through the 6 reconstruction methods ($p < 0.05$) after the variance analysis. Figure 1 shows the CT images processed by different reconstruction methods, including the images of group A reconstructed by FBP, and the images of group B reconstructed by FBP, iDose4, IMR1, IMR2, and IMR3, respectively. It was found that the images with high current were relatively clear (A-FBP), while the CT images obtained by different reconstruction algorithms in group B were slightly different in quality. The reconstructed images of FBP, IMR1, IMR2, and IMR3 were relatively clear, but the reconstructed images of iDose4 were quite fuzzy, which was not good for observation.

3.2. Computed Tomography Values of Gray and White Matter in the Brain. Table 1 and Figure 2 show that the CT values of gray and white matter reconstructed by FBP in patients from group A were 56.23 ± 2.45 Hu and 36.23 ± 2.12 Hu, respectively. In contrast to group A, the obtained CT values of gray and white matter reconstructed by FBP and iDose4 increased dramatically in patients of group B ($p < 0.05$); there were no obvious differences in CT values of gray and white matter reconstructed by IMR1 in patients from group B ($p > 0.05$); the CT value of gray matter reconstructed by IMR2 reduced sharply ($p < 0.05$), but the value of CT in white matter was not considerably different ($p > 0.05$); and the values of CT in gray and white matter reconstructed by IMR3 reduced hugely both ($p < 0.05$).

3.3. Standard Deviation Values of Gray and White Matter in the Brain. Table 1 and Figure 3 reveal that the values of SD in gray and white matter reconstructed by FBP were 7.82 ± 1.43 Hu and 5.21 ± 0.98 Hu in patients from group A, respectively. By comparing with group A, the SD values of gray and white matter obtained from FBP and iDose4 image reconstruction increased markedly in patients from group B ($p < 0.05$); the values of SD in gray and white matter reconstructed by IMR1 were not significantly different ($p > 0.05$); and the SD values of gray and white matter reconstructed by IMR2 and IMR3 reduced extremely ($p < 0.05$).

3.4. The Values of Signal-to-Noise Ratio in Gray and White Matter from the Brain. Table 1 and Figure 4 indicate that the values of SNR in gray and white matter reconstructed by FBP in patients from group A were 9.41 ± 1.53 and 10.06 ± 1.32, respectively. Besides, the SNR values of gray and white matter reconstructed by FBP and iDose4 decreased enormously in patients from group B compared with those of group A ($p < 0.05$); the SNR of gray matter did not change significantly under the reconstruction of IMR1 ($p > 0.05$), but the white matter SNR value rose dramatically ($p < 0.05$); and the SNR values of gray and white matter reconstructed by IMR2 and IMR3 grew hugely in patients from group B.

3.5. The Values of Contrast-to-Noise Ratio in Gray and White Matter from the Brain. Table 1 and Figure 5 show that the CNR of gray matter in patients from group A was 0.40 ± 0.09 after the reconstruction. The CNR of gray matter reconstructed by FBP and iDose4 dropped extremely in patients from group B ($p < 0.05$) compared with that of group A; there was no great difference in the CNR of patients from group B after IMR1 reconstruction ($p > 0.05$); besides, CNR of gray matter increased dramatically in patients from group B after the reconstruction of IMR2 and IMR3 ($p < 0.05$).

3.6. Comparison of Subjective Indicators. The subjective score of FBP and iDose4 image reconstruction was 0 in patients of group B, which could not meet the standard of clinical diagnosis. The subjective scores of FBP reconstruction in patients of group A and IMRE1, IMR2, and IMR3 reconstruction in patients of group B were 7.45 ± 0.34, 7.84 ± 0.84, 7.29 ± 0.62, and 7.34 ± 0.67, respectively. There were no huge differences in the subjective scores of image quality among patients from the two groups after multiple rank sum tests ($\chi^2 = 0.78$ and $p = 0.92$).

3.7. Comparison on the Values of Perfusion Indicators. Table 2 presents that there were statistically obvious differences in CBV of white matter and CBF and MTT of gray matter among patients in the two groups under the six reconstruction methods ($p < 0.05$) based on the analysis of variance. In addition, the overall differences of white matter CBV and gray matter TPP were statistically marked among patients in the two groups under the six reconstruction methods ($p < 0.05$).

3.8. The Values of Cerebral Blood Volume in the Gray and White Matter. As given in Table 2 and Figure 6, CBV of gray and white matter reconstructed by FBP was 5.08 ± 0.42 mL/100 g and 3.12 ± 0.23 mL/100 g in patients of group A, respectively. In contrast to group A, CBV of gray and white matter reconstructed by iDose4, IMR1, IMR2, and IMR3 had no obvious difference ($p > 0.05$) and CBV of white matter showed no obvious difference in patients from group B ($P > 0.05$), while those reconstructed by FBP reduced steeply ($p < 0.05$).

3.9. The Values of Cerebral Blood Flow in the Gray and White Matter. As given in Table 2 and Figure 7, the CBF of gray and white matter reconstructed by FBP in patients from group A was 54.23 ± 4.97 mL/100 g/min and 23.32 ± 2.16 mL/100 g/min, respectively. In contrast to group A, there was no considerable difference in CBF of gray and white matter in patients from group B under the reconstruction of iDose4, IMR1, IMR2, and IMR3 ($P > 0.05$), while the CBF of gray and white matter reconstructed by FBP increased substantially ($p < 0.05$).

Table 1: Comparison results of objective values of image quality among patients from the two groups.

Group	Reconstruction methods		CT (Hu)	SD (Hu)	SNR	CNR
Group A	FBP	Gray matter	56.23 ± 2.45	7.82 ± 1.43	9.41 ± 1.53	0.40 ± 0.09
		White matter	36.23 ± 2.12	5.21 ± 0.98	10.06 ± 1.32	
Group B	FBP	Gray matter	78.69 ± 3.12	12.43 ± 1.54	7.83 ± 0.93	0.21 ± 0.03
		White matter	57.12 ± 2.56	9.26 ± 0.98	7.82 ± 0.72	
	iDose4	Gray matter	65.98 ± 3.12	10.79 ± 1.87	8.21 ± 1.10	0.24 ± 0.02
		White matter	48.34 ± 2.17	8.15 ± 0.85	7.73 ± 0.91	
	IMR1	Gray matter	55.43 ± 3.45	7.24 ± 1.27	10.52 ± 2.13	0.42 ± 0.06
		White matter	38.63 ± 1.91	4.83 ± 0.62	10.98 ± 1.17	
	IMR2	Gray matter	53.24 ± 3.19	6.39 ± 1.28	11.23 ± 2.15	0.57 ± 0.11
		White matter	37.03 ± 4.23	4.97 ± 0.92	11.83 ± 1.86

3.10. The Values of Mean Transit Time in the Gray and White Matter. As given in Table 2 and Figure 8, the values of MTT in gray and white matter reconstructed by FBP in patients from group A were 5.65 ± 0.76 seconds and 7.38 ± 1.12 seconds, respectively. In contrast to group A, the MTT values of gray and white matter reconstructed by FBP and iDose4 rose remarkably in patients from group B ($p < 0.05$), while there were no marked differences in the values of MTT reconstructed by IMR1, IMR2, and IMR3 ($p > 0.05$).

3.11. Computed Tomography Perfusion Image Example. Figure 9 shows the CT images of ACI. To be specific, Figure 9(a) is the CT image and Figure 9(b) is the CTP image. It was found that CTP could present richer intracranial information by comparing with CT, which was beneficial to diagnose accurately the patient's lesions.

4. Discussion

The normal physiological activity of brain tissues depends on certain blood oxygen supply, and the compensatory contraction of capillary smooth muscle and small artery can alleviate the limited fluctuation of cerebral blood perfusion pressure, so as to maintain basically stable cerebral blood flow [14]. When the reduction in perfusion pressure is less than the circulating reserve capacity of the brain, CBF

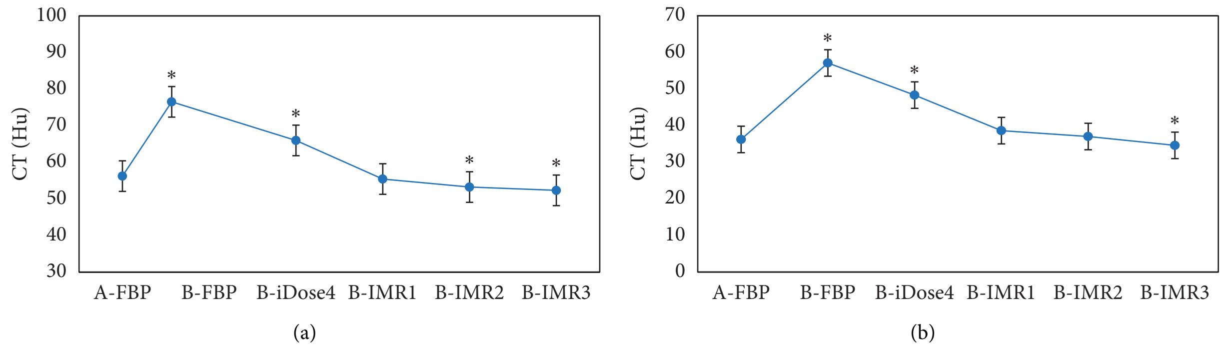

Figure 2: Statistical results of CT values of gray and white matter in the brain among patients from groups A and B by different reconstruction methods. A and B are the statistical results of gray and white matter in patients from both groups under various reconstruction methods, respectively. *CT value of patients from group B was dramatically different compared with group A ($p < 0.05$).

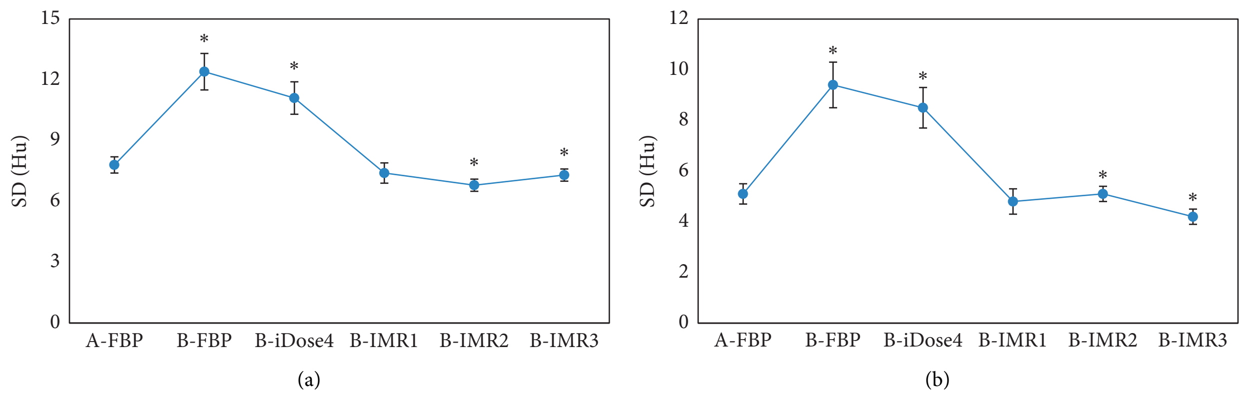

Figure 3: Statistical results of SD values of gray and white matter in the brain among patients from groups A and B by different reconstruction methods. A and B are the statistical results of gray and white matter in patients from the two groups under various reconstruction methods, respectively. *The SD value of patients from group B was different greatly in contrast to group A ($p < 0.05$).

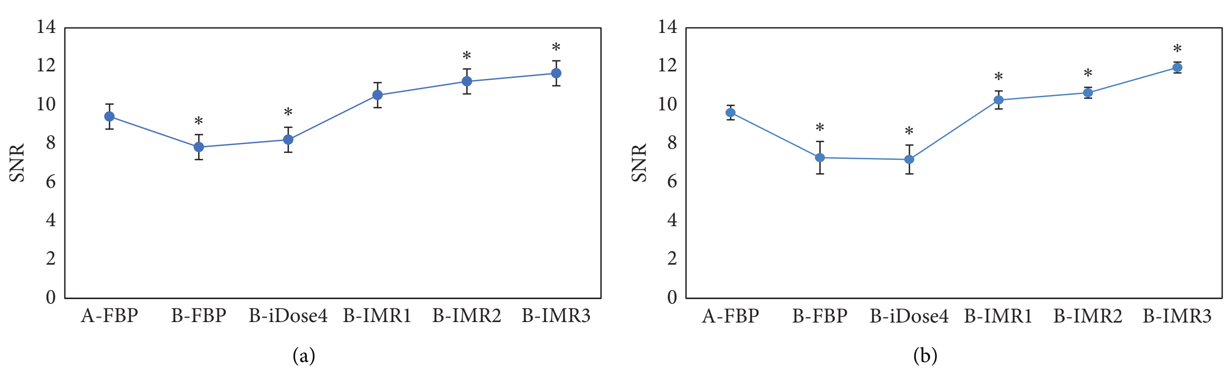

Figure 4: Statistical results of SNR values of gray and white matter in the brain among patients from groups A and B by different reconstruction methods. A is the statistical result of gray matter in patients from the two groups under various reconstruction methods; B is the statistical result of white matter in patients from the two groups under different reconstruction methods. *The SNR value of patients from group B was different obviously compared to group A ($p < 0.05$).

expresses to be normal or a slight decrease, and CBV often increases at this moment due to arteriolar and capillary dilatation. When the decrease of CBF is greater than that of cerebral circulation reserve force, neurons absorb excess glucose and increase oxygen content to maintain normal cell physiological metabolism. At this time, CBF falls below the threshold of electrical failure, so CBF reduces significantly and CBV is normal or decreases. With the continuous decline of CBF, the metabolism level in the brain changes dramatically, the balance of various substances is disrupted, and there is irreversible apoptosis in neurons, namely, ACI [15], with CBF and CBV both dropping obviously.

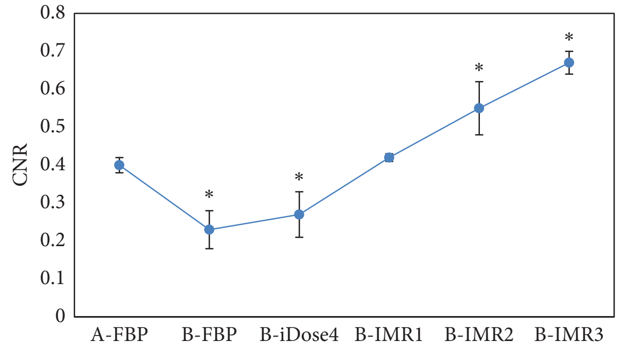

Figure 5: Statistical results of CNR of gray matter in the brain among patients from both groups by various reconstruction methods. *The CNR value of group B was different hugely from that of group A ($p < 0.05$).

Table 2: Comparison results of perfusion indicators in gray and white matter among patients in the two groups.

Group	Reconstruction methods		CBV (mL/100 g)	CBF (mL/100 g/min)	MTT (s)	TTP (s)
A	FBP	Gray matter	5.08 ± 0.42	54.23 ± 4.97	5.65 ± 0.76	18.65 ± 2.87
		White matter	3.12 ± 0.23	23.32 ± 2.16	7.38 ± 1.12	19.86 ± 2.97
B	FBP	Gray matter	4.76 ± 0.45	61.65 ± 8.32	8.23 ± 1.98	18.74 ± 2.31
		White matter	3.16 ± 0.72	31.54 ± 3.21	11.76 ± 2.12	19.23 ± 2.76
	iDose4	Gray matter	4.98 ± 0.47	53.09 ± 3.97	6.54 ± 1.19	18.54 ± 2.13
		White matter	3.17 ± 0.64	25.76 ± 2.96	10.09 ± 2.01	19.76 ± 3.21
	IMR1	Gray matter	5.32 ± 0.71	51.85 ± 3.21	6.21 ± 0.87	18.65 ± 2.45
		White matter	3.16 ± 0.42	23.76 ± 2.93	7.86 ± 1.32	19.93 ± 2.87
	IMR2	Gray matter	5.54 ± 0.89	51.23 ± 3.63	6.26 ± 0.76	18.65 ± 2.52
		White matter	3.21 ± 0.41	23.67 ± 2.87	7.63 ± 1.06	19.78 ± 2.76
	IMR3	Gray matter	5.39 ± 0.75	52.98 ± 5.87	6.24 ± 0.52	18.76 ± 2.61
		White matter	3.23 ± 0.51	22.54 ± 2.12	7.80 ± 1.13	19.72 ± 2.84
Z		Gray matter	5.42	4.87	18.65	0.008
		White matter	0.8	12.43	39.76	0.5
p		Gray matter	<0.001	0.001	<0.001	1.8
		White matter	0.72	<0.001	<0.001	0.93

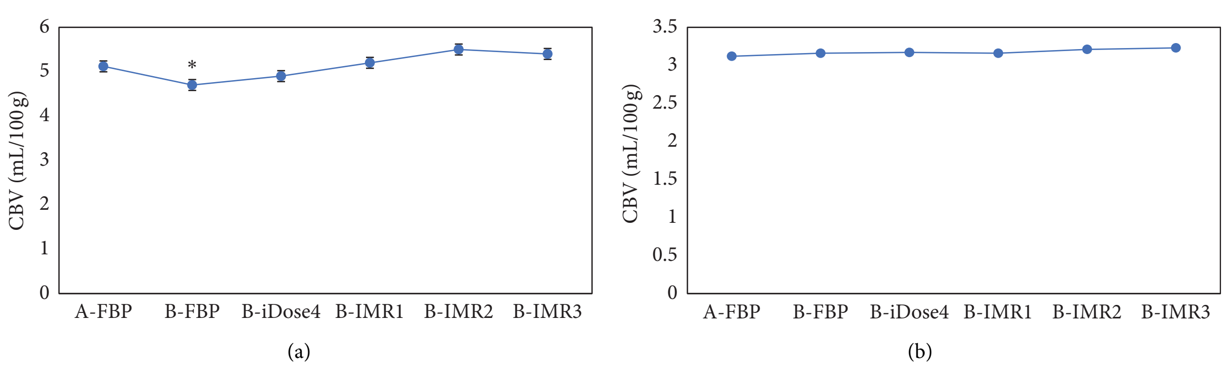

Figure 6: Statistical results of CBV of gray and white matter in the brain among patients from groups A and B under the six reconstruction methods. A is the statistical result of gray matter in patients from the two groups under various reconstruction methods; B is the statistical result of white matter in patients from the two groups under different reconstruction methods. *The CBV value of patients from group B was different considerably by comparing with group A ($p < 0.05$).

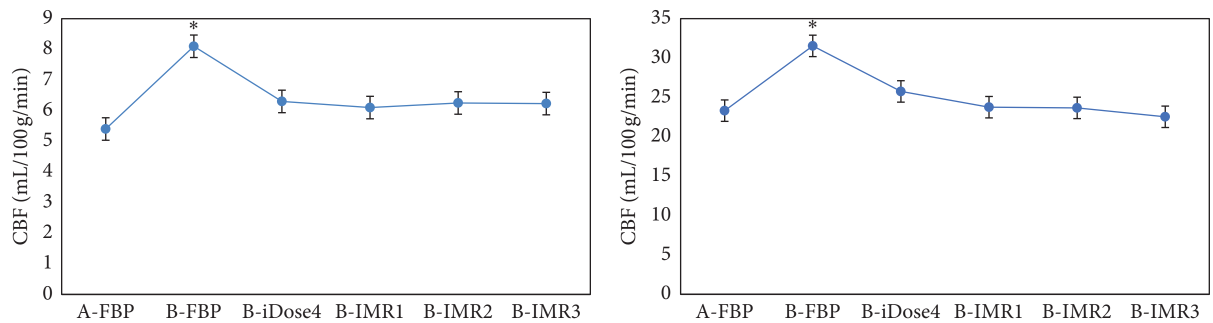
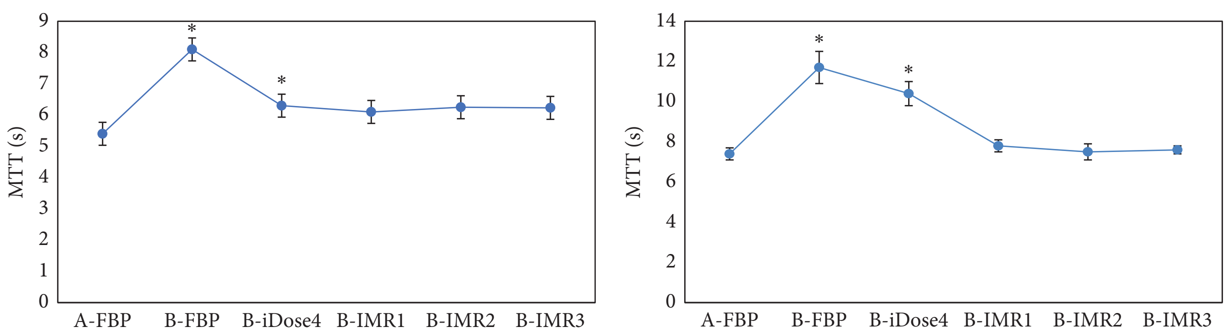
CTP requires continuous repeated scanning of the target area, so the radiation dose of a patient is higher enormously than that of CT scanning. Therefore, how to reduce the radiation dose of CTP has been attracting the attention of scholars. The traditional methods for radiation reduction include reducing tube voltage, tube current, and acquisition



(a) (b)

Figure 7: Statistical results of CBF of gray and white matter among patients from the two groups under different reconstruction methods. A is the statistical result of gray matter in patients from the two groups under the six reconstruction methods; B is the statistical result of white matter in patients from the two groups under different reconstruction methods. *The CBF value of patients from group B had a significant difference compared with group A ($p < 0.05$).



(a) (b)

Figure 9: The (a) CT and (b) CTP images of ACI.

time and frequency, but these measures are easy to increase image noise. With the application of IMR, the image quality can be guaranteed within the maximum range, thus making the traditional methods well applied [16]. In this study, patients with the CTP scanning mode of 80 kV–150 mAs routine dose combined with FBP image reconstruction were regarded as group A to evaluate the changing patterns of each indicator of gray and white matter in patients from group B under different image reconstruction methods. The results indicated that FBP was for reconstruction in the mode of low dose, and the average CT values of gray and white matter in patients from group B were 40% and 55% higher than that of group A, respectively. Moreover, the average CT values of gray and white matter in patients from group B increased by 20% and 28% after the iDose4 reconstruction, respectively. Therefore, the above data could determine that FBP and iDose4 reconstruction were not suitable for the image reconstruction of the low-dose scanning mode. On the contrary, there was no obvious change in the CT value of gray and white matter in the brain with the application of IMR, the CT value of gray and white matter reconstructed by IMR1 in patients of group B had no great difference from those of group A, the CT value reconstructed by IMR2 in patients of group B was at the middle level, and the CT value reconstructed by IMR3 in patients of group B was less than that of group A. This was related to the superior noise reduction function of IMR, making the CT value of gray and white matter return to normal or even lower than the normal value. Previous studies have shown that IMR has an excellent image noise reduction capability and can also improve image resolution [17]. In addition, studies have indicated that the average image noise and CNR under IMR reconstruction are superior markedly to hybrid iterative reconstruction and FBP technology, and IMR improves remarkably the image quality under low-tube voltage that especially helps to promote the display effect of distal vessels [18]. This is consistent with the results of this study.

5. Conclusion

The advantages of the IMR full-model iterative reconstruction algorithm in CTP image reconstruction were verified by comparing with low and conventional dose CTP. The results showed that IMR could ensure the quality of CT images under lower dose of radiation and complete the diagnosis of patients with ACI compared with FBP and iDose4, which could be promoted clinically. Therefore, a new direction was provided by this study for the diagnosis of patients with ACI, and the safety of patients was greatly enhanced during examination. The shortcoming of this study was that it had not been compared with other imaging methods, leading to a relatively single standard for judgment.

The performance characteristics of deep learning fully convolutional neural network (DLFCNN) algorithm-based computed tomography (CT) images were investigated in the detection and diagnosis of perianal abscess tissue. 60 patients who were medically diagnosed as perianal abscesses in the hospital were selected as the experimental group, and 60 healthy volunteers were selected as the control group. In this study, the DLFCNN algorithm based on deep learning was compared with the CNN algorithm and applied to the segmentation training of CT images of patients with perianal abscesses. Then, the segmentation metrics Jaccard, Dice coefficient, precision rate, and recall rate were compared by extracting the region of interest. The results showed that Jaccard (0.7326) calculated by the CNN algorithm was sharply lower than that of the DLFCNN algorithm (0.8525), and the Dice coefficient (0.7264) was also steeply lower than that of the DLFCNN algorithm (0.8434) ($P < 0.05$). The thickness range of the epidermis and dermis in patients from the experimental group was 4.1–4.9 mm, which was markedly greater than the range of the control group (1.8–3.6 mm) ($P < 0.05$). Besides, the CT value of the subcutaneous fascia in the experimental group (-95.45 ± 8.26) hugely reduced compared with the control group (-76.34 ± 7.69) ($P < 0.05$). The accuracy rate of the patients with perianal abscesses was 96.67% by multislice spiral CT (MSCT). Therefore, the DLFCNN algorithm in this study had good stability and good segmentation effect. The skin at the focal site of anal abscess was obviously thickened, and it was simple and accurate to use CT images in the diagnosis of patients with perianal abscesses, which could effectively locate the lesion and clarify the relationship between the lesion and the surrounding structure.

1. Introduction

Perianal region refers to the area extending 5-6 cm from the junction between the anal squamous mucosa and the skin [1]. Perianal abscess is an abscess caused by acute and chronic infections of the perianal space [2], which is manifested as redness, pain, swelling, and agglomeration of the skin around the anus, accompanied by systemic symptoms of varying degrees [3]. Perianal abscess is a common and frequently occurring disease in surgery, which has a high incidence and seriously affects the normal life and work of patients. In the past, the comprehensive diagnosis of perianal abscess was mainly made by digital surgical rectal examination, clinical symptoms, clinical vital signs, etc., which could not directly determine the location and range of the lesion and resulted in high blindness in diagnosis and treatment [4]. Therefore, the surgical treatment of perianal abscess has to be accurately positioned and diagnosed preoperatively to improve the safety of the surgery.

In recent years, with the continuous development of electronic imaging technology, multislice spiral computed tomography (MSCT) has gradually been applied in the clinical treatment of perianal abscess [5]. CT scanning has the characteristics of fast scanning speed, powerful image postprocessing function, and clear image [6]. Furthermore, CT scanning is used for the examination of the human abdomen and pelvis, without special bowel preparation such as enema or inflation [7]. Therefore, the application of CT scanning to examine the tissue structure of human perianal abscesses will help improve the clinical diagnosis of anal diseases.

Segmentation algorithms based on deep learning can deeply learn the mapping relationship between images and are widely used in computer vision and sound effects. They can methodically sort out a large amount of data, extract image features, and efficiently deal with complex problems, which have become the mainstream application of segmentation algorithms at present [8, 9]. Mastragostino et al. [10] used the deep learning-based convolutional neural network to evaluate CT images of liver tissue with high segmentation accuracy. In this study, a deep learning fully convolutional neural network (DLFCNN) algorithm was proposed to replace the full connection layer in the later stage of the CNN with the convolutional layer so that the number of neurons in the input layer was not restricted. The input of the convolutional layer could accept images of different sizes; the window for each value in the output to be mapped to the receptive field in the input image was fixed, which greatly improved the speed.

In this study, DLFCNN algorithm was proposed and compared with the CNN algorithm, which was applied in the CT imaging diagnosis of 60 patients with perianal abscesses. The objective of this study was to investigate the ability of CT images to distinguish the structure of perianal abscess tissue and to summarize the specific signs of perianal abscess tissue, so as to lay a foundation for the CT diagnosis of anorectal diseases.

2. Materials and Methods

2.1. General Data. In this study, 60 patients with medical diagnosis of perianal abscess in the Department of Anorectal Surgery of our hospital from October 2018 to December 2019 were selected as the experimental group, including 68 males and 52 females, with an average age of 54.23 ± 11.46 years. Another 60 healthy volunteers were selected as the control group, and the experimental group was diagnosed by MSCT scanning. The study was approved by the Medical Ethics Committee of the hospital, and the research objects and their family members learnt about the study and signed informed consent forms.

The criteria for inclusion were defined to include research objects who were diagnosed with perianal abscesses and had anal mass with pain, had complete clinical data and imaging data, and had suffered from the disease for more than 4 weeks.

The criteria for exclusion were defined to include research objects who were combined with cardiovascular disease, mental illness, speech impairment, and hearing impairment, did not undergo anorectal surgery in the past 6 months, and had unclear CT images.

2.2. Deep Learning Fully Convolutional Neural Network (DLFCNN) Algorithm. Neuron is the basic functional unit of the whole neural network structure (Figure 1). A large number of neurons together form a neural network structure. The essence of the internal convolution operation of the DLFCNN algorithm model is the integral operation, and the calculation equation is as follows:

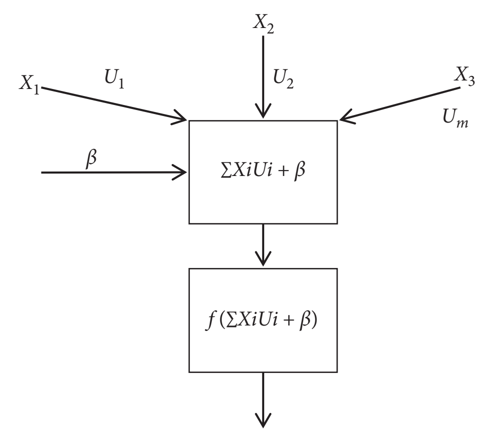

Figure 1: The basic structure of a neuron.

$$(g \cdot h)(s) \triangleq \int_{-\infty}^{\infty} g(\gamma)h(s-\gamma)\mathrm{d}\gamma. \quad (1)$$

In equation (1), function g and function h represent continuous functions, and both of them are integrable functions in the range of real numbers. Assume that the two-dimensional vector P and the convolution kernel Q are the input, and the output L is a two-dimensional tensor, which can be expressed in the following:

$$L(i,j) = (P \cdot Q)(i,j) = \sum_a \sum_b P(a+i, b+i) \cdot Q(a,b). \quad (2)$$

In equation (2), P is a 6×6 two-dimensional vector, Q is a 4×4 convolution kernel, and the output L is a two-dimensional tensor with 4×4. According to the equation, the size of the input image $(i \times i)$ directly affects the size of the output image $(L \times L)$, and it will also be affected by the size of the convolution kernel $(q \times q)$ during the operation. In order to better segment the edge of the image, a supplementary parameter o is often added. The specific equation is as follows:

$$L = \left[\frac{i-q+2o}{t}\right] + 1. \quad (3)$$

In equation (3), i stands for the size of the input image, q represents the size of the convolution kernel, and L means the size of the output image. Model networks often have multilayer superimposed hollow convolution, and the use of a zigzag structure can avoid the superposition of information and maintain the continuity of information. The zigzag structure uses time intervals of different lengths to integrate information from different distances and nearby locations. Thus, the following equation can be obtained:

$$N_i = \max\left[N_{i+1} - 2\lambda_i, N_{i+1} - 2\left(N_{i+1} - \lambda_i\right), \lambda_i\right]. \quad (4)$$

In equation (4), λ_i represents the hole interval of the ith layer, and N_i indicates the hole interval of the last layer, which is also the maximum value of the hole interval. In this study, the void interval was set to (2, 4, 5). The essence of the operation of the convolutional layer is to perform weighted summation. The function used in this study was the sigmoid function for classifying and outputting, and the ReLU function was adopted for extracting image features. Among them, the calculation and derivative equations of the sigmoid function are shown in the following:

$$\mathrm{Sig} = \frac{1}{1+e^{-c}} = \frac{1}{1+e^{-(vx+b)}}, \tag{5}$$

$$\mathrm{Sig}'(c) = \frac{e^{-c}}{\left(1+e^{-c}\right)^2}. \tag{6}$$

The function values in equations (5) and (6) are both in (0, 1), and the sigmoid function is a differentiable function. The ReLU function can reduce the problem of the disappearance of the gradient, and its mathematical operation and derivative equations are as follows:

$$\mathrm{ReLU}(c) = \max(0, c), \tag{7}$$

$$\mathrm{ReLU}'(c) = \begin{cases} 0, & c<0, \\ 1, & c>0. \end{cases} \tag{8}$$

In equations (7) and (8), the derivative of the ReLU function is negative, and the gradient is in a saturated state when $c<0$. When $c>0$, the derivative of the ReLU function is 1, and no gradient disappears. Compared with the sigmoid function, the ReLU function has a faster calculation speed and convergence speed. For the input P, the gap between $g(P)$ obtained by the model output and the actual value K usually requires a loss function to express the degree of deviation, which is recorded as $R(K, g(P))$ that is presented in the following equation:

$$R = \frac{1}{2m}\sum (K - g(P))^2. \tag{9}$$

2.3. Extraction of the Region of Interest from the CT Image of the Perianal Abscess Tissue. The main purpose of segmenting the CT image of the perianal abscess tissue was to classify the lesion. There was some irrelevant noise information in the CT image. If there was an error in the segmentation process, the classification result would be inaccurate, resulting in the perianal abscess. The iterative threshold method was adopted in this study to effectively solve the problems of inconspicuous contrast of light and dark in CT images, the dark overall image, and the too small difference between pixels. A clear CT image of perianal abscess could be obtained after a series of operations, such as expansion, corrosion, cavity filling, open operation, close operation, and mask operation. Figure 2 shows the extraction process of the region of interest in the image of perianal abscess tissue through the iterative threshold method. After the extraction of the region of interest, the image of perianal abscess tissue could reduce the amount of data and the interference of noise, complete the outline of the lesion, and realize the preprocessing of the image.

2.4. Examination Method. The diagnosis was made by using Somatom Definition AS+ 64-slice, 128-slice 4-dimensional spiral CT (Siemens, Germany). Before the examination, routine bowel preparations were performed. After the bladder was properly filled, the scanning was started. Each patient held his head with his hands, his lower limbs were in an external stand, and he was in a supine position in the center of the examination bed. The central sagittal position of his body was perpendicular to the plane of the bed, and his head was advanced. During the examination, the patient should keep a calm state of mind, not move his body, and hold his breath as required.

Scanning parameters were as follows: the flat sweep tube voltage was 120 kV and tube current was 175 mA; layer thickness was 2.5 mm and layer spacing was 5.0 mm; enhanced tube voltage and tube current were also 120 kV and 175 mA in turn; scanning rotation speed was 0.8 s/r, pitch was 1.0, field of view (FOV) was 250 mm × 250 mm, and the matrix was 512 × 512; the reconstruction layer thickness was 1.5 mm, and the layer spacing was 1.5 mm. 0.9% sodium chloride (NaCl) injection and 20 mL of iohexol injection were used as contrast agents. After probe exploration, the catheter was inserted, and the contrast agent was injected. After completion, image processing was carried out. On the AmbiVU 4.2.3 workstation, the image of the third sacral vertebra-anus area was reconstructed with a thickness of 1.5 mm, and the multiplanar reconstruction and maximum intensity projection reconstruction technology were employed to observe and save the relevant data. Two experienced doctors reviewed the CT images separately and reached a conclusion after discussion when their opinions were inconsistent.

2.5. Simulation Experiment Design of Deep Learning Fully Convolutional Neural Network Algorithm. In order to verify the effectiveness of the CT image segmentation method of perianal abscess tissue based on DLFCNN, a comparative experimental platform was designed in this study. The CT images of 60 patients with perianal abscesses were processed in batch by DLFCNN based on deep learning. Colloidal operation was performed in the convolutional layer of the convolutional network. Finally, the segmentation results were output in the output layer of the full connection layer. Table 1 shows the number of feature graphs and the size of the convolution kernel in each convolutional layer of DLFCNN. Moreover, C1 represented the convolutional layer, which mainly performed the convolution operation of the filter and then output the activation function. S2 stood for the sampling layer, and the input data of the previous layer were processed by dimensionality reduction. C3 and S4 both expressed the network layers, C3 was similar to C1, and S4 was similar to S2, which indicated the second downsampling layer. C5 meant the convolutional layer, which had 28 feature maps; the size of the feature map was changed after processing. S6 represented the downsampling layer, and the principles of C7 and S8 were the same as before. In addition, F9 stood for the full connection layer, which contained multiple neural units, and each neural unit was fully connected to the previous layer.

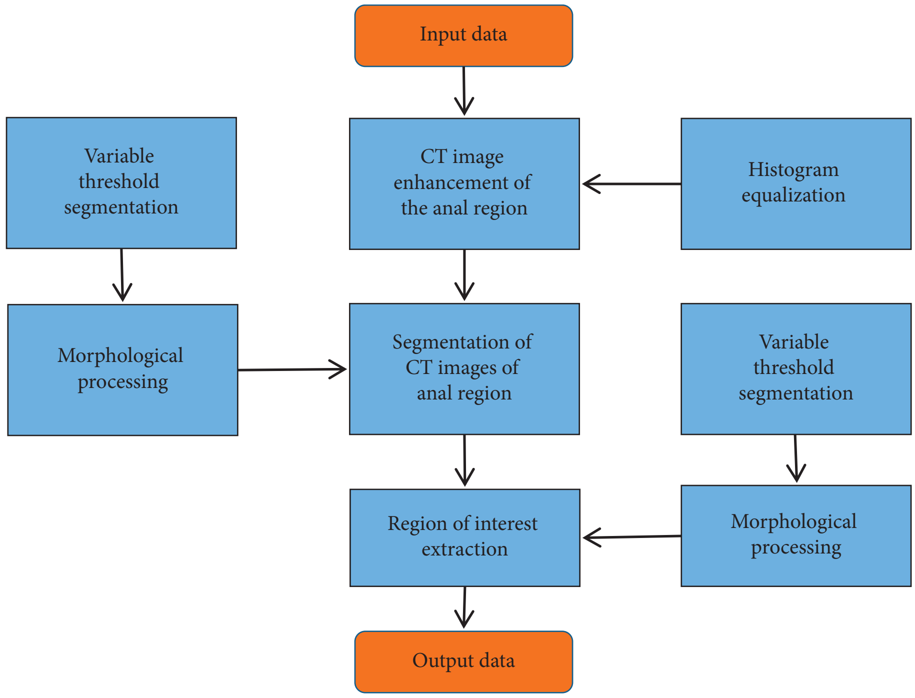

Figure 2: The extraction process of the region of interest in the image of perianal abscess tissue by the iterative threshold method.

2.6. Design of Evaluation Indicators for Deep Learning Fully Convolutional Neural Network Algorithm. In this study, it was necessary to select the appropriate image segmentation indicators in order to evaluate the extraction effect of the perianal abscess tissue segmentation process in the segmentation method. Commonly used segmentation metrics included Jaccard, Dice coefficient, precision rate, and recall rate. Jaccard was mainly employed to evaluate the effect of image segmentation, which could be calculated as follows:

$$\text{Jaccard} = \frac{C \cap D}{C \cup D}. \tag{10}$$

In equation (10), C stood for the label of the anal abscess tissue delineated in the image segmentation, representing the gold standard; D meant the segmentation result. If $\text{Jaccard} = 1$, the segmentation result completely overlapped with the gold standard. The Dice coefficient could be adopted to evaluate the similarity of two sets, and its equation is expressed as follows:

$$\text{Dice} = \frac{2|C \cap D|}{|C| + |D|}. \tag{11}$$

In equation (11), $\text{Dice} = 1$ indicated that the segmentation result was very ideal. Besides, the calculation of accuracy was as follows:

$$\text{Accuracy rate} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \tag{12}$$

In equation (12), TP stood for that the detected perianal abscess tissue showed a true positive, and FP meant that the detected perianal abscess tissue showed a false positive. Furthermore, the equation for calculating the recall rate was as follows:

$$\text{RR} = \frac{\text{TP}}{\text{TP} + \text{FN}}. \tag{13}$$

In equation (13), TP suggested that the detected perianal abscess tissue presented a true positive, and FN indicated that the detected perianal abscess tissue presented a false negative.

2.7. Statistical Methods. SPSS 22.0 statistical software was used for analysis. The data which met the normal distribution were represented by the mean ± standard deviation ($\overline{x} + s$), and the data of the nonnormal distribution were expressed as the frequency and percentage. Furthermore, the t-test or χ^2 test was used for comparison between the control group and the experimental group. In addition, $P < 0.05$ indicated that the difference was statistically substantial.

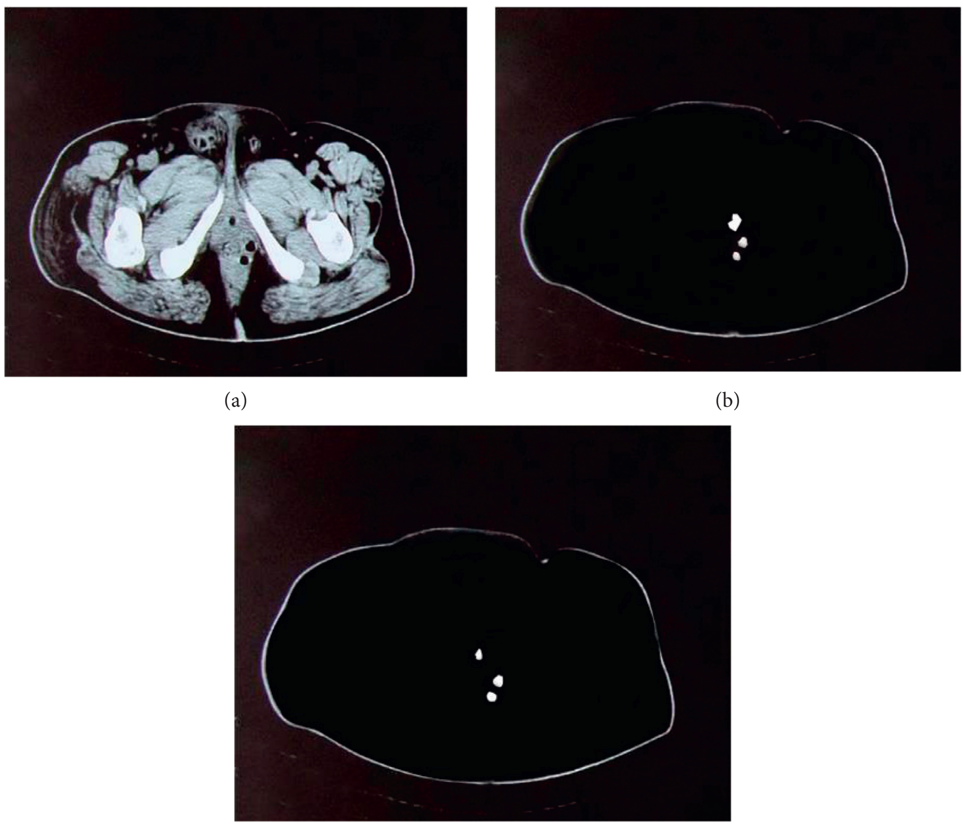
3. Results

3.1. Comparison on CT Image Segmentation Effects of the Two Algorithms. Figure 3 shows the comparison of the CT image segmentation effect between the CNN and FCNN. In this study, the DLFCNN algorithm was proposed based on deep learning and compared with the CNN algorithm, which were applied in the CT image evaluation of 60 patients with perianal abscesses. According to the general structure, the segmentation effect of the CNN was not particularly prominent, while the segmentation of the DLFCNN was relatively accurate.

3.2. Analysis on the Simulation Effects of the Two Algorithms. The simulation effects of the two algorithms were compared, and the results are shown in Figure 4. The maximum entropy

Table 1: The number of feature maps of the DLFCNN and the size of the convolution kernel.

Convolutional layer	The number of feature maps	The size of the convolution kernel
C1	14	2×2
S2	14	5×5
C3	14	5×5
S4	14	2×2
C5	28	5×5
S6	28	2×2
C7	28	5×5
S8	28	2×2
F9	52	5×5



(a) (b) (c)

Figure 3: Comparison on the segmentation effect of the two algorithms. (a) Input CT image of perianal abscess tissue. (b) Segmentation effect of CNN algorithm. (c) Segmentation effect of DLFCNN algorithm.

method of the DLFCNN algorithm in this study began to converge around 25 iterations. The final loss value of the CNN was around 0.09. The image segmentation algorithm of the algorithm explored in this study had a faster convergence rate than the CNN in the training process, and the lowest final loss value was between 0.03 and 0.04.

Jaccard (0.7326) calculated by the CNN algorithm was sharply lower than that of the DLFCNN algorithm (0.8525) ($P < 0.05$), and the Dice coefficient (0.7264) hugely dropped in contrast to that of the DLFCNN algorithm (0.8434) ($P < 0.05$). The precision rate and recall rate of the CNN were also lower than the rates of the FCNN, but there was no significant difference. It revealed that the CNN was prone to oversegmentation and missing-segmentation. If the gold standard was taken as a reference, it indicated that the segmentation results differed greatly between the gold standards. However, the segmentation indicators of the DLFCNN in this study were improved to varying degrees, and the segmentation effect was better than that of the CNN.

3.3. Comparison on the General Data of Research Objects from the Two Groups. There was a comparison on the general data of research objects from the two groups, as shown in Figure 5. There were 36 males (60%) and 24 females (40%) in the experimental group, while there were 32 males (53.33%) and 28 females (46.67%) in the control group. Thus, the gender ratio of the two groups had no obvious difference ($P > 0.05$).

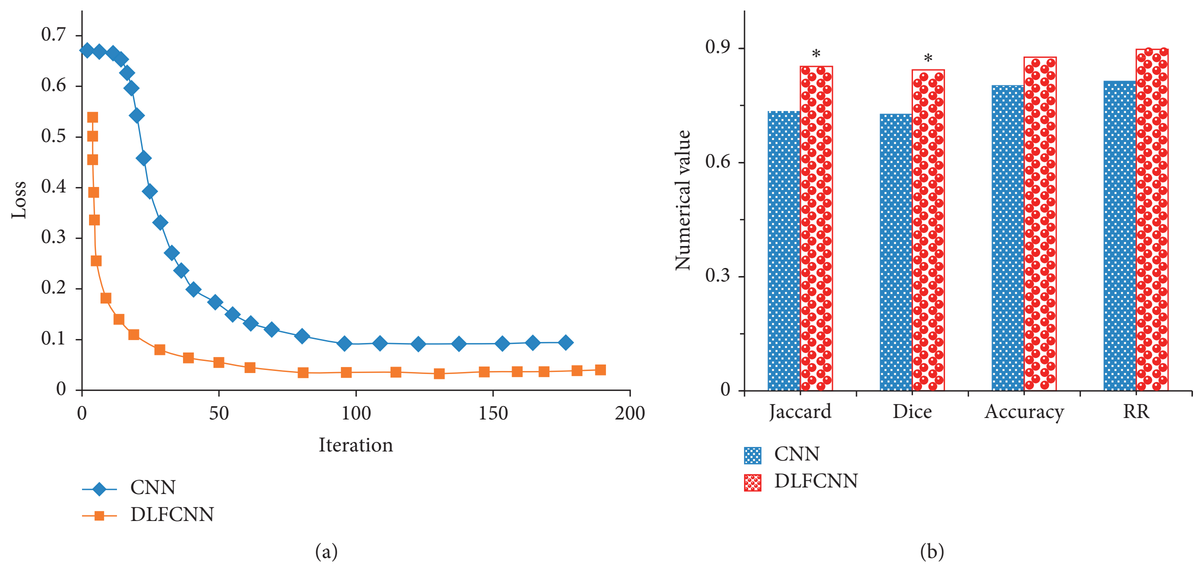


FIGURE 4: Comparison on simulation effects of the two algorithms. (a) Loss training curve diagram of the two algorithms. (b) Comparison of the segmentation indicators of the two algorithms; *meant $P < 0.05$ compared with the CNN.

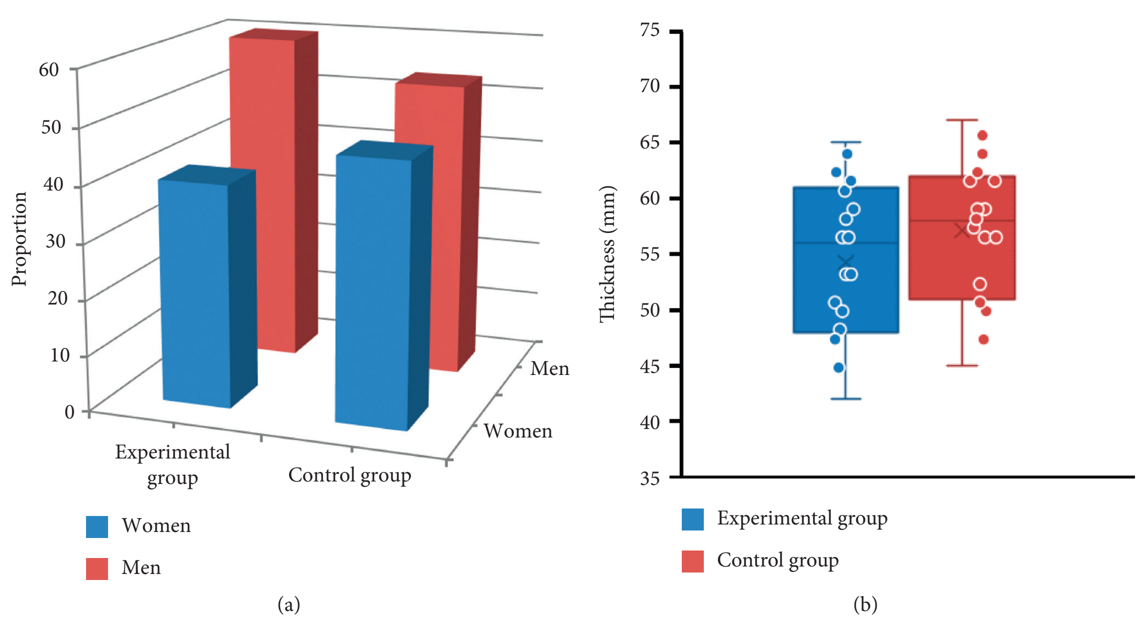

FIGURE 5: Comparison on the general data of research objects from the two groups. (a) The proportion of gender between the experimental group and the control group. (b) The age distribution of the experimental group and the control group.

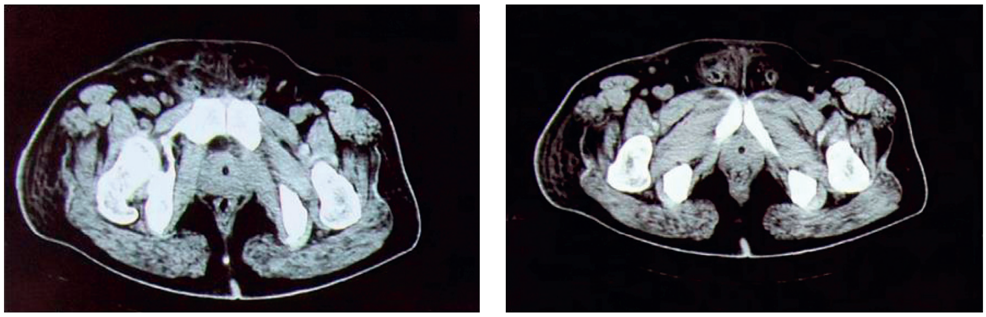
The age range of the experimental group was 42–65 years, and the age range of the control group was 45–67 years. There was no marked difference in age between the experimental group and the control group ($P > 0.05$).

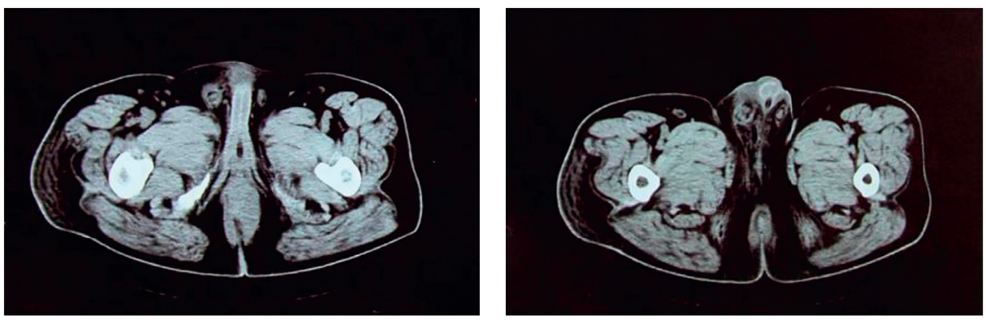
3.4. CT Imaging Features of Patients with Perianal Abscesses. Figures 6 and 7 display the axial and coronal CT images of two cases with perianal abscesses, respectively. The CT image of the soft tissue around the anal canal showed U-shaped thickening, uneven density, low-density shadows in the center, blurred edges of the lesion, and obvious enhancement of the central lesion on the enhanced scan. The central low-density shadow showed no obvious enhancement. The short strips were clearly intensified and connected with the posterior edge of the anal canal.

3.5. The Thickness of the Epidermis and Dermis in the Research Objects from the Experimental Group and the Control Group. According to the statistical results, it was found that the thickness of the epidermis and dermis of men was 2.8–3.6 mm, and the thickness of the epidermis and dermis of women was 1.8–2.6 mm. The thickness of the epidermis and dermis of men was obviously greater than the thickness of women, and the difference was statistically significant



(a) (b)

Figure 6: CT image with a perianal horseshoe abscess (asterisk) (case 1, a male patient, aged 53 years). (a) Axial CT image. (b) Coronal CT image.



(a) (b)

Figure 7: CT image with the spread of abscess upward to the left levator ani muscle, forming an abscess (case 2, a male patient, aged 56 years). (a) Axial CT image. (b) Coronal CT image.

($P < 0.05$) (Figure 8); the thickness of the epidermis and dermis of the experimental group was 4.1–4.9 mm, and the thickness of the control group was 1.8–3.6 mm, so the thickness of the experimental group markedly increased compared with that of the control group ($P < 0.05$) (Figure 9).

3.6. Comparison on the CT Observation of the Superficial Fascia and Subcutaneous Fascia between the Experimental Group and the Control Group. The comparison results of the CT observation of the superficial fascia and subcutaneous fascia between the experimental group and the control group are presented in Figure 10. The display rate of the superficial fascia in the experimental group was 46.35%, and the display rate of the control group was 37.56%, so there was no marked difference between the two ($P > 0.05$). Furthermore, the CT value (-95.45 ± 8.26) of the subcutaneous fascia in patients from the experimental group was substantially greater than the value of the control group (-76.34 ± 7.69), with a statistical difference ($P < 0.05$).

3.7. The Detection Rate of CT Images in Patients with Perianal Abscesses. Figure 11 shows the accuracy and misdiagnosis rate of lesions in patients with perianal abscesses. 60 cases of perianal abscesses were examined by MSCT, 58 cases were in line with pathological examination, and 2 cases were misdiagnosed. After postoperative pathological examination, 58 patients had accurate location of the lesions, with an accuracy rate of 96.67%, including 21 cases of upper levator ani muscle abscess and 37 cases of lower levator ani muscle abscess.

4. Discussion

In this study, the deep learning fully convolutional neural network algorithm was compared with the CNN algorithm, which were applied to the segmentation training of CT images of patients with perianal abscesses to solve the problem that the segmentation effect was not ideal due to incomplete feature extraction of the CNN segmentation. By extracting the region of interest, the commonly applied segmentation metrics of medical images were compared, including Jaccard, Dice coefficient, accuracy, and recall rate [11]. The results disclosed that the maximum entropy method of the DLFCNN algorithm in this study started to converge when the times of iteration were around 25, and the final loss value of the CNN was around 0.09. The lowest loss value of the image segmentation algorithm in this study was between 0.03 and 0.04 in the final training, suggesting that the convergence speed of the DLFCNN was fast. Jaccard (0.7326) calculated by the CNN algorithm sharply reduced compared with the DLFCNN algorithm (0.8525); the Dice coefficient (0.7264) was obviously lower than the Dice coefficient (0.8434) of the DLFCNN algorithm ($P < 0.05$) [12].

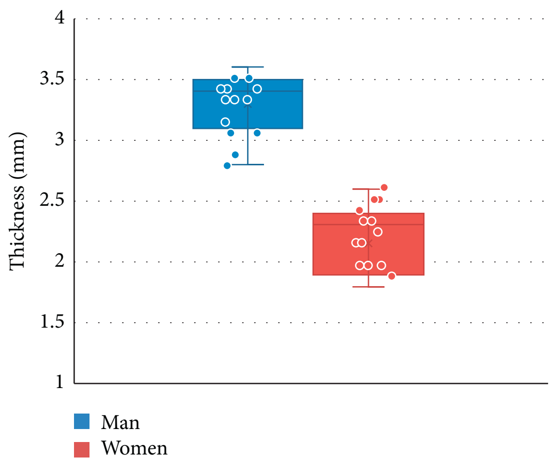


Figure 8: Comparison on dermal and epidermal thickness between men and women in the control group. *indicated $P < 0.05$ compared with men.

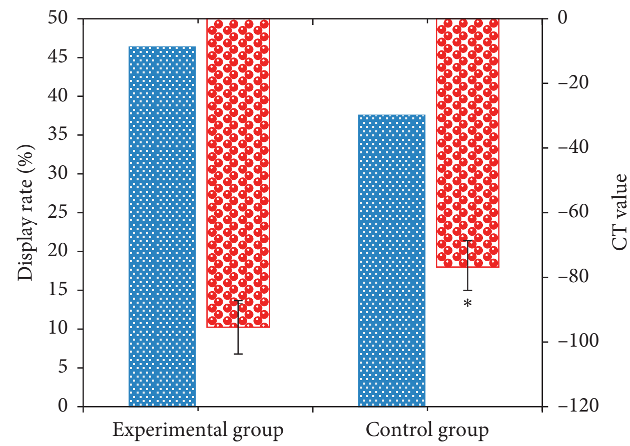

Figure 10: Comparison on the CT observation of the superficial fascia and subcutaneous fascia between the experimental group and the control group. *indicated $P < 0.05$ in contrast to the experimental group.

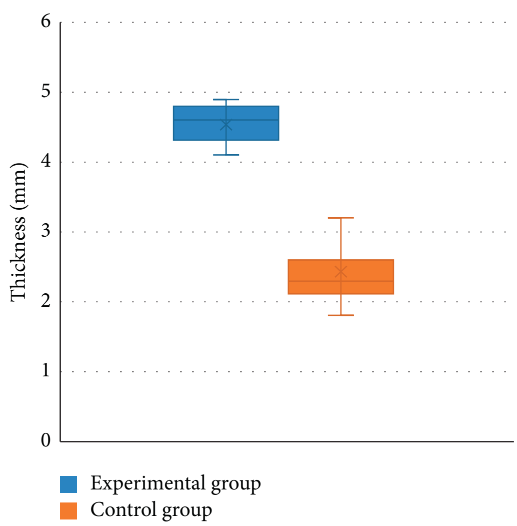

Figure 9: Comparison on epidermal and dermal thickness between the experimental group and the control group. *meant $P < 0.05$ compared with the experimental group.

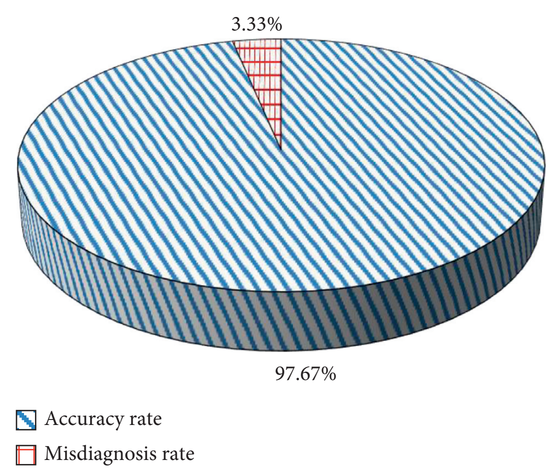

Figure 11: The accuracy and misdiagnosis rate of lesions in patients with perianal abscesses.

It showed that the CNN was prone to oversegmentation and missing-segmentation. If the gold standard was used as a reference, it indicated that the segmentation results were quite different among the gold standards [13]. DLFCNN in this study was improved to varying degrees in terms of segmentation indicators, with good stability and good segmentation effects [14].

Perianal abscess is a common and frequently occurring disease after clinical surgery, which is generally caused by primary infection. Some perianal abscesses are caused by trauma, inflammatory lesions, and drug injection [15]. Under normal circumstances, clinical diagnosis focuses on the number of lesions and the location of the relationship between the lesion location and the levator ani muscle. Besides, the use of CT imaging diagnosis before surgery has a very positive significance in preventing postoperative recurrence. MSCT images continue to expand the diagnostic methods of perianal abscess tissue imaging. It has the characteristics of fast inspection, thin layers, and high resolution and is widely used in the diagnosis of anal diseases [16]. When perianal abscess is detected with MSCT, it is usually not affected by the weak peristalsis of the anorectum, with few motion artifacts, and the lesion can be clearly shown in the image. Perianal abscesses are affected by the pus, the boundaries are not clear, and the density of the abscess is not uniform over time. In this study, the CT value of the subcutaneous fascia of the experimental group was -95.45 ± 8.26, which was significantly lower than the value of the control group (-76.34 ± 7.69) ($P < 0.05$). It might be that patients with early perianal abscess had more inflammatory exudate, and the CT scan had a uniform density and a low CT value [17]. In the middle and late stages of the formation of pus in the perianal abscess tissue, the absorption or discharge of pus will occur, forming an abscess cavity, which is manifested as a thick wall and abscess cavity [18]. With enhanced CT scanning, it can be observed that the thick wall of the abscess is obviously strengthened, in a ring shape, and the abscess cavity is not strengthened, showing a lower density. After the CT image is segmented by the DLFCNN algorithm, the relationship between the perianal abscess and the anorectum can be better displayed, and the number and location of the abscess can be accurately located, providing a reliable basis for the treatment of clinicians [19]. 60 patients with perianal abscesses were examined by MSCT. 58 patients had accurate location of the lesion with an accuracy rate of 96.67%, which confirmed that the MSCT scan could clearly show the morphology and structure of the lesion, thereby providing intuitive clinical diagnosis. This was consistent with the research findings of Zhao et al. [20].

CT image measurement of skin thickness is mainly used in the application research of breast skin, but there are few reports on the research of skin thickness measurement in the anal area. The statistical results of this study found that the thickness of the epidermis and dermis of men was in the range of 2.8–3.6 mm, and the thickness of the epidermis and dermis of women was 1.8–2.6 mm. The thickness of the epidermis and dermis of men was markedly greater than that of women, and there was a statistically great difference ($P < 0.05$). Moreover, the thickness of the epidermis and dermis of the experimental group was 4.1–4.9 mm, and the thickness of the control group was 1.8–3.6 mm. The thickness of the epidermis and dermis of the experimental group was greatly larger than that of the control group ($P < 0.05$), meaning that the skin at the lesion site was significantly thickened when a lesion occurred in the anal area, which could clearly distinguish between perianal abscess and other anal diseases.

5. Conclusion

In this study, DLFCNN was compared with the CNN and applied to the CT images of 60 patients with perianal abscesses. The DLFCNN algorithm had good stability and segmentation effect, and the skin at the focal area of anal abscess was obviously thickened. The CT image was simple and accurate in the diagnosis of patients with perianal abscess, which could be applied to effectively locate the lesion and clarify the relationship between the lesion and the surrounding structure. The shortcomings of this study are that the sample size is small, and the DLFCNN training images are few. Subsequently, the sample size should be expanded to further improve the accuracy of image segmentation. In this study, MSCT was adopted to detect the perianal abscess tissue, which could improve the reference basis for the clinical development of the scientific surgical treatment plan, effectively reduce the incidence of lesion omission, and prevent the recurrence of the patient's disease.

The purpose of this research is to study the application effect of Lucas–Kanade algorithm in right ventricular color Doppler ultrasound feature point extraction and motion tracking under the condition of scale invariant feature transform (SIFT). This study took the right ventricle as an example to analyze the extraction effect and calculation rate of SIFT algorithm and improved Lucas–Kanade algorithm. It was found that the calculation time before and after noise removal by the SIFT algorithm was 0.49 s and 0.46 s, respectively, and the number of extracted feature points was 703 and 698, respectively. The number of feature points extracted by the SIFT algorithm and the calculation time were significantly better than those of other algorithms ($P < 0.01$). The mean logarithm of the matching points of the SIFT algorithm for order matching and reverse order matching was 20.54 and 20.46, respectively. The calculation time and the number of feature points for the SIFT speckle tracking method were 1198.85 s and 81, respectively, and those of the optical flow method were 3274.19 s and 80, respectively. The calculation time of the SIFT speckle tracking method was significantly lower than that of the optical flow method ($P < 0.05$), and there was no statistical difference in the number of feature points between the SIFT speckle tracking method and the optical flow method ($P > 0.05$). In conclusion, the improved Lucas–Kanade algorithm based on SIFT significantly improves the accuracy of feature extraction and motion tracking of color Doppler ultrasound, which shows the value of the algorithm in the clinical application of color Doppler ultrasound.

1. Introduction

Commonly used imaging techniques for evaluating cardiac tissue function include Doppler tissue imaging, magnetic resonance imaging (MRI), computerized tomography (CT), and ultrasound. Ultrasound imaging is widely used in the evaluation of cardiac tissue function due to its advantages of fast imaging speed, high safety, and low price [1]. At present, the evaluation of cardiac function by clinical diagnostic technology is mainly the evaluation of left ventricular function, and the research of right ventricle is still relatively vacant in the medical field. The change of right ventricular function is of great significance for the evaluation, diagnosis, and prognosis of pulmonary hypertension and a variety of heart diseases [2]. Cardiac color Doppler ultrasound is the main examination method in the clinical diagnosis of CHF, and it is also the only imaging method that can display the internal structure of the heart and internal circulation of organs. This method is simple to operate, has no wound, and can carry out repeated operation. When examining patients with CHF, it can display the cardiac image structure comprehensively and intuitively, Therefore, cardiac color Doppler ultrasound can accurately and comprehensively evaluate the function of right ventricle and myocardium, which plays an important role in the diagnosis and treatment of heart disease [3]. Due to the randomness of ultrasound scattering signals in biological tissues, a large amount of irregular speckle noise will be distributed in the generated image, which will make the image blurred, and the artifacts of different organs will also affect the ultrasound imaging [4]. The acoustic field characteristics of the ultrasound beam make the lateral resolution of ultrasound imaging low. Ordinary ultrasound images usually cannot clearly reflect the tissue morphology and differences between tissues [5]. The complexity of the geometry leads to the lack of accurate measurement of right ventricular function by ultrasound inspection methods [6].

The optical flow method can process continuous image sequences and has real-time characteristics in digital image data. Lucas–Kanade algorithm is an optical flow estimation algorithm based on two-frame difference. Lucas–Kanade point matching algorithm has a wide range of applications in realizing single and multiple target tracking because of its fast calculation speed and simple application [6]. However, the tracking effect of Lucas–Kanade algorithm in practice is not good [7]. Some researchers proposed that the idea of image pyramids can be introduced into the Lucas–Kanade algorithm, which can significantly increase its tracking effect [8]. There were studies applying the Lucas–Kanade algorithm to the motion tracking of cardiac color Doppler ultrasound. However, the effect of feature point extraction and tracking is still poor when the motion between frames of the sequence image is large, because the Lucas–Kanade algorithm uses linear estimation [6], and further optimization is needed.

In summary, although Lucas–Kanade algorithm has significant advantages in target tracking, it still needs further improvement in cardiac color Doppler ultrasound feature point extraction and motion tracking. Therefore, the idea of pyramid was proposed based on the Lucas–Kanade algorithm and the SIFT algorithm to improve the accuracy and computing speed of the Lucas–Kanade algorithm, which was applied to the right ventricular color Doppler ultrasound feature point extraction and motion tracking. It was hoped that this research can provide a reference basis for the evaluation, diagnosis, and prognosis of pulmonary hypertension and a variety of heart diseases.

2. Materials and Methods

2.1. Lucas–Kanade Algorithm Improvement. Differentiation method [9] and region-based matching method [10] are the most commonly used algorithms for optical flow algorithms, and Lucas–Kanade algorithm is an algorithm based on the local constraints of optical flow. For the small plane S with the center line A, the gray values of the pixels in the regional coordinates of any two images in the image sequence are $F(x)$ and $G(x)$, respectively. Then, the smallest difference between the two images is expressed as shown in equation (1), where b is the vector for calculating the matching.

$$D = \sum_{x \in S} |F(x+b) - G(x)|. \tag{1}$$

If $b \longrightarrow 0$, then there the following equations:

$$\begin{aligned} F(x) &\approx \frac{F(x+b) - F(x)}{b} = \frac{G(x) - F(x)}{F(x)}, \\ b &\approx \frac{G(x) - F(x)}{F(x)}. \end{aligned} \tag{2}$$

The weight of b obtained at the x field is expressed as follows:

$$w(x) = \frac{1}{|G(x) - F(x)|}. \tag{3}$$

The iterative equation of the matched vector b is expressed as equation (4), where k is the number of iterations.

$$b_{k+1} = b_k + \frac{\sum_x \left(\left(w(x)\left[G(x) - F\left(x + b_k\right)\right]\right) / \left(F\left(x + b_k\right)\right)\right)}{\sum_x w(x)}. \tag{4}$$

For the accuracy and speed of the Lucas–Kanade algorithm, the pyramid idea was introduced into the Lucas–Kanade algorithm to iterate the Lucas–Kanade algorithm by levels and reduce the calculation amount of Lucas–Kanade algorithm caused by excessive image pixel motion [11]. For the point (x, y) on the ultrasound image, the iterative equation of the improved Lucas–Kanade algorithm based on the pyramid idea is expressed as follows:

$$\begin{aligned} C^l = \frac{1}{4}(2x, 2y) &+ \frac{1}{8}\left[C^{l-1}(2x-1, 2y) + C^{l-1}(2x+1, 2y)\right. \\ &\left. + C^{l-1}(2x, 2y-1) + C^{l-1}(2x, 2y+1)\right] \\ &+ 16\left[C^{l-1}(2x-1, 2y-1) + C^{l-1}(2x-1, 2y+1)\right. \\ &\left. + C^{l-1}(2x+1, 2y-1) + C^{l-1}(2x+1, 2y+1)\right]. \end{aligned} \tag{5}$$

In equation (6), C^{l-1} is the gray value of the point (x, y) at time l.

As the number of pyramid layers progresses downwards, the resolution of the image gradually decreases. The optical flow field motion result obtained in the image of the previous resolution will be used as the initial value for the calculation of the next resolution. Calculating the Lucas–Kanade algorithm in a hierarchical manner can greatly reduce the massive data calculations generated when a large amount of optical flow moves and shortens the calculation time. The iterations were repeated until the final optical flow result was calculated. The schematic diagram of the improved operation of the Lucas–Kanade algorithm pyramid is shown in Figure 1.

2.2. Ultrasonic Image Preprocessing. The ultrasound imaging system will cause the image to be damaged to a certain extent during image acquisition, transmission, and preservation. Therefore, it is necessary to perform operations such as line filtering noise on the cardiac color Doppler ultrasound image to reduce the impact on the image before the data analysis on cardiac color Doppler ultrasound. Commonly used medical image noise reduction methods include mean filter, adaptive Wiener filter, and median filter [12]. The linear-mean filtering method filters out isolated noise points by means of averaging neighborhoods and has a good removal effect on salt and pepper noise, Gaussian noise, and impulse noise [13]. For the image pixel point (x, y) to be filtered, the corresponding R of the linear-mean filtering is expressed as follows:

$$\begin{aligned} R = w(-1,-1)f(x-1, y-1) &+ w(-1,0)f(x-1, y) \\ &+ w(0,0)f(x, y) + \cdots + w(1,0)f(x+1, y) \\ &+ w(1,1)f(x+1, y+1). \end{aligned} \tag{6}$$

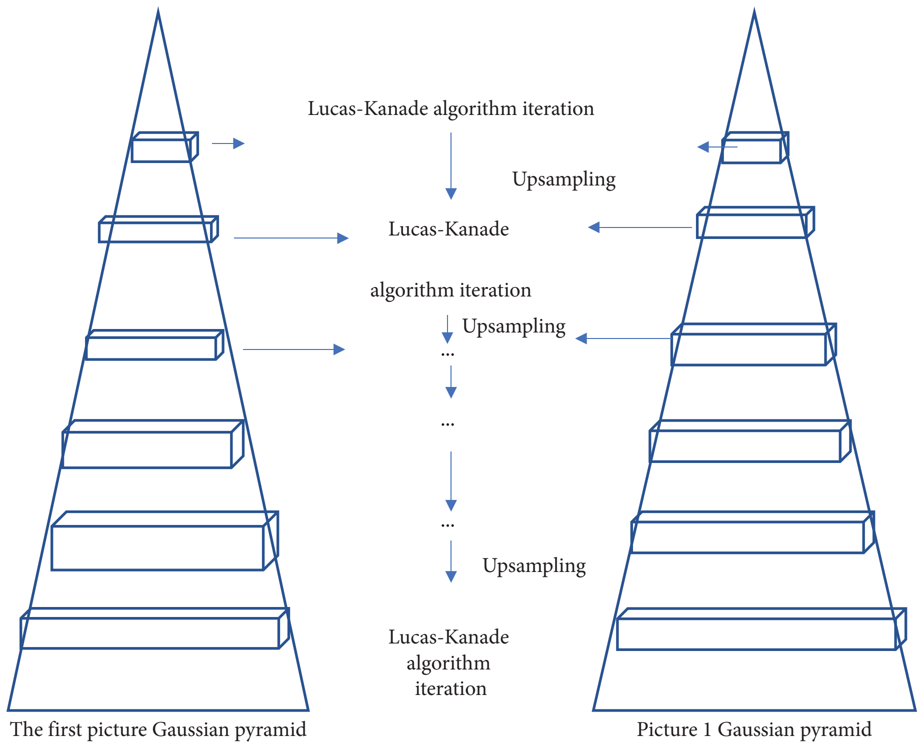

FIGURE 1: Schematic diagram of pyramid improvement of Lucas–Kanade algorithm.

On the image g with a mask size of $M \times N$, the filter mask of linear-mean filtering is $m \times n$, and the corresponding pixel is expressed as follows:

$$f(x, y) = \frac{1}{D} \sum_{(x,y)\in N} g(x, y). \tag{7}$$

D represents the sum of pixels in the mask including the current pixel, and $g(x, y)$ is the pixel value in the x-th row and y-column.

2.3. Feature Points Extraction of Cardiac Ultrasound Images. Ultrasound image speckle is a feature often used in medical ultrasound image processing. The feature speckles of cardiac ultrasound images usually reflect changes in the heart cavity, myocardium, and valves during movement. Forstner algorithm, SUNSAN algorithm, SIFT algorithm, and Harris algorithm are commonly used point feature extraction methods in the field of image registration. Among them, the SIFT algorithm has the characteristics of strong matching ability, stable extraction of features, and high matching accuracy. It can also match features between two images with large differences [14]. Gaussian normal distribution function $G(x, y, \sigma)$ of the SIFT algorithm in a two-dimensional plane image is expressed as follows:

$$G(x, y, \sigma) = \frac{1^{e-(x2+y2)/2\sigma^2}}{2\pi\sigma^2}. \tag{8}$$

Its scale space is expressed as follows:

$$L(x, y, \sigma) = G(x, y, \sigma) * I(x, y). \tag{9}$$

In equations (8) and (9), (x, y) is the position of a certain pixel of the target image, $L(x, y, \sigma)$ is the scale space of the target image, and σ is the scale coordinate. σ is related to the smoothness of the image. The smaller the σ, the lower the smoothness. The calculation of Gaussian difference scale space is as follows:

$$\begin{aligned} D(x, y, \sigma) &= [G(x, y, k\sigma) - G(x, y, \sigma)] * I(x, y) \\ &= L(x, y, k\sigma) - L(x, y, \sigma). \end{aligned} \tag{10}$$

A fitted quadratic function was used to increase the accuracy of the position detection of the feature point. For the key points and boundary points with insignificant features in the extraction process, the spatial scale function was used to eliminate the algorithm to enhance the robustness and accuracy of the algorithm. The spatial scale function is expressed as follows:

$$D(x, y, \sigma) = D(x, y, \sigma) + \left(\frac{\partial D^t}{\partial x} + \frac{1}{2} x^t \frac{\partial^2 D}{\partial x^2} x \right). \tag{11}$$

Derivation of the above function is the calculation method of accurate position.

$$\hat{x} = -\frac{\partial^2 D^{-1^t}}{\partial x^2} \frac{\partial D}{\partial x}. \tag{12}$$

The key points with insignificant features are eliminated, and the following equation is obtained.

$$D(\hat{x}) = D(x, y, \sigma) + \frac{1}{2} x \frac{\partial D^t}{\partial x}, \tag{13}$$

$\hat{x}$ is the transpose of the matrix (x, y, σ). If $D(\hat{x}) \geq 0.03$, the feature point is retained; otherwise, it is discarded.

SIFT algorithm makes use of the gradient direction distribution characteristics of neighborhood pixels of key points to specify direction parameters for each key point, so that the operator has rotation invariance [15].

$$m(x, y) = \sqrt{[L(x+1, y) - L(x-1, y)]^2 + [L(x, y+1) - L(x, y-1)]^2}, \tag{14}$$

$$\vartheta(x, y) = \alpha \tan 2\left[\frac{L(x+1, y) - L(x-1, y)}{L(x, y+1) - L(x, y-1)}\right]. \tag{15}$$

In equations (15) and (16), $m(x, y)$ is the calculation equation for gradient modulus at position (x, y), and $\delta(x, y)$ is the calculation equation for Angle at position (x, y). L is the scale space.

The required calculation method of the circular image area in the process of generating the features of key points is as follows:

$$R = \frac{3\sqrt{2}\sigma(d+1) + 1}{2}. \tag{16}$$

The coordinate of rotation Angle obtained after movement is expressed as follows:

$$\begin{bmatrix} \hat{x} \\ \hat{y} \end{bmatrix} = \begin{bmatrix} \cos\alpha - \sin\alpha \\ \cos\alpha + \sin\alpha \end{bmatrix} \times \begin{bmatrix} x \\ y \end{bmatrix}, \tag{17}$$

In equations (16) and (17), σ is the intragroup scale of the group, where the feature points are located, and α is the rotation Angle.

The calculation method of specification description subvector element is as follows:

$$l_j = \frac{w_j}{\sqrt{\sum_{i=1}^{128} w_i}}, \tag{18}$$

w_i and w_j are eigenvectors of i and j dimensions, and l_i is normalized vector.

The extraction steps of feature points in cardiac ultrasound images based on SIFT algorithm mainly included five parts: generation of scale space, detection of extreme points in scale space, accurate positioning of extreme points, direction parameters of key points, and generation of feature vectors of key points. The specific SIFT algorithm feature point extraction flow chart is shown in Figure 2.

2.4. Feature Point Matching and Tracking Based on Improved Lucas–Kanade Algorithm. Euclidean distance is often used to verify whether the feature points of two images match [16]. It is assumed that the two images to be matched are A and B, and SIFT is used to extract feature points for the two images. If $f_a = \{a_1, a_2, \ldots, a_m\}$ and $f_b = \{b_1, b_2, \ldots, b_m\}$ are the feature point sets of A and B, respectively, and m and n are the number of feature points of A and B, respectively, then the Euclidean distance of k-dimensional space is expressed as follows:

$$s(f_a, f_b) = \mathrm{sqrt}\left[\sum_{i=1}^{k} (a_i - b_i)^2\right]. \tag{19}$$

For a certain point, the Euclidean distance in f_a and f_b was calculated to find the minimum distance and the second smallest distance $\widetilde{d}_{\min}$, $r = d_{\min}/\widetilde{d}_{\min}$. Whether the feature points are matched is evaluated according to the following equation, where evaluation is the threshold set by the experiment, which was set as 0.44 in this research.

$$\begin{cases} r < \eta, & \text{success}, \\ r \geq \eta, & \text{failure}. \end{cases} \tag{20}$$

K-D tree index tree and Best Bin First (BBF) algorithm are commonly used in feature point matching process. BBF algorithm reduces the node backtracking of K-D tree nearest neighbor search algorithm, improves the search efficiency, and is suitable for high-dimensional data search. For two images to be matched, feature points extraction and feature vector set analysis were carried out by SIFT, and the corresponding point set of SIFT feature matching was finally obtained. The flowchart of feature point matching based on the improved Lucas–Kanade algorithm is shown in Figure 3.

2.5. Statistical Methods. The experimental data was processed using SPSS 19.0, the count data was tested by χ^2 test, and $P < 0.05$ indicated that the difference was statistically considerable.

3. Results and Discussion

3.1. Image Motion Feature Point Detection Based on Improved Lucas–Kanade Algorithm. The image sequence of frames 1 to 2 of the right ventricular movement cycle was selected for comparative analysis, and the vector image of gray-scale movement from frame 1 to frame 2 was obtained. The results are shown in Figure 4. It can be concluded from Figure 4(c) that the improved Lucas–Kanade algorithm has better real-time performance in feature point tracking. The gradient direction histogram of Lucas–Kanade algorithm represented the gradient direction and the total number of gradients. Gradient direction histogram was used to obtain the direction synthesis vector of an image pixel in a certain area. The reference direction was calculated through the small area, where the key points were obtained, so that the algorithm had spatial rotation invariance [17].

3.2. Special Point Trajectory Based on Improved Lucas–Kanade Algorithm. The improved Lucas–Kanade algorithm was used to compare the movement tracks of right

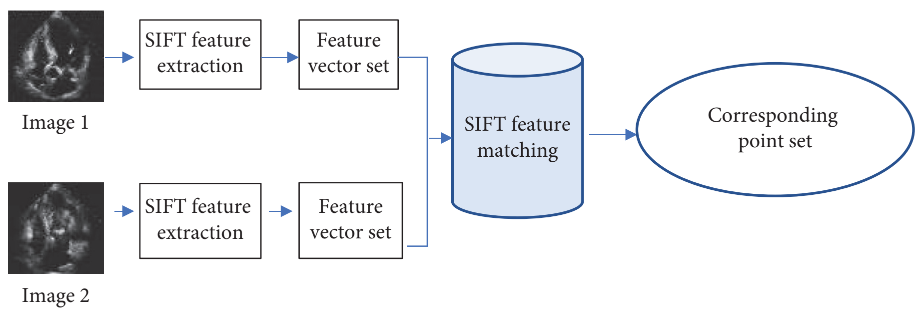

FIGURE 3: Flow chart of feature point matching based on improved Lucas-Kanade algorithm.

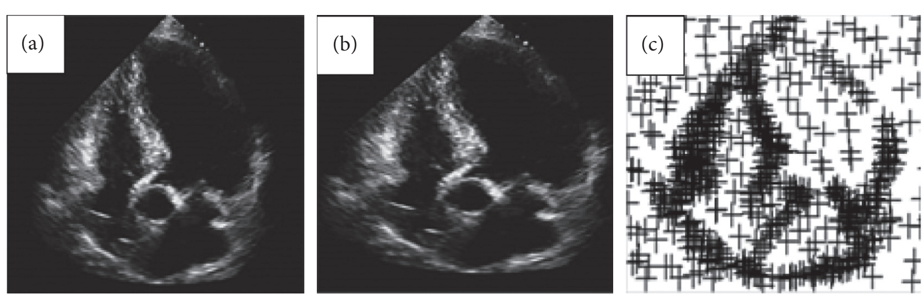

FIGURE 4: Image sequence of frames 1-2 of right ventricular movement cycle. (a) Image of frame 1; (b) Image of frame 2; (c) vector diagram of gray-scale motion.

ventricular myocardium, right atrioventricular septal tricuspid valve ring, and left atrioventricular septal tricuspid valve ring (Figure 5). The motion trajectory of feature points based on the improved Lucas–Kanade algorithm had significant differences for different parts. The variation range of the right ventricular myocardium in the X direction was 372~405, and the variation range of the right atrioventricular septal tricuspid valve in the X direction was 385~450. The left ring of the atrioventricular septal tricuspid valve varied from 415 to 450 in the X direction. Heart movement is a very complex nonlinear movement, which includes rotation, torsion, and circular movement, in addition to contraction and diastole, and the motion parameters of each point and region are often different [18].

3.3. Analysis of Feature Point Extraction Results Based on Improved Lucas–Kanade Algorithm. The improved Lucas–Kanade algorithm was used to extract ultrasonic images with feature points, and the number of feature points under different image frame sequences was statistically analyzed (Figure 6). The number of feature points extracted under different image frame order had great difference. When the image frame order was 1, the maximum number of feature points extracted was 75.

The calculation time and the number of feature points of different algorithms before and after noise removal were compared (Figure 7). The calculation time of SIFT algorithm before noise removal was 0.49 s, and the calculation time of Forstner, SUNSAN, and Harris was 1.71 s, 3.04 s, and 2.25 s,

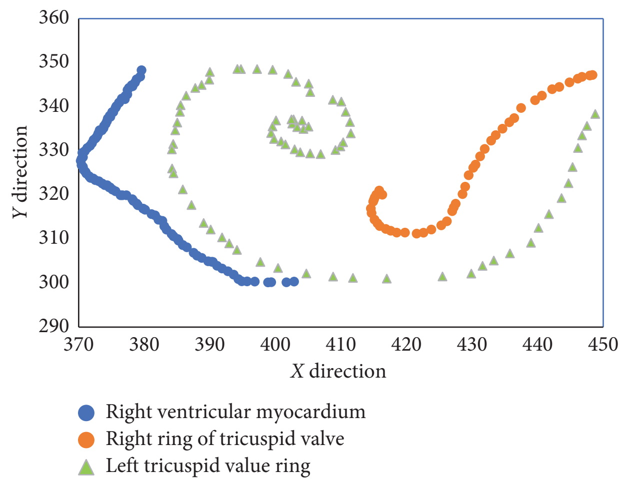

FIGURE 5: Motion trajectories of special points in optical flow method.

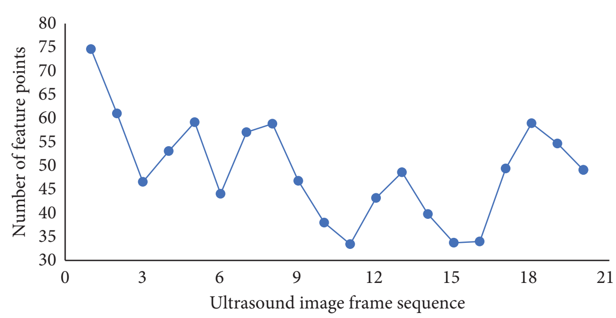

FIGURE 6: Statistics of the number of special points extracted by the SIFT algorithm.

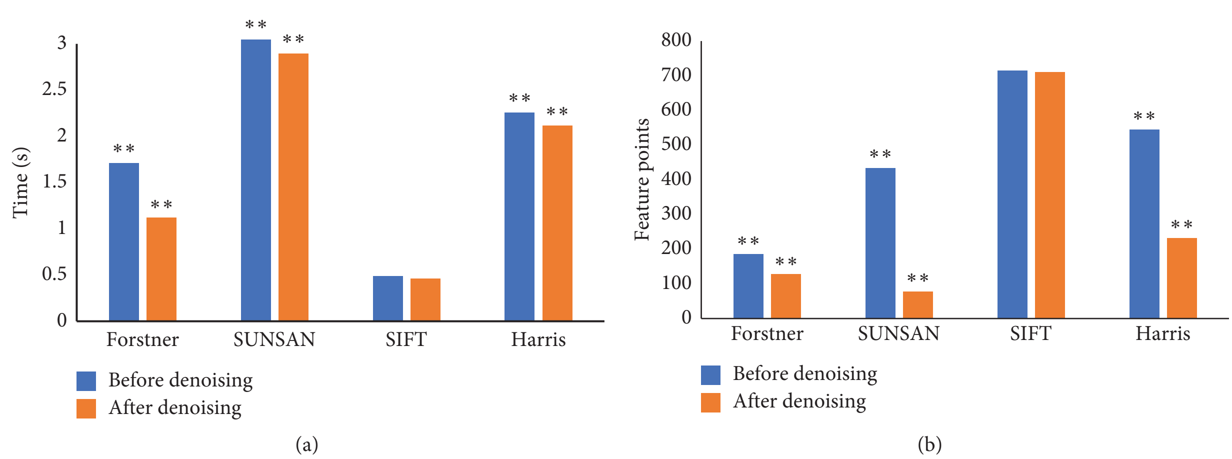

FIGURE 7: Comparison of calculation time and number of feature points before and after noise removal by different algorithms. (a) Comparison of calculation time before and after noise removal by different algorithms; (b) comparison of the number of feature points before and after noise removal by different algorithms. *indicates a remarkable difference compared with SIFT, $P < 0.01$.

respectively. The calculation time of SIFT algorithm after noise removal was 0.46 s, and the calculation time of Forstner, SUNSAN, and Harris was 1.12 s, 2.89 s, and 2.11 s, respectively. The calculation time of the SIFT algorithm before and after the noise was removed was obviously shorter than that of other algorithms. The calculation time of all algorithms after noise removal was significantly shorter than that before noise removal. The number of feature points extracted by the SIFT algorithm before noise removal was 703, and the number of feature points extracted by the Forstner, SUNSAN, and Harris algorithms was 182, 426, and 535, respectively. The number of feature points extracted by the SIFT algorithm after noise removal was 698, and the number of feature points extracted by the Forstner, SUNSAN, and Harris algorithms was 126, 76, and 228, respectively. The number of feature points extracted by SIFT algorithm before and after noise removal was more than that of other algorithms, and the number of feature points extracted by all algorithms after noise removal was significantly less than that before noise removal. It showed that, among the four feature point extraction algorithms, the SIFT algorithm extracted the largest number of speckles and took the least time. The number of feature points extracted by the SIFT algorithm and the calculation time were significantly better than those of other algorithms ($P < 0.01$).

The different algorithms before and after noise removal were compared on the first frame of the heart motion image to extract the feature point images (Figure 8). Different algorithms had large differences in the number of feature points extracted from the diastolic motion image of the short-axis motion of the left ventricle with a size of 172×172. The speckles extracted by the Forstner operator were more uniformly dispersed, but the number of extracted feature points was small. Although SUNSAN and Harris algorithms extracted more features than Forstner operators, their calculation time was longer. The number of feature extraction points of SIFT algorithm was obviously more than that of other algorithms. Forstner operator was the best method for feature points compared with the other three methods.

3.4. Analysis of Feature Point Matching Results Based on Improved Lucas–Kanade Algorithm. To test the accuracy of the SIFT algorithm, the ultrasound images of the first and second frames of the same heart were matched, and the results were shown in Figure 9. By observing the distribution of red spots in the image, it can be concluded that sift algorithm has good stability and accuracy.

To further objectively analyze the accuracy of the feature point matching of the SIFT algorithm, the order matching method and the reverse order matching method were used to extract the matching point logarithms under different frame sequences (Figure 10(a)). The logarithm of the matching points extracted by the sequential matching method and the reverse matching method was not much different. The mean logarithm of the matching points of the sequential matching method and the reverse matching method was 20.54 and 20.46, respectively, which indicated that, for the same two sets of images, the matching algorithm can be used as a template for each other, which had little effect. The matching results of different ultrasonic image feature extraction points were compared (Figure 10(b)). When the image frame order was 5–11, the feature extraction point matching effect was ideal.

3.5. Analysis of Feature Point Tracking Results Based on Improved Lucas–Kanade Algorithm. Based on the characteristics of two-dimensional speckle tracking in ultrasonic image, the tolerance method was selected to track the image sequence. The selected feature points were modified within 1~20 pixels, and a point (130,165) on the myocardial interval between the left and right ventricles was selected for tracking under different tolerance conditions. The tracking results of the first 30 frames of the ultrasonic image sequence were shown in Table 1 and Figure 11. Feature points were extracted in both the 6th and 7th frames. The reason may be that the sequences of matching points between two adjacent frames are not identical, leading to the occurrence of missing matching [19].

3.6. Comparison of Tracking Results of Feature Points by Different Algorithms. The shrinkage of feature points per frame of SIFT speckle tracking method and optical flow method was compared (Figure 12). The highest point and curvature of SIFT speckle tracking method were close to the original curve, while the highest point and curvature of optical flow method were different from the original curve. The differences between the two methods were analyzed. The possible reason was that the intraregion matching of SIFT speckle tracking method improved the accuracy of matching, while optical flow tracking in the neighborhood of key points was less affected by noise and had good stability, but its accuracy was low [20].

The calculation time and number of tracking speckles of SIFT speckle tracking method and optical flow method were compared (Figure 13). The calculation time and number of tracking speckles of SIFT speckle tracking method were 1198.85 s and 81, respectively, and the calculation time and number of tracking speckles of optical flow method were 3274.19 s and 80, respectively. The calculation time of SIFT speckle tracking method was significantly lower than that of optical flow method, and the difference between them was great ($P < 0.05$). There was no remarkable difference in the number of tracking speckles between SIFT and optical flow method ($P > 0.05$).

The above results show that Lucas–Kanade algorithm improved by pyramid idea, SIFT algorithm, and denoising algorithm is superior to other algorithms in terms of calculation time, number of feature points identified, and number of tracking spots. Yang et al. [21] used the improved ROAM algorithm based on pyramid idea to preprocess large amount of terrain and texture data in layers and blocks and obtained the conclusion combined with the algorithm, the 3D terrain of Huairou Reservoir in Beijing was rendered, and the real-time network roaming was carried out. Liu et al. [22] also studied the defect image registration based on SIFT algorithm and found that the algorithm can effectively register the defect image and lay a good foundation for the subsequent defect information extraction. The above research results show that the application effect of pyramid idea and sift algorithm is basically consistent with this research. However, Lv et al. [23] used the pyramid Lucas–Kanade combined with U-net technology to study its matching performance on renal free breathing multi-b-value diffusion MRI and obtained the segmentation based on U-net and pyramid Lucas–Kanade registration method, so as to improve the alignment of multi-b-value diffusion weighted MRI and reduce the interference in free breathing.

4. Conclusion

The application value of the improved Lucas–Kanade algorithm based on SIFT in the extraction of feature points and motion tracking of heart color ultrasound was discussed. Pyramid idea, SIFT algorithm, and noise reduction algorithm were introduced to improve the Lucas–Kanade algorithm. The results showed that the improved Lucas–Kanade algorithm was better than other algorithms in the computation time, the number of recognized feature points, and the number of tracking speckles. However, there are still some shortcomings in this study. There are mismatching problems in multiple similar regions in the process of speckle tracking. In the future work, the coherence of the feature points of the image sequence will be enhanced according to the image features of the heart color ultrasound, so as to reduce the mismatching phenomenon and further improve the accuracy of the matching of the feature points. In conclusion, the improved Lucas–Kanade algorithm based on SIFT proposed significantly improves the accuracy of feature point extraction and motion tracking of cardiac color ultrasound. It shows that the algorithm has a good prospect in the clinical application of cardiac color Doppler ultrasound.

This study was to explore the use of convolutional neural network (CNN) for the classification and recognition of computerized tomography (CT) images of chronic obstructive pulmonary disease (COPD) and the therapeutic effect of clarithromycin combined with salmeterol/fluticasone. First, the clinical data of COPD patients treated in hospital from September 2018 to December 2020 were collected, and CT and X-ray images were also collected. CT-CNN and X ray-CNN single modal models were constructed based on the LeNet-5 model. The randomized fusion algorithm was introduced to construct a fused CNN model for the diagnosis of COPD patients, and the recognition effect of the model was verified. Subsequently, the three-dimensional reconstruction of the patient's bronchus was performed using the classified CT images, and the changes of CT quantitative parameters in COPD patients were compared and analyzed. Finally, COPD patients were treated with salmeterol/fluticasone (COPD-C) and combined with clarithromycin (COPD-T). In addition, the differences between patients' lung function indexes, blood gas indexes, St. George respiratory questionnaire (SGRQ) scores, and the number of acute exacerbations (AECOPD) before and after treatment were evaluated. The results showed that the randomized fusion model under different iteration times and batch sizes always had the highest recognition rate, sensitivity, and specificity compared to the two single modal CNN models, but it also had longer training time. After CT images were used to quantitatively evaluate the changes of the patient's bronchus, it was found that the area of the upper and lower lung lobes of the affected side of COPD patients and the ratio of the area of the tube wall to the bronchus were significantly changed. The lung function, blood gas index, and SGRQ score of COPD-T patients were significantly improved compared with the COPD-C group ($P < 0.05$), but there was no considerable difference in AECOPD ($P > 0.05$). In summary, the randomized fusion-based CNN model can improve the recognition rate of COPD, and salmeterol/fluticasone combined with clarithromycin therapy can significantly improve the clinical treatment effect of COPD patients.

1. Introduction

Chronic obstructive pulmonary disease (COPD) is a disease with a high prevalence and fatality rate in the world. The quality of life of patients with advanced COPD will be significantly reduced, and long-term oxygen therapy and drug treatment are required, which brings a huge burden to the patient's family [1]. The main pathological changes of COPD are lung parenchymal damage and airway damage, among which the main manifestation of lung parenchymal damage is emphysema, and airway damage is classified into central trachea or small trachea injury [2]. The main clinical methods used to detect COPD small airway damage are computerized tomography (CT) and pulmonary function test (PFT) examinations. PFT examination focuses on spirometry, single breathing method, repeated breathing method, and pulse oscillation method, which is the gold standard for clinical diagnosis and grading of COPD [3, 4].

With the improvement of the computing level, deep learning has harvested excellent results in many fields such as speech recognition, and medical image classification based on deep learning has gradually replaced manual operation [5, 6]. The deep learning method mostly used in the field of medical imaging is convolutional neural network (CNN). The model contains special structures such as convolutional layer and pooling layer, which significantly improve the classification and recognition accuracy of the model [7].

At present, anti-inflammatory therapy is of great significance in the treatment of COPD disease. The drugs used in anti-inflammatory treatment are mainly glucocorticoids. Most studies recommend the use of salmeterol/fluticasone inhalation [8]. However, the drug used in the treatment of COPD can increase the risk of pneumonia, and it is difficult for most patients to accept it. In recent years, studies found that macrolide antibiotics have certain antibacterial effects, as well as anti-inflammatory and immunomodulatory effects, which have good results in the treatment of chronic inflammatory reactive lung diseases [9]. Studies have shown that oral clarithromycin combined with inhaled salmeterol in the treatment of chronic pulmonary obstruction has a good effect and high safety.

A model for image classification and recognition of COPD patients was proposed based on the CNN model, and the morphological changes of the small trachea of COPD patients were quantitatively analyzed based on the CT images after classification. Moreover, the therapeutic effects of inhaled corticosteroids on COPD patients were compared and analyzed, aiming to provide a reference for improving the clinical diagnosis rate of COPD and improving the treatment effect of patients.

2. Materials and Methods

2.1. Research Subjects. The clinical data of 58 patients with COPD who were treated in hospital from September 2018 to December 2020 were collected. COPD patients met the diagnostic criteria of the *Guidelines for the Diagnosis of Chronic Obstructive Pulmonary Disease Pulmonary Diseases* (2013 revision). Among them, 35 were males and 23 were females, aged 44 to 63 years old. The 50 healthy people who had undergone physical examinations in the hospital served as controls. Among them, 32 were males and 18 were females, aged 42–61 years old. Exclusion criteria: (i) those with bronchiectasis, pulmonary bullae, pulmonary fibrosis, and pulmonary space-occupying diseases that affect lung function; (ii) those with organic heart disease; (iii) those underwent chest surgery in history; and (iv) those who suffered from other diseases that restrict respiratory movement. The experimental procedure of this study had been approved by the Medical Ethics Committee of the Hospital, and all subjects had signed written informed consent.

2.2. Lung Function and Blood Gas Index Measurement. All subjects were required to complete pulmonary function measurements within seven days before and after the CT scan. Measurement function parameters included forced expiration in the first second (FEV1), forced expiratory volume percentage (FEV%), and forced expiratory volume in the first second/forced vital capacity (FEV1/FVC%). In addition, the PaO_2 and $PaCO_2$ blood gas indexes in the arterial blood of the patient were measured. All patients needed to undergo pulmonary function tests and be able to meet the criteria for diagnosing COPD.

2.3. CT Scan Process. The patient's chest image was scanned using 64-slice MSCT, and the patient underwent breathing training before the scan. During the examination, the patient was placed in the supine position for CT scan, and the whole lung was examined when the patient took a deep breath and reached the optimal inflatable state after holding his breath. Scanning parameters were set as follows: 0.875 pitch, 38×38 cm field of view, 512×512 matrix, 1500 window width, −650U window level, 0.5 cm layer thickness, and 0.5 cm layer spacing. CT image reconstruction was performed using the standard CT reconstruction algorithm, and the layer thickness was set as 0.625 mm and the layer spacing was set as 0.625 mm. The reconstructed CT images were uploaded to the workstation, and Thoracic VCAR Airway Analysis software was used to measure the airway. The lumen diameter, area ratio of trachea to bronchial wall, wall thickness, and diameter ratio of the air duct (trachea, main bronchus, apical segment of upper lobe/posterior segment/anterior segment, etc.) were measured.

2.4. COPD Image Classification and Recognition Based on CNN. Firstly, a single mode CNN model was constructed to extract the feature vectors of the CNN full connection layer, and a randomized function was constructed. The data of the full connection layer of different modes were randomly fused, and the fused feature recognition was used for the classification of COPD images, so as to improve the image classification effect.

2.4.1. Multimodal Feature Fusion Based on Stochastic Fusion. The methods of multimodal feature fusion recognition designed in this study were (i) the processing of CT images and chest X-ray images; (ii) multimodal lung image features extracted using LeNet-5 network; (iii) stochastic function used for the fusion of parallel multimodal features and the reconstruction of target features in the same dimension; and (iv) the full connection layer and the classification layer added to carry out the regression training of the network, so as to get the results after classification.

The basic structure of the LeNet-5 network model [10] is shown in Figure 1, and the algorithm flow of using randomized fusion algorithm combined with multimodal CNN lung image recognition is shown in Figure 2.

The LeNet-5 model was employed to extract the features of the image, and then the model's own parameter transfer learning ability was adopted to adjust the parameters of the model. The size of the training data needed to be randomly selected when the model was trained, and the data were

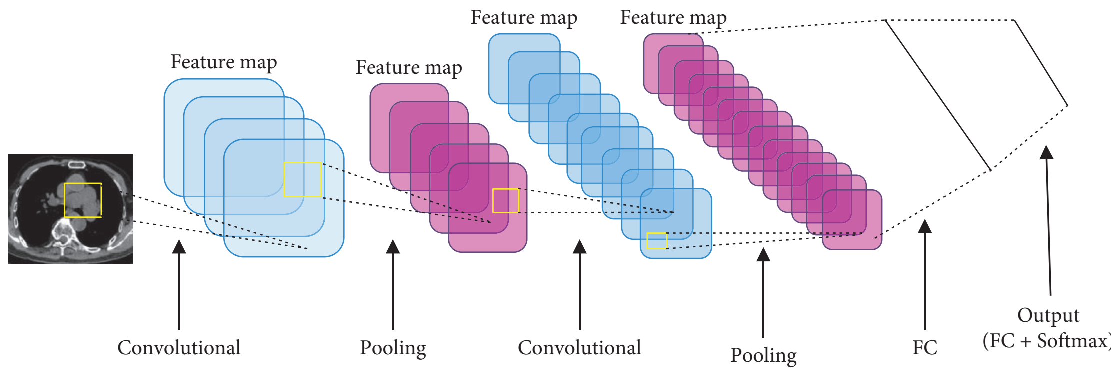

FIGURE 1: The basic structure of the LeNet-5 model. FC is the fully connected layer; Softmax is the activation function.

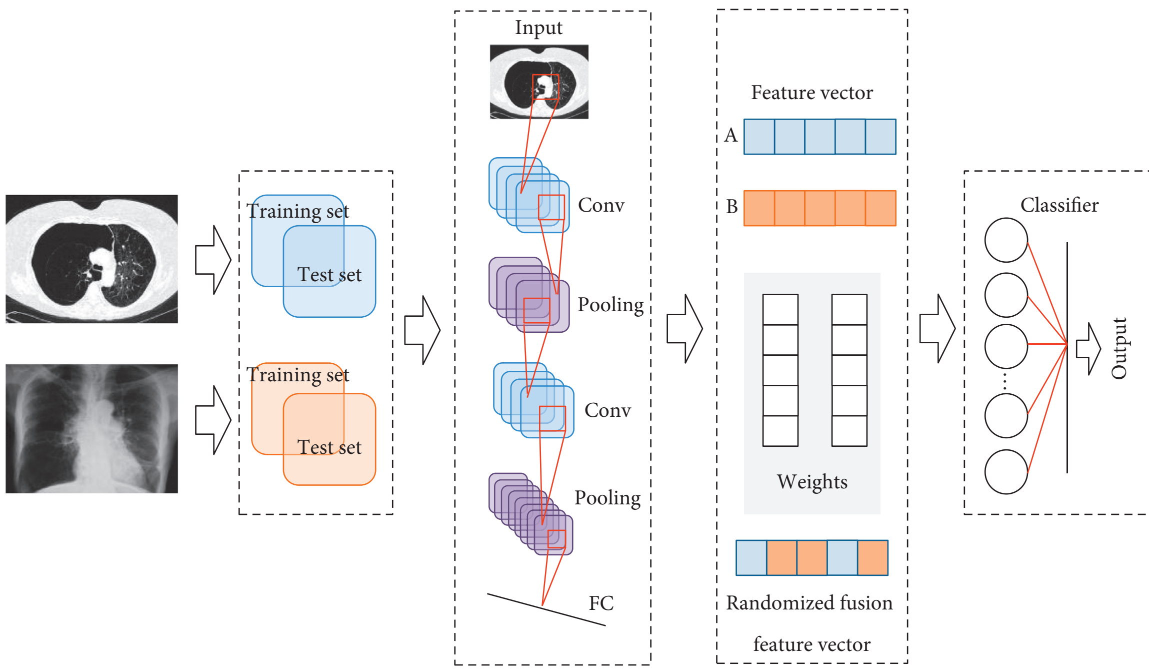

FIGURE 2: Multimodal CNN lung image recognition process based on randomized fusion algorithm.

sequentially input into the model for training according to the set batches. At the same time, the weight value and bias of the model needed to be adjusted. It is required to input all the data in the test set into the network when the model was tested. The network parameters were set to the optimal number of adoption during training, and the classifier was used to recognize COPD. The network structure constructed in this study is shown in Figure 3.

From Figure 3, there were two CNN network models designed, namely, CT-CNN and X ray-CNN, and the specific parameter settings of the network are shown in Table 1. There were certain differences in the parameters between different network layers. The input data of the input layer needed to be randomly selected from the training set according to the size of the batch and form a vector with a certain dimension. The convolutional layer needed to initialize the convolution kernel size, weight value, and bias. Then, the convolution kernel and the input data were convolved to enhance the feature matrix in the image and remove noise. The activation function used was the Sigmoid function [11], and the pooling operation was an average pooling operation. Rand random function [12] was used to randomize the feature vector, weight, and bias in the last layer of the fully connected layer.

2.5. Treatment Methods. 58 COPD patients were randomly divided into two groups—the control group (COPD-C) and the treatment group (COPD-T)—with 28 and 30 patients, respectively. Patients in the COPD-C group inhaled 50/250 μg of salmeterol/fluticasone twice a day. Patients in the COPD-T group were given oral clarithromycin sustained-release tablets for combination therapy based on the inhalation of salmeterol/fluticasone. In addition, 0.5 g clarithromycin sustained-release tablets should be taken orally once a day, and 50/250 μg salmeterol/fluticasone should be inhaled twice a day. All patients took 10 days as a course of treatment and cannot take β-agonist and hormone

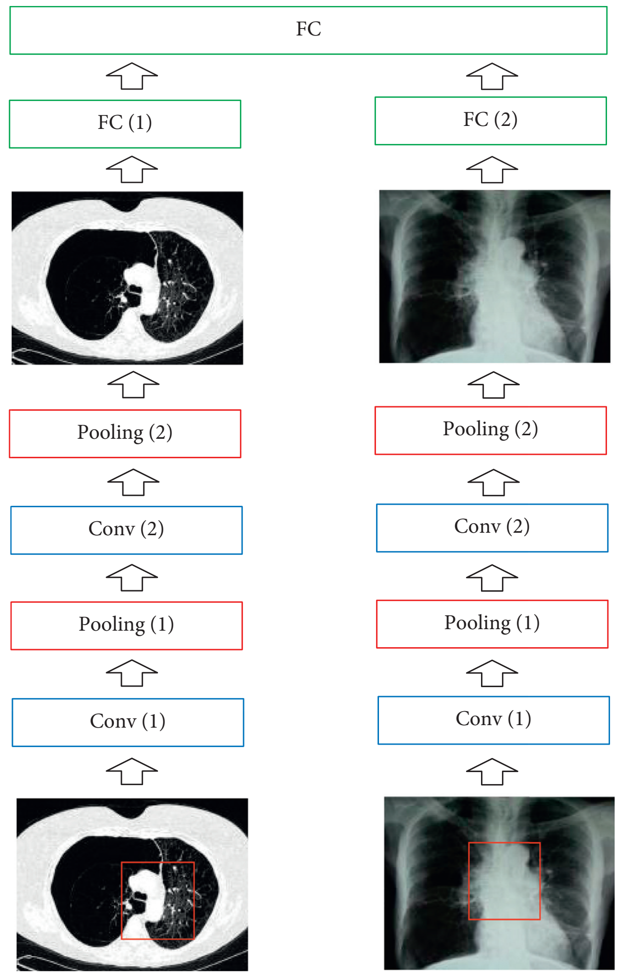

Figure 3: The basic structure of the CNN model.

Table 1: Structure and parameter setting of the CNN model.

Framework	Input	Convolution		Pooling		Structure				
		Convolution kernel	Step size	Size	Step size	Convolutional layer	Sigmoid	Average pooling	Fc	Rand
Input layer	28 × 28	—	—	—	—	—	—	—	—	—
Conv (1)	24 × 24 × 6	3 × 3	1	2 × 2	2	+	+	+	—	—
Conv (2)	8 × 8 × 12	3 × 3	1	2 × 2	2	+	+	+	—	—
Fc (1)	4 × 4 × 12	1 × 1	—	—	—	—	+	—	+	—
Fc (2)	192 × 3	1 × 1	—	—	—	—	+	—	+	+

Note. + means yes; —means no.

inhalation therapy within 15 days before receiving the treatment. After treatment, a 3-month follow-up was conducted to record the patient's drug use, changes in the condition, the number of acute exacerbations, and adverse reactions.

2.6. Evaluation Indexes. The number of acute exacerbations of COPD (AECOPD) in the patient was recorded. St. George Respiratory Questionnaire (SGRQ) score sheet was used to evaluate the patient. The lower the score is, the better the patient's function is, and it was meaningful to reduce the total score of SGRQ by more than 4 points in clinical practice. After treatment, the lung function indexes were evaluated, as shown in Section 2.2. Moreover, the probability of adverse reactions in patients after treatment was recorded.

The recognition rate, sensitivity, and specificity were calculated to evaluate the construction model. The calculation equations for different indexes were as follows:

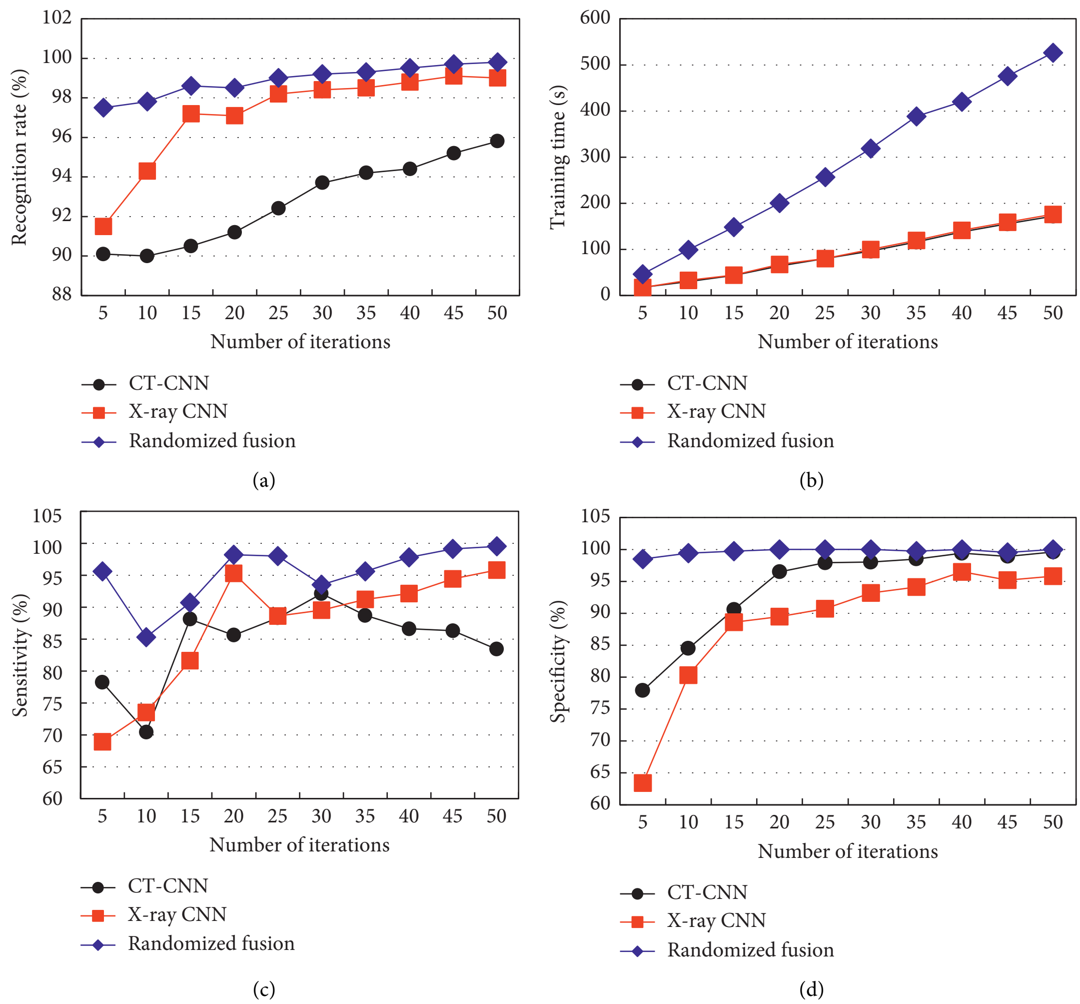

FIGURE 4: Changes in the recognition efficiency of single-modal CNN and randomized fusion models under different iteration times. (a) The recognition rate. (b) The training time. (c) The recognition sensitivity. (d) The recognition specificity.

$$\text{recognition} = \frac{TP + TN}{TP + TN + FP + FN},$$
$$\text{sensitivity} = \frac{TP}{TP + FN}, \tag{1}$$
$$\text{specificity} = \frac{TN}{TN + FP}.$$

TP is true positive, FP is false positive, TN is true negative, and FN is false negative.

2.7. Statistical Methods. Subsequently, SPSS 19.0 was used for statistical analysis. Measurement data were expressed as mean ± standard deviation, and independent sample *t*-test was used for difference comparison. Count data were expressed by frequency (percentage), and the difference was compared using chi-square test or Fisher's test. $P < 0.05$ means that the difference was statistically significant.

3. Results

3.1. Model Training for CT Image Classification. The parameter transfer method was adopted to train the constructed CNN model. Comparison and analysis of the differences among model recognition rate, training time, sensitivity, and specificity under different iteration times are shown in Figure 4. From Figure 4(a), as the number of iterations increased, the recognition rates of CT-CNN, X ray-CNN, and randomized fusion showed a gradual increase trend. However, the recognition rate of the randomized fusion model was always higher than that of other models. The recognition rates of CT-CNN, X ray-CNN, and randomized fusion under the maximum number of iterations were 95.8%, 99.0%, and 99.8%, respectively. From Figure 4(b), as the number of iterations increased, the training times of different models showed a gradual increase trend. Among them, the training time of the randomized fusion model was always the longest, and there was no significant difference between the training time of the CT-CNN and X ray-CNN models. From Figure 4(c), the recognition sensitivity of different models showed different changes as the number of iterations increased. The sensitivities of CT-CNN, X ray-CNN, and randomized fusion at the maximum number of iterations were 83.4%, 95.8%, and 99.5%, respectively. From Figure 4(d), as the number of iterations increased, the recognition specificity of different models gradually increased. CT-CNN, X ray-CNN, and the recognition specificity of the randomized fusion model was 99.6%, 95.8%, and 100.0%, respectively.

The differences of model recognition rate, training time, sensitivity, and specificity under different batch sizes are shown in Figure 5. From Figures 5(a) and 5(b), as the training batch increased, the recognition rate and training time of CT-CNN, X ray-CNN, and randomized fusion models showed a gradual decline. When the maximum training batch was reached, the recognition rates were 97.4%, 96.0%, and 98.6%, and the training time was 67.2 s, 63.4%, and 193.6 s, respectively. Among them, the randomized fusion model had the highest recognition rate and the longest training time. From Figure 5(c), with the increase of training batches, the recognition sensitivity of different models first increased and then decreased. When the training batch reached 100, the sensitivity was the lowest, but the randomized fusion model had the highest sensitivity compared with the CT-CNN and X ray-CNN models. From Figure 5(d), the recognition specificity of each model changed with the training batch, and the recognition specificity of the randomized fusion model was always the highest.

3.2. Quantitative Analysis of CT Bronchus in Patients with COPD. The differences between the baseline data of the healthy control group and COPD patients are shown in Table 2. There was no significant difference in average age, sex ratio, and BMI indexes between the control group and COPD group ($P > 0.05$

The difference between the LA and WA% of the bronchi of the upper and lower lobe of the affected lung in the control group and the COPD group was evaluated (Figure 6). CT images classified by CNN were used to reconstruct the patient's bronchi in three dimensions. From Figure 6(a), the lung bronchus of the COPD group showed obvious obstruction. From Figures 6(b) and 6(c), the upper lobe of the affected side of the COPD group had significantly increased LA in the upper lobe of the lung and significantly reduced LA in the 5 and 6 levels compared with the control group ($P < 0.05$), and WA% in the 5 and 6 levels greatly increased ($P < 0.05$). From Figures 6(d) and 6(e), the LA of the lower lobe of the affected lung in the COPD group was significantly reduced in grade 6, 7, and 8, while the WA% was significantly increased compared with the control group ($P < 0.05$).

3.3. Analysis of the Treatment Effect of Patients with COPD

3.3.1. Changes in Lung Function and Blood Gas Indexes in Patients with COPD. The changes in lung function and blood gas indexes of patients before and after treatment are compared in Figure 7. There was no significant difference in the FEV1, FVC, FEV1/FVC, PaO_2, and $PaCO_2$ between patients in COPD-C group and COPD-T group before treatment ($P > 0.05$). After treatment, compared with patients in the COPD-C group, FEV1, FVC, FEV1/FVC, and PaO_2 in COPD-T patients increased significantly, and $PaCO_2$ decreased significantly ($P < 0.05$).

3.3.2. Comparison of Differences in Other Indexes of COPD Patients after Treatment. The difference of the SGRQ scores before and after treatment and the number of AECOPD during treatment between the two groups of patients is compared in Figure 8. From Figure 8(a), there was no considerable difference in SGRQ scores between the two groups before treatment ($P > 0.05$). Compared with the COPD-C group, the SGRQ score of the COPD-T group was significantly reduced after treatment ($P < 0.05$). From Figure 8(b), there was no great difference in the number of AECOPDs between the two groups of patients during treatment ($P > 0.05$).

4. Discussion

The CNN model is a feed forward neural network, and it is a multilayer perceptron model constructed to recognize two-dimensional and above images [13,14]. The current CNN model includes LeNet and AlexNet models, among which the LeNet-5 model is relatively mature, and the network structure is simpler [15,16]. To improve the clinical diagnosis rate of COPD, two single-modal CNN models were constructed using patient CT images and X-ray images. Then, the randomized fusion algorithm was adopted to fuse the CT-CNN and X ray-CNN models to obtain a randomized fusion model. The model recognition effect was evaluated, and the test results showed that the recognition rate, sensitivity, and specificity of the randomized fusion model increased greatly. It showed that the use of single-modal CNN model fusion for feature extraction of patient images can improve the effect of patient feature extraction and classification and recognition.

COPD is a common and frequent disease in respiratory system diseases. Clarithromycin combined with salmeterol and fluticasone has a significant effect in the treatment of chronic pulmonary obstruction. Patients with stable chronic obstructive pulmonary disease have a relatively stable condition. However, if patients with acute-onset chronic obstructive pulmonary disease cannot be further treated, their condition will become worse and cause respiratory failure, hypoxemia, and other serious complications [17,18]. The results of Renkema et al. [19] showed that the airway hyper-responsiveness of nonallergic patients with chronic obstructive malignant disease increased over time. In this research, the patient's affected lung lobe bronchus was scanned for quantitative evaluation. The results showed that COPD patients had significant changes in LA and WA% of grades 5~6 bronchus in the upper lobes of the lung and had LA and WA% of grades 6~8 in the lower lobes of the lung compared with healthy people. Studies revealed that, with

Table 2: Comparison of baseline data of patients.

Item	Control group ($n = 50$)	COPD group ($n = 58$)	Statistics	P
Age (years old)	56.7 ± 5.7	58.3 ± 6.2	$t = 0.133$	0.883
Male (cases/%)	32/64.0	35/60.3	$\chi^2 = 1.204$	0.559
BMI (kg/m^2)	21.4 ± 1.6	21.6 ± 1.4	$t = -2.125$	0.936

BMI: body mass index.

the aggravation of COPD disease, LA gradually decreases, while WA% gradually increases.

Due to the relatively poor diffusion function of small airways, the inflammatory response of COPD is determined by the activation of respiratory epithelial cells and macrophages. Therefore, the bronchial tube wall is thickened, and the lumen is narrowed in patients with COPD. Combined with the results obtained in this study, it was suggested that LA and WA% can be used to quantitatively assess the morphological changes of the bronchus in patients with COPD and can also be used for the diagnosis of COPD.

Salmeterol is a long-acting $\beta 2$ receptor agonist, which is used for the relaxation of airway smooth muscle and can also inhibit the release of inflammatory mediators [20]. Fluticasone is an inhaled glucocorticoid, which acts on glucocorticoid receptors and increases the sensitivity of $\beta 2$ receptors, thereby delaying airway remodeling. The results of Jin [21] and other studies showed that patients with chronic obstructive disease had higher serum levels, and the impairment of lung function was related to symptoms such as serum levels and dyspnea. In addition to antibacterial properties, clarithromycin also has anti-inflammatory and immunomodulatory effects. Salmeterol/fluticasone and clarithromycin were combined for the treatment of COPD in this research. The results showed that salmeterol/fluticasone and combined clarithromycin treatment can significantly reduce the SGRQ score of COPD patients. It was proved that salmeterol/fluticasone combined with

clarithromycin treatment can significantly improve the lung function of COPD patients.

5. Conclusion

The randomization and fusion of the single-modal CNN model can improve the recognition effect of COPD, and CT quantitative indexes can be used for the diagnosis of COPD. Moreover, combined treatment of salmeterol/fluticasone and clarithromycin can significantly improve the lung function of COPD patients and enhance the clinical treatment effect. However, this study only analyzed the CT image and X-ray image of COPD patients based on the constructed CNN model. Follow-up work should combine it with clinical biology and other indexes to comprehensively compare the differences between the diagnosis rates of COPD. In short, this study can provide a reference for improving the clinical diagnosis and treatment of COPD.

Objective. To explore the application value of ultrasound image based on back propagation (BP) neural network algorithm in knee osteoarthritis (KOA) and evaluate the application effect and value of ultrasound image technology based on the BP neural network in the diagnosis of knee osteoarthritis cartilage lesions, 98 patients who were admitted to our hospital were diagnosed with KOA and had undergone arthroscopic soft tissue examinations were randomly selected. According to whether image processing was performed, the ultrasound images of all patients were divided into two groups. The control group was image before processing, and the experimental group was image after processing optimization. The consistency of the inspection results of the ultrasound images before and after the processing with the arthroscopy results was compared. The results showed that the staging accuracy of the control group was 68.3% and that of the experimental group was 76.9%. The accuracy of staging cartilage degeneration of the experimental group was higher than that of the control group, and the difference was not remarkable ($P > 0.05$). The kappa coefficient of the experimental group was 0.61, and that of the control group was 0.40. The kappa coefficient of the experimental group was higher than that of the control group, and the difference was significant ($P < 0.05$). *Conclusion*. The inspection effect of the ultrasound image processed by the BP neural network was superior to that of the conventional ultrasound image. It reflected the good adoption prospect of neural networks in image processing.

1. Introduction

Knee osteoarthritis (KOA) is a common joint degenerative disease in clinical orthopedic diseases, also known as osteoarthritis, degenerative arthritis, etc. [1]. Most of the people with high incidence of KOA are the elderly. Therefore, with the aging of China's population, the disease also gradually presents an upward trend [2]. The general clinical manifestations of KOA are knee pain and limitation of movement, but it often causes joint soft tissue lesions such as cartilage, subchondral bone, synovial capsule of the joint, and knee osteoarticular ligament in severe cases. Then, along with the development of pathological changes, cartilage tissue damage, bone spurs, and even joint deformation can lead to bone and joint failure [3–5], which will bring great inconvenience to the life of patients. At present, the main treatment for knee cartilage lesions is conservative treatment, which is targeted at the early stage of knee cartilage lesions. Arthroscopic therapy may be appropriate for patients with stage II lesions according to the condition of the disease. Surgical treatment is recommended for patients with stage III to moderate lesion stage [6–8]. Accurate diagnosis is essential in order to adopt reasonable and appropriate treatment methods and ensure the treatment effect. At present, the diagnosis of KOA joint disease is mainly based on the results of imaging techniques, including X-ray, CT, MRI, and ultrasound. However, X-ray and CT have great limitations in the display of soft tissue around the joint, which cannot be well displayed. Although MRI can display the soft tissue lesions around the joint, there are still many inconveniences [4, 9, 10]. Therefore, ultrasonic testing has been favored by more people due to its high-resolution display characteristics, noninvasiveness, safety and simple operation mode, and easy-to-accept test price [11]. With the continuous adoption of this technique in clinical practice, its accuracy in the examination of KOA disease and peripheral soft tissue lesions caused by this disease has become a hot spot in clinical research.

At present, ultrasound imaging technology is mainly used for the detection of Doppler ultrasound imaging, by showing the patient's disease location to the doctor in the form of black-and-white image to diagnose the disease. With the rapid development of artificial intelligence (AI) technology, its algorithm has been widely used in medical image processing. The principle of this technology is extracting the feature map of the original image and comparing it with the expert's to make a detection diagnosis [12]. AI algorithms include a kind of neural network calculation that has been used in various industries. Among them, the back propagation (BP) feed forward neural network is a kind of AI learning algorithm, which is widely used at this stage. It can well process images and has good adoption value in forecasting [13]. The principle of the BP neural network is as follows. Firstly, the corresponding network connection weight is obtained through the given training samples. Secondly, the input samples to be processed are taken to obtain the corresponding output samples. When the process is completed, the weight will not be changed. To put it simply, the training process of neural network algorithm for image processing is actually a process of obtaining network weights, and the methods to obtain them are mainly the back propagation of error and the speediest gradient method [14].

In this study, it used the BP neural network algorithm to optimize the ultrasound image of KOA cartilage lesions for the diagnosis of the disease and compare with the results of conventional ultrasound image examination, so as to evaluate the application effect and value of ultrasound image technology based on the BP neural network in the diagnosis of knee osteoarthritis cartilage lesions. It aimed to study more effective and feasible detection techniques for clinical diagnosis and treatment of KOA patients.

2. Methods

2.1. Research Objects. A total of 98 patients with KOA who were admitted to our hospital from October 2018 to March 2020 and had undergone arthroscopic soft tissue examination by arthroscopy were randomly selected in this study. Among them, 42 male patients and 56 female patients ranged in age from 50 to 78 years old, with an average age of (64.3 ± 7.9) years old. All patients had completed ultrasound diagnosis at admission, with complete arthroscopic results and general clinical data. The ultrasound images of all patients were processed and optimized by the BP neural network algorithm, and the consistency between the ultrasound images and arthroscopy results before and after treatment was compared. Ultrasound images of all patients were divided into two groups according to whether image processing was performed. The group before processing was set as the control group, and the group after optimized processing was set as the experimental group. This study had been approved by the medical ethics committee of our hospital. The patients and their families were informed of the study and signed the informed consent.

Inclusion criteria: (a) according to the diagnostic criteria for KOA prescribed by the American Rheumatology Association (ACR) in 2001 [15], as shown in Figure 1, patients with knee pain were diagnosed as KOA if they had five of the following nine items. (b) All patients were over 50 years old (inclusive). (c) None of the patients had undergone surgical treatment for KOA.

Exclusion criteria: (a) patients complicated with severe cardiovascular and cerebrovascular diseases and severe dysfunction of the liver, kidney, and hematopoietic system. (b) Patients with KOA lesions due to other causes and cartilage lesions around joints.

2.2. Experimental Methods

2.2.1. Inspection Method. First, high-frequency ultrasound examination was performed on all patients. All patients were scanned using the same machine and equipment, and all the examination process were carried out by the same experienced, skilled, and accurate imaging doctor. The linear array probe was used for the ultrasonic equipment, and the probe frequency was set at 10 MHz. Figure 2 showed the specific operation. Then, arthroscopy was performed on the patients who needed it. The procedure must be performed by two experienced orthopedic surgeons, and all patients were treated with a unified arthroscopic device to avoid greater individual differences. The degeneration of knee cartilage was staged according to the staging criteria in Table 1. The process of reviewing the ultrasound images was carried out by two highly qualified imaging doctors. The state of the cartilage surface around the joint, the echo state of the ultrasonic image inside the cartilage, and the morphological changes of part of the cartilage were mainly evaluated, and the thickness of the cartilage was measured. According to Table 2, lesions were staged. When the result is different, the final result should be agreed through discussion and consultation.

2.2.2. Ultrasonic Image Based on the BP Neural Network Algorithm. BP neural network algorithm was adopted to denoise and optimize the image under the ultrasonic image technology. The algorithm process is as follows.

First of all, the speckle noise in the ultrasonic image was studied. According to the study, if the particles scattered in the human tissues are sufficient and evenly distributed, the distribution of speckle noise in ultrasonic images conforms to Rayleigh distribution and is expressed by the multiplicative model in the following equation:

$$Q = we. \tag{1}$$

Q in equation (1) represents the undenoised image disturbed by noise e, and w is the original undisturbed image. If the noise distribution conforms to Rayleigh distribution, the following equation is obtained:

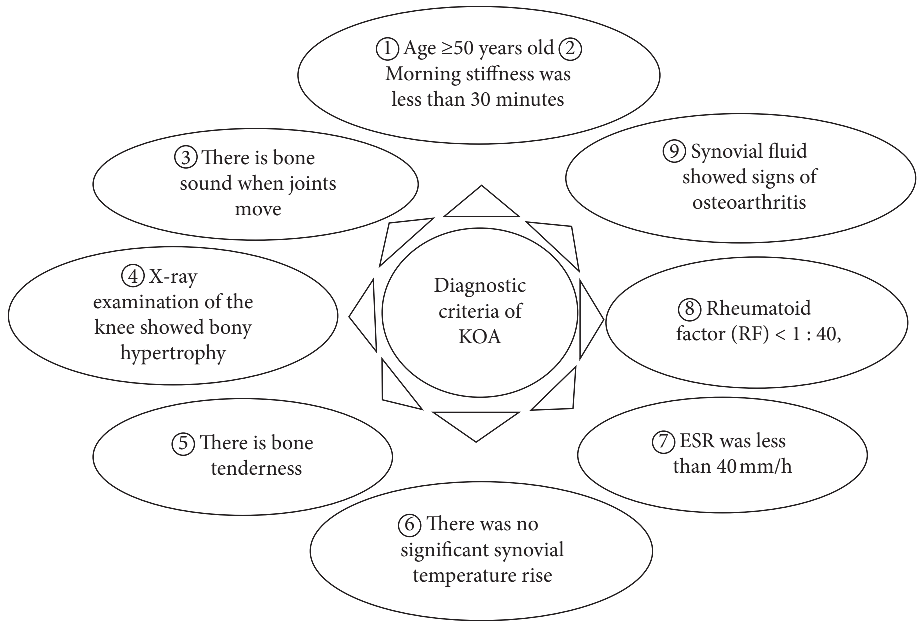

Figure 1: KOA diagnostic criteria customized by the American Association of Rheumatology (ACR) in 2001.

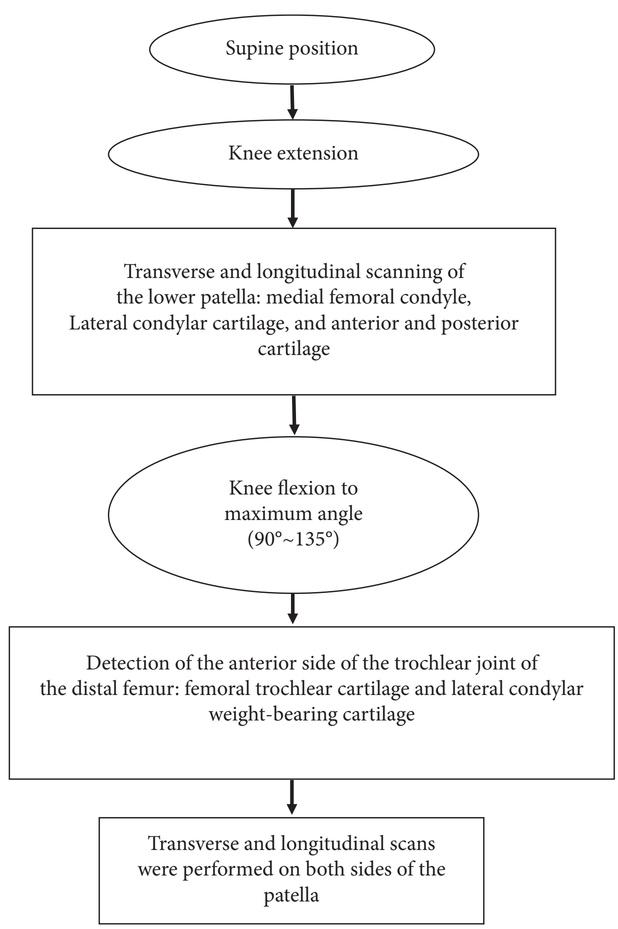

Figure 2: Process of high-frequency ultrasound examination.

Table 1: Staging criteria of knee cartilage degeneration under arthroscopy.

Stage	The state of cartilage lesions
Stage I	The cartilage tissue loses its luster and becomes hard in texture
Stage II	The surface of the cartilage is not smooth, with blisters or velvet-like changes, and the invasion range of the damage is less than 1/2 of the depth of the cartilage.
Stage III	The cartilage lesions are severe, with local thinning or even fibrosis, and the invasion range of the injury is more than 1/2 of the cartilage depth.
Stage IV	The cartilage has ulcerated lesions, complete defects, and exposed subchondral bone tissue.

Table 2: Staging criteria of knee cartilage degeneration under ultrasound detection.

Stage	Cartilage status under ultrasound
No lesion	The surface shows high echo and the lines are smooth, clear, and continuous. The boundary between cartilage and its inferior bone is normal, and the lower vocal cords are evenly distributed and of normal thickness.
Stage I	The change degree is small or the surface is rough, the thickness is close to normal, the degenerated deep layer shows high echo, the sound line is continuous, the smooth slightly less, and the internal echo distribution is basically uniform
Stage II	The surface shows hyperecho and coarse sound line with localized uplift. The deep sound line of the lesion site shows continuous hyperecho with increased echo and uneven distribution.
Stage III	Thin, with obvious defect, but no invasion of subchondral tissue, uneven distribution of low vocal cords, cartilage interruption defect, degenerative deep high echo, irregular voice line increase, showing extremely coarse, local defect
Stage IV	The subchondral bone is exposed, the deep high echo line is discontinuous, the central low echo cord is thinned, the cartilage defect area is enlarged, and the subchondral bone is invaded, obviously thinned, and the whole layer is thinned.

$$R = f\left[\sum tQ\right]. \quad (2)$$

In equation (2), f is a nonlinear function, which is relatively complex; t is the nonlinear coefficient; and R is the result of nonlinear transformation after the weighted sum of gray values of all pixels in the noisy image Q.

The processing of the BP neural network is the forward signal transmission of the original image-reverse transmission error-continuous training and correction-inspection effect. The BP network includes input layer, hidden layer, and input layer. During training, the output relationship of the BP neural network is represented by equation (3), where W_i, X_i, O_i, and y represent the weight, input value, bias, and output value of the ith neuron in the hidden layer, respectively.

$$y = \sum_{i=0}^{T-1} w_i x_i + o_i. \quad (3)$$

The error function calculation method in the back propagation process is shown in the following equation, where a_j is the output result of node j.

$$P(w,o) = \frac{1}{2}\sum_{j=0}^{s-1}\left(a_j - d_j\right)^2. \quad (4)$$

The optimization algorithm of the BP neural network often uses the gradient descent method, as shown in equation (5), where β_{i+1} is the weight after optimization, β_i is the weight before optimization, α is the learning probability, and $\chi J(\beta)/\chi\beta_i$ is the gradient in the weight direction.

$$\beta_{i+1} = \beta_i - \alpha\frac{\chi J(\beta)}{\chi\beta_i}. \quad (5)$$

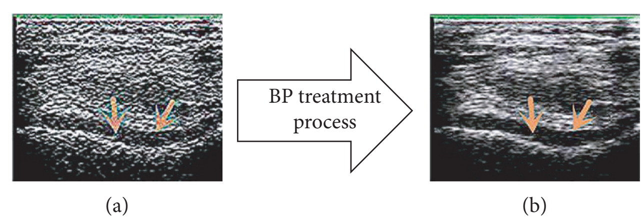

Figure 3: Comparison of ultrasound images (a) before and (b) after BP neural network algorithm processing. The red arrow refers to the articular cavity.

At this time, the BP neural network obtains the relational expression of the function, and the training is completed. The denoising effect is evaluated regarding peak signal-to-noise ratio, which is expressed by the following equation:

$$F = 101g\left[\frac{\max(h)^2}{\text{MSE}}\right]. \quad (6)$$

In equation (6), h is the ultrasonic image after denoising and MSE is mean square error, which is calculated in equation (7), where h_0 is the original unprocessed ultrasound image and M is the ultrasound image number:

$$\text{MSE} = \frac{\sqrt{\sum_{i=1}^{M}(h - h_0)^2}}{M}. \quad (7)$$

The before and after comparison of the optimized ultrasound image processed by the BP neural network algorithm is shown in Figure 3.

2.3. Statistical Methods. SPSS 22.0 was employed for data entry, sorting, and statistical analysis. The comparison of count data was performed by χ^2 test, while the comparison of measurement data was performed by t-test. Multiple sample means were compared using analysis of variance. The LSD method was used when the variance was uniform, and the Dunnett T3 method was used when the variance was uneven. $P < 0.05$ was statistically different. The kappa test was performed on the consistency between the staging results shown in the two groups of ultrasound images and those seen under arthroscopy. When kappa > 0.75, the consistency between the two was strong. When $0.4 \leq$ kappa < 0.75, the consistency between the two was general. When kappa < 0.4, the consistency between the two was poor.

3. Results

3.1. Staging Results of Cartilage Lesions under Arthroscopy. 98 patients were examined for cartilage lesions on a total of 490 articular surfaces under arthroscopic surgery. Among them, the cartilage of 206 articular surfaces was normal and uninvolved and caused disease. The cartilage of the remaining 284 articular surfaces had different degrees of disease, with a total of 320. Among them, 56 were in stage I, 85 were in stage II, 94 were in stage III, and 85 were in stage IV. The staging results of different detection parts are summarized in Table 3. Figure 4 shows the performance of different stages under arthroscopy. It was obvious that the pathological differences of the cartilage around the joints in each stage can be observed.

3.2. The Staging Results of Cartilage Lesions under Ultrasound Imaging in the Control Group. Among cartilage lesions on 490 articular surfaces of 98 patients in the staging results of the ultrasound image of the control group, the echo distribution of the ultrasound image of cartilage with 242 articular surfaces was a normal high-low-high distribution. The cartilage of the remaining 248 articular surfaces all had different degrees of lesions, with a total of 284 lesions. Among them, 38 were in stage I, 99 were in stage II, 83 were in stage III, and 64 were in stage IV. The staging results of different detection sites are summarized in Table 4. Figure 5 shows the ultrasound imaging manifestations of different stages of the control group. There were certain differences in the pathological changes of the cartilage around the joints in each stage.

3.3. The Results of Staging of Cartilage Lesions under Ultrasound Imaging in the Experimental Group. Among cartilage lesions on 490 joint surfaces of 98 patients in the staging results of the ultrasound image of the experimental group, the echo distribution of the ultrasound image of cartilage with 231 articular surfaces was normal. The cartilage of the remaining 269 articular surfaces had different degrees of lesions, with a total of 307 lesions. Among them, 44 were in stage I, 87 were in stage II, 87 were in stage III, and 89 were in stage IV. The staging results of different detection sites are summarized in Table 5. Figure 6 shows the ultrasound image manifestations of different stages in the experimental group. There were certain differences in the lesions of the cartilage around the joints in each stage.

3.4. Comparison of Consistency between the Staging Results of the Two Groups of Ultrasound Images and the Results under Arthroscopy. The examination results of the two sets of ultrasound images of the cartilage lesions around the KOA of all patients were compared with the results observed under arthroscopy. There were 335 cartilage degenerations that were accurately detected by the ultrasound image of the control group, and the staging accuracy of the inspection results was 68.3%. In the experimental group, 377 cartilage degenerations were detected, and the staging accuracy of the inspection results was 76.9%. The accuracy of staging of cartilage degeneration in the experimental group was higher than that in the control group, but the difference was not remarkable ($P > 0.05$). Moreover, the kappa coefficient of the ultrasound image staging and arthroscopic staging results of the experimental group was 0.61, while the kappa coefficient of the control group and arthroscopic staging was 0.40. The kappa coefficient of the two groups indicated that they were generally consistent with the arthroscopic staging results, but the kappa coefficient of the experimental group was higher than that of the control group, with considerable difference ($P < 0.05$), as presented in Figure 7.

4. Discussion

The progression of KOA disease is very likely to cause degenerative lesions of the cartilage around the knee joint. Patients will feel the pain of the knee joint, flexion, and extension, which even bring difficulties in walking, seriously affecting the patient's daily life. Therefore, timely and effective diagnosis is necessary for the control of cartilage involvement in patients with KOA. In order for the treatment to be effective, symptomatic treatment is necessary. The accuracy of examination of the degree of knee cartilage degeneration has an effective guiding significance for doctors to make a reasonable clinical treatment plan. There are a variety of detection methods for KOA disease, including MRI, X-ray, CT, and ultrasound, but all of them have certain adoption limitations. Ultrasound diagnosis has been welcomed by its effect on the adoption of research analysis which has been analyzed by a lot of researchers and clinicians for its excellent characteristics such as no radiation, low cost, short examination time, and simple operation, especially for the diagnosis of osteoarthritis. Researchers studied the effectiveness of ultrasound in the detection of cartilage lesions in the knee. It was found that when the knee joint was in complete flexion, ultrasound examination could clearly show the tissue structure of the cartilage around the joint, including the trochlea, femur, and medial and lateral condyle. Other researchers proposed that when the knee flexion angle was maximized, the articular surface of the patella pulley was fully exposed. The blocked range of the medial and lateral condyles of the femur can also be reduced, so that it can observe the cartilage lesions on the articular surface of the femur more completely [16]. In this study, the knee flexion of the two aspects was observed, and the results were basically the same, except that the femoral articular surface could not be fully exposed due to various obstructions. In addition, it was found through studies that

ultrasound imaging can show significant differences in the degree of cartilage degeneration, which can be regarded as an important examination and evaluation method for staging of knee cartilage lesions [17].

With the development of AI, deep neural network algorithm has been applied more and more widely in various fields [18, 19]. Some researchers have studied and analyzed the application of BP neural network in medical ultrasound image denoising. The results showed that the BP neural network has a good denoising effect on the ultrasonic image and can also preserve the edge features of the ultrasonic image well [20]. Other researchers studied the feed forward neural network ultrasonic diagnosis method based on BP algorithm and proposed the results of continuous clinical testing. BP neural network ultrasonic diagnosis software can not only improve the efficiency of ultrasonic diagnosis and reduce the time of medical treatment but also use expert knowledge base to share expert knowledge, so as to improve the accuracy of disease diagnosis [21]. The BP neural network algorithm in AI algorithm was used to process the ultrasonic image of knee cartilage to study the stage of cartilage lesions, and a good effect was obtained. The adoption of BP neural network algorithm is very wide, not only in the medical field. For example, some research experts have done a study on using the denoising characteristics of the BP neural network to deal with the noise in seismic data.

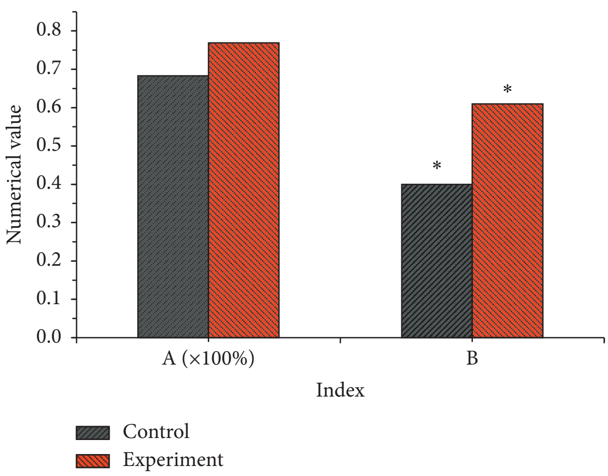

Figure 7: Comparison of the staging results of the two groups of ultrasound images with the results under arthroscopy. A: staging accuracy. B: kappa coefficient. *: the kappa value of the two groups was statistically significant ($P < 0.05$).

The experimental results showed that if BP neural network was used to denoise the seismic data, the peak signal-to-noise ratio was greatly improved, and the details of the effective information were well protected, which was in line with the expected results [22]. For the evacuation of public places, the simulation of subway station building based on the deep neural network model is used to conduct evacuation training.

5. Conclusion

In this study, it observed the cartilage degeneration stage of KOA under arthroscopy as the standard, observed the consistency between the ultrasound images of KOA cartilage lesions processed by the BP neural network algorithm and the conventional ultrasound images and the results under arthroscopy, and compared the results of the two groups. The results showed that the inspection effect of the ultrasonic image processed by the BP neural network was better than that of the conventional ultrasonic image. However, due to the small amount of data in this study, there was a lack of strong representativeness, but it also reflected the good application prospect of neural network technology in image processing. In the future, more ultrasound images will be optimized to improve the recognition accuracy of the neural network and bring more convenience for clinical ultrasound image diagnosis.

The neural network algorithm of deep learning was applied to optimize and improve color Doppler ultrasound images, which was used for the research on elderly patients with chronic heart failure (CHF) complicated with sarcopenia, so as to analyze the effect of the deep-learning-based color Doppler ultrasound image on the diagnosis of CHF. 259 patients were selected randomly in this study, who were admitted to hospital from October 2017 to March 2020 and were diagnosed with sarcopenia. Then, all of them underwent cardiac ultrasound examination and were divided into two groups according to whether deep learning technology was used for image processing or not. A group of routine unprocessed images was set as the control group, and the images processed by deep learning were set as the experimental group. The results of color Doppler images before and after processing were analyzed and compared; that is, the processed images of the experimental group were clearer and had higher resolution than the unprocessed images of the control group, with the peak signal-to-noise ratio (PSNR) = 20 and structural similarity index measure (SSIM) = 0.09; the similarity between the final diagnosis results and the examination results of the experimental group (93.5%) was higher than that of the control group (87.0%), and the comparison was statistically significant ($P < 0.05$); among all the patients diagnosed with sarcopenia, 88.9% were also eventually diagnosed with CHF and only a small part of them were diagnosed with other diseases, with statistical significance ($P < 0.05$). In conclusion, deep learning technology had certain application value in processing color Doppler ultrasound images. Although there was no obvious difference between the color Doppler ultrasound images before and after processing, they could all make a better diagnosis. Moreover, the research results showed the correlation between CHF and sarcopenia.

1. Introduction

Cardiovascular and cerebrovascular diseases are high-morbidity diseases in the elderly population. With the aging of the population in China, the occurrence and mortality of cardiovascular and cerebrovascular diseases are gradually increasing, especially in the aspect of heart. Chronic heart failure (CHF) will appear in the late stage of heart disease development [1]. According to the statistics, the probability of suffering from CHF is between 1.3% and 1.8% in our population at the present stage and 30% to 50% of the CHF patients eventually die [2]. Sarcopenia, also known as age-related sarcopenia, is a complication of developing CHF, which mainly refers to an age-related degenerative syndrome in which the content of human skeletal muscle gradually decreases with the increase of age, as well as the strength and function of muscle gradually deteriorates [3]. The incidence of sarcopenia varies by region and race, but it is a general trend that increases with age, so it can also be called a progressive geriatric syndrome [4]. Studies have shown that grip strength, muscle strength of quadriceps femoris, 6-minute walking distance, reduced left ventricular ejection fraction, and high oxygen consumption will appear due to low exercise peak when CHF patients are complicated with sarcopenia [5]. Moreover, it is proposed that this complication will not only reduce the quality of life of the patients but also increase the probability of death of the patients through the analysis of patients with CHF complicated with sarcopenia [3].

Cardiac color Doppler ultrasound is a major examination method in diagnosing CHF disease, which is now the only imaging method that can display circulation situation in the internal structure of the heart and organs, and the method has simple operation, causes no wound, and can be repeated [6]. When patients with CHF are examined, the cardiac image structure is comprehensively and intuitively displayed, thereby providing a more favorable and reliable basis for doctors' diagnosis [7].

Deep learning is a kind of artificial intelligence technology that has developed very rapidly in recent years. The neural network system of deep learning has made great progress in image classification and examination. Furthermore, this technology is also widely applied in the medical field. Intelligent medical care, which is a combination of deep learning artificial intelligence and the medical industry, has become a research hotspot [8]. It also solves two major problems for the medical industry: the first one is the imbalance between the amount of imaging data and the amount of clinical imaging data, and the second one is the imbalance between the level of imaging doctors and the allocation of resources [9]. Deep learning methods have been fully and reasonably utilized in image processing and analysis in the medical field. In particular, the deep convolutional network model can more effectively learn image features from a large number of samples, avoid the complex feature extraction process in traditional image classification algorithms, and realize end-to-end classification and detection [10].

In this study, deep learning convolutional neural network technology was combined with color Doppler ultrasound images, which was used for the diagnosis of CHF to analyze the correlation between CHF and sarcopenia.

2. Methods

2.1. Research Objects. A total of 259 patients were randomly selected in this study, who were diagnosed as sarcopenia and admitted to hospital from October 2017 to March 2021, including 119 males and 140 females. They were 60 to 76 years old, with an average age of 69.5 ± 3.5 years. All patients underwent cardiac ultrasound examinations, who were rolled into two groups according to whether deep learning technology was used for image processing or not. A group of routine unprocessed images was set as the control group, and the images processed by deep learning were set as the experimental group. This study was approved by the Medical Ethics Committee, and all the patients participating in the study signed the informed consent forms.

The criteria for inclusion were defined to include patients who were over 50 years of age, were diagnosed as sarcopenia based on the diagnostic criteria proposed by the Asian Working Group for Sarcopenia (AWGS) [11] (Table 1), and were able to undergo a complete color ultrasound examination, whose color ultrasound images were well preserved.

The criteria for exclusion were defined to include patients who had skeletal disease or motor obstruction disease, had previous history of fracture, suffered from diabetes, thyroid, and parathyroid gland and other endocrine system diseases, had diseases of the digestive system and renal insufficiency that affected skeletal muscle metabolism, suffered from malignant tumors and connective tissue diseases, and took calcium, hormone drugs, and antitumor drugs within 1 year, with female ovarian lesions.

2.2. Research Methods

2.2.1. Diagnostic Methods of Chronic Heart Failure. For the diagnosis of CHF, the method of combining the clinical manifestations with the results of other auxiliary examinations was adopted to make the combined diagnosis, as shown in Figure 1.

2.2.2. Convolution Neural Network Algorithm Model. In this study, a convolutional neural network algorithm-based color Doppler ultrasound image model would be established according to the pixel resolution and the performance of stable deep neural network. Then, it would be trained and applied in this study.

The convolution layer was set as the layer q, so the feature graph of the input color ultrasound image at the layer $q-1$ could be expressed as follows:

$$W(q,p) = \sum_{e=1}^{E} Y^{(q,p,e)} \otimes Z^{(q-1,e)} + l^{(q,p)}. \tag{1}$$

In addition, $W^{(q,p,e)}$ represented the convolution kernel, $l^{(q,p)}$ stood for the bias, and e meant the number of feature graphs.

In this study, the commonly used and high-rate ReLu was used as the activation function, which is shown in equation (2), and the corresponding derivative function expression is presented in equation (3). However, due to the excessive data gradient passing through the ReLu neuron, once the data were updated, the neuron would not be able to activate any data again, so it was improved into equation (3). It was a self-gated activation function, which could be called swish.

$$f(x) = \max(0,x), \tag{2}$$

$$f'(x) = \begin{cases} x, & x > 0, \\ 0, & x \leq 0, \end{cases} \tag{3}$$

$$F_1(x) = \left(R_1 * X + L_1\right) \times \frac{Y}{Y + u^{-\alpha\left(R_1 * X + L_1\right)}}. \tag{4}$$

In equation (4), R_1 stands for the convolution kernel, $i \times f_1 \times f_1$ expresses the size, i indicates the number of channels of the input graph, L_1 represents the offset vector,

Table 1: Diagnostic criteria for AWGS sarcopenia.

	Evaluation content	Gender	Criteria
One	The mass of skeletal muscle measured by the dual energy X-ray absorption method; calculation of the ratio of the mass to the height square	Male	<7.0 kg/m^2
		Female	<5.4 kg/m^2
Two	Grip strength	Male	<26 kg
		Female	<18 kg
	Walking speed	6-minute walking speed	<0.8 m/s

Note. Patients who met any of these criteria could be diagnosed with sarcopenia.

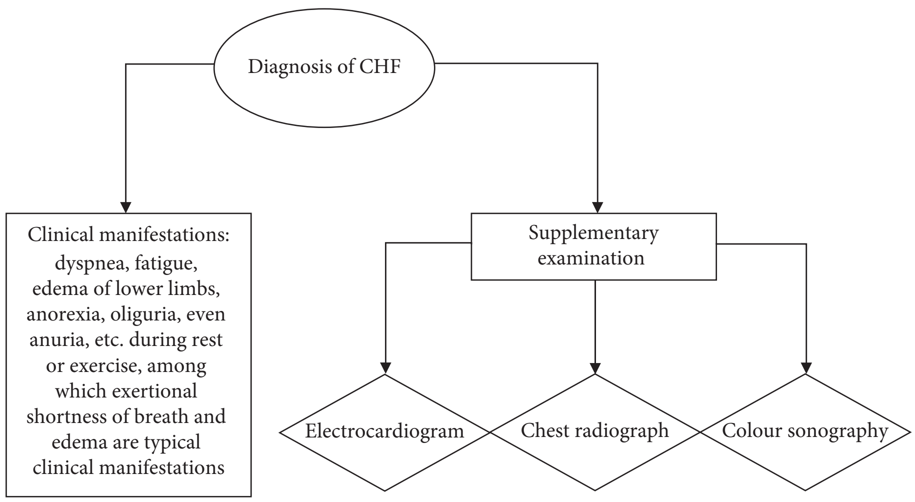

Figure 1: Diagnostic criteria for CHF.

$*$ means the convolution operation, and α stands for the parameter that could be trained.

In this model, the first layer was mainly for the operation of extracting the feature map of the original color ultrasound image, and the second layer to the $q-2$ layer was the nonlinear mapping process of the extracted feature map, which could be expressed by the following equation:

$$F_2(x) = (R_2 * X + L_2) \times \frac{Y}{Y + u^{-\alpha(R_2 * X + L_2)}}. \quad (5)$$

The reconstruction process of the image could be expressed as equation (6), where R_3 represents the mean filter and L_3 expresses the offset of dimension i.

$$F_3(x) = R_3 * F_2(X) + L_3. \quad (6)$$

The convolutional neural network algorithm needed to be reconstructed according to the error, and the parameter error in the propagation process was constantly corrected. If the current propagation was q, the output parameter of the layer was x^q, and the weight and bias could be expressed by R^q and L^q in turn, as shown in the following equations:

$$x^q = f(p^q), \quad (7)$$

$$(p^q) = R^q x^{q-1} + l^q. \quad (8)$$

The expression of loss function was as shown in the following equation:

$$\mathrm{Loss}(s, s') = \frac{1}{n}\sum_{j=1}^{n}\left(s_j, s_j'\right)^2. \quad (9)$$

The method of reducing the gradient was adopted to minimize the sum of squares of errors, and the specific algorithm is shown in the following equations:

$$R_j = R_j - \beta\frac{\chi}{\chi R_j} M(R, l), \quad (10)$$

$$R_j = R_{jk} - \beta\frac{1}{z}\sum_{j=1}^{z}\left[V_{r,l}\left(x^j\right) - s^j\right]x^j. \quad (11)$$

Among them, β represents the weight, χ represents the volume number, and s refers to the loss data.

For the semisupervised learning algorithm aiming at the inherent noise and uncertainty in ultrasonic images, its calculation method was displayed as follows, but the derivation process was omitted:

$$L_{\mathrm{label}} = -B[\ln g(y \mid x)] = -ly + \mathrm{LSE}(l), \quad (12)$$

$$\begin{aligned} L_{\mathrm{unlabel}} &= -E[\ln(1 - g(H+1) \mid x)] \\ &= -\mathrm{LSE}(l) + \mathrm{sofplus}(\mathrm{LSE}(l)), \end{aligned} \quad (13)$$

$$L_{\text{fake}} = -E[\ln g(H+1 \mid x)] = \text{softplus}(\text{LSE}(l)), \tag{14}$$

$$L_D = L_{\text{label}} + \frac{v(L_{\text{unlabel}} + L_{\text{fake}})}{2}. \tag{15}$$

In equations (12)–(15), H stands for the classifier and $H+1$ means the output graph of the discriminator. The whole system included real data with labels, noise data without labels, and generated data, and the corresponding probabilities were L_{label}, L_{unlabel}, and L_{fake}, respectively.

Figure 2 shows the comparison of the cardiac color ultrasound images before and after processing and optimization by this algorithm.

2.2.3. Evaluation Criteria for the Algorithm Effect. In order to evaluate the effect achieved by the abovementioned algorithm model, the peak signal-to-noise ratio (PSNR) and structural similarity index measure (SSIM) were applied in this study. Besides, the smaller the value of PSNR, the smaller the degree of image distortion. However, the closer the SSIM value was to 1, the more similar the processed image would be to the original. The specific algorithm of PSNR is shown in equations (16) and (17), where K expresses the image height, H means the image width, and n stands for the bit value of each pixel.

$$\text{MSE} = \frac{1}{K \times L} \sum_{i=1}^{K} \sum_{j=1}^{H} (X(i,j) - Y(i,j))^2, \tag{16}$$

$$P = 10 \log_{10}\left(\frac{(2^n - 1)^2}{\text{MSE}}\right). \tag{17}$$

SSIM could be calculated as in equation (18), where α_x indicates the average value of x, α_y means the average value of y, β_x^2 represents the variance of x, β_y^2 stands for the variance of y, and β_{xy} expresses the covariance of x and y.

$$\text{SSIM}(x,y) = \frac{(2\alpha_x\alpha_y + e_1)(2\beta_{xy} + e_2)}{(\alpha_x^2 + \alpha_y^2 + e_1)(\beta_x^2 + \beta_y^2 + e_2)}. \tag{18}$$

2.3. Observation Indicators. The left atrial diameter (LAD), left ventricular ejection fraction (LVEF), and left ventricular end-diastolic diameter (LVDD) of the two groups were observed and recorded by using a color Doppler ultrasound, so as to evaluate and compare the positive rates of LAD, LVEF, and LCDD in the two groups. Positive criteria for diagnosis of CHF by using the cardiac ultrasound [12]: ① LAD > 30 mm was positive; ② LVDD > 55 mm in male and >50 mm in female were positive; and ③ LVEF < 50% was positive.

The detection results of the two groups were compared, the number of sarcopenia patients diagnosed with CHF was contrasted, and the clinical manifestations and other auxiliary examinations were combined to confirm the diagnosis, so as to analyze the accuracy of the cardiac ultrasound examination.

2.4. Statistical Methods. SPSS 23.0 statistical software was used for data processing, in which measurement data were expressed as ($x \pm s$), and the two independent samples t-test was used for comparison between groups. Count data were represented by [n (%)], and the χ^2 test was used for comparison between groups. In addition, $P < 0.05$ indicated that the difference was statistically substantial.

3. Results

3.1. Comparison on Cardiac Color Ultrasound Images of Patients with Chronic Heart Failure and Other Heart Diseases from Two Groups. The cardiac color ultrasound images of patients from the two groups were observed, clearly showing that the processed images of the experimental group were clearer than the untreated images of the control group, which also had higher resolution. Therefore, it indicated that the deep learning convolutional neural network algorithm had a certain effect on optimization for color ultrasound images, and the specific comparison is shown in Figures 3 and 4. In addition, PSNR and SSIM were adopted to evaluate the effect of processing, achieving good results (PSNR = 20 and SSIM = 0.09).

3.2. Comparison of LVEF, LCDD, and LAD Results between the Two Groups. By statistical analysis of the diagnostic results of LVEF, LCDD, and LAD in the two groups of cardiac color ultrasound of all patients (Table 2), it was found that the indicators of LVEF, LCDD, and LAD of the control group were lower than the indicators of the experimental group, and the comparison was statistically significant ($P < 0.05$), as shown in Figure 5.

3.3. Statistical Comparison on the Positive Rates of LVEF, LCDD, and LAD Results from Cardiac Color Ultrasound Diagnosis between the Two Groups. There was statistical analysis on the positive rates of diagnostic results of LVEF, LCDD, and LAD in the two groups of heart color ultrasound of all patients (Table 3). Figure 6 reveals that the positive rates of LVEF, LCDD, and LAD of the experimental group were higher than the rates of the control group, and the comparison was statistically significant ($P < 0.05$).

3.4. Comparison on the Results of CHF Patients Diagnosed in the Two Groups and the Final Confirmed Results. Table 4 shows the comparison of the number of patients diagnosed with CHF by using the cardiac color ultrasound and the final diagnosis combined with other clinical examinations. The study results suggested that the similarity between the final diagnosis results and the examination results of the experimental group was 93.5%, while the similarity between the results and the control group was 87.0%. Thus, the similarity between the experimental group and the control group was higher, and the comparison was statistically significant ($P < 0.05$). Among all the patients diagnosed with sarcopenia in this study, 88.9% were also finally diagnosed with CHF, and only a small part suffered from other diseases,

which showed statistical significance ($P < 0.05$). In contrast, 77.2% of the patients from the control group and 83% from the experimental group had the combination of the two diseases. There was statistical significance in comparing the probability of patients with CHF among the three groups ($P < 0.05$), as shown in Figure 7.

4. Discussion

In today's medical field, the application of medical imaging technology in the screening, diagnosis and treatment, and evaluation of clinical diseases has become more and more extensive, and it is a very critical examination method [13]. Since the diagnosis and evaluation of image maps in the past was mainly carried out by excellent doctors and they had the uneven experience level, the results of the review were very different, and it was also highly subjective [14]. Therefore, as the deep learning artificial intelligence technology research has achieved excellent results, the technology has been extensively used in all aspects of the medical field, especially in the improvement and promotion of medical imaging technology, and has achieved good research results, showing good results in clinical examination and diagnosis [15]. At this stage, the medical imaging technology system and medical image processing and analysis are the most typical application scenarios of medical technology based on deep learning methods, and significant results have been achieved.

In this study, the neural network algorithm of deep learning was adopted to optimize and improve the color Doppler ultrasound images, which was applied in the diagnosis of CHF complicated with sarcopenia. The comparison of images before and after processing showed that the algorithm model had certain effect on image improvement, not only for color Doppler ultrasound image processing but also for other commonly used imaging techniques such as CT and MRI. Voets et al. [16] reported on the diagnosis of diabetic retinopathy in the *Journal of the American Medical Association*. It was proved that the end-to-end deep learning model could be directly applied to medical image processing, and the diagnostic results obtained were very similar with experts, which were even better than the diagnosis made by experts. Varghese et al. [17] combined imaging with machine learning (ML) to cross examine the accuracy of multiple ML algorithms for the detection of clinically significant PCa (csPCa). The results showed that the second kernel-based support vector machine (SVM) had the best accuracy, up to 92%. Zhang et al. [18] applied MSCTA three-dimensional reconstruction technology in the treatment of colorectal cancer. By comparing the consistency of the MSCTA three-dimensional reconstruction with the actual surgical plan, they found that the kappa consistency test between the two was $k = 0.769$,

Table 4: Comparison on the results of CHF patients diagnosed from the two groups and the final diagnosis results.

Symptom	Group		
	Control group	Experimental group	The final diagnosis results
CHF	200	215	230
Other diseases	59	44	29
CHF proportion	77.4%	83.1%	88.9%

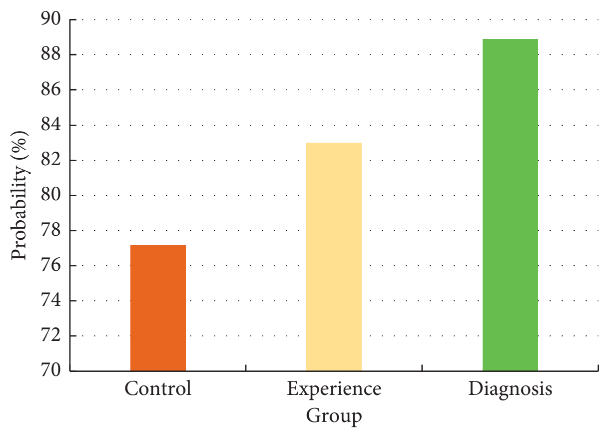

Figure 7: Comparison on the probability of patients with CHF in the three groups.

which proved MSCTA three-dimensional reconstruction had a good effect in guiding the treatment of colorectal cancer under laparoscopy.

In this study, CHF patients complicated with sarcopenia accounted for a large part of the total number of patients, which fully reflected that there was a certain connection between the two. Besides, the correlation between CHF and sarcopenia was extensively investigated. Some experts conducted a statistical study on 200 CHF patients with an average age of 70.8 ± 8.3 years, and the results showed that the incidence of CHF with sarcopenia was 19.5% [19]. A large number of studies have shown that 68% of patients with CHF are complicated with muscle fiber atrophy, the body mass of elderly patients with CHF is decreased, and the decreased exercise tolerance may be related to skeletal muscle fiber and skeletal muscle mass loss [20]. By exploring and analyzing CHF patients complicated with sarcopenia, foreign research experts have found recently that there is a certain correlation between skeletal muscle decline and pathological changes such as coronary atherosclerosis in elderly people and have proposed that sarcopenia may also have a reliable influence on the disease development of CHF [21]. Those mentioned above were similar to the results of this study, and there was a close correlation between CHF and the occurrence of sarcopenia.

5. Conclusions

In this study, the deep learning neural network algorithm is used to optimize and improve the color Doppler ultrasound image for the diagnosis of CHF complicated with myopenia. It is found that the processed image of the experimental group is clearer and has higher resolution than the unprocessed image of the control group. The final diagnosis result is more similar to the experimental group, which also indicates the correlation between CHF and myopenia. However, due to the limitation of the research scope, this study lacks a certain representativeness. However, the overall results show that the application of deep learning artificial intelligence in the field of imaging is still very promising.

This work aimed to explore the relationship between spine surgery lumbar facet joint (LFJ) and lumbar disc herniation (LDH) via compressed sensing algorithm-based MRI images to analyze the clinical symptoms of patients with residual neurological symptoms after LDH. Under weighted BM3D denoising, Epigraph method was introduced to establish the novel CSMRI reconstruction algorithm (BEMRI). 127 patients with LDH were taken as the research objects. The BEMRI algorithm was compared with others regarding peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM). Patients' bilateral LFJ angles were compared. The relationships between LFJ angles, lumbar disc degeneration, and LFJ degeneration were analyzed. It turned out that the PSNR and SSIM of BEMRI algorithm were evidently superior to those of other algorithms. The proportion of patients with grade IV degeneration was at most 31.76%. Lumbar disc grading was positively correlated with change grading of LFJ degeneration ($P < 0.001$). LFJ asymmetry was positively correlated with LFJ degeneration grade and LDH ($P < 0.001$). Incidence of residual neurological symptoms in patients aged 61–70 years was as high as 63.77%. The proportion of patients with severe urinary excretion disorders was 71.96%. Therefore, the BEMRI algorithm improved the quality of MRI images. Degeneration of LDH was positively correlated with degeneration of LFJ. Asymmetry of LFJ was notably positively correlated with the degeneration of LFJ and LDH. Patients aged 61–70 years had a high incidence of residual neurological symptoms after surgery, most of which were manifested as urinary excretion disorders.

1. Introduction

LDH is a common chronic spinal degenerative disease [1]. In recent years, the incidence of LDH has shown a significant upward trend, and a large number of studies have shown that LFJs are related to the occurrence of LDH [2]. In addition, studies have shown that the angle and asymmetry of LFJs are related to the occurrence of LDH [3]. Magnetic resonance imaging (MRI) technology is utilized in the diagnosis of LDH due to its noninvasiveness and multiple imaging angles. However, in the current research, there are generally cases where the results of imaging examinations do not match the patient's signs and symptoms. Moreover, due to the limited quality of MRI images, there are certain controversies about the occurrence of LFJ and LDH. Clinically, there are also cases where the images and physical signs do not match [4]. The quality of reconstructed images in traditional MRI algorithms is low. Some researchers applied compressed sensing (CS) theory to the reconstruction of MRI images and established the CSMRI algorithm, which can not only obtain the precise sparsity prior of the image but also capture the rich structural information of the image, and thus it is widely adopted in the field of MR image reconstruction. However, the CSMRI algorithm still cannot manage both image quality and calculation speed, and there is still room for further improvement in the quality of MR image reconstruction at low sampling rates [5].

At present, surgical methods are often adopted to treat LDH in clinic. Although surgical methods can significantly relieve the clinical symptoms of LDH patients, some patients still have residual neurological symptoms after surgery. The incidence of residual neurological symptoms after LDH is 5%–40%, with an average of 15%. The main manifestations are swelling, numbness, limp, and weakness of the lower limbs. Studies pointed out that the proportion of patients with lower extremity numbness after LDH operation was up to 21%–67%, and studies reported that patients with hip pain after LDH operation accounted for 63.1% [1]. At present, there are few studies on residual neurological symptoms in patients with LDH. Moreover, the proportion of symptoms after LDH is quite different, and further research on its symptoms is needed to provide a reference for the prognosis of LDH.

The deep ResNet method was introduced based on the deep learning algorithm to remove the Rician noise in MRI images and was applied to the diagnosis of LDH patients. From June 2018 to March 2020, 127 patients who underwent MRI diagnosis and were confirmed as LDH with residual neurological symptoms in our hospital's spine surgery were taken as the research objects. The relationship between LFJ, LDH, and residual neurological symptoms after surgery was explored to find out the cause of LDH and the residual neurological symptoms after surgery and provide a reference for the diagnosis and prognosis of LDH.

2. Materials and Methods

2.1. Research Objects. From June 2018 to March 2020, 127 patients who underwent MRI diagnosis and were confirmed as LDH with residual neurological symptoms in our hospital's spine surgery were taken as the research objects. 381 lumbar intervertebral discs and 381 pairs of LFJs and LFJs were measured.

The inclusion criteria in this study were defined as follows: patients diagnosed as LDH; patients without a history of lumbar spine surgery; patients who suffered from recurrent or persistent low back pain, sciatica, or its branch nerve compression symptoms 3 months after LDH surgery; and patients without prominent or nerve root compression or damage of original surgery segment after the surgery. The exclusion criteria could be determined as follows: patients whose MRI diagnosis images could not be found in the information query system of the hospital; patients with ankylosing spondylitis; patients with spinal tumors or lumbar tuberculosis; patients with failed LDH surgery; and patients accompanied by serious cardiovascular, cerebrovascular, liver and kidney, hematopoietic system or other serious diseases of other organs. The experimental process had been approved by the Ethics Committee of the hospital, and all subjects included in the study had signed the informed consent forms.

2.2. Denoising Algorithms for MRI Images Based on the Deep Learning. The traditional image denoising algorithms cannot completely remove the Rician noise in MRI images with relatively fuzzy image edge contours, and the deep learning mainly focuses on removing the Gaussian white noise. Therefore, the deep ResNet method was proposed based on the deep learning to remove the Rician noise in MRI images.

Gradient reduction could be found during the training of convolutional neural network (CNN) model, while the ResNet idea could solve this problem well. It was assumed that the input neural network of the ResNet was x and the function mapping was $H(x)$; then the expression of the residual mapping $F(x)$ was as follows:

$$F(x) = H(x) - x. \tag{1}$$

The expression equation of the hidden layer could be written as follows:

$$H(x) = F(x) + x. \tag{2}$$

It was expected to obtain the mapping $H(x)$ by training the deep network, while the residual learning could fit the residual mapping $F(x)$, and the residual learning equation was more suitable for solving the image denoising. The structure of ResNet is shown in Figure 1.

In the ResNet, the batch normalization (BN) method was used for intermediate preprocessing, so that the input of the previous layer was processed by BN before entering the next layer, which can avoid gradient explosion and improve the training speed. When the model was designed, BN was introduced after each convolutional layer. If one layer of the network was a d-dimensional input $x = \{x_1, x_2, \ldots, x_d\}$, it could be normalized as in the following equation:

$$x_k = \frac{x_k - E(x_k)}{\sqrt{\mathrm{Var}(x_k)}}, \tag{3}$$

where $E(x_k)$ refers to the expectation and $\mathrm{Var}(x_k)$ represents the variance.

Parameters γ_k and β_K were introduced to avoid influences on network learning features of this layer:

$$y_k = \gamma_k x_k + \beta_k. \tag{4}$$

If BN was not introduced, the activation function layer y could be expressed as follows:

$$y = s(\omega x + b), \tag{5}$$

where w refers to the weight; b and s represent the bias and activation function, respectively.

If the BN was introduced, the forward conduction could be written as in the following equation:

$$y = s(BN(\omega x + b)). \tag{6}$$

The above equation could be normalized as follows:

$$y = s(BN(\omega x)). \tag{7}$$

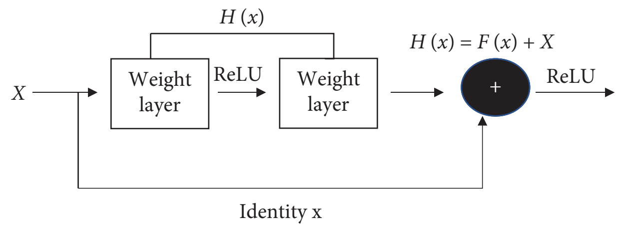

Figure 1: The structure of residual network.

The gradient descent algorithm was the commonly used optimization algorithm in the neural network training process so as to obtain the minimum parameters of the loss function. The single-step weight and bias update expressions were as follows:

$$\omega_k \longrightarrow \omega_k' = \omega_k - \left(\partial\frac{\delta C}{\delta \omega_k}\right),$$
$$b_l \longrightarrow b_l' = b_l - \left(\partial\frac{\delta C}{\delta b_l}\right). \tag{8}$$

The gradient descent algorithm was slow when the amount of data was large, so a stochastic gradient descent (SGD) algorithm was proposed. However, it adopted individuals to represent the overall change and cannot obtain the global optimal solution in each iteration. Therefore, the Adam algorithm was proposed in this study. The SGD algorithm updated all weights so that the learning rate remained stable during the network training. The Adam algorithm iteratively updated the weights of the neural network, which can solve the high-intensity noise or sparse gradient well.

As regards the Adam algorithm, the noise objective function was set to $f(\theta)$; the exponential moving average and square gradient were updated; and the deviation correction term was initialized.

$$v_t = (1-\beta_2)\sum_{i=1}^{t}\beta_2^{t-i}\cdot g_i^2, \tag{9}$$

where t represents the time step; β_2 refers to the exponential decay rate; and g represents the gradient.

After deviation correction, the expected value could be written as in the following equation:

$$\begin{aligned} E[v_t] &= E\left[(1-\beta_2)\sum_{i=1}^{t}\beta_2^{i-1}\cdot g_i^2\right],\\ &= E\left[g_t^2\right]\cdot(1-\beta_2)\sum_{i=1}^{t}\beta_2^{i-1} + \varsigma\\ &= E\left[g_t^2\right]\cdot(1-\beta_2) + \varsigma. \end{aligned} \tag{10}$$

If the second moment $E[g_t^2]$ was static, the ς value was 0.

The structure of the deep ResNet denoising model proposed in this study is shown in Figure 2. There were 15 network layers in total, 13 of which were hidden layers. Both the training image and the test image were grayscale ones. The size of the input layer was $3\times3\times1\times64$, including the activation function and the convolutional layer. The size of the hidden layer was $3\times3\times64\times64$, including activation function, BN, convolution, and pooling operations. The output layer size was $3\times3\times64\times1$, and the convolutional layer was reconstructed to output the image.

2.3. Degeneration Classification and Measurement Methods of LFJs and Lumbar Disc. The classification of LFJs could refer to the classification standards (0–3 levels) of LFJs degradation image defined by Song et al. [6]. L3/4, L4/5, and L5/S1 of the patients were scanned with MRI, and the scan line was parallel to the intervertebral space and passed through the corresponding LFJs. If the angle difference between two sides of LFJs of the same segment was greater than 7°, it was deemed that LFJs were asymmetric.

The grades of lumbar disc degeneration were divided into grades I–V [7]. The height of the first-level lumbar disc of the MRI image was to determine the degeneration grade. The vertical height of the center of the lumbar disc was calculated according to the two reference lines. According to the results of Brayda-Bruno et al. (2018) [8], the normal values of the height of each lumbar disc were 1.073 cm–1.247 cm for L3/4, 1.18 cm–1.272 cm for L4/5, and 0.939 cm–1.121 cm for L5/S1. It was determined as the slight decrease if the height was higher than 80% of the normal height. If the height was lower than 80% and higher than 60% of the normal height, it was deemed as a moderate decrease; and it was determined as gap collapse if the height was lower than 60% of the normal height.

2.4. Observation Indicators. The asymmetry of LFJs, LFJs degeneration grade, and lumbar disc degeneration were measured based on the MRI images of all patients. The basic clinical data, postoperative clinical manifestations, influencing factors, and nerve entrapment points were recorded for all patients.

2.5. Statistical Analysis. The experimental data was processed using SPSS 19.0 statistical software, the mean $\pm$ standard deviation ($\overline{x}\pm s$) was adopted to show the measurement data, and the t-test was employed for normal distribution. Spearman's rank correlation analysis was to analyze the lumbar disc degeneration grades, LFJs asymmetry, LFJs degeneration grades, LDH, and age, which did not obey the normal distribution ($\alpha = 0.005$). The count data of patients with postoperative residual neurological symptoms of different ages and different genders were expressed in percentage (%), tested by the χ^2 test. $P < 0.05$ indicated that the difference was considerable.

3. Results

3.1. Analysis of Denoising Performance of Different Algorithms. The proposed deep learning denoising algorithm was compared with the weighted stable matching (WSM) algorithm and denoising CNN (DnCNN) algorithm in terms of PSNR value (Figure 3(a)). The PSNR value of the

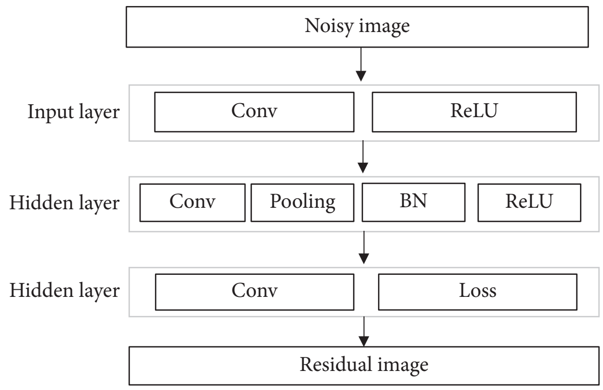

FIGURE 2: The structure of the deep ResNet denoising model.

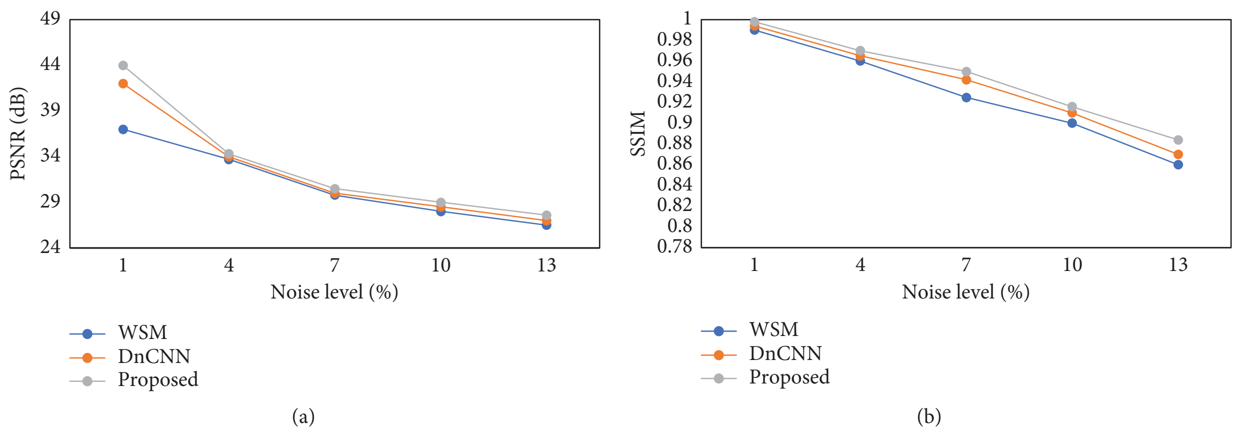

FIGURE 3: Comparison of PSNR and SSIM values under different algorithms. *Note.* (a) illustrates the comparison results of PSNR, and (b) discloses the comparison results of SSIM.

image after denoising by the proposed algorithm was higher than those of the WSM algorithm and DnCNN algorithm under different noise intensities. Further analysis of the SSIM values of various algorithms (Figure 3(b)) revealed that the SSIM value of the image after denoising by the proposed algorithm was still higher than those of other algorithms. Based on the above results, it was obtained that the proposed algorithm had obvious advantages in denoising of the medical MRI images.

3.2. MRI Examination of Patients with Lumbar Disc Herniation. The MRI image of the LDH patient was compared with the MRI image of the normal human body, and the results are shown in Figure 4. The MRI image of the patient showed an obvious disc herniation and compression of the nerve root and the right dural sac.

3.3. The Correlation between the Grades of Lumbar Disc Degeneration and Lumbar Facet Joint. The proportion of patients in different lumbar disc degeneration grades was analyzed and compared, as shown in Figure 5. The proportion of patients with degeneration grade 4 was up to 31.76%. Further, there was an obviously positive correlation between the lumbar disc degeneration grade and the LFJ degeneration grade ($r = 0.753$, and $P < 0.001$).

3.4. Correlation between Lumbar Facet Joint Degeneration and Lumbar Disc Herniation. The correlation between LFJ degeneration grade and LDH was analyzed, and the results are shown in Table 1. They were extremely and negatively correlated ($r = -0.306$, and $P < 0.001$).

3.5. Correlation between Lumbar Facet Joint Asymmetry and Lumbar Disc Herniation. As shown in Table 2, LFJ asymmetry was extremely and positively correlated with the LDH ($r = 0.543$, and $P < 0.001$).

3.6. Distribution of Patients with Postoperative Residual Neurological Symptoms. A total of 81 patients with LDH had postoperative residual neurological symptoms, accounting for 63.77%. As age increased, the number of patients with postoperative residual neurological symptoms tended to increase and then decrease. Moreover, the patients aged 61–70 years accounted for the highest proportion (Figure 6). There were 18 male patients (22.22%) and 15 female patients (18.52%) with residual neurological symptoms in the age

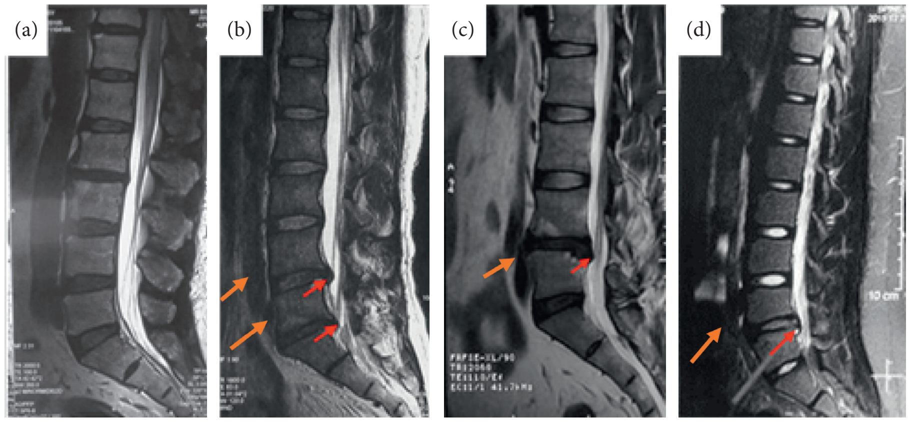

FIGURE 4: MRI of patients with LDH. (a) shows an MRI image of lumbar disc of a normal human body; (b) shows an MRI image of a male patient aged 42 years with L4/5 disc herniation; (c) shows an MRI image of L3/4 disc herniation for a female patient aged 39 years; and (d) shows an MRI image of L5/S1 right disc herniation for a male patient aged 64 years.

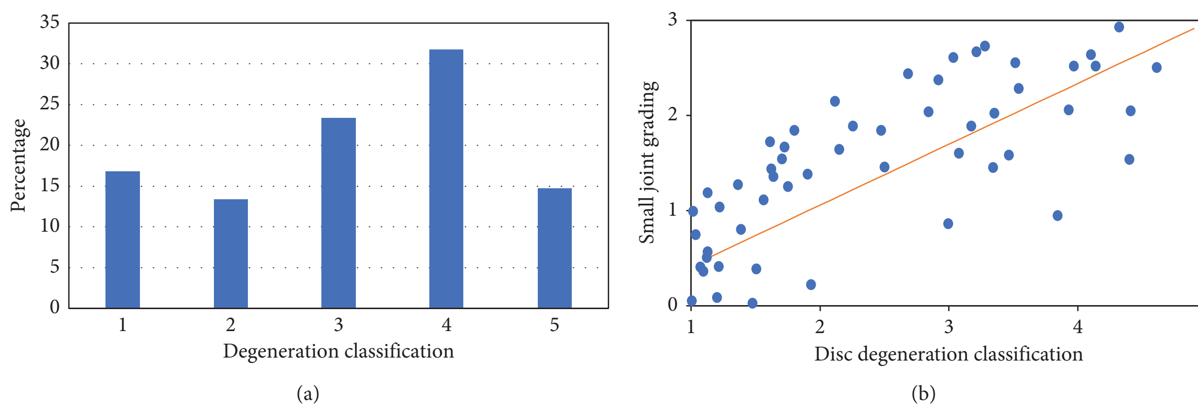

FIGURE 5: Distribution of lumbar disc degeneration grade and its correlation with LFJ degeneration grade. Figure 6: Analysis of the age and gender distribution of patients with postoperative residual neurological symptoms.

group of 61–70 years. In the entire age distribution, the proportion of males was higher than that of women, but the differences were not considerable ($P > 0.05$).

3.7. Symptoms of Postoperative Residual Neurological Symptoms. In this study, PRNSs of LDH were mainly manifested in waist pain, lower extremity radiating pain, buttock pain, waist movement limitation, lower extremity pain, lower extremity paresthesia, lower extremity weakness, severe urinary excretion disorder, and intermittent claudication (Figure 7). Most of patients suffered from serious urinary excretion disorders, reaching 71.96%.

4. Discussion

In this study, PSNR and SSIM values of the deep learning denoising algorithm were higher than those of other algorithms, showing that the quality of image treated with the deep learning denoising algorithm was higher [9, 10]. The proportion of patients with grade 4 degeneration was as high as 31.76%, and there was a dramatically positive correlation between the degeneration grade of lumbar disc and the degeneration grade of LFJ and age ($r = 0.753$, and $P < 0.001$). Ezemagu et al. [11] believed that herniation was caused when the pressure of the lumbar disc exceeded the load pressure. LFJs could protect the lumbar disc from damage due to excessive spine activity, so LFJ was positively correlated with herniation [12], which was similar to the results of this study. Cao et al. (2020) [13] found that the degeneration of LFJ could cause differences in the direction of the force on the lumbar disc nucleus pulposus, which could lead to different positions of LDH. There was a significantly positive correlation between LFJ degeneration grade and patient age ($r = 0.694$, and $P < 0.001$). There was a considerably negative correlation between LFJ degeneration and LDH ($r = -0.306$, and $P < 0.001$), and there was a significantly positive correlation between the asymmetry of LFJs and LDH ($r = 0.543$, and $P < 0.001$). The asymmetry of LFJs could cause the LFJs on one side to bear greater pressure, aggravate the degeneration and damage of the

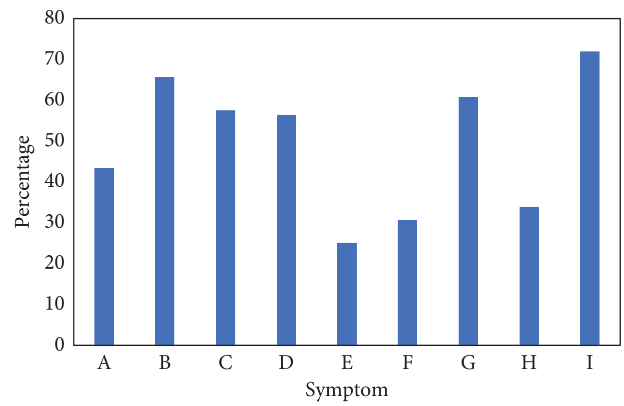

Figure 7: Symptoms of postoperative residual neurological symptoms. Note: A, B, C, D, E, F, G, H, and I in the horizontal coordinate refer to waist pain, hip pain, lower extremity radiating pain, lower extremity pain, waist movement limitation, lower extremity weakness, lower extremity paresthesia, intermittent claudication, and severe urinary excretion disorder, respectively.

lumbar disc, and result in the occurrence of LDH [14]. LDH patients with PRNSs accounted for 63.77%, and patients aged 61–70 years accounted for the highest proportion, which was consistent with the results of Wu et al. (2020) [15]. The proportion of patients with severe urinary excretion disorders accounted for more than 71.96%, which might be because most of patients were 61–70 years old and some older patients suffered from different degrees of prostate disease.

5. Conclusion

The deep ResNet method was introduced based on the deep learning algorithm to construct a deep learning denoising algorithm for MRI image. The constructed denoising algorithm was applied to the diagnosis of LDH patients. The correlations among LFJ angle, lumbar disc degeneration, and LFJ degeneration were analyzed. However, there were still some shortcomings in this study. The age span of the observation objects was large, and the different age groups were not classified and analyzed with the grading of intervertebral disc degeneration and the degree of degeneration of LFJs. It will supplement related data in the future research. In summary, the deep learning denoising algorithm can improve the quality of MRI image. The degeneration of the lumbar disc was extremely and positively correlated with the degeneration of LFJ; the asymmetry of LFJs was significantly and positively correlated with LFJ degeneration grade and LDH; and PRNSs were mainly concentrated in the people aged 61–70 years. This work provides a reference basis for the diagnosis, treatment, and prognosis of LDH [16–18].

Objective. This study aimed to optimize the CT images of anal fistula patients using a convolutional neural network (CNN) algorithm to investigate the anal function recovery. *Methods*. 57 patients with complex anal fistulas admitted to our hospital from January 2020 to February 2021 were selected as research subjects. Of them, CT images of 34 cases were processed using the deep learning neural network, defined as the experimental group, and the remaining unprocessed 23 cases were in the control group. Whether to process CT images depended on the patient's own wish. The imaging results were compared with the results observed during the surgery. *Results*. It was found that, in the experimental group, the images were clearer, with DSC = 0.89, precision = 0.98, and recall = 0.87, indicating that the processing effects were good; that the CT imaging results in the experimental group were more consistent with those observed during the surgery, and the difference was notable ($P < 0.05$). Furthermore, the experimental group had lower RP (mmHg), AMCP (mmHg) scores, and postoperative recurrence rate, with notable differences noted ($P < 0.05$). *Conclusion*. CT images processed by deep learning are clearer, leading to higher accuracy of preoperative diagnosis, which is suggested in clinics.

1. Introduction

Anal fistula, also known as "anal leakage," is a chronic inflammatory disease that starts with the anal gland and then invades the anal canal and other normal skin tissues around the anus [1], so it is also defined as inflammatory rectum disease (RD) [2]. The anal fistula is composed of the internal opening, the fistula, and the external opening [3]. Complex anal fistula refers to the one with 2 or more internal or external openings and fistulas [4], which will bring great inconvenience to the patient's life. Its incidence is reported to be approximately 0.01%, and the young are predominantly affected [5]. There are two main treatment methods for anal fistula: one is conservative treatment based on traditional Chinese medicine, and the other is surgical treatment [6]. Nevertheless, for complex anal fistula, it is reported that the recurrence rate is as high as 30% to 50% or even 10% patients cannot be radically cured after another operation [7]. There are many factors that affect surgical treatment. The main factor is whether the positioning of the internal mouth is accurate before surgery [8, 9], and the symptomatic degree of the surgical plan will affect the probability of recurrence and the degree of anal function retention [10, 11]. The complex anal fistula is mainly treated by the surgery, with traditional Chinese medicine used for adjuvant treatment. Therefore, imaging examination is of great significance for the treatment of the complex anal fistula [12, 13].

The commonly used imaging examination methods include CT, MRI, and B-ultrasound. However, in the examination of complex anal fistulas, CT has low resolution for soft tissues, such as pelvic tissue and anal sphincter, so the accuracy rate is only 24%~60% [14]. With the rapid development of the technology, deep learning artificial intelligence technology is widely used in the field of imaging and the neural network system has made great progress in processing medical images, which has become a research hotspot [15]. Deep learning has solved two major problems in the medical field: one is the imbalance between the number of imaging doctors and clinical imaging data; the other is the imbalance in the level of imaging doctors and the allocation of resources [16]. Deep convolutional network models can learn image features from a large number of samples, achieving end-to-end classification and detection [17].

In this study, deep learning was used to process CT images of patients with complex anal fistula, which was expected to provide guidance for the clinical diagnosis and treatment of the disease.

2. Methods

2.1. Research Subjects. 57 patients admitted to our hospital from January 2019 to February 2020 who had been diagnosed with complex anal fistula were selected as research subjects, including 35 males and 22 females, aged 18~70, with an average age of (39.2 ± 2.1) years. All patients had the CT examination, and the CT images of 34 cases were processed using the convolutional neural network, defined as the experimental group, while the remaining unprocessed 23 cases were in the control group. Whether to process CT images depended on the patient's own wish. Clinically, all patients suffered from repeated swelling and pain around the anus, accompanied by pus discharge. The duration of the disease was 3 to 12 months, and the average duration of the disease was 7 months. Physical examination revealed purulent secretions around the anus and external opening on the skin surface. This study has been approved by the ethics committee, and the patients and their families have signed the informed consent forms. Intrarectal ultrasound, MRI, and CT examinations were conducted [18].

Patients were selected as per these inclusion criteria: (1) patients diagnosed with complex anal fistulas based on digital rectal examination, (2) the disease course lasted more than 3 months, (3) the length of the fistula was more than 3 cm (including 3 cm), (4) patients who had not undergone anal fistula surgery before, and (5) those aged between 18 and 75.

Exclusion criteria were as follows: (1) patients with the complex anal fistula caused by trauma, foreign body, infection, etc.; (2) patients accompanied by severe heart, lung, liver, and kidney dysfunction; (3) patients with cervical cancer, vaginal rectal fistula, rectal tumor, etc.; (4) patients in pregnancy and lactation; (5) patients with mental disorders; (6) patients with a history of pelvic and rectal radiotherapy; (7) patients with hematopoietic, endocrine, and immune system diseases.

2.2. Research Methods

2.2.1. CT Examination. The anti-infection treatment was performed on all patients 1 to 2 weeks before the CT scan, to improve the symptoms of the patients to meet the examination standards. 2 hours before the scan, intestine cleaning was needed. The specific process is shown in Figure 1. All patients shared an instrument and the same skilled and experienced imaging doctor who was responsible for the CT examination and image reconstruction. After image reconstruction, 2 experienced radiologists and anorectal doctors read the films together and recorded the various conditions of the fistula. Surgical plans were formulated based on the results of the CT examination and other auxiliary examinations.

2.2.2. CT Image Optimization Model Based on Convolutional Neural Network Algorithm. In this research, the convolutional neural network was used to optimize CT images. The convolutional neural network consists of the convolutional layer, the pooling layer, the fully connected layer, and the deconvolutional layer [19].

First, it is needed to collect the feature map of the CT image, provided that the convolutional layer has q layers, and then the feature map of the CT image input at the q-1 layer can be expressed by equation (1). Then, the feature map of the CT image input at the $q-1$ layer can be expressed by the following equation:

$$W(q,p) = \sum_{b=1}^{B} Y^{(q,p,b)} \otimes Z^{(q-1,b)} + l^{(q,p)}, \tag{1}$$

where $Y^{(q,p,b)}$ is the convolutional kernel, b is the number of feature maps, and $Y^{(q,p,b)}$ is the bias.

The activation function is a sigmoid transfer function, with a domain of $(-\infty, +\infty)$ and a value domain of (0, 1). It is continuously derivable in the domain, and its reciprocal $f(x)$ is easy to calculate. The specific equation is as follows:

$$\begin{aligned} Y &= f(x) = \frac{1}{1+e^{-x}}, \\ f'(x) &= f(x)(1-f(x)). \end{aligned} \tag{2}$$

Assume T is the CT image and U represents all pixels in T. The segmentation part of T is represented by O. Then, the probability that U_n outputs O_i in the i-th path can be expressed as follows:

$$T(u_n = O_i) = \frac{1}{A}\exp(\alpha(O_i)), \tag{3}$$

where $\alpha(O_i)$ is the value of Oi and A is a regularization term. Then, the S_n predicted by U_n can be expressed as follows:

$$Sn = argmax[T(u_n = O_i)]. \tag{4}$$

The corresponding loss function is as follows:

$$L = -\frac{1}{c\ d}\sum_n \sum_j y_{nj} \ln[T(u_n = O_i)]. \tag{5}$$

To minimize the loss function, the stochastic gradient descent [20] is used to solve equation (5).

If the function to be fitted is expressed as follows:

$$g(\delta) = \sum_{j=0}^{l} \delta_j x_j, \tag{6}$$

then the square loss function is

$$B(\delta) = \frac{1}{2m}\sum_{i=1}^{1}\left(y^i - g_\delta\left(x^i\right)\right)^2. \tag{7}$$

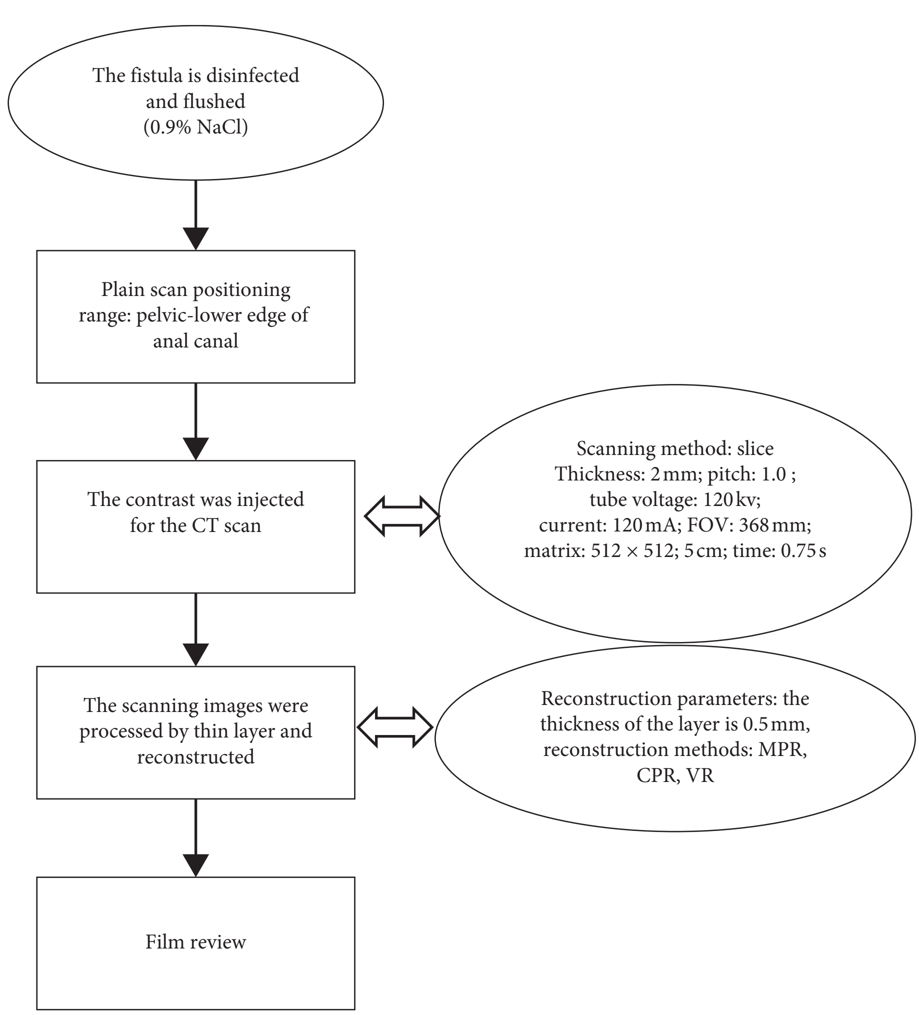

Figure 1: The specific process of CT examination.

The stochastic gradient descent method is used to update δ_j according to the sample:

$$\delta_j' = \delta_j + \left(y^i - g_\delta\left(x^i\right)\right)x^i. \tag{8}$$

The network parameters are obtained by solving equation (9), so as to obtain the network model as follows:

$$NLL(\delta, M) = -\sum_{i=0}^{|M|} logK\left(Y = y^{(i)}|x^{(i)}, \delta\right). \tag{9}$$

The processed pelvic CT image through the CNN algorithm is shown in Figure 2.

2.3. Evaluation of the Processed CT Image

2.3.1. Dice Similarity Coefficient. Dice similarity coefficient (DSC) is used to measure the similarity of two sets. The data pile can be regarded as a set, and the Dice distance is used to measure the similarity of strings.

The DSC is expressed as follows:

$$\mathrm{DSC} = \frac{2\times|G\cap J|}{|G| + |J|}\times 100\%, \tag{10}$$

where G is the algorithm segmentation result and J is the gold standard. If the DSC is closer to 1, the segmentation result is more accurate. If the DSC value is infinitely close to 0, it indicates that the segmentation result basically does not overlap with the gold standard and the segmentation fails.

2.3.2. Precision. Precision refers to the proportion of the number of correctly classified positive samples to the total number of classified positive samples. A closer precision value to 1 indicates a lower error rate. The precision is expressed as follows:

$$Pre = \frac{TP}{TP + FP}\times 100\%, \tag{11}$$

where TP stands for true positive, which is consistent with the gold standard; on the contrary, FP stands for false positive, which is inconsistent with the gold standard.

2.3.3. Recall Rate. Recall represents the ratio of the number of correctly classified positive samples to the total number of positive samples. A closer recall value to 1 indicates an error

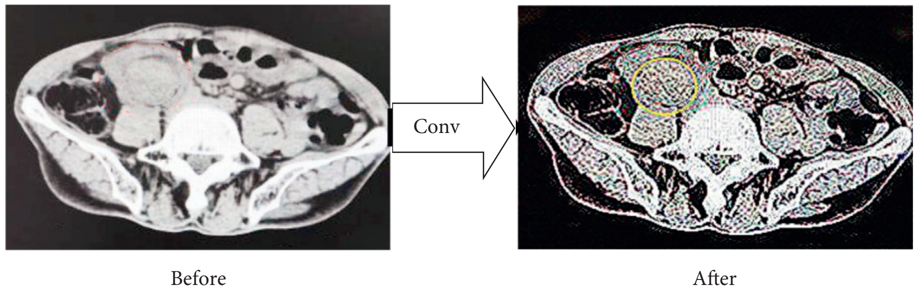

Figure 2: The processed pelvic CT image.

rate that the positive samples are incorrectly classified as negative samples. Recall is expressed as follows:

$$RE = \frac{TP}{TP + FN} \times 100\%, \quad (12)$$

where TP stands for true positive, FN stands for false negative, and the classification is also inconsistent with the gold standard.

Finally, it is concluded that DSC = 0.89, precision = 0.98, and recall = 0.87, which proves the feasibility of the model established in Section 2.3 and the effectiveness of image processing.

2.4. Observation Indicators

(1) The number and position of the internal and external openings of the fistula, whether the rectum, anal sphincter, and levator ani, are associated with the fistula, the area and length of the fistula, the diameter of the fistula, the fistula trend, whether there are complicated branches, and whether there is abscess formation.

(2) The recovery of anal function of the two groups of patients after surgical treatment was observed based on the CT images before and after the treatment. The Wexner anal incontinence score (Table 1) and anorectal manometry were used to evaluate its function. The parameters of anorectal manometry were anal rest pressure (ARP) and anal maximal construction pressure (AMCP).

2.5. Statistics. SPSS 22.0 was used to process data. Count data were expressed by percentage (%), the $Y2$ test was performed, and the rank sum test was performed for grade count data. The measurement data were expressed by the mean ± standard deviation, and the t-test was performed. $P < 0.05$ was the threshold for significance.

3. Results

3.1. Basic Information of Patients. As shown in Table 2, there was no notable difference in age, gender, and disease course of patients in the control group and the experimental group ($P > 0.05$), suggesting the feasibility of this study.

3.2. Examination Results and the Results after Surgical Treatment. After analyses, there was no difference in the external opening, while parameters such as the internal openings, the trend of the fistula, whether there was branch, whether the fistula was associated with the perianal muscle, and fistula diameter ≥ 2 mm were different from the results observed during the surgical treatment in both the experimental group and the control group, and notable differences were noted between the CT examination results and the postoperative results in both groups ($P < 0.05$), suggesting that the accuracy of CT examination was insufficient (Table 3). Figure 3 shows the CT images of the two groups of patients. Obviously, the optimized CT images were clearer.

3.3. Consistency between Examination Results and Postoperative Results. Table 4 shows the consistency between the examination results and the postoperative results. It was observed that in the experimental group, the consistency of the CT examination results and the postoperative results were higher than in the control group ($P < 0.05$) (Figure 4).

3.4. Postoperative Anal Function Recovery and Postoperative Recurrence Rate. Table 5 shows the statistics of Wexner anal incontinence score and anorectal manometry scores. It was found that the postoperative Wexner anal incontinence score of the experimental group was lower than that of the control group, showing notable differences. Additionally, the experimental group had lower RP (mmHg), AMCP (mmHg) scores, and the postoperative recurrence rate, and the difference was notable ($P < 0.05$). Figure 5 shows the CT images and the postoperative recovery of the two groups of patients, suggesting that both had good curative effects.

4. Discussion

Recently, CT imaging has been widely used in the examination of anal fistula diseases and it has certain advantages compared with other imaging techniques. Researchers have conducted a comparative study on the ordinary X-ray and CT imaging. The study found that the diagnosis of anal fistula with CT imaging is almost the same as the results of the surgery, with 96.7% of patients radically cured at one time, while the one-time cure rate of X-ray angiography is 70% [21]. The trend of fistulas is diverse and extremely irregular. Conventional two-dimensional CT images cannot

Table 1: Wexner anal incontinence score sheet.

Grade	Characteristics
Grade A	The anus function is normal, and the solid, liquid, and gas are well controlled
Grade B	The solid and liquid is well controlled but the gas is out of control
Grade C	Good control of solids, but there is a little liquid, infiltrating clothing
Grade D	Unable to control the liquid, it will often stain the clothes
Grade E	Both solids and liquids are out of control

Note. Grades A, B, and C indicate good anal function, while grades D and E indicate poor anal function.

fully display its distribution, and it is impossible to make accurate judgment. Hence, it is urgent to optimize the technology. There is abundant research combining CT imaging technology with three-dimensional reconstruction and applying them to the examination of anal fistulas. The results found that the accuracy, sensitivity, and specificity of the diagnosis of the internal opening of anal fistula have reached more than 90%, suggesting good effects [15]. The artificial intelligence in deep learning has made good progress in the field of medicine, especially in the field of medical imaging. Higaki et al. [22] applied fully convolutional neural networks and dense 3D conditional random field (CRF) technology to CT images for liver segmentation studies, to understand liver lesions. Tao et al. [23] applied FCN technology to the automatic analysis of cardiac magnetic resonance (CMR). In this study, the deep neural network was used to process the CT images of patients with anal fistulas. It was found that the deep learning-based CT imaging demonstrated good examination, diagnosis, and treatment results. Studies have also shown that higher accuracy of the preoperative diagnosis leads to better surgical effects, a greater possibility of recovery of anal function, and a lower probability of recurrence. Some experts have statistically studied 17 patients with complex anal fistula who underwent MSCT angiography diagnosis before the surgery. Some experts have statistically studied 17 patients with complex anal fistula who underwent multislice CT (MSCT) angiography diagnosis before the surgery. It was found that the consistency between the preoperative diagnosis and the surgical findings was close to 100%, and in the 1-year follow-up survey, there was no recurrence and the anal function recovered well [24]. In conclusion, deep learning-based CT imaging is worthy of promotion for the preoperative diagnosis of patients with anal fistula.

5. Conclusion

In this study, the deep learning neural network was used to process the CT images of patients with anal fistula and the preoperative imaging results were compared with the results observed during the surgery. It was found that in the experimental group, the CT imaging results were more consistent with those observed during the surgery ($P < 0.05$) and the images were clearer. Furthermore, the anal function recovery in the experimental was better.

To sum up, CT images processed by deep learning are clearer, leading to higher accuracy of preoperative diagnosis, better surgical effects, a higher possibility of recovery, and a lower recurrence rate, which is suggested in clinics.

The impulse noise in CT image was removed based on edge-preserving median filter algorithm. The sparse nonlocal regularization algorithm weighted coding was used to remove the impulse noise and Gaussian noise in the mixed noise, and the peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM) were calculated to evaluate the quality of the denoised CT image. It was found that in nine different proportions of Gaussian noise and salt-and-pepper noise in Shepp-Logan image and CT image processing, the PSNR and SSIM values of the proposed denoising algorithm based on edge-preserving median filter (EP median filter) and weighted encoding with sparse nonlocal regularization (WESNR) were significantly higher than those of using EP median filter and WESNR alone. It was shown that the weighted coding algorithm based on edge-preserving median filtering and sparse nonlocal regularization had potential application value in low-dose CT image denoising.

1. Introduction

CT images are susceptible to the interference of quantum noise and electronic noise of detectors and other noises during the acquisition process, which causes the quality of reconstructed images to decrease, which in turn affects the diagnosis of diseases by doctors [1]. Under normal circumstances, the scan dose is proportional to the sharpness of the CT image. However, CT radiation dose is accumulated throughout the life, and multiple CT scans will increase the risk of cancer [2, 3]. Low-dose CT scan can reduce the radiation dose of patients, reduce equipment damage, reduce costs, and is conducive to the general investigation and cure of certain diseases [4]. However, the reduction of low-dose CT tube current leads to rapid degradation of projection data. After traditional algorithms are reconstructed, there are still obvious noises and artifacts in the CT reconstructed image, which seriously affects the credibility of the doctor's diagnosis. Low-dose CT scan technology is unable to give full play to its accurate diagnostic efficacy in clinical practice [5]. There may be some isolated impulse noise points in some areas of low-dose CT images. After these isolated impulse noise points are filtered, the CT image data is distributed in the form of Gaussian noise [6]. Due to the complexity of the distribution of noise and artifacts in low-dose CT images, it is difficult to establish a suitable and accurate prior model of noise in the image domain reconstruction method. The image preprocessing is complex, and the calculation is large, which affects the real-time clinical application of CT. The postprocessing method is a method that is directly applied to the reconstructed low-dose CT image to improve its image quality [7]. The method is simple and easy to implement and has good compatibility with existing CT equipment.

According to the sparse representation theory, the differences in the learning dictionary caused by individual differences and differences in tissues and organs in CT images are very small [8]. Chen et al. [5] improved the reconstruction quality of low-dose CT images with a sparse image reconstruction method. Cui et al. [9] proposed a learning method based on morphological component analysis, which can automatically generate an adaptive discriminant dictionary and effectively suppress the artifacts of low-dose CT images under the framework of sparse representation. Jiang et al. [10] proposed a denoising algorithm based on weighted coding and sparse nonlocal regularization (WESNR), which simultaneously removes impulse noise and Gaussian noise through soft impulse pixel detection. The principal component analysis (PCA) dictionary was used to encode image blocks, and the coding residuals were weighted to suppress the heavy tail of the distribution. The image sparse prior and nonlocal self-similarity prior were merged into a single nonlocal sparse regularization term, which enhances the stability of weighted coding. However, when this method was applied to low-dose CT image denoising, details were lost, and edges were destroyed. A variety of edge preservation filters can solve the problem of incorrect removal of edges and lines in the image denoising process. The feature of edge-preserving filtering is that it can extract the spatial constraint factors of the edge information in the reference image to process the original image, thereby smoothing and edge-preserving it. Among them, edge-preserving median filter (EP median filter) has a good performance in terms of operation speed and edge protection [11]. However, the edge-preserving filtering algorithm is not effective for mixed noise and noise with low signal-to-noise ratio.

In this exploration, a denoising algorithm based on EP median filter and WESNR is proposed, which can remove the mixed noise of low-dose CT image and preserve the edge information of the image.

2. Algorithm Based on WESNR and EP Median Filter

2.1. Mixed Noise Model. For image x with size $m \times n$, $x_{i,j}$ is the gray value at (i, j), and y is set as the observed image of image x. For adding Gaussian noise, the pixels $y_{i,j}$ in y are defined as $y_{i,j} = x_{i,j} + v_{i,j}$, where $v_{i,j}$ is the independent and identically distributed noise; for the salt-and-pepper noise, $[d_{\min}, d_{\max}]$ represents the dynamic range of y pixels in the observation image, and the probability of salt-and-pepper noise is s, $0 \le s \le 1$. Then, the probability of $y_{i,j} = d_{\min}$ is $s/2$, and the probability of $y_{i,j} = d_{\max}$ is $s/2$. Therefore, the observation image mixed with Gaussian noise and salt-and-pepper noise can be described as follows:

$$y_{i,j} = \begin{cases} d_{\min}, & \text{the probability is } \dfrac{s}{2}, \\ d_{\max}, & \text{the probability is } \dfrac{s}{2}, \\ x_{i,j} + v_{i,j}, & \text{the probability is } 1 - s. \end{cases} \tag{1}$$

2.2. EP Median Filter Algorithm. The pixel at $(i, j)(3 \le i \le m-2, 3 \le j \le n-2)$ in image y has the neighborhood of 5×5 in Figure 1. If (i, j) is a point in a flat area, most of the gray values of 24 pixels in its neighborhood should be close to it. Even if there are few noise points, it can be set to less than one-fourth; that is, the number $t_{i,j}$ of absolute values of gray value difference greater than a certain threshold T is less than or equal to 6; if (i, j) is an edge point, about half of the gray values of the 24 pixels in its neighborhood should be close to it, and the other half should have a large difference with it; that is, the number $t_{i,j}$ of gray values whose absolute value is greater than a certain threshold T should be about 12; if (i, j) is a noise point, most of the gray values of the 24 pixels in its neighborhood should not be close to it. It can be set as no less than three-fourths; that is, the number $t_{i,j}$ of absolute values of gray value difference greater than a certain threshold value T is greater than or equal to 18.

The standard deviation of image y is taken as the threshold T; that is,

$$T = \sqrt{\frac{\sum_{i=1}^{m} \sum_{j=1}^{n} \left(y_{i,j} - \overline{y}\right)^2}{m \cdot n}}, \tag{2}$$

where $\overline{y}$ is the mean value of all gray values of image y; that is,

$$\overline{y} = \sqrt{\frac{\sum_{i=1}^{m} \sum_{j=1}^{n} \left(y_{i,j}\right)}{m \cdot n}}, \tag{3}$$

Based on the above assumption, $(i, j)(3 \le i \le m-2, 3 \le j \le n-2)$ can be divided into points in flat area, edge points, and noises.

① $t_{i,j} \le 6$, (i, j) is the point of the flat area.

② $6 < t_{i,j} < 18$, (i, j) is the edge point.

③ $t_{i,j} \ge 18$, (i, j) is the noise.

When (i, j) is noise, the gray value at (i, j) of the original image is replaced by the mean value of $y_{i,j}$, $y_{i,j-1}$, $y_{i-1,j}$, $y_{i+1,j}$, $y_{i,j+1}$, $y_{i-1,j-2}$, $y_{i+1,j-2}$, $y_{i-2,j-1}$, $y_{i+2,j-1}$, $y_{i-2,j+1}$, $y_{i+2,j+1}$, $y_{i-1,j+2}$, and $y_{i+1,j+2}$. The pixels participating in the assignment and their gray values are the shadow parts in Algorithm 1, and the mean value is $a_{i,j}$; that is,

$y_{i-2,j-2}$	$y_{i-2,j-1}$	$y_{i-2,j}$	$y_{i-2,j+1}$	$y_{i-2,j+2}$
$y_{i-1,j-2}$	$y_{i-1,j-1}$	$y_{i-1,j}$	$y_{i-1,j+1}$	$y_{i-1,j+2}$
$y_{i,j-2}$	$y_{i,j-1}$	$y_{i,j}$	$y_{i,j+1}$	$y_{i,j+2}$
$y_{i+1,j-2}$	$y_{i+1,j-1}$	$y_{i+1,j}$	$y_{i+1,j+1}$	$y_{i+1,j+2}$
$y_{i+2,j-2}$	$y_{i+2,j-1}$	$y_{i+2,j}$	$y_{i+2,j+1}$	$y_{i+2,j+2}$

$y_{i-2,j-2}$	$y_{i-2,j-1}$	$y_{i-2,j}$	$y_{i-2,j+1}$	$y_{i-2,j+2}$
$y_{i-1,j-2}$	$y_{i-1,j-1}$	$y_{i-1,j}$	$y_{i-1,j+1}$	$y_{i-1,j+2}$
$y_{i,j-2}$	$y_{i,j-1}$	$y_{i,j}$	$y_{i,j+1}$	$y_{i,j+2}$
$y_{i+1,j-2}$	$y_{i+1,j-1}$	$y_{i+1,j}$	$y_{i+1,j+1}$	$y_{i+1,j+2}$
$y_{i+2,j-2}$	$y_{i+2,j-1}$	$y_{i+2,j}$	$y_{i+2,j+1}$	$y_{i+2,j+2}$

Figure 1: Gray value of (i, j) and its neighborhood Algorithm 1 Pixels participating in $a'_{i,j}$ assignment and their gray values.

Input: noisy image y.
For $(i, j)\,(1 \le i \le m, 1 \le j \le n)$:
① When $i \le 2$, or $i \ge m-1$, or $j \le 2$, or $j \ge n-1$, make: $y'_{i,j} = y_{i,j}$.
② When $3 < i < m-2$, $3 < j < n-2$, and $t_{i,j} < 18$, make: $y'_{i,j} = y_{i,j}$.
③ When $3 < i < m-2$, $3 < j < n-2$, and $t_{i,j} \ge 18$, make: $y'_{i,j} = a_{i,j}$.
Image y' is obtained.
Initialization: $e^{(0)} = y' - x^{(0)}$, $W_{ii} = \exp(-ae_i^2)$, $\mu = 0$, $k = 1$, $y''^{(0)} = y'$.
When $k \le K$, the following cycle is performed:
(1) $\hat{\alpha}^{(k)} = (\Phi^T W \Phi + V^{(k)})^{-1} (\Phi^T W y' - \Phi^T W \Phi \mu) + \mu$ is calculated;
(2) $y''^{(k)} = \Phi \alpha^{(k)}$ is calculated and the nonlocal coding vector μ is updated;
(3) $e^{(k)} = y' - y''^{(k)}$ is calculated;
(4) $W_{ii} = \exp(-ae_i{}^2)$ is used to calculate weight W;
(5) $k \le k+1$
$y'' = \Phi \alpha^{(K)}$
Output: denoised image y''.

Algorithm 1: Flow chart of the algorithm proposed.

$$a_{i,j} = \frac{\left(y_{i,j} + y_{i,j-1} + y_{i-1,j} + y_{i+1,j} + y_{i,j+1} + y_{i-1,j-2} + y_{i+1,j-2} + y_{i-2,j-1} + y_{i+2,j-1} + y_{i-2,j+1} + y_{i+2,j+1} + y_{i-1,j+2} + y_{i+1,j+2}\right)}{13}. \tag{4}$$

The gray values of all the pixels in $(i, j)\,(i \le 2$, or $i \ge m-2$, or $j \le 2$, or $j \ge n-2)$ are not modified, the gray values of the points in the flat area and the edge points in $(i, j)\,(3 \le i \le m-2, 3 \le j \le n-2)$ are not modified, and the noise in $(i, j)\,(3 \le i \le m-2, 3 \le j \le n-2)$ is replaced by the value of $a_{i,j}$, so that the gray values of the pixels in the (i, j) position of the denoised image are $y'_{i,j}$. There is

$$y'_{i,j} = \begin{cases} y_{i,j}, & i \le 2, \text{ or } i \ge m-1, \text{ or } j \le 2 \text{ or } j \ge n-1, \\ y_{i,j}, & 3 < i < m-2,\ 3 < j < n-2 \text{ and } t_{i,j} < 18, \\ a_{i,j}, & 3 < i < m-2,\ 3 < j < n-2 \text{ and } t_{i,j} \ge 18. \end{cases} \tag{5}$$

If y' is the image with size $m \times n$ and the gray value at (i, j) is $y'_{i,j}$, y' is the denoised image of observation image y by EP median filter algorithm.

2.3. WESNR Algorithm. For image x, $x_i = R_i x \in R^{n'}$ represent the image block of size $\sqrt{n'} \times \sqrt{n'}$, where R_i is the matrix vector. Based on the sparse representation theory, the image block is sparse-coded through the overcomplete dictionary $\Phi = [\phi_1; \phi_2; \ldots; \phi_n] \in R^{n' \times m'}$, so that $x_i = \Phi\alpha_i$, where α_i is the sparse coding vector of nonzero matrix. The results are as follows:

$$x = \Phi\alpha, \quad (6)$$

where α is the set of all sparse coding vectors α_i.

The traditional sparse representation denoising algorithm can be expressed as

$$\widehat{\alpha} = \arg\min_{\alpha} \|y - \Phi\alpha\|_2^2 + \lambda R(\alpha), \quad (7)$$

where $R(\alpha)$ is a regularization term corresponding to α and λ is a regularization parameter.

To make the distribution of data fitting residuals more regular, data residuals are weighted [12]. A new loss function is used, and the following mixed noise removal model is obtained:

$$\widehat{\alpha} = \arg\min_{\alpha} \left\|W^{(1/2)}(y - \Phi\alpha)\right\|_2^2 + \lambda R(\alpha), \quad (8)$$

where W is a diagonal weight matrix with diagonal elements.

Image block x_i and its nonlocal prediction are encoded by a given dictionary ϕ_i; that is, $x_i = \phi_i\alpha_i$ and $\widehat{x}_i = \phi_i\mu_i$, and then the encoding coefficients x_i and μ_i are similar. Therefore, $\sum_i \|\alpha_i - \mu_i\|_{l_p}$ is used as the regularization term and applied to the above equation. There is

$$\widehat{\alpha} = \arg\min_{\alpha} \left\|W^{(1/2)}(y - \Phi\alpha)\right\|_2^2 + \lambda \sum_i \left\|\alpha_i - \mu_i\right\|_{l_p}, \quad (9)$$

where l_p ($p = 1$ or $p = 2$) is the l_p norm. l_1 is chosen as the norm. The model is as follows:

$$\widehat{\alpha} = \arg\min_{\alpha} \left\|W^{(1/2)}(y - \Phi\alpha)\right\|_2^2 + \lambda \sum_i \left\|\alpha_i - \mu_i\right\|_1, \quad (10)$$

where W is a diagonal weighted matrix whose element W_{ii} will be determined automatically. The coding residual e_i can be used to determine the weight W_{ii}, and the strength of W_{ii} is inversely proportional to that of e_i. $W_{ii} \in [0, 1]$ is set. W_{ii} is determined as

$$W_{ii} = \exp\left(-ae_i^2\right). \quad (11)$$

Iterative reweighting is used to solve the problem. V is set to a diagonal matrix and initialized as an identity matrix. In $k+1$ times of iteration, each element of V is updated as follows:

$$V_{ii}^{(k+1)} = \frac{\lambda}{\left(\left(\alpha_i^{(k)} - \mu_i\right)^2 + \varepsilon^2\right)^{(1/2)}}, \quad (12)$$

where ε is a scalar and α_i^k is the i-th element of the coding vector α in the k-th iteration. The sparse coding α is updated by the following function:

$$\widehat{\alpha}^{(k+1)} = \left(\Phi^T W \Phi + V^{(k+1)}\right)^{-1}\left(\Phi^T W y - \Phi^T W \Phi\mu\right) + \mu. \quad (13)$$

A set of local PCA dictionaries are learned from natural images, and the model can be solved by iteratively updating W and α. The update of W depends on the coding residual e, and the adaptive median filter is selected for y to get an initial image $x^{(0)}$. Then, e is initialized to

$$e^{(0)} = y - x^{(0)}. \quad (14)$$

The above optimization is repeated for the subproblem until the iteration stop condition is satisfied. When there is no significant change in the solution of continuous iteration or the corresponding objective function value, that is, when the difference norm between two continuous iterative solutions is less than the given positive norm, the algorithm stops, or when the running time exceeds the upper limit, the iterative process stops. In this exploration, $t = \|\Phi\alpha^{(k+1)} - \Phi\alpha^{(k)}\|_2 / \|\Phi\alpha^{(k)}\|_2 < \tau$ is regarded as the termination condition. The obtained image is the denoised image of the observed image y by the WESNR algorithm.

2.4. Denoising Algorithm Based on EP Median Filter and WESNR. The general denoising algorithm will inevitably lose the details of the image. In particular, for the image with more lines, it will cause the blurring of the visual effect. In order to avoid the situation that the lines and edges of objects in the image are eliminated by mistake in the process of denoising, EP median filter algorithm distinguishes lines or edges from noise in advance, which has good performance in image details and edge preservation. However, EP median filter algorithm is only suitable for the removal of impulse noise in the image, and it does not perform well in the removal of other noises or mixed noises. When low-dose CT images with complex noise are processed, the phenomenon of incomplete noise removal will appear.

WESNR algorithm encodes each noise contaminated block, which can remove the mixed noise of impulse noise and Gaussian noise at the same time. However, for low-dose CT image denoising, when WESNR algorithm is used directly, there will be loss of details and edge damage.

In order to achieve the purpose of removing mixed noise in the process of low-dose CT image denoising without destroying the details and edges, EP median filter algorithm is combined with WESNR algorithm. First, the points in the center region of the noisy image y are classified into points in flat areas, edge points, and noise points. The points in the flat area, the edge points, and the points outside the central area are not replaced. The noise in the central region is replaced by the mean value of the gray value of 13 pixels around it to get image y' after the first step. Then, y' is input into WESNR algorithm as noisy image, and local PCA dictionary is selected to iterate the target problem, subproblem, and parameters. When the preset termination condition is satisfied, image y'' is the result of the denoising algorithm based on EP median filter and WESNR. Algorithm 1 shows the flow of the algorithm.

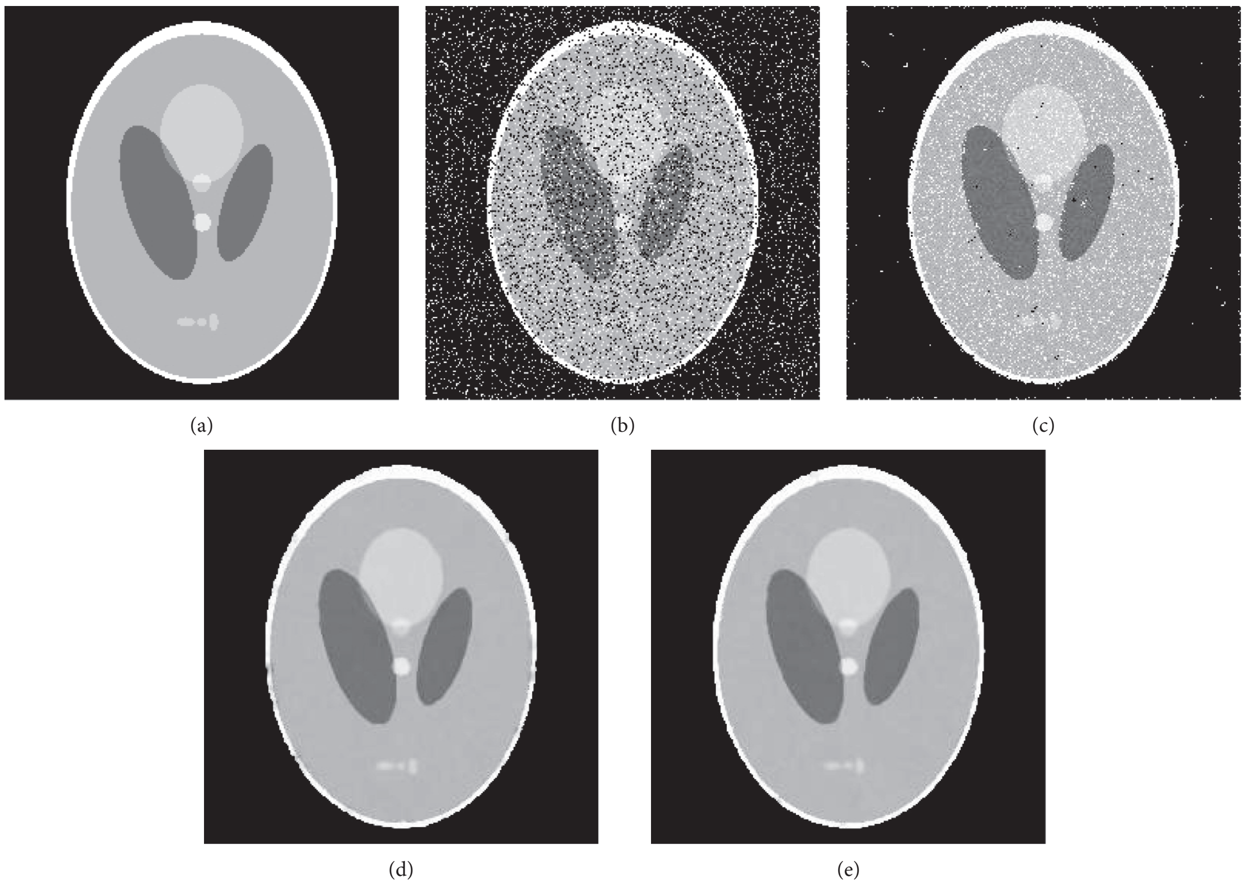

Figure 2: Denoising effect of different methods on Shepp-Logan image. (a) The original Shepp-Logan image. (b) The Shepp-Logan image after adding mixed noise $\sigma = 5$, $\rho = 20\%$. (c) Denoising effect of EP median filter algorithm. (d) Denoising effect of WESNR algorithm. (e) Denoising effect of the algorithm proposed in this exploration.

The steps of denoising algorithm based on EP median filter and WESNR are as follows.

3. Experiment

In addition to the visual effect comparison, the following numerical criteria are given: peak signal-to-noise ratio (PSNR) and structural similarity (SSIM). PSNR is the most commonly used objective index to evaluate image quality, which is an objective description of the degradation degree of an image. The higher the value of PSNR is, the closer it is to the original image. SSIM is mainly used to measure the similarity between the original image and the restored image. The higher the SSIM, the higher the image quality [13].

3.1. Shepp-Logan Head Model Experiment. The Shepp-Logan head model of $256 * 256$ is selected as the experimental object. This model was proposed by Shepp and Logan in 1974 [14]. The image is composed of 10 ellipses with different positions, sizes, directions, and densities. Different gray value of ellipse can simulate attenuation coefficient of different tissues, and Shepp-Logan head model can simulate human head sectional image well. In Shepp-Logan image, the mixed noise with different proportions of Gaussian noise and salt-and-pepper noise are added, respectively. EP median filter algorithm, WESNR algorithm, and the algorithm proposed in this exploration are used to denoise the image. The reconstruction effect and numerical comparison of various algorithms under nine kinds of noise are listed, as shown in Figure 2 and Table 1. The bold fonts in the table indicate the advantages of the algorithm.

The experimental results show that, for nine kinds of Shepp-Logan images with different proportions of Gaussian noise and salt-and-pepper noise, the reconstruction effect and numerical comparison of the proposed denoising algorithm based on EP median filter and WESNR are better than those of EP median filter algorithm and WESNR algorithm alone. Moreover, the proposed algorithm has the advantages of good edge preservation and good effect of removing mixed noise.

3.2. Low-Dose Brain CT Simulation Image. A brain CT image with $512 * 512$ pixels is selected as the experimental object. Different proportions of Gaussian noise and salt-and-pepper noise are added to simulate the image output effect of low-dose CT. The reconstruction effect and numerical comparison of various algorithms under nine kinds of noise are

Table 1: Comparison of PSNR and SSIM of denoised Shepp-Logan image.

σ	ρ (%)	EP median filter		WESNR		The algorithm proposed in this exploration

listed, as shown in Figure 3 and Table 2. The bold fonts in the table indicate the advantages of the algorithm.

The experimental results show that, for nine kinds of simulated low-dose brain CT images with different proportions of Gaussian noise and salt-and-pepper noise, the proposed denoising algorithm based on EP median filter and WESNR outperforms EP median filter algorithm and WESNR algorithm alone in terms of reconstruction effect and numerical comparison. Moreover, the proposed algorithm has the advantages of good details and edge preservation and good effect of removing mixed noise.

4. Conclusion

In this exploration, a new low-dose CT image denoising algorithm is proposed. According to the characteristics of low-dose CT image and noise, this algorithm is to combine EP median filter with WESNR. The experimental results show that the algorithm proposed in this exploration has a good ability to suppress the mixed noise in low-dose CT images, and the edge information is well preserved. However, this study still has some shortcomings. The proposed method is not compared with other related low-dose CT image noise reduction algorithms, and its effect on low-dose CT image noise reduction needs further study. In the future work, we will continue to compare it with related algorithms to clarify the value of this algorithm in low-dose CT images for noise reduction. In short, the algorithm of this research has a significant effect on denoising mixed noise in low-dose CT images.

Academic Editor: Enas Abdulhay

The vast majority of primary hepatocellular cancer is hepatocellular carcinomas (HCCs). Currently, HCC is one of the more common cancers in humans, and it has a high mortality and disability rate. Mitoxantrone (MTX) is an antitumor drug that can block type II topoisomerase. It has been reported that immunogenic cell death evoked by MTX can induce the discharge of damage associated with molecular patterns (DAMPs) and subsequently influence immune cell infiltration in the tumor microenvironment. High mobilities aggregation box 1 (HMGB1) is the prototypical extracellular DAMP. Many cellular processes have been reported to involve EPHB4 receptor tyrosine kinases, but the relation of DAMP and EPHB4 is uncertain. In this research, we assessed the impact of miR-130-3p by Edu incorporation test on cell proliferation, and we have proven its impact on HCC cell migration through Transwell and wound healing tests. Flow cytometry was applied to study its influence on apoptosis. Luciferase report test was integrated in detecting the miR-130-3p target gene. The influence of miR-130-3p on the manifestation of classical DAMPs was studied, such as HMGB1, ATP, and Calreticulin. A coculture experiment was carried out to further confirm its effects on immune cell infiltration. The result displayed that miR-130-3p overexpression considerably facilitates apoptosis and suppresses the migration or proliferation of HCC cells. EPHB4 was confirmed as the target gene of miR-130-3p. Overexpression of this target gene promotes emission of Calreticulin, ATP, and HMGB1 and subsequently promotes DCs maturation and proliferation of CD4+ T cells. In summary, our results demonstrated that miR-130-3p inhibits HCC cell proliferation and migration by targeting EPHB4 and promotes drug-induced immunogenic cell death.

1. Introduction

Primary liver cancer is predominantly hepatocellular carcinoma [1–3], which is currently the leading cause of cancer worldwide. Traditional therapeutic strategies for HCC include surgery, radiotherapy, and chemotherapy [4, 5]. However, the effect of this treatment is not satisfactory.

Mitoxantrone, also known as MTX, is an Adriamycin analogue that was developed in the 1980s to specifically inhibit type II topoisomerase based on its antitumor properties [6]. It is often employed for the management of various cancer types, including acute leukemia, breast cancer, myeloma, and lymphomas [7].

Most importantly, MTX can induce immunogenic cell death and promote immune cell infiltration. Immunogenic cell death is known to induce adaptive immunity against dead cell antigens, especially when they are released from cancer cells [8–10].

DAMPs are signals that can be released or exposed when dying, stressed, or injured cells are present. These molecules often play the role of danger signals or adjuvants, thus helping the immune system [11]. HMGB1 is a highly conserved nuclear protein that senses and coordinates the stress response of cells. It plays an especially important part not only as it was intracellularly a defender of DNA chaperones, apoptosis, and autophagy, but also outside the cell as the prototypic DAMP. Classical DAMPs include ATP and HMGB1, and the DAMPs advance the development of dendritic cells and further activate the immune system [12].

EPHB4, a part of the biggest group of receptor tyrosine kinases-protein tyrosine kinases is ordinarily communicated on neurons and endothelial cells, where it plays a vital part in the vascular era and organizes gathering.

EPHB4 is a constituent of the biggest family of receptor tyrosine kinases. It is often manifested as a protein tyrosine kinase on endothelial and neuronal cells and has a significant role in multiple cellular processes including cell growth, survival, and angiogenesis. Its receptor could be a tyrosine kinase, which is included in numerous cellular forms such as angiogenesis, cell development, and survival.

A few reports propose that EPHB4 is overexpressed in different cancers, counting breast, prostate, and colon [13, 14]. MicroRNAs are evolutionarily conserved small RNAs that do not code and which are useful in almost all bioprocesses by targeting mRNAs [15, 16]. A new study suggests that miRNA dysregulation is included in tumor movement [17]. Nevertheless, the potential part played by miR-130-3p in HCC cells still remains unknown. MiR-130 was first found in regulating respiratory syndrome virus replication and porcine reproduction. A previous study demonstrated that the downregulation of miR-130 contributed to the activation of lung fibroblasts by targeting IGF-1. A previous study demonstrated that miR-130 was served as a tumor promotive miRNA in most human cancer.

In this study, our research was aimed at exploring the embedded mechanism on molecules of miR-130-3p-EPHB4 in terms of transfer of MTX-induced immunogenicity in hepatocellular carcinoma cells, as well as providing any potential effective targets of therapy for PC treatment.

2. Materials and Methods

2.1. Patients and Tumor Samples. Our experimental samples were all provided by the Department of the Second Affiliated Hospital of Shandong First Medical University. We obtained approval letters from the University's ethics committee. Our conducted study was also aligned with Helsinki Declaration in terms of the guidelines and principles. We examined the samples (patients) by PCR and explored the pattern of expression in EPHB4 in liver cancer tissues and regular controls with the help of TANRIC software platform.

2.2. Cell Lines and Antibodies for Immunoblotting. The HepG2 cells employed in the experiment were acquired from ATCC Cell Bank (Manassas, VA, USA). Under suitable conditions of 5% CO_2 and 37°C, these cell cultures are cultured in Dulbecco's modified Eagle medium (DMEM). The first antibody (CST, Trask Lane Danvers, MA) was a rabbit polyclonal antibody at a dilution of 1 : 1000. The first antibodies are Cleaved Caspase-3, AIFM1, Pro-Caspase-3, and Bcl-2. The secondary antibody is the anti-rabbit polyclonal antibody GADPH (CST, Trask Lane Danvers, MA) at a dilution of 1 : 2000.

2.3. In Vitro Cell Multiplication Measure. 96-well plates with a density of 5,000 cells/well in the total medium were used to inoculate the cells. After 24 hours of cell culture, the cells became precipitated with 4% formaldehyde and recolored with 0.5% crystal violet. Finally, the crystal violet was dissolved in 10% acetic acid and cells were tested for transfection at $\lambda = 580$ nm using an ELx800 spectrophotometer after 24 and 48 h, respectively.

2.4. Plasmid Development and Transfection. We transfected inhibitors and mimics of miR-130-3p using Lipofectamine 3000, which was sourced from Life Technologies. The concentration of the solution was set at 20 nM according to the instructions from the manufacturer. Based on the expression of green fluorescent protein (GFP), we harvested and cultured cells after sorting lentivirus-infected cells with MoFlo XDP (Beckman, USA) for subsequent functional studies. In addition, to explore whether miR-130-3p could regulate EPHB4 manifestation by directly binding to the established 3′ UTR sequence, we established luciferase reporter plasmids that had binding sites or wild-type for EPHB4. To induce the overexpression of circ-EPHB4, we cloned the coding sequence into the pEX-3 vector (Shanghai Gene Pharma Co., Ltd.), respectively. We transfected the above vectors with Lipofectamine® 3000 (Invitrogen, Thermo Fisher Scientific, USA) based on the instructions of the manufacturer. Following a 48 hour transfection, the efficiency of each group of cells was identified using qRT-PCR.

2.5. Public Clinical Datasets. We obtained immune infiltration information associated with EPHB4 expression from the TIMER2.0 online dataset.

2.6. Wound Healing Test. After the cells have grown all over the cell vial, a fine needle is scraped in one direction over the cell monolayer. Wounded cell monolayers were washed with phosphate-buffered saline to remove cellular debris. We analyzed the wound healing and migration of cells in the remaining slits at different time points by using an inverted microscope.

2.7. Western Blotting Analysis. Based on the instructions of the manufacturer, we extracted the total protein from each group. The selected protein assay kit was then employed in determining the concentration of total cellular proteins. Samples of denatured protein were denatured at 100°C for 10 min and then analyzed on 10% SDS-PAGE gels and moved to PVDF membranes (Millipore, MA, USA) through electroblotting. The membrane was closed with 5% skim milk for 1 h at room temperature before incubating them overnight using primary antibody at 4°C. Then, a secondary antibody was used in incubating the membrane after its washing (Proteintech) for 2 hours at room temperature. Finally, the immunoblots were visualized and analyzed with an ECL chemiluminescence detection system (Thermo Scientific), and the relative integrated density values (IDVs) were determined using GAPDH as an internal control. The assessments were performed in three samples. The main antibodies included the following: IKKβ (1 : 1000; Cell Signaling Technology, USA); GAPDH (1 : 6000, Sigma, St. Louis, MO, USA).

2.8. ATP Detection. Intracellular and extracellular ATP concentrations were measured by utilizing the fluorescein-based ENLITEN ATP test (Promega, Madison, WI, USA).

2.9. Stream Cytometry Examination. The processing of cells was achieved through trypsin before being washed using PBS. Apoptosis tests were performed utilizing Annexin V-FITC Apoptosis Detection Kit (Beyotime). According to the instructions provided by the manufacturer, anaplastic cells were dual-stained with PI and Annexin V-FITC utilizing the Annexin V/FITC kit (Thermo Logical, Shanghai, China). Analysis was performed on a BDTM LSRII stream cytometer (BD Biosciences).

2.10. Luciferase Columnist Test. Firefly correspondent quality expression vectors driven by SV40 enhancers were acquired from Gene Copeia. 3′-UTR arrangements of wild-type or mutant EPHB4 were included downstream of the luciferase quality, where no oligonucleotides were included within the control vector. Renilla luciferase was utilized as a marker to screen transfection productivity. The luciferase movement was measured with a discuss photo-switch reagent.

2.11. Statistical Analysis. All collected data are expressed as mean ± SEM. A single evaluation of variance via ANOVA used to be carried out using SPSS 21.0 (SPSS Inc., Chicago, Illinois, USA) for assessment between groups. We also performed pairwise comparisons between groups using the Student-Newman-Coors (SNK) test. The statistical results with P values of below 0.05 were identified as significant, with significant differences.

3. Results

3.1. miR-130-3p Suppresses Restraint of Movement and Overgrowth of HCC Cells. The miR-130-3p expression in the clinical sample was confirmed by PCR. As shown in Figure 1(a), HCC tumor tissue expresses lower miR-130-3p than paracancer normal tissue, implying that miR-130-3p may serve as a tumor-suppression effect. To affirm the function of miR-130-3p of HCC cells, EdU incorporation assay was confirmed. As shown in Figure 1(b), after the transfection of miR-130-3p mimic, the percentage of EdU positive cells decreased, showing that miR-130-3p suppressed HCC proliferation. To explore the impacts of miR-130-3p on HCC cell migration, a Transwell assay was performed. As shown in Figure 1(c), after the transfection of miR-130-3p mimic, migrated cancer cells decreased significantly. The result showed that miR-130-3p suppresses the migration of HCC cells. To further confirm this conclusion, a wound healing assay was performed. As shown in Figure 1(d), the result confirmed our previous conclusion that miR-130-3p overexpression impaired HCC cells migration. We further confirmed the impacts of miR-130-3p on the overgrowth of cells. As shown in Figure 1(e), the CCK8 assay indicated that after transfection of mimic, the proliferation of tumor cells was suppressed. To confirm if miR-130-3p overexpression promotes MTX-induced apoptosis, flow cytometry was used. As shown in Figure 1(f), 12 treatments of MTX increased the apoptosis rate of HCC cells. After miR-130-3p overexpression, the apoptosis rate was further enhanced. Western blot was conducted to investigate the underlying mechanism. As shown in Figure 1(g), Bcl-2 was suppressed by MTX, Bax, and cleaved caspase-3 expression was enhanced by MTX treatment. After the transfection of miR-130-3p mimic, the expression of cleaved caspase3 was further enhanced. Those results indicated that the overexpression of miR-130-3p promotes MTX-induced apoptosis.

Our result affirmed that miR-130-3p suppresses the migration and proliferation of HCC cells, and the overexpression of miR-130-3p promotes MTX-induced apoptosis.

3.2. miR-130-3p Targeting EPHB4 and Promotes Apoptosis of HCC Cells. To confirm target gene of miR-130-3p, TargetScan dataset was used. Given the dataset, EPHB4 may act as the target protein of miR-130-3p. As shown in Figure 2(a), the *d* showed that EPHB4 expresses higher in tumor tissue relative to normal tissue, indicating that EPHB4 may function as a tumor-promote gene. As shown in Figure 1(c), the online dataset showed that the expression of EPHB4 is negatively associated with the expression of miR-130a-3p in HCC. After the overexpression of miR-130-3p, as shown in Figure 2(d), EPHB4 expression was limited, indicating that miR-130-3p expression may regulate EPHB4 expression. To further confirm that EPHB4 is a direct target gene for miR-130-3p, a luciferase report measure was undertaken. Wild-type EPHB4 3′-UTR and mutant EPHB4 3′-UTR with nucleotide substitution within the putative binding site were built, and after that, subcloned into luciferase columnist vectors. As displayed in Figure 2(b), the transfection of miR-130-3p significantly suppresses luciferase activity, and insignificant differences were observed in luciferase with mutating UTR.

We are curious about whether the effects of miR-130-3p are through the regulation of EPHB4. To answer this question, the development of the EPHB4 overexpression vector and the effects of EPHB4 overexpression were evaluated by western blot. As shown in Figure 2(e), the result indicated that EPHB4 was successfully overexpressed. The mechanism of miR-130-3p-induced effects was further studied. As shown in Figure 2(f), as previously mentioned, the integration of MTX enhances the manifestation of Bax and cleaved caspase-3, and the transfection of miR-130-3p mimic further promotes these effects. But after transfection of the EPHB4 overexpression vector, miR-130-3p induced apoptosis was partly inhibited. The effect was also affirmed

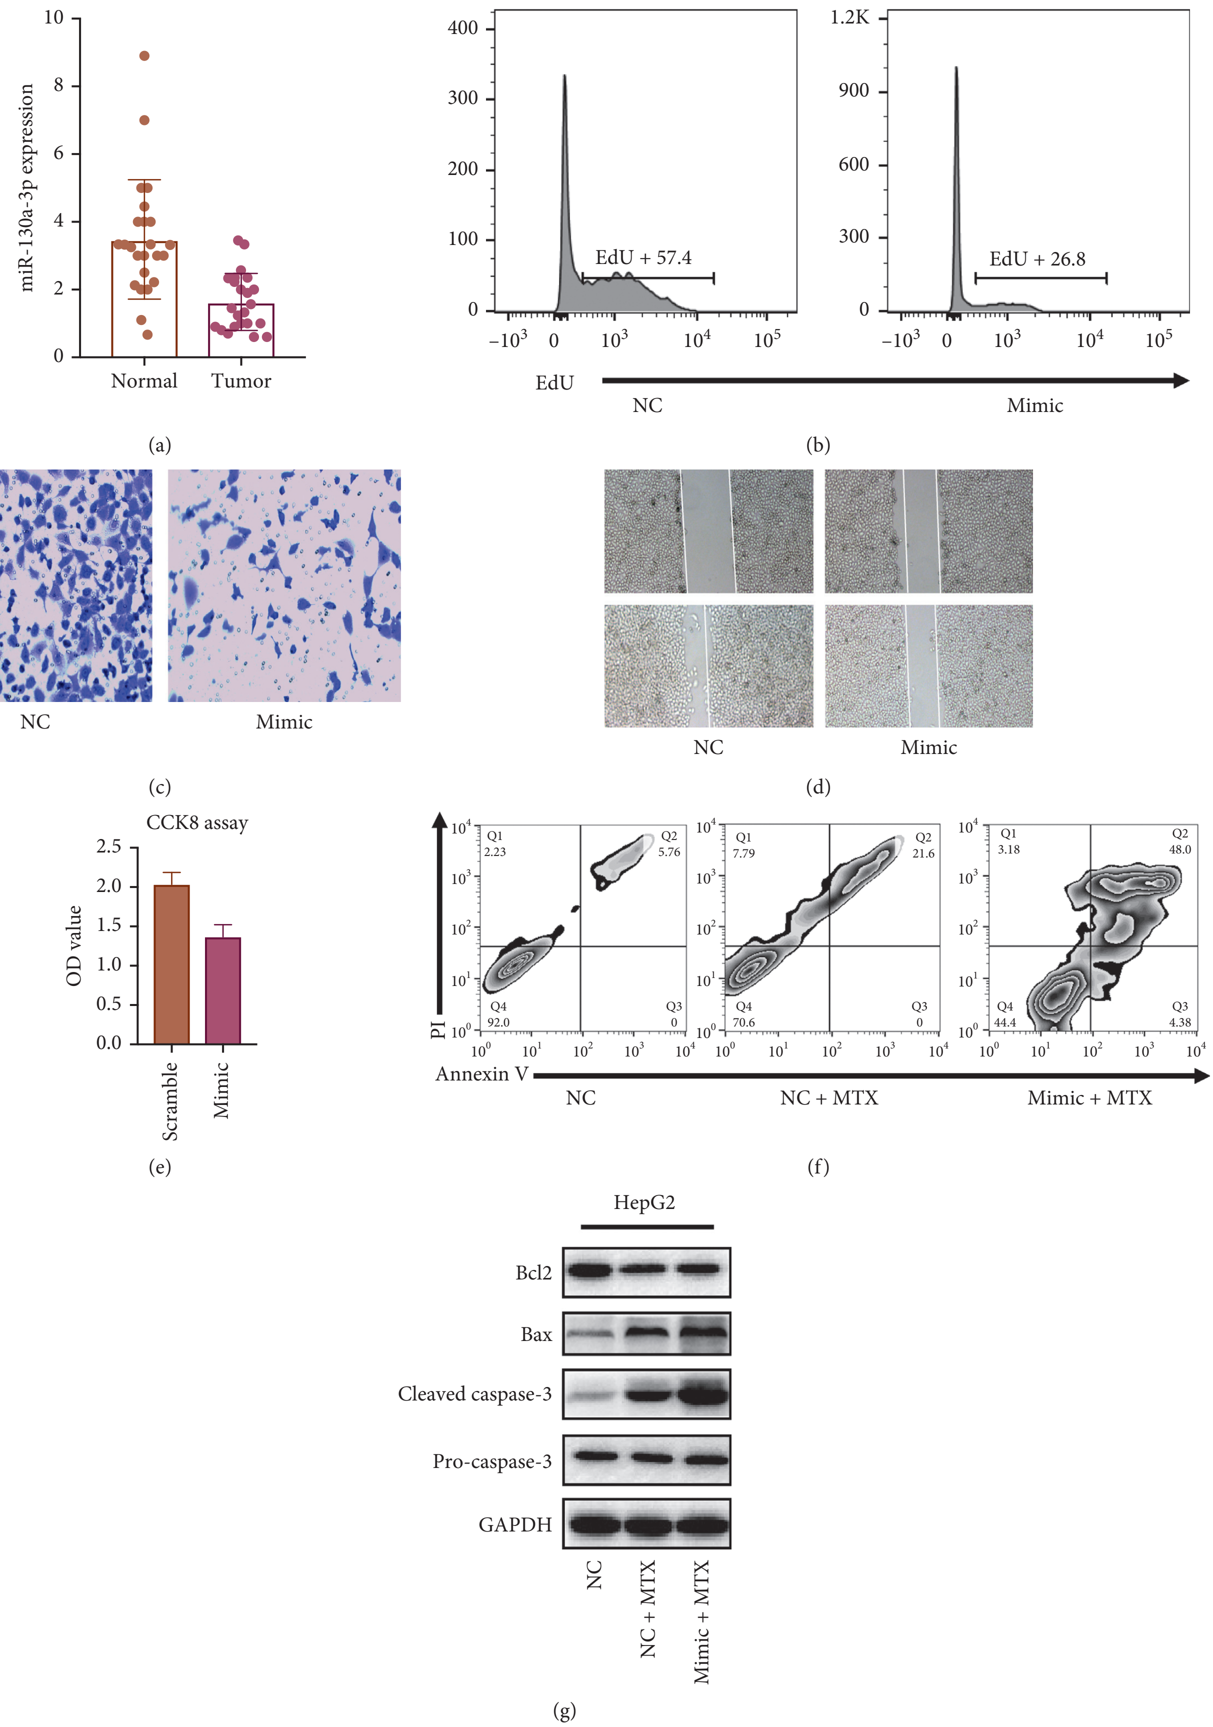

FIGURE 1: miR-130-3p suppresses migration and proliferation of HCC cells. (a) CR evaluation of miR-130a-3p expression in HCC tumor tissues and regular tissues adjoining to cancer. (b) EdU binding assay after transfection of HCC cells with NC and mimic. (c) Transwell assay after transfection of HCC cells with NC and mimic. by flow cytometry, as depicted in Figure 2(f); overexpression of EPHB4 reversed miR-130-3p induced apoptosis. These results indicated that miR-130-3p promotes the apoptosis of HCC cells through the downregulation of EPHB4.

Taken together, our result indicated that miR-130-3p targets EPHB4 and promotes the apoptosis of HCC cells.

3.3. miR-130-3p Overexpression Promotes Emission of DAMPs upon MTX Treatment. Based on the prediction of the TIMER dataset, EPHB4 expression is associated with the alternation of immune cell infiltration, including macrophages, as shown in Figure 3(a). We next study the effects of miR-130-3p on immune cells. Immunogenic cell death is a

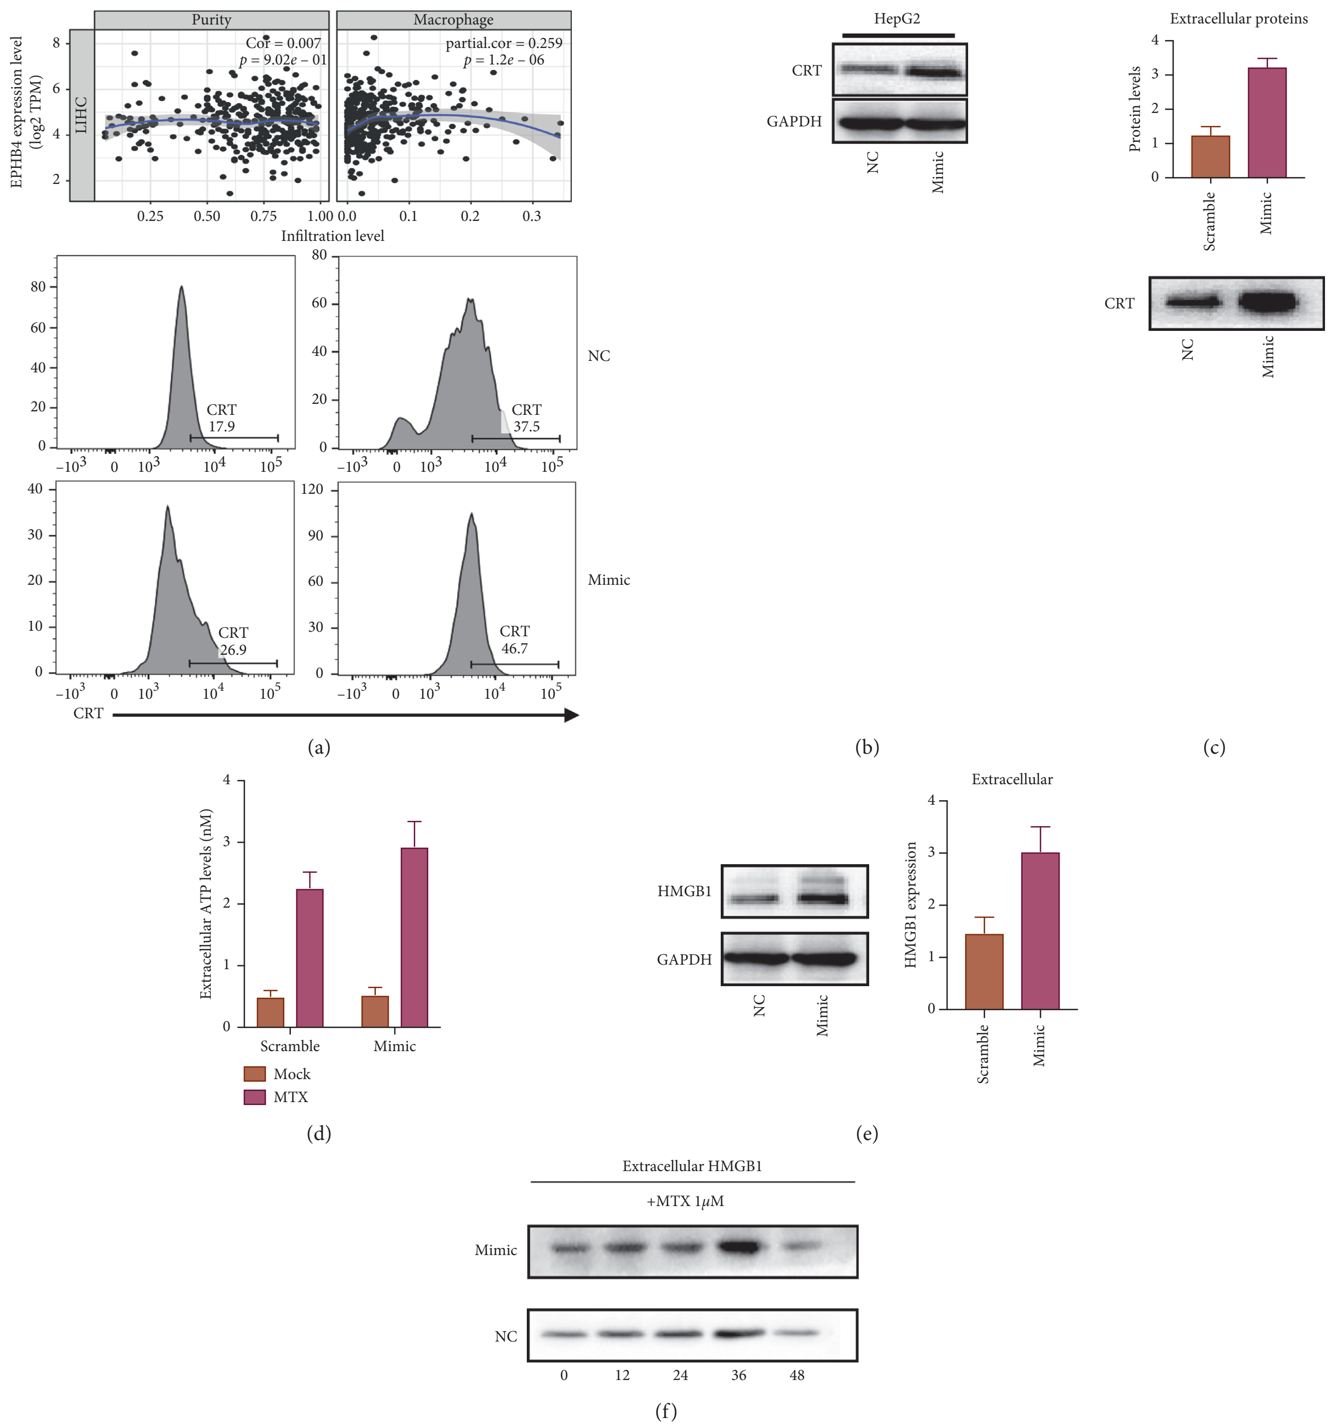

Figure 3: miR-130-3p overexpression promotes emission of DAMPs upon MTX treatment. The best segment shows the affiliation of safe cell invasion with EPHB4 expression. (b) Western smudge investigation of calreticulin after overexpression of miR-130-3p. (c) Immunodetection of CRT within the medium and extracellular calmodulin communicated by entirety cell lysis. (d) The energy of initiated ATP discharge. (e) Immunodetection of extracellular HMGB1 and HMGB1 in medium. (f) Time course of HMGB1 discharge after MTX treatment. Blunder bars imply ± s.d.

cell death that does stimulate an immune response by the emission of DAMPs. Classical DAMPs include ATP, high mobility group protein B, and calreticulin, and miR-130-3p may influence the emission of DAMPs and subsequently affect immune cells. As shown in Figure 3(a), the calreticulin expression in the cell surface was detected by flow cytometry. Our results showed that MTX treatment greatly increased the expression of calmodulin on the cell surface. After the overexpression of miR-130-3p, it was further increased. Interestingly, the basement expression of calreticulin was moreover expanded after the transfection of the miR-130-3p mirror. As shown in Figure 3(b), calreticulin expression in HCC cells was evaluated by western blot. After the transfection of mimic, the calreticulin expression in HCC cells was increased. We then tested the amount of calreticulin that was released by HCC cells after MTX treatment. As shown in Figure 3(c), secreted calreticulin that was induced by MTX treatment was increased as miR-130-3p was overexpressed in HCC cells.

As illustrated in Figure 3(d), the kinetics of ATP release in cell culture medium showed that cells overexpressing miR-130-3p had a stronger response to MTX's along with an increase in the amount of ATP secreted. HMGB1 expression was also evaluated. As shown in Figure 3(e), after miR-130-3p overexpression, the total expression of HMGB1 and its secretion were increased. As shown in Figure 3(f), the temporal profile of the HMGB1 release indicated that the HMGB1 release was slightly amplified by MTX treatment. miR-130-3p overexpression generally amplified extracellular HMGB1.

In conclusion, our results confirm that overexpression of miR-130-3p promotes the release of DAMPs when MTX is treated.

3.4. miR-130-3p Overexpression Promotes T-Cell Proliferation and DC Maturation. It has been reported that the DAMPs advance the further active immune system and the maturation of dendritic cells. In order to confirm whether miR-130-3p overexpression induced DAMPs influence activation of immune cells, HCC cells were transfected with miR-130-3p mimic. NC served as control and was treated with MTX for 12 h and cocultured with human youthful DCs for 24 hours.

As shown in Figure 4(a), after DC was cocultured with HCC cells and miR-130-3p overexpression, the maturation marker of DCs such as CD80 and CD83 was increased compared with the coculture and HCC cells without miR-130-3p overexpression.

Phagocytosis of dying tumor cells and mature DCs play an active immune role, so we stimulated the proliferation of T-cell receptors (CD3/CD28) using a medium with DCs cocultured with tumor cells under such conditions. As shown in Figure 4(b), the conditioned medium derived from coculture of DCs and HCC cells with miR-130-3p overexpression significantly promotes the proliferation of CD4+ T cells. The released IFN from CD4+ T cells was evaluated by ELISA. As shown in Figure 4(c), the conditioned medium derived from the coculture of DCs and HCC cells with miR-130-3p overexpression promotes the IFN production from CD4+ T cells.

Our result indicated that miR-130-3p overexpression promotes DC maturation and T-cell proliferation.

4. Discussion

Liver cancer is one of the common cancers in humans. It has the characteristics of a high fatality rate and high disability rate. Despite the continuous development of surgical technology, it is still a medical problem [18]. Chemotherapy is the traditional remedy approach for hepatocellular carcinoma, and MTX is one of the most secure and most famous anticancer marketers at therapeutically utilized doses and has anticancer outcomes on a range of hepatocellular carcinoma cellphone lines, inclusive of HepG2, MHCC97, Huh7, and Morris 5123 cells.

For the patient with advanced HCC, MTX did now not exhibit a favorable tumor response or normal survival. However, the combination of MTX with other chemotherapy strategies is under investigation [19, 20].

EphB4 has been detailed in that EphB4 includes a potential oncogenic part and is a critical controller of essential physiological and pathophysiological forms, such as tissue designing, amid advancement, angiogenesis, and tumor movement. It has been reported that EPHB4 overexpression is related to destitute forecast in patients with ovarian cancer. The overexpression of EPHB4 in colorectal cancer cells promotes its proliferation and migration, invasion, and angiogenesis [21, 22]. EphB4 expression was too essentially higher in delicate tissue sarcomas, and mRNA and protein expression were altogether expanded in synovial sarcomas, while the regulation mechanism of EPHB4 still remains unknown [23]. In this experiment, the Edu incorporation assay method was conducted to detect the effects of miR-130-3p on cell proliferation. At the same time, we also detected the effect of HCC cell migration by the Transwell method and other experiments. Flow cytometry was performed to study its influence on apoptosis. Luciferase report assay was carried out to confirm the target gene of miR-130-3p. The influence of miR-130-3p on the expression of classical DAMPs such as Calreticulin, ATP, and HMGB1 was studied. A coculture experiment was used to further confirm its effects on immune cells infiltration.

In this study, we confirmed that EPHB4 is a target gene of miR-130-3p. After miR-130-3p was overexpressed, the migration and proliferation of HCC cells were significantly inhibited. miR-130-3p overexpression also promotes MTX-induced cancer cell apoptosis. After EPHB4 was reexpressed, miR-130-3p induced proapoptosis effect was partly inhibited, indicating that miR-130-3p promotes MTX-induced apoptosis through the downregulation of EPHB4.

It has been reported that MTX treatment can induce Immunogenic Cell Death (ICD) melanoma, osteosarcoma, and mouse colon cancer cells, acting through an eIF2α phosphorylation-dependent mechanism [24, 25]. Immunogenic cell death is the effect. Dying cancer cell triggers robust immunological memory and immune response [26]. It has been reported that ICD is actuated by harm related atomic designs (DAMPs) and the outflow of numerous DAMPs. Cell surface presentation to CALR, extracellular discharge of ATP, and the atomic protein HMGB1 are considered to be all-inclusive donors to nearly all ICD sorts. Subsequently, these DAMPs are commonly utilized as markers for in vitro evaluation of ICD inducers.

In this basic study of liver cancer, we confirmed that after miR-130-3p increased, and the expression of calmodulin on the cell surface also increased significantly. After the

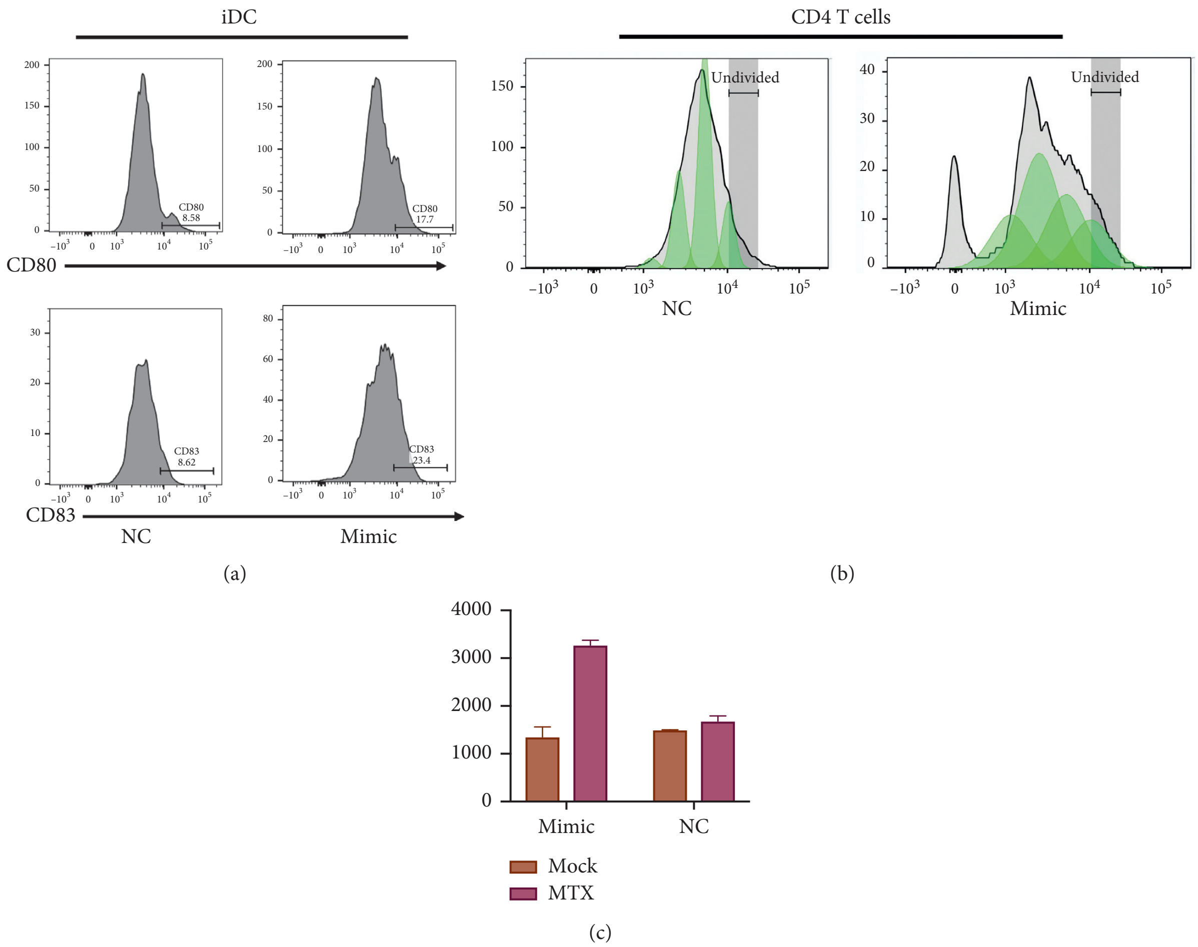

Figure 4: miR-130-3p overexpression promotes DC maturation and T-cell proliferation. (a) Investigation of expression of CD86 and CD80 by flow cytometry following DC coculture with cancer cells. (b) Analysis of CD4 T-cell proliferation by CFSE following treatment with CM acquired from tumour cells cultured with DC. (c) IFN expression in conditioned medium of CD4+ T cells by ELISA.

transfection of mimic, the total calreticulin expression in HCC cells was increased. We then tested the amount of calreticulin that is released by HCC cells after MTX treatment. Secreted calreticulin that was induced by MTX treatment was increased because miR-130-3p was overexpressed in HCC cells. After miR-130-3p overexpression, the total expression of HMGB1 and its secretion were all increased. The increased emission of DAMPs increased DCs maturation and subsequently promoted CD4+ T-cell proliferation. Increased IFN secretion was also observed when CD4+ T cells were treated by condition medium derived from the coculture of DCs and HCC cells with miR-130-3p overexpression.

In summary, our results confirm that miR-130-3p inhibits the proliferation and migration of HCC cells by targeting EPHB4 and induces immune death of hepatocellular carcinoma cells by promoting drug.

Nonetheless, there are several limitations to the present study. The study did not investigate the association between other MircroRNAs and primary hepatocellular cancer and any other potential interactions between genes. Therefore, future studies will focus on the interactions between microRNAs.

Data Availability

The data of this article are included in pictures and illustrations. The datasets used and analyzed during the current study are available from the corresponding author upon reasonable request.

Ethical Approval

The protocol of this experiment was considered and affirmed by the Ethics Committee of the Second Affiliated Hospital of Shandong First Medical University. The review and approval were based on the acquisition of written informed consent from each participant.

Consent

Written informed consent was obtained from each participant.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

Liangtian Shao drafted the paper and cooperated with Qing Ye to conduct the experiment. Liangtian Shao collected the data, with Moyang Jia to interpret the data. Liangtian Shao designed this work.

Academic Editor: Enas Abdulhay

The clinical characteristics and vascular computed tomography (CT) imaging characteristics of patients were explored so as to assist clinicians in diagnosing patients with atherosclerosis. 316 patients with atherosclerosis who were hospitalized for emergency treatment were treated with rapamycin (RAPA) in the hospital. A group of manually delineated left ventricular myocardia (LVM) on the patient's coronary computed tomography angiography (CCTA) were selected as the region of interest for imaging features extracted. The CCTA images of 80% of patients were randomly selected for training, and those of 20% of patients were used for verification. The correlation matrix method was used to remove redundant image omics features under different correlation thresholds. In the validation set, CCTA diagnostic parameters were about 40 times higher than the manually segmented data. The average dice similarity coefficient was 91.6%. The proposed method also produced a very small centroid distance (mean 1.058 mm, standard deviation 1.245 mm) and volume difference (mean 1.640), with a segmentation time of about 1.45 ± 0.51 s, compared to about 744.8 ± 117.49 s for physician manual segmentation. Therefore, the deep learning model effectively segmented the atherosclerotic lesion area, measured and assisted the diagnosis of future atherosclerosis clinical cases, improved medical efficiency, and accurately identified the patient's lesion area. It had great application potential in helping diagnosis and curative effect analysis of atherosclerosis.

1. Introduction

The coronary atherosclerotic heart disease (CAHD) is a common cardiovascular disease endangering human physical and mental health in China. It is the most common type of organ disease caused by atherosclerosis, and the acute myocardial infarction (AMI) is the most serious type of coronary heart disease [1, 2]. In recent years, with the continuous development of China's economy and the continuous rise of the people's happiness index, the incidence of atherosclerosis in China has also increased year by year, with 45–55 deaths per 100,000 people from atherosclerosis. Besides, people who get sick are getting younger and younger, making the occurrence and prognosis of AMI a central issue in current research [3].

Rapamycin (RAPA) is the first known mammalian target of rapamycin (mTOR) pathway inhibitor, and the molecular formula is $C_{51}H_{79}NO_{13}$. As a traditional macrolide antibiotic, RAPA was first isolated from the fungus *Streptomyces hygroscopicus* and used as an antifungal drug in the 1970s. It was certified by the U.S. Food and Drug Administration in 1999 to resist acute immune rejection of organ transplant patients [1]. In recent years, the antitumor activity and antiaging function of RAPA and its analogues have been gradually discovered; they also have certain effects on diabetes and cardiovascular diseases (CVD) and so forth and have been gradually applied in relevant clinical treatment [4].

The imaging examination plays an important role in assessing whether patients with coronary heart disease are accompanied by myocardial ischemia [5]. However, ultrasound examination has strong subjective dependence, which is related to the experience of the operator. Its current application value in diagnosing myocardial ischemia is limited. Coronary computed tomography angiography (CCTA) can clearly show the structure of the heart and the condition of the coronary arteries [6]. Clinicians can assess the degree of stenosis of the coronary arteries and the characteristics of stenosis plaques, and then they can stratify patients for risk. However, the radiology department or clinician cannot directly identify whether the patient is accompanied by myocardial ischemia on the resting CCTA. CCTA combined with stress perfusion examination can visually display whether the myocardium has perfusion defects and can identify myocardial ischemia. However, compared with resting state CCTA, stress perfusion examination will increase the radiation dose, and the use of stress drugs will increase the risk of patient examination, and some patients cannot tolerate it [7]. Therefore, if advanced image analysis methods, such as artificial intelligence (AI) technologies, can be used to identify myocardial ischemia on the CCTA in the conventional resting state, the various follow-up invasive examinations can be reduced, which has important clinical significance.

AI is a branch of the field of computer science, which aims to imitate human thinking process, learning ability, and knowledge storage as much as possible [8]. Some research limitations based on traditional methods have gradually become prominent with the advent of the "big data" era. With the development of computer hardware and software, the application research of AI in the medical field has become a hot topic [9]. At present, the research results of AI in the medical field continue to emerge, and it has applications in disease screening, diagnosis, choice of treatment methods, and patient prognosis judgments. At present, many studies showed that some diagnostic or predictive models based on AI methods were better than those based on traditional methods. For example, Esteva et al. [10, 11] established a machine learning-based model to predict the 5-year all-cause mortality of patients with suspected coronary heart disease. This model evaluated 25 clinical features and 44 CCTA-based features. This model based on machine learning had better predictive performance than the Framingham risk assessment model established by traditional statistical methods. However, the above-mentioned work required the clinician to manually outline the contour of the myocardium on the corresponding image, which was undoubtedly a heavy and laborious work [12]. At present, studies showed that some deep learning-based methods can quickly, efficiently, and automatically outline the structure of interest, which not only greatly reduced the workload of clinicians, but also avoided subjective differences between different doctors to a certain extent [13].

Therefore, the research aimed to study the use of imaging omics methods combined with machine learning methods to analyze LVM characteristics. As a reference, the fractional flow reserve (FFR) of invasive coronary artery was compared with the hemodynamically significant stenosis judged by CCTA and invasive coronary angiography (ICA) to evaluate the effectiveness of different methods in diagnosing atherosclerosis. In addition, through the deep learning method and with the contour of the left ventricle myocardium manually drawn by the clinician as a reference, a deep learning model that can accurately and automatically outline the left ventricle was constructed to reduce the workload of the clinician.

2. Methods

2.1. Research Object. 316 patients with CAHD who underwent emergency treatment for the first time within 12 hours of onset of hospitalization were selected in the research from May 2017 to March 2021. There were 221 males and 95 females, aged 60.66 ± 12.19 years. The CAHD patients met the 2014 American College of Cardiology/American Heart Association (ACC/AHA) AMI diagnostic criteria.

Inclusion criteria were as follows: a) patients who met the diagnostic criteria of AMI and received emergency treatment within twelve hours; b) patients with complete case data and complete follow-up on time.

Exclusion criteria were as follows: (a) patients with a history of myocardial infarction or coronary revascularization; (b) patients with previous arrhythmia such as persistent atrial fibrillation; (c) patients with hematological diseases, malignant tumors, autoimmune diseases, infections, or inflammatory diseases; (d) patients with severe heart, liver, and kidney dysfunction; (e) patients with recent major trauma and major surgery; (f) patients with incomplete clinical data.

A total of 316 patients with coronary atherosclerosis met the above inclusion criteria and exclusion criteria in the research. The research had been approved by the medical ethics committee of hospital, and the family members of the patients included in the research had signed an informed consent form.

2.2. Data Acquisition and Image Analysis

2.2.1. CCTA Data Collection. The CCTA data was collected for all patients using 64 rows, and CCTA images were collected by scanning machines from four different CT manufacturers (Siemens, Somatom Flash, Definition Flash, Somatom Definition FlashAS+, Force; GE Discovery CT 750 HD, Light Speed VCT; Toshiba, Aquilion One Vision; Philips BrillianceiCT 256). The patients took nitroglycerin sublingually to dilate the coronary arteries five minutes before the CCTA examination. For patients with a fast heart rate, they can consider taking oral p-blockers (25–75 mg) before the examination according to the doctor's recommendation. The CT scan range was determined according to location phase, which was from tracheal protrusion to lower edge of the heart. All patients received adaptive sequence acquisition triggered by prospective electrocardiogram.

2.2.2. Image Analysis. The CCTA images of all patients were locally anonymized to remove sensitive information, then transmitted to the core laboratory, and imported into the Siemens postprocessing workstation for further analysis. The CCTA image quality was assessed by two experienced imaging doctors (with 3 years and 18 years of CCTA-related work experience, respectively). A 4-point method was used for evaluation: 1 = undiagnosable; 2 = acceptable; 3 = good; 4 = excellent. When there was a difference, the two radiologists reached a consensus through consultation. The cases with an image quality score of one were excluded.

2.3. Experiment Environment

2.3.1. Construction of the Deep Learning Segmentation Model. Before the deep learning model was constructed, the contours of the left ventricular myocardium (LVM) of 100 patients were manually sketched as a reference for the deep learning method to learn from CCTA images. The deep learning model was composed of U-Net and deep attention, which mainly included two parts: training phase and segmentation phase. The flow chart of the research is shown in Figure 1. Before the training was started, the 3D-patches on the CCTA images and the corresponding hand-drawn myocardial contours were collected. A voxel window with a window size of $512 \times 512 \times 32$ was used to slide on the Z axis of the image to extract 3D-patches. The data augmentation methods were used, such as flipping, rotating, and scaling, to increase the heterogeneity of the training set. Figure 2 shows that the deep learning network was composed by an encoding path and a decoding path. The long-hop connection bypassed the feature extracted from the encoding path and was mapped to the decoding path.

2.3.2. Deep Learning Model. After training, first the 3D-patches of the CCTA image were input into the trained model to obtain the probability map that each pixel on the CCTA image was the myocardial tissue, so as to obtain the myocardial segmentation result of the new patient. Then, these probability maps were merged into the entire image, and the final segmentation result of the LVM contour was obtained by gathering the myocardial probability maps and merging them on average. The fivefold cross-validation was used to verify the segmentation performance of the deep learning model. That is, the data of the above-mentioned patients were randomly classified into five equal parts, and four groups were selected for training, and the remaining group was used for verification. The dice similarity coefficient (DSC), mean surface distance (MSD), residual mean square distance (RMSD), center mass distance (CMD), and volume of difference (VOD) were used to evaluate the difference between LVM contour drawn by the model and that drawn manually by the doctor. The image segmentation accuracy was evaluated visually, and the segmentation time was recorded.

2.3.3. Statistical Analysis. The data conforming to the normal distribution was represented by the mean ± standard deviation in the research, and the data not conforming to the normal distribution was represented by the median or percentage. The categorical variables were expressed in frequency and percentage. The commercial software (Med Calc; version 18.2.1) and SPSS 22.0 version were used for statistical analysis of data. The Kolmogorov–Smirnov test was used to determine whether the data fit a normal distribution. The t-test was used to compare the difference between LVM time by the automatic segmentation model and that drawn manually by the doctor. The bilateral $P < 0.05$ was considered statistically significant in the research.

2.4. Therapeutic Reagents and Methods

2.4.1. Preparation of Therapeutic Reagent RAPA Nanoparticles (RAPA NP). 10 mg of RAPA and 20 mg of indomethacin (IND) were accurately weighed and added into 1 mL dimethyl sulfoxide (DMSO), which were fully suspended and dissolved with ultrasound. Then, 1 mL of DMSO suspension solution of 10 mg/mL PEI was added. After full and uniform mixing, the mixed solution was transferred into a dialysis bag (molecular weight was 3500 Da). The suspension of RAPA nanoparticles (PEI/IND/RAP) was obtained after dialyzed with ultrapure water for 24 hours. The suspensions containing different masses of small molecule shuttle-based drugs ursodeoxycholic acid (UDCA) were prepared in the same way.

2.4.2. Treatment Method. 300 mg aspirin and 180 mg ticagrelor/300 mg clopidogrel were given before treatment. RAPA was injected intravenously during treatment. Coronary angiography was performed via femoral artery or radial artery using standard techniques to assess coronary artery disease. Other treatments included angiotensin converting enzyme inhibitors (ACED) receptor blockers, diuretics, and nitrates, which can be used depending on the patient's own specific conditions.

2.5. Observation Index. The 0, 12, and 24 weeks were selected as the evaluation time points. The intima-media thickness (IMT) and plaque thickness (course integral) were detected at each evaluation point, and the patients in the treatment group were followed up to test the carotid artery intima-media thickness after three months to monitor the degree of treatment.

2.6. Statistical Method. The appropriate statistical analysis method was selected according to the nature of clinical trial data (measurement, classification, and grade data). The chi-square test or exact probability test was used for classification data, normality test and homogeneity test of variance were used for measurement data first, t-test was used for comparison of sample means for those who met the requirements, and paired t-test was used for the comparison of sample mean before and after treatment. The paired signed rank sum test was used to compare the samples that did not meet the conditions. The Wilcoxon rank sum test (correction) for sample comparisons or the Kruskal–Wallis test for multigroup comparisons were used for grade data. The repeated measure analysis of variance was used for quantitative primary outcome indexes at multiple observation time points. A two-sided test was used, with the baseline comparison test level $P = 0.05$, the efficacy group comparison test level $P = 0.05$, and the pairwise comparison between groups $P = 0.01670$.

3. Results

3.1. Visual Assessment of the Results of the Deep Learning Model and the Doctor's Manual Segmentation. In the axial CCTA image, the comparison of the contour results of visual assessment method and the left ventricular muscle manually segmented by the doctor is shown in Figure 3. On the CCTA image, the contrast between the LVM and the surrounding tissues was not very different, while the segmentation effect of the proposed deep learning-based segmentation method was basically consistent with the contour of the myocardium manually segmented by the doctor.

3.2. Objective Parameters Evaluating the Results of the Deep Learning Model and Manual Segmentation by Doctors. In the data set of all patients, the LVM contour segmented by the proposed method was consistent with the myocardial contour drawn by doctors. The average DSC = 91.6%, and the standard deviation was 4.1%. The proposed method also produced very small CMD (average of 1.058 mm, standard deviation of 1.245 mm) and VOD (average of 1.640, standard deviation of 1.777), and the specific results are shown in Figure 4. The distance of HI was less than 10 mm, which meant that the pixels of the myocardium segmented by this method were very close to the pixels of the manually segmented myocardium, and LVM can be well positioned by this method.

In addition, the MSD and RMSD were both less than 2 mm, which indicated that the accuracy of the segmentation method was high. The differences of DSC and VOD between this method and manual segmentation of myocardium were evaluated at different levels of myocardium, and the results are shown in Figure 5.

3.3. The Time Required for Automatic Segmentation of Deep Learning Models and Manual Segmentation of LVM by Physicians. The time required for LVM by the automatic segmentation model and that of manual segmentation by the doctor were compared in the research. Through a randomized analysis of the time required for myocardial segmentation in 20 patients, it was found that LVM segmentation based on deep learning method required significantly short time. The deep learning method only needed an average of about 1.45 ± 0.51 seconds to complete segmentation, while the doctor's manual segmentation needed about 744.8 ± 117.49 seconds to complete segmentation ($P < 0.001$). The results showed that the efficiency and quality of automatic segmentation were much higher than those of manual segmentation by doctors.

3.4. Data Results after RAPA Treatment

3.4.1. IMT Results. A paired t-test was performed in the control group and the treatment group to test the data before and after treatment. Wilcoxon signed rank test was used for the measurement data that did not meet the conditions before and after treatment. The Shapiro-Wilk normality test is shown in Figure 6. After inspection, the difference of the left carotid artery before and after IMT treatment in the treatment group showed that $P = 0.043$, and the difference of the right carotid artery before and after IMT treatment showed that $P = 0.025$. There were statistical differences before and after treatment, which proved that the use of a deep learning-based imaging system had a certain therapeutic effect in improving the thickness of carotid artery intima-media in patients with carotid atherosclerotic plaque.

3.4.2. Carotid Artery Intima-Media Thickness Results. Before treatment, at the end of treatment, and during follow-up, the thickness of carotid medial artery was statistically analyzed and compared between groups, as shown in Figure 7. The IMT of left carotid artery was significantly different between the three groups at the end of treatment and 3 months of follow-up ($P = 0.025$). At the end of treatment, there was a difference between the control group and the treatment group ($P = 0.011$), while there was no statistical difference between the control group and the treatment group ($P = 0.618$). After three months of follow-up, there was a difference between the control group and the treatment group ($P = 0.019$), while there was no statistical difference between the control group and the treatment group ($P = 0.865$). It was concluded that, in terms of the improvement of carotid artery thickness, the group using deep learning-based CT imaging characteristics analysis was superior to the control group with respect to the left carotid artery.

4. Discussion

How to accurately monitor the occurrence of adverse cardiac events in patients with atherosclerosis is always the core of cardiovascular disease research. The process of diagnosis and treatment of cardiovascular patients generates a large amount of data, including the patient's symptoms, laboratory test results, medical imaging data, and drug prescriptions. In general, clinicians judge the prognosis of patients based on their own models, their own experience, and the current condition of the patient. However, most prediction models were based on regression models and only used limited variables, which may not meet the requirements of accurate prediction [14]. The routine diagnosis and treatment of patients with CVD generated a large amount of data. At the same time, the amount of cardiovascular imaging data was also increasing. Clinically, doctors were unlikely to be familiar with various electronic medical record information including genetic data and cardiovascular imaging data and made full use of this information in clinical practice. This may lead to misdiagnosis due to insufficient information utilization. A recent study pointed out that about 40,000–80,000 people die every year because of diagnostic errors [15]. The autopsy studies found that diagnosis based on imaging data had an error rate of up to 20%. However, a fivefold cross-validation method was used to verify the

segmentation effect of the LVM based on the proposed deep learning model. The subjective and objective methods were used to evaluate the contour difference between the proposed method of automatic segmentation of the LVM contour and the manual segmentation drawn by the doctor. It was verified that the proposed method could accurately segment the LVM tissue from CCTA images by analyzing six objective parameters, including DSC, HD, MSD, RMSD, C1VID, and VOD, and the proposed method significantly shortened the time needed to segment LVM from CCTA images. It reduced the time that would normally take about 12 minutes on average to about a second, which greatly reduced the workload of the doctor [16].

In the past, some scholars had achieved good results by establishing a deep learning-based method to automatically segment cardiac tissue of cardiac MRI images [17]. However, the contrast of myocardial tissue on CCTA images was not obvious compared with cardiac MR images, so there were few studies on the automatic segmentation of LVM on CCTA images. For the first time in the research, a neural learning network was used to integrate a deep-attention network to detect and segment LVM on CCTA images. After the model was trained, automatic LVM recognition and segmentation were performed on newly inputted CCTA images of patients. At present, some scholars have proposed to use different AI-based methods to segment the LVM on CCTA images. The imaging omics method used in this study can extract many quantitative and qualitative features from the region of interest on the image with high throughput. These imaging omics features can reflect the internal features of the organizational structure. Combined with machine learning methods, a lot of information was provided for the diagnosis of myocardial ischemia, which overcame the limitation of clinicians to analyze CCTA solely based on the naked eye. For example, Smyth et al. [18] used a multiscale convolutional neural network (CNN) to segment the LVM. The segmentation performance of CNN network on CCTA images of 20 patients was analyzed, and the average DSC was 0.910. Gertsen et al. [19] used a fully convolutional network to analyze the virtual single-energy CCTA data, and the best DSC value was 90.1 through CCTA image verification in 40 patients. The 3D fully convolutional neural network was used for CT brain tissue image segmentation, which can improve the accuracy of image analysis of atherosclerotic hard blood vessel function, and significantly improved the clearance rate of vascular plaque deposition and the recovery of carotid artery intima-media thickness after treatment. In this retrospective study, the feasibility of using imaging omics combined with machine learning method to analyze the characteristics of left ventricular myocardium on CCTA images to predict whether patients with coronary heart disease had myocardial ischemia was established and verified. Compared with the method that clinicians identify lesions based on CT images and determine myocardial ischemia based on the degree of coronary artery stenosis, the proposed method of image omics combined with machine learning had a better performance in predicting myocardial ischemia. The ability of the model to predict myocardial ischemia was relatively stable, and the accuracy was still high in the validation group. In addition, CCTA images generated by a number of hospitals and a variety of CT devices across the country were collected, and the model was randomly trained and verified, which reflected the universality and generalization of the model. To our knowledge, this was the first time that left ventricular myocardial features were analyzed using image omics to investigate whether patients with coronary heart disease had myocardial ischemia. Unlike the traditional clinical use of the degree of coronary artery stenosis as a standard to determine whether patients with CHD had myocardial ischemia, the characteristics of myocardium supplied by coronary arteries were analyzed to assess whether patients with CHD had myocardial ischemia, which also provided a new idea for future research.

5. Conclusion

The research showed that the CT angiography images were used during the treatment of atherosclerosis with rapamycin. Compared with the LVM contour manually drawn by the doctor on the CCTA image, the method proposed in the research had little difference with the LVM contour manually drawn by the doctor regardless of whether subjective or objective evaluation methods were used. The method significantly reduced the time required to segment LVM compared with traditional manual segmentation. However, there are still some shortcomings in this study. First, although patients with atherosclerosis were included in this study, CCTA images of only 100 patients were randomly and continuously selected for model training and validation. The results need to be further validated for the segmentation of myocardium on CCTA images collected by hospitals and CT scanning equipment in the future. Due to the different expertise and experience of imaging doctors, each doctor will have different contour labeling of the left ventricular myocardium, and such difference cannot be corrected by this deep learning algorithm. Second, there are only patients with suspected or confirmed coronary heart disease involved. The results of the myocardial segmentation model in patients with other diseases and at different stages of the disease need further study. Finally, the model is currently in the initial stage of establishment, and the extent to which it can reduce the workload of doctors in clinical practice is still unknown. Future research needs to be improved.

In this paper, the application of 3-dimensional (3D) functional magnetic resonance imaging (FMRI) in the diagnosis of the 5th lumbar (L5) nerve root compression and brain functional areas in patients with lumbar disc herniation (LDH) was analyzed. The traditional fast independent component analysis (Fast ICA) algorithm was optimized based on the modified whitening matrix to establish a new type of Modified-Fast ICA (M-Fast ICA) algorithm that was compared with the introduced traditional Fast ICA and ICA. M-Fast ICA was applied to the 3D FMRI diffusion tensor imaging (DTI) evaluation of 65 patients with L5 nerve root pain due to LDH (group A) and 50 healthy volunteers (group B). The values of fractional anisotropy (FA) and apparent diffusion coefficient (ADC) in the lumbar nerve roots (L3, L4, L5, and the 1st sacral vertebra (S1)) were recorded among subjects from the two groups. Besides, the score of edema degree in the lumbar nerve roots (L5 and S1) and activity of brain functional areas were also recorded among all subjects of the two groups. The results showed that the mean square error of M-Fast ICA was smaller than that of traditional Fast ICA and ICA, while its signal-to-noise ratio (SNR) was greater than that of Fast ICA and ICA ($P < 0.05$). The FA of L5 and S1 nerve roots in patients of group A was sharply lower than the values of group B, while the ADC of patients in group A was greater than that of the control group ($P < 0.05$). Besides, the score of edema in L5 and S1 nerve roots of patients in group A increased in contrast to group B ($P < 0.05$). The brain areas were activated after surgery including bilateral temporal lobe, left thalamus, splenium of corpus callosum, and right internal capsule. In conclusion, the 3D image denoising performance of M-Fast ICA optimized and constructed in this study was superior to that of the traditional Fast ICA and ICA. The FA of patients with L5 nerve root pain due to LDH decreased steeply, while the ADC increased dramatically. L5 nerve root pain caused by LDH resulted in changes in brain functional areas of the patients to inhibit the resting state default network activity, and the corresponding brain functional areas could be activated through treatment.

1. Introduction

LDH is a common and frequent-occurring disease in spine surgery, and low back pain and lumbocrural pain are the most common causes. Its clinical manifestations include low back pain, sciatica, and lower extremity radiation pain and weakness, and patients with severe symptoms suffer from incontinence of defecation and urination and abnormal sensation in the saddle area [1, 2]. Moreover, the main pathogenic factors of this disease include degenerative changes, annulus fibrosus disruption, or nerve root and cauda equina nerve stimulated and compressed by disc herniation in various parts of lumbar intervertebral disc (nucleus pulposus, annulus fibrosus, and cartilage plate) [3]. In addition, the incidence of L4-L5 and L5-S1 is the highest of patients with LDH, accounting for about 95% of the whole symptoms, while the incidence of multiple intervertebral disc herniation only occupies about 15%. LDH tends to emerge in young adults aged 20–40 years old (more males suffer from this disease than females), and it is often common in information technology (IT) practitioners, teachers, civil servants, drivers, and other long-term office workers [4, 5]. Excessive bending down should be avoided in life, and the back muscle should be exercised in order to improve lumbar muscle strength. Generally speaking, LDH cannot be completely cured, and most patients need mild conservative treatment to alleviate the disease. Therefore, it is very important to discuss the compression conditions of each lumbar vertebra in patients with LDH [6].

With the rapid development of imaging, MRI has been gradually applied in the diagnosis of LDH. By comparing with multiple indicators, it can clearly show the height, outline, annular tear, and high signal area of the intervertebral disc, with advantages of multidimensional imaging, high resolution, and high sensitivity. However, conventional MRI has a false positive rate and false negative rate in the diagnosis of elderly patients with lumbar nerve root pain, so it is necessary to adopt more excellent diagnostic tools [7,8]. Theoretically speaking, FMRI is designed to reflect the functional states of tissues and organs, and DTI, as an extension technique of conventional MRI, can visually display highly anisotropic nerve fibers [9]. On this basis, 3D MRI can process the cross-sectional images of any part or direction of one scan through electronic computers to form a 3D image, which can be further applied to diagnose the patient. ICA has been a new signal processing technology since the 1990s and mainly refers to the way to separate the source signals from the linear mixed signals of multiple source signals, which is featured with rapid convergence. However, it is easy to be interfered with by the SNR of data when processing FMRI data, which affects the results of analysis [10, 11]. Therefore, this study intended to optimize Fast ICA to explore its value in the MRI diagnosis of LDH.

To sum up, ICA is a traditional method for FMRI denoising, but it has some defects. On this basis, the traditional Fast ICA was optimized through the modified whitening matrix to construct the M-Fast ICA, so as to apply to the DTI evaluation of 65 patients with L5 nerve root pain due to LDH (group A) and 50 healthy volunteers (group B). Besides, the traditional Fast ICA and ICA were compared with M-Fast ICA. The FA and ADC of L3, L4, L5, and S1 lumbar nerve roots and brain activation areas after surgery in patients from the two groups were compared to comprehensively evaluate the application of FMRI in the diagnosis of L5 nerve root compression and brain functional areas in patients with LDH.

2. Materials and Methods

2.1. Sample Selection. In this study, 65 patients with L5 nerve root pain due to LDH were selected as group A, who were admitted to the hospital from January 1, 2019, to July 15, 2020; and 50 healthy volunteers were selected as group B, who underwent physical examination during the same period. During the surgery, the edema degree of the diseased nerve roots was evaluated based on the color of nerve roots (1 point for yellow-white, 2 points for pink, and 2 points for purplish red) and the thickness (0 points for no obvious thickening and 1 point for thickening). In addition, the higher the score, the greater the edema. This study had been approved by the Medical Ethics Committee of the hospital. Moreover, the subjects and their family members had known about this study and signed informed consent and failed examination consent.

The criteria for inclusion were defined to include the subjects who were older than 18 years old, were right-handed, had clear consciousness, could cooperate with the examination, were diagnosed with LDH accompanied by root pain, and suffered from LDH of the unilateral lower extremity.

The criteria for exclusion were defined to include the subjects who were pregnant, suffered from cardiovascular diseases, had taken relevant drugs, had mental diseases, and interrupted the examination.

2.2. Magnetic Resonance Imaging Scanning. MR Prisma 3.0 magnetic resonance machine produced by Siemens, Germany, was adopted to scan all subjects. Subjects were placed in the supine position with quiet breathing. Standard Siemens spinal coils were placed in the subject's scanning sequence and scanned based on the location of LDH. Conventional MRI scan parameters were shown as follows: the repeat time was 4,500 ms, echo time was 115 ms, field of view was 250×250 mm, matrix was 251×325, the thickness of a layer was 3.5 mm, and the number of layers was 10. The scan parameters of DTI included repeat time of 7,500 ms, echo time of 82 ms, view field of 310×150 mm, matrix of 108×308, thickness of 3.5 mm, layer number of 40, and scanning time of 20 minutes. The obtained image sent to the workstation was completed after the scanning, and the Neuro Space was employed to select the region of interest (near the lumbar intervertebral foramen) to measure the FA and ADC. What is more, the activation rate of each brain area was recorded (it indicated that the low-frequency fluctuation amplitude was active brain area with statistical significance when the voxel value in the magnetic resonance image was equaled to or more than 2.262).

2.3. Magnetic Resonance Imaging Denoising Algorithm Based on Fast Independent Component Analysis Algorithm. Fast ICA was a fixed point recursive algorithm proposed by Hyvarinen et al. from the University of Helsinki, Finland. With its fast convergence speed and good separation effect, Fast ICA was widely applied in signal processing and could well estimate the mutually statistically independent original signals mixed by unknown factors from the observed signals.

This algorithm firstly centralized the observed signals so that the mean vectors of the observed signals were all 0, and then, the centralized observed signals were whitened. It could be expressed as follows:

$$F = W_N (S - \overline{S}), \tag{1}$$

where S stood for an observed signal, $\overline{S}$ expressed the mean vector of an observed signal, W_N represented a whitening matrix, and f stood for a whitened signal. Then, the matrix N was initially separated so that $\|N\| = 1$. The matrix should be updated, and the iterative processing was for the separated matrix by Newton iteration method to obtain N_1 that was orthogonalized. Thus, the matrix N was shown as the following equation:

$$N = \left(N_1 N_1^T\right)^{-(1/2)} N_1, \tag{2}$$

where T represented the orthogonalization factor. Finally, the convergence of the separated matrix N was judged. If the convergence state was reached, the optimal estimation value of the source signal at this time could be calculated as follows:

$$\overrightarrow{U} = NS, \tag{3}$$

where U stood for a source signal. If the separation matrix N did not converge, the return iteration continued until it converged. Considering that the traditional Fast ICA did not exclude the interference of image noise to the signal during whitening, the whitening processing was optimized and the whitening matrix was formed by the combination of eigenvalues of the noise subspace and the eigenvalues of the signal subspace. Firstly, the autocorrelation matrix of the observed matrix was obtained through the following equation:

$$R_{ss} = G\left[SS^T\right], \tag{4}$$

where R_{ss}, T, and $G[\cdot]$ expressed the autocorrelation matrix, the orthogonalization factor, and the autocorrelation function, respectively. Then, the eigenvalues were discomposed, as shown in the following:

$$R_{ss} = V_s \exists V_S^H, \tag{5}$$

where $\exists$, V, and H represented the eigenvalue corresponding to signal subspace, the eigenvalue vector corresponding to signal subspace, and the signal factor of the matrix, respectively. Besides, $\exists = \mathrm{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$ and $V_S^H = [V_i / V_{n-i}]^H$. Thus, the whitening matrix was formed by the eigenvalues and eigenvalue vectors, which was expressed in the following equation:

$$N = \exists_i^{-(1/2)} V_i^H. \tag{6}$$

Then, the main eigenvalue was modified to obtain the following:

$$\exists_i = \exists_i - \overline{\Delta}^2 \sigma_i, \tag{7}$$

where $\exists_i$ stood for the main eigenvalue after modification, $\overline{\Delta}^2$ expressed the weight matrix corresponding to the average eigenvalue of noise, and σ_i represented the weight matrix corresponding to the eigenvalues of the signal subspace. What is more, $\overline{\Delta}^2 = \sum_{i+1}^{n} (\lambda_{i+1} / (n - i))$ and $\sigma_i = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_n)$. The new whitening matrix could be calculated as follows:

$$N = \exists_i^{-(1/2)} V. \tag{8}$$

The above was the M-Fast ICA optimized on the basis of the modified whitening matrix, which fully considered the impact of noise and helped to separate the signal with low signal noise.

2.4. Evaluation Indicators of Image Enhancement Performance. The traditional Fast ICA [12] and ICA [13] were introduced to compare with M-Fast ICA constructed in this study. The root mean square error (RMSE) and SNR were regarded as evaluation indicators.

RMSE referred to the square root of the variance between the original signal and the denoised signal, which can be expressed as follows:

$$\mathrm{RMSE} = \left\{ \frac{[f(n) - f(n)^*]^2}{n} \right\}^{1/2}, \tag{9}$$

where $f(n)$ and $f(n)^*$ stood for the original signal and the denoised signal, respectively.

SNR was a traditional method for detecting noise measurement in signals, which can be calculated as the following:

$$\mathrm{SNR} = 10 \log 10 \left(\frac{P_s}{P_z} \right), \tag{10}$$

where P_s and P represented the power of the original signal and the power of noise, respectively. In addition, $P_s = \{[\sum f^2(n)]/n\}$ and $P_z = \mathrm{RMSE}^2$.

2.5. Statistical Methods. SPSS19.0 version statistical software was adopted to analyze the data processing in the study, measurement data were expressed as mean ± standard deviation, and enumeration data was represented by percentage (%). The SNR and RMSE of Fast ICA, ICA, and M-Fast ICA were pairwise compared through the one-way variance analysis. The independent t-test was applied to compare the FA and ADC of the lumbar nerve roots (L3, L4, L5, and S1) with the edema degree score of the lumbar nerve roots (L5 and S1) of the subjects in the two groups. $P < 0.05$ meant the difference was statistically significant.

3. Results

3.1. Comparison of Basic Information of the Subjects in the Two Groups. Figure 1 shows the comparison of basic information of the subjects in the two groups. It indicates that the age of the subjects in group A was 50.17 ± 8.83 years old, the height was 160.21 ± 12.33 cm, the weight was 58.28 ± 7.82 kg, the male proportion was 56.08%, and the female proportion was 43.92%. Besides, the age, height, weight, male

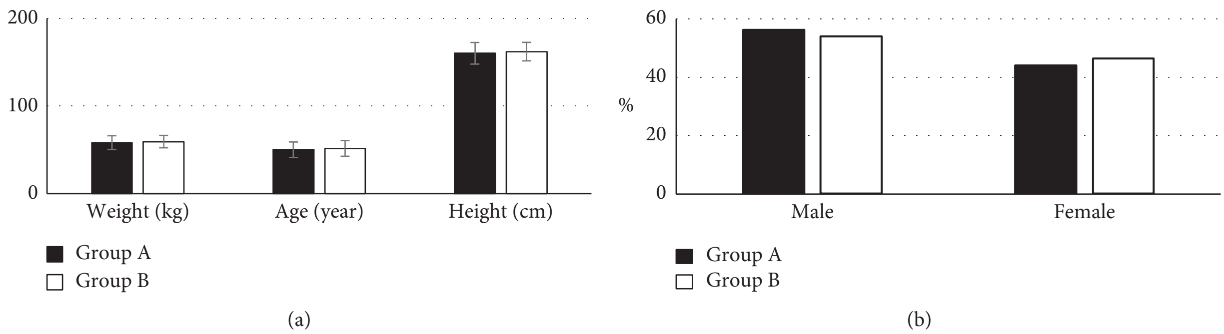

Figure 1: Comparison of basic information of the subjects in both groups. (a) Comparison of the age, height, and weight of the subjects in groups A and B; (b) comparison of the male and female proportion of the subjects in the two groups.

proportion, and female proportion of the subjects in group B were 51.62 ± 8.91 years old, 162.13 ± 10.56 cm, 59.41 ± 7.07 kg, 53.81%, and 46.19%, respectively. There were no great differences in the age, height, weight, male proportion, and female proportion of the subjects from groups A and B ($P > 0.05$).

3.2. Comparison of the Root Mean Square Error and Signal-to-Noise Ratio of the Three Algorithms. Figure 2 indicates the comparison of RMSE and SNR of the three algorithms. It reveals that the values of RMSE in the ICA, Fast ICA, and M-Fast ICA were 6.38 ± 0.52, 6.25 ± 0.72, and 4.91 ± 0.38, respectively; and the values of SNR in the ICA, Fast ICA, and M-Fast ICA were 71.42 ± 5.49 dB, 72.37 ± 5.18 dB, and 86.36 ± 6.77 dB, respectively. Therefore, the RMSE of M-Fast ICA was obviously higher than the values of ICA and Fast ICA, showing a statistical substantial difference ($P < 0.05$). However, the SNR of M-Fast ICA increased dramatically in contrast to ICA and Fast ICA, with a statistical great difference ($P < 0.05$).

Figure 3 expresses the MRI image reconstruction results of the lumbar spine by the three algorithms. Figure 3 shows the original ultrasound image of one patient, with a blurred lumbar spine and a lot of noise. The image resolution of M-Fast ICA was higher markedly than that of ICA and Fast ICA after denoising, and the noise reduction was obvious, so M-Fast ICA could fully meet the requirements of clinical imaging diagnosis.

3.3. Comparison of the Fractional Anisotropy of the 3rd, 4th, and 5th Lumbar and the 1st Sacral Vertebra Nerve Roots in the Subjects from Both Groups. Figure 4 shows the comparison of FA of L3 and L4 lumbar nerve roots among the subjects in the two groups. It was known that the FA of L3 and L4 lumbar nerve roots were 314.24 ± 17.71 and 308.41 ± 17.55 in patients from group A, respectively. Besides, the FA of L3 lumbar nerve root was 319.41 ± 30.31 and the FA of L4 lumbar nerve root was 315.76 ± 27.45 in the subjects from group B. The values of FA in L3 and L4 lumbar nerve roots of patients from group A were not statistically considerable in contrast to group B ($P > 0.05$).

Figure 5 indicates the comparison of FA in the L5 and S1 lumbar nerve roots among the subjects from the two groups. The FA of L5 lumbar nerve root was 250.58 ± 16.62 and its S1 lumbar nerve root was 239.64 ± 18.85 in patients of group A; and the values of FA in L5 and S1 lumbar nerve roots were 331.71 ± 18.93 and 316.46 ± 28.82, respectively. Among them, the values of FA in the L5 and S1 lumbar nerve roots were lower sharply in patients of group A than those of group B, and the difference was statistically remarkable ($P < 0.05$).

3.4. Comparison of the Apparent Diffusion Coefficient of the 3rd, 4th, and 5th Lumbar and the 1st Sacral Vertebra Nerve Roots in the Subjects from Both Groups. In Figure 6, there are comparisons of the ADC of L3, L4, L5, and S1 lumbar nerve roots among the subjects in the two groups. It was observed that the values of ADC in the L3, L4, L5, and S1 lumbar nerve roots were $0.64 \pm 0.025 \times 10^3$ s/mm^2, $0.52 \pm 0.016 \times 10^3$ s/mm^2, $0.86 \pm 0.024 \times 10^3$ s/mm^2, and $0.79 \pm 0.033 \times 10^3$ s/mm^2 in the patients from group A, respectively. What is more, the values of ADC in the S1, L3, L4, and L5 lumbar nerve roots were $0.58 \pm 0.011 \times 10^3$ s/mm^2, $0.71 \pm 0.018 \times 10^3$ s/mm^2, $0.54 \pm 0.021 \times 10^3$ s/mm^2, and $0.51 \pm 0.016 \times 10^3$ s/mm^2 in the subjects from group B, respectively. The ADC of the L3 and L4 lumbar nerve roots in the subjects from group A was not statistically substantial compared with that of group B ($P > 0.05$). However, ADC of the L5 and S1 lumbar nerve roots in the subjects from group A increased enormously in contrast to group B, and there was a statistically obvious difference ($P < 0.05$).

3.5. The Edema Scoring of the 3rd, 4th, and 5th Lumbar and the 1st Sacral Vertebra Nerve Roots in the Subjects from the Two Groups. There was a comparison of edema scoring of the L5 and S1 lumbar nerve roots among the subjects in the two groups, as shown in Figure 7. It revealed that the edema scores of the L5 and S1 lumbar nerve roots were 5.62 ± 1.43 and 4.07 ± 1.13 in the patients of group A, respectively. The edema scores of the L5 and S1 lumbar nerve roots were 1.62 ± 0.33 and 1.25 ± 0.24 in the patients of group B, respectively. Among them, the edema scores of the L5 and S1 lumbar nerve roots were higher hugely in the subjects of group A than those of group B, indicating a statistically great difference ($P < 0.05$).

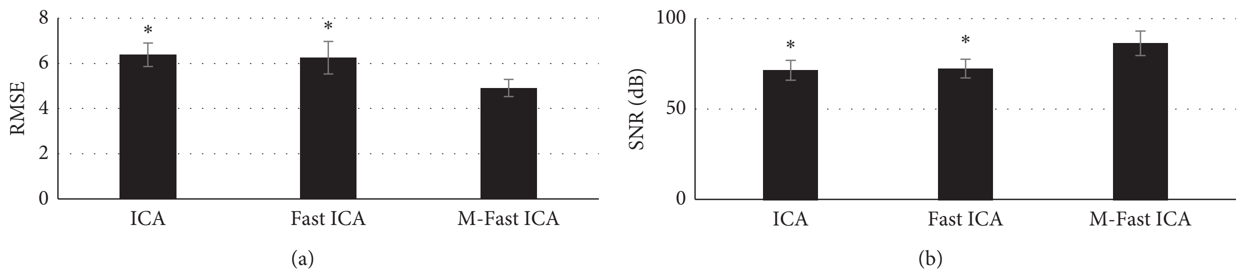

Figure 2: (a, b) Comparison of RMSE and SNR of the three algorithms. *There was a statistical difference in contrast to M-Fast ICA ($P < 0.05$).

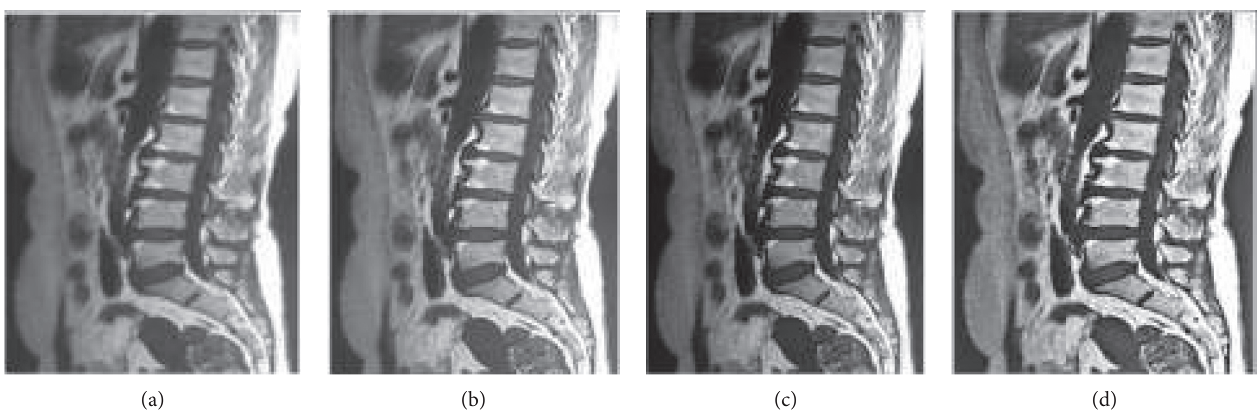

Figure 3: MRI image reconstruction results of lumbar nerves by the three algorithms. (a) Original MRI image of a male patient; (b) image denoised by ICA; (c) image denoised by Fast ICA; and (d) image denoised by M-Fast ICA.

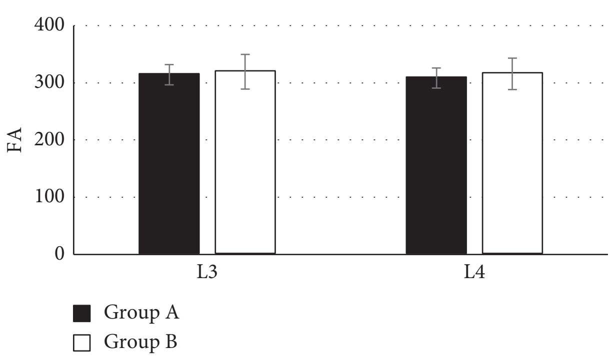

Figure 4: Comparison of FA of L3 and L4 lumbar nerve roots among the subjects in both groups.

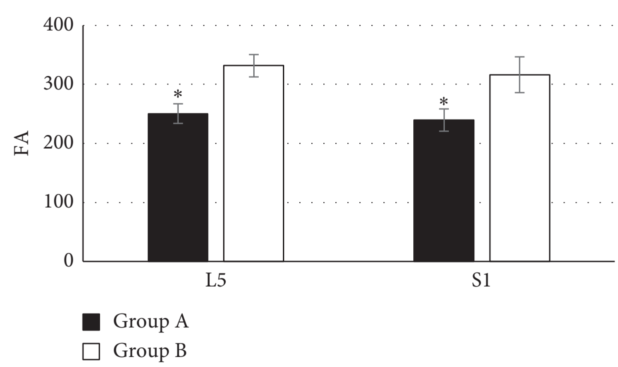

Figure 5: Comparison of FA of L5 and S1 lumbar nerve roots among the subjects in both groups. *There was a statistical difference in contrast to group B ($P < 0.05$).

3.6. Brain Areas with Higher Activation Rates in the Patients of Group A after Surgery. Figure 8 shows the brain regions after surgery with a higher rate of activation in all patients of group A. It indicates that the activation rates of the left temporal lobe, right temporal lobe, left thalamus, splenium of corpus callosum, and right internal capsule were 100%, 100%, 100%, 68.31%, and 87.43%, respectively.

4. Discussion

LDH is a very common medical lesion, with about 80% of people experiencing low back pain in their lifetime. Herniated lumbar disc can lead to lumbar nerve root compression, so as to let patients suffer from sciatica, and the area with the highest incidence is the gap between the L4 and L5 lumbar roots [14]. The 3D FMRI is a typical method for the clinical diagnosis of LDH. Due to various objective factors that cause the original FMRI image quality, the traditional Fast ICA was optimized based on the modified whitening matrix to establish the M-Fast ICA, and the traditional Fast ICA and ICA were introduced for simulation denoising comparison with M-Fast ICA. The results showed that the RMSE of M-Fast ICA was greater markedly than that of ICA and Fast ICA, indicating that the difference was statistically obvious ($P < 0.05$), while the SNR of M-Fast ICA

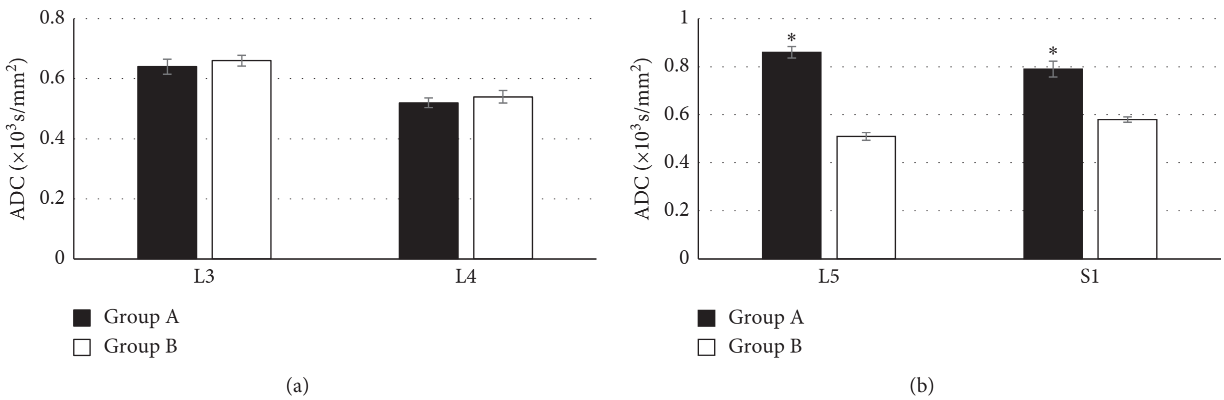

Figure 6: Comparison on ADC of the L3, L4, L5, and S1 lumbar nerve roots among the subjects in the two groups. *The difference was statistically significant in contrast to group B ($P < 0.05$).

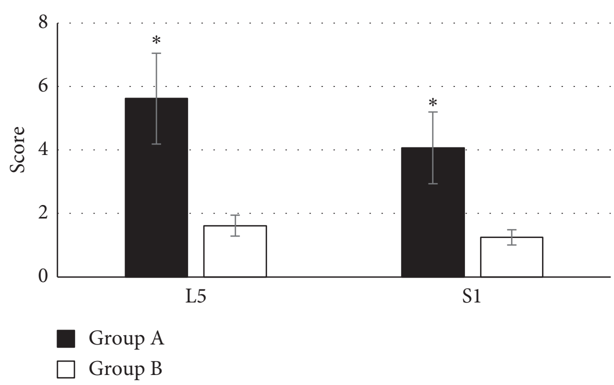

Figure 7: Comparison of the edema scores of the L5 and S1 lumbar nerve roots among the subjects in both groups. *The difference was statistically obvious in contrast to group B ($P < 0.05$).

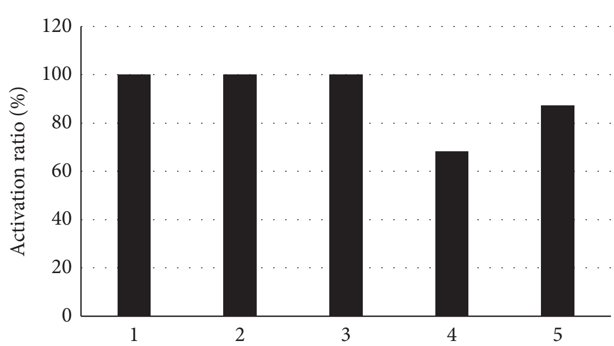

Figure 8: Brain regions with a higher activation rate in the patients of group A after surgery. 1, 2, 3, 4, and 5 stand for the activation rates of the left temporal lobe, right temporal lobe, left thalamus, splenium of corpus callosum, and right internal capsule in sequence.

was smaller extremely than that of ICA and Fast ICA, suggesting that there was a statistically huge difference ($P < 0.05$). It was similar to the research results of Ariyasu et al. [15], showing that the denoising effect of M-Fast ICA constructed in this study with good generalization was far better than that of Fast ICA and ICA for FMRI images. Under the reconstruction results of lumbar neurological MRI images by the three algorithms, the image definition after denoising by M-Fast ICA was higher dramatically than that of ICA and Fast ICA, and the noise reduced sharply. In addition, it was consistent with the above quantitative data results and also demonstrated the superiority of M-Fast ICA [16].

M-Fast ICA was applied to evaluate the DTI of 65 patients with L5 nerve root pain caused by LDH (group A) and 50 healthy volunteers (group B). The results suggested that the FA of L3 and L4 lumbar nerve roots in the subjects of group A were not statistically extreme compared with that of group B ($P > 0.05$), which was similar to the research results of Wang et al. [17], indicating that patients with L5 nerve root pain caused by LDH had no lesion changes in L3 and L4 lumbar nerve roots, which were not different from healthy volunteers. The FA of L5 and S1 lumbar nerve roots was lower steeply in the subjects of group A than that of group B, and the difference has statistical significance ($P < 0.05$), which was different from the results of Wu et al. [18]. It might be associated with histopathological changes in nerve roots generated from the nerve root compressed by herniated disc, and DTI images presented the disorder and narrow of nerve fibers and the decline of FA. The ADC of L3 and L4 lumbar nerve roots in the subjects from group A was not statistically substantial compared to that of group B ($P > 0.05$), but its ADC of L5 and S1 lumbar nerve roots was higher greatly than that of group B ($P < 0.05$). Chronic compression of the same lumbar nerve roots would lead to changes of edema and hyperemia in the nerves, and their continuous development would even reduce blood flow to the blood vessels, resulting in nerve root ischemia; thus, the ADC increased. The edema score of L5 and S1 lumbar nerve roots in the patients from group A was obviously higher than that of group B, and the difference was statistically remarkable ($P < 0.05$), indicating that there were pathological tissue changes and the increasing edema degree of the nerve roots in patients with LDH [19]. The activation rates of the right temporal lobe, left temporal lobe, left thalamus, right internal capsule, and splenium of corpus callosum were 100%, 100%, 100%, 87.43%, and 68.31%, respectively, in the patients of group A. Therefore, it revealed that the L5 nerve root pain result caused by LDH led to the changes in the brain functional area to restrain the resting state of the default network activity, which could be activating the corresponding brain regions through treatment.

5. Conclusion

This study optimized the traditional Fast ICA based on the modified whitening matrix to construct the M-Fast ICA that was compared with the introduced traditional Fast ICA and ICA. Moreover, M-Fast ICA was adopted to the 3D DTI evaluation of 65 patients with L5 nerve root pain caused by LDH and 50 healthy volunteers. It was found that the image denoising performance of M-Fast ICA constructed in this study was better than the traditional Fast ICA and ICA. The FA of patients with L5 nerve root pain caused by LDH dropped sharply but its ADC rose obviously. Changes in the functional areas of the patient's brain were affected by L5 nerve root pain caused by LDH to inhibit the resting state default network activity, and the corresponding brain functional areas could be activated by the treatment. However, the number of lumbar disc herniation patients with L5 nerve root pain was relatively small in this study and from a single source, which was less supportive of the results. Therefore, the sample size of patients should be increased in the future to further explore the application value of Fast ICA. In summary, the results of this study provided a theoretical basis for the clinical diagnosis of nerve roots in patients with lumbar disc herniation.

Retracted: ANOVA-Based Analysis of Early Blood Transfusions on Hemodynamics with Severely Injured Trauma Using Bedside Ultrasound Imaging

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

In addition, our investigation has also shown that one or more of the following human-subject reporting requirements has not been met in this article: ethical approval by an Institutional Review Board (IRB) committee or equivalent, patient/participant consent to participate, and/or agreement to publish patient/participant details (where relevant).

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

The focus of the study was to quantitatively analyze the influence of early massive blood transfusions (MBTs) on the hemodynamics and prognostic living quality of patients with severely injured trauma. 114 patients with severely injured trauma were enrolled into MBT group (67 cases) and nonmassive blood transfusions (NBT) group (47 cases) according to whether they accepted MBTs within 24 hours after the admission. All patients had bedside ultrasound technology scanning. Furthermore, the indexes were calculated for inferior vena cava (IVC), peripheral arteries, and heart. The prognostic deaths were recorded. It was found that, in the MBT group, the mortality was lower (7.55% vs. 24.23%) ($P < 0.05$), and these indexes were higher for the IVC expansion (IVCE), the respiration variation index (RVI) of IVC (ΔIVC_2), the peak flow velocity RVI of brachial artery ($\Delta Vpeak_{BA}$), femoral artery ($\Delta Vpeak_{FA}$), left ventricular outflow tract ($\Delta Vpeak_{L}$), and aorta ($\Delta Vpeak_{AO}$), as well as peak flow velocity time integral RVI of aorta (ΔVTI_{AO}) ($P < 0.05$). In conclusion, early MBTs can elevate survival rate and prognostic living quality and alleviate the atrophy degree of IVC, peripheral artery, and blood vessel of patients with severely injured trauma. Furthermore, bedside ultrasound scanning demonstrated superb capabilities in quantitatively displaying hemodynamics and outcomes of MBTs of patients with severely injured trauma.

1. Introduction

Trauma refers to the destruction of tissues or organs caused by mechanical factors. Due to the differences in injured parts, injured tissues, and skin integrity, the severity of trauma is also different [1, 2]. Among them, severely injured trauma may cause systemic reactions, with local manifestations such as pain, swelling, tenderness in the injured area, and even fatal symptoms such as hemorrhage, shock, suffocation, and disturbance of consciousness [3]. Relevant studies have reported that trauma has become the leading cause of death for people under the age of 40, even exceeding the total number of deaths from AIDS, tuberculosis, and malaria [4]. Furthermore, the people who die from trauma every year are mostly teenagers, which greatly affect social stability and economic development. Traumatic bleeding has always been the main cause of death in trauma patients. Clinical observations have revealed that, in addition to bleeding caused by liver and spleen lacerations and fractures, the abnormal coagulation function of patients is also a very key factor for continuous bleeding [5, 6]. At present, the clinical treatment methods of bleeding in patients with severely injured trauma mainly contain permissive hypotension, hemostasis, and resuscitation. Patients with heavy bleeding need timely blood transfusion therapy to correct coagulation disorders and improve the prognosis of trauma patients. Therefore, the primary objective of the study was to explore the influence of massive transfusions on patients with severely injured trauma.

With the advancement of imaging, there are various imaging examination methods used in clinical practice. However, being time-consuming, the routine imaging scan is not suitable for the diagnosis of trauma and bleeding patients, such as ultrasound, conventional CT, X-ray, and angiography [7]. Plain X-ray is the earliest imaging method used. It features simple operation and low price, but the display of soft tissue is poor, and it is prone to misdiagnosis and missed diagnosis [8, 9]. Angiography can be used to observe the blood flow in the arteries or veins of the head, arms, legs, chest, back, or abdomen, but it is easily affected by body movements. Although conventional CT is easy to operate, it cannot show minor damage [10]. As a result, bedside ultrasound has been a hotspot in clinical research in recent years. It is usually used in emergency and life-threatening conditions to speed up diagnosis and treatment [11]. Because bedside real-time ultrasound performs a single or local examination for a specific clinical phenotype, it greatly shortens the examination time and can quickly provide crucial information, such as the patient's systolic, diastolic function, volume load, heart structure, and hemodynamics. Balík [12] adopted transcranial Doppler ultrasound to monitor the cerebral blood flow of severely injured trauma patients. The results showed that ultrasound images can accurately diagnose the hemodynamics and position the blood vessels before intubation to avoid potential complications and unnecessary platelet transfusion. Gomora-García et al. [13] used ultrasound to guide the treatment of patients with painful shoulder trauma syndrome. The results found that ultrasound-guided treatment demonstrated better effects in contrast with conventional treatment and was safer. Therefore, the further aim was to apply bedside ultrasound to analyze the diagnostic results of severely injured trauma.

In summary, bedside ultrasound demonstrated superb capabilities in clinical diagnosis and treatment of severely injured trauma patients. Based on this, 114 patients with severely injured trauma were enrolled into MBT group (67 cases) and NBT group (47 cases) according to whether they accepted MBTs within 24 hours after the admission. All patients had bedside ultrasound technology scanning. Furthermore, the indexes were calculated for IVC, peripheral arteries, and heart, to quantitatively analyze the influence of early MBTs on the hemodynamics and prognostic living quality of patients with severely injured trauma.

2. Materials and Methods

2.1. Selection of Samples. 114 patients with severely injured trauma, who were admitted to the hospital between November 25, 2017, and February 10, 2020, were selected for analysis, with an average age between 20 and 67. All of them had bedside ultrasound scanning. The study has been approved by the Medical Ethics Committee of the hospital. The patient and his/her family members have been informed of the study and signed the consent letters.

Inclusion criteria: (i) patients older than 18 years; (ii) patients who underwent bedside ultrasound within 12 hours after trauma; (iii) patients with an abbreviated injury scale (AIS) score greater than 3; (iv) patients who can cooperate with the doctors.

Exclusion criteria: (i) patients with unstable hemodynamics; (ii) patients with congenital heart disease; (iii) patients with severe kidney disease; (iv) patients with aortic and great vessel split; (v) patients with incomplete clinical data; and (vi) patients with head trauma.

2.2. Grouping of Subjects. 114 patients with severely injured trauma were enrolled into MBT group (67 cases) and NBT group (47 cases) according to whether they accepted MBTs within 24 hours after the admission. The standard of massive blood transfusions no less than 20 U red blood cells were injected within 24 hours after admission.

2.3. Bedside Ultrasound Scanning. Patients accepted bedside ultrasound scanning before and after treatment by Sono ultrasonic machine (USA). A 2.5 MHz heart probe was used. The patient was in a supine position. The long axis of the left heart next to the sternum was selected, that is, the long axis of the left ventricle. The heart probe was placed between 3 and 4 intercostals of the left edge of the sternum. The detection direction was parallel to the right sternoclavicular joint to center the transverse section of the thoracic aorta. The probe was slightly upward on the basis of the four-chamber heart at the apex of the heart, and the scanning plane passed through the aortic root to obtain the transverse section of the aortic root, the longitudinal section of the left ventricle, the longitudinal section of the right atrium, the longitudinal section of the right ventricle, and the longitudinal section of the right atrium, namely, the image of the five-chamber heart at the apex. IVCE, ΔIVC_2, $\Delta Vpeak_{BA}$, $\Delta Vpeak_{FA}$, $\Delta Vpeak_L$, $\Delta Vpeak_{AO}$, and ΔVTI_{AO} were recorded. IVCE refers to the difference between the maximum diameter (IVC_{max}) and the minimum diameter (IVC_{min}) of IVC at 2 cm of the opening of right atrium which was then divided by IVC_{min}. The equation is as follows:

$$IVCE = \frac{IVC_{max} - IVC_{min}}{IVC_{min}} \times 100\%. \quad (1)$$

2.4. Statistics. The data were processed by SPSS19.0. The mean ± standard deviation ($\overline{x} \pm s$) illustrated how to calculate the measurement data. Count data were expressed as a percentage (%). Age, BMI, length of hospital stays, male-female ratio, and mortality were compared using independent t-test. The analysis of variance was applied to compare indexes for IVC, peripheral arteries, and heart. $P < 0.05$ indicated statistically significant differences.

3. Results

3.1. Comparison of Basic Data. Figures 1 and 2 show the comparison of basic data of patients. In the MBT group, the patients were 43.51 ± 9.73 years old, their BMIs were $24.76 \pm 4.79\ m^2/kg$, the ratio of males was 68.56%, and the length of hospital stay was 33.51 ± 7.53 days. In the NBT group, the patients were 41.73 ± 11.24 years old, their BMIs were $26.11 \pm 5.22\ m^2/kg$, the proportion of males was 64.37%, and the length of hospital stay was 31.75 ± 8.22 days. There was no notable difference in age, BMI, the ratio of males, and the length of hospital stays ($P > 0.05$).

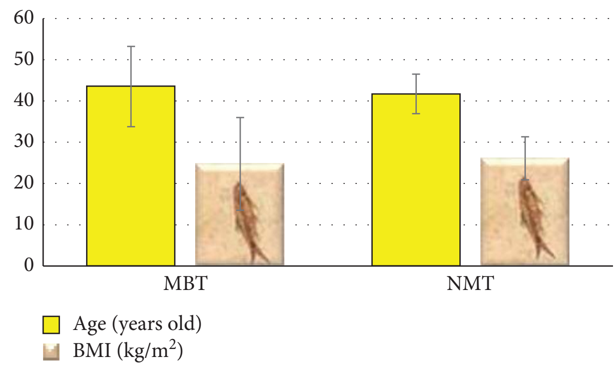

Figure 1: Comparison of the age and the BMI.

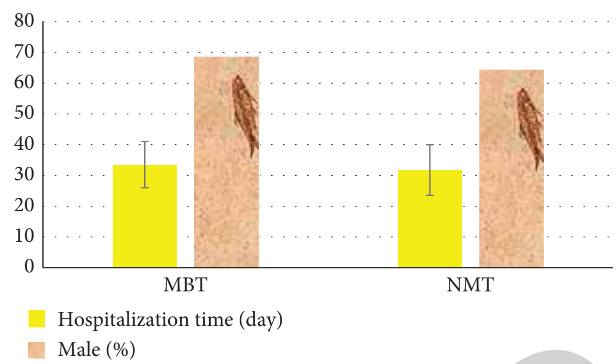

Figure 2: Comparison of the hospitalization time and the male ratio.

Figure 3 shows traumatic kidney injury in a male patient (aged 34 years old) caused by a car accident. It was evident that the lower part of the right kidney was morphologically abnormal, there was a heterogeneous echogenic mass, and an acoustic image of a clot can be seen in the bladder. Figure 4 shows traumatic renal parenchymal laceration caused by a car accident in a female (aged 26 years old). The renal parenchymal laceration with hematoma was visible, the renal capsule was intact, and a hypoechoic mass was seen in the middle parenchyma with a clear boundary.

3.2. Comparison of Mortality. Figure 5 shows the comparison of mortality of the two groups. It was evident that, in the MBT group, the mortality was lower (7.55% vs. 24.23%) ($P < 0.05$).

3.3. Comparison of IVCE and IVC_2. Figure 6 shows the comparison of IVCE and IVC_2. It was evident that, in the MBT group, IVCE (21.54 ± 4.11 vs. 13.52 ± 3.27) and IVC_2 (13.52 ± 3.27 vs. 13.17 ± 2.86) were obviously higher ($P < 0.05$).

3.4. Comparison of $\Delta Vpeak_L$. Figure 7 shows the comparison of $\Delta Vpeak_L$. It was evident that, in the MBT group, $\Delta Vpeak_L$ was obviously higher (19.56 ± 2.76 vs. 14.11 ± 1.85) ($P < 0.05$).

Figure 3: The ultrasound image of a male (aged 34) with traumatic renal laceration caused by a car accident.

Figure 4: The ultrasound image of a female (aged 26) with traumatic renal parenchymal laceration caused by a car accident.

3.5. Comparison of $\Delta Vpeak_{AO}$ and ΔVTI_{AO}. Figure 8 presented the comparison of $\Delta Vpeak_{AO}$ and ΔVTI_{AO}. It was evident that, in the MBT group, $\Delta Vpeak_{AO}$ (15.77 ± 1.48 vs. 12.75 ± 1.51) and ΔVTI_{AO} (18.88 ± 1.62 vs. 13.47 ± 1.36) were obviously higher ($P < 0.05$).

3.6. Comparison of $\Delta Vpeak_{BA}$ and $\Delta Vpeak_{FA}$. Figure 9 shows the comparison of $\Delta Vpeak_{BA}$ and $\Delta Vpeak_{FA}$. It was evident that, in the MBT group, $\Delta Vpeak_{BA}$ (21.55 ± 1.42 vs. 14.92 ± 1.36) and $\Delta Vpeak_{FA}$ (17.53 ± 1.38 vs. 13.66 ± 1.51) were obviously higher ($P < 0.05$).

4. Discussion

Patients with severely injured trauma should see a doctor in time to determine the degree of trauma as quickly as possible, so as to provide targeted clinical treatment. Although the domestic diagnostic technology has been greatly improved in recent years, the shock and mortality caused by severely injured trauma are still high, so it is very important to adopt effective diagnostic methods [14, 15]. In the study, bedside ultrasound scanning was applied to patients to analyze the influence of early MBTs on hemodynamics and

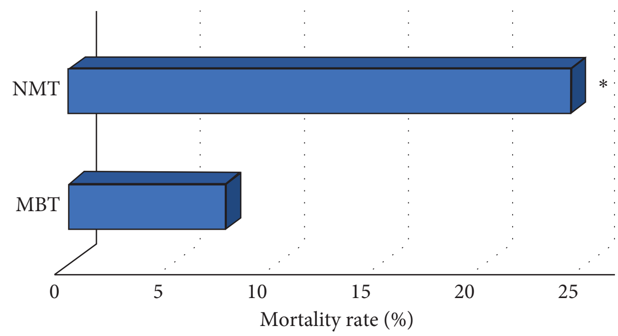

FIGURE 5: Comparison of mortality. *Note.* * indicates that there was a notable difference in contrast with the MBT group ($P < 0.05$).

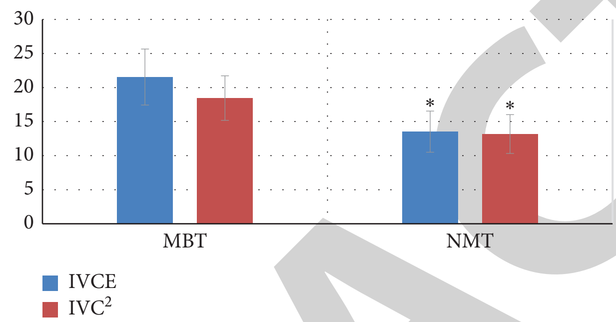

FIGURE 6: Comparison of IVCE and RVI. *Note.* * indicates that there was a notable difference in contrast with the MBT group ($P < 0.05$).

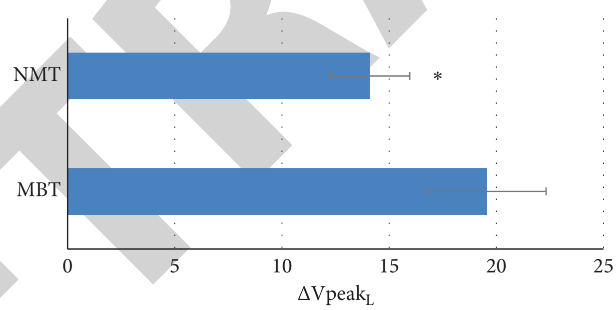

FIGURE 7: Comparison of $\Delta Vpeak_{L}$. *Note.* * indicated that there was a notable difference in contrast with MBT group ($P < 0.05$).

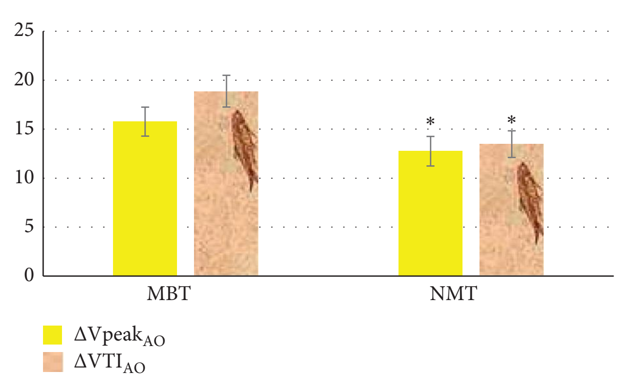

FIGURE 8: Comparison of $\Delta Vpeak_{AO}$ and ΔVTI_{AO}. *Note.* * indicates that there was a notable difference in contrast with the MBT group ($P < 0.05$).

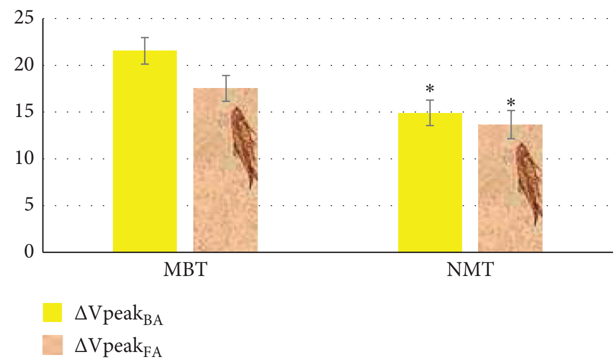

FIGURE 9: Comparison of $\Delta Vpeak_{BA}$ and $\Delta Vpeak_{FA}$. *Note.* * indicates that there was a notable difference in contrast with the MBT group ($P < 0.05$).

prognostic living quality of them. It was found that, in the MBT group, the mortality was lower (7.55% vs. 24.23%) ($P < 0.05$). This was in line with the research results of Nolte et al. [16]. Existing research believes that early MBTs for severely injured trauma can actively improve the coagulation disorder after acute trauma, thereby enhancing the prognosis of trauma patients. It suggested that early MBTs can elevate survival rate and prognostic quality of patients and reduce shock death. In the MBT group, IVCE (21.54 ± 4.11 vs. 13.52 ± 3.27) and IVC_2 (13.52 ± 3.27 vs. 13.17 ± 2.86) were obviously higher ($P < 0.05$). This was inconsistent with the research results of Cui and Wu [17]. IVC is the main blood vessel that returns blood to the abdominal organs and lower limbs. In the early stage of trauma, the internal diameter is reduced due to the reduction of blood flow back to the lower limbs and abdomen. However, early MBTs can effectively compensate for the ischemic state of patients with severely injured trauma and improve IVCE and IVC_2.

In the MBT group, $\Delta Vpeak_L$ was obviously higher (19.56 ± 2.76 vs. 14.11 ± 1.85) ($P < 0.05$). This was different from the research results of Endo et al. [18], which may be because of the different sample sources. It demonstrated that MBTs allow the patient to receive enough blood to restore normal blood flow. In the MBT group, $\Delta Vpeak_{AO}$ (15.77 ± 1.48 vs. 12.75 ± 1.51) and ΔVTI_{AO} (18.88 ± 1.62 vs. 13.47 ± 1.36) were obviously higher ($P < 0.05$). This illustrated that the early MBTs greatly affected the abdominal aortic vessels, which may be due to the fact that the abdominal aortic vessels mainly regulate blood flow through changes in tube diameter and distal resistance and will supplement the overall capacity of human body by reducing its own blood flow when there is trauma [19]. In the MBT group, $\Delta Vpeak_{BA}$ (21.55 ± 1.42 vs. 14.92 ± 1.36) and $\Delta Vpeak_{FA}$ (17.53 ± 1.38 vs. 13.66 ± 1.51) were obviously higher ($P < 0.05$). This was aligned with the research results of Roden-Foreman et al. [20]. Arteries transport blood rich in oxygen and various nutrients to various parts of the body, while severely injured trauma can cause abnormal operation of peripheral arteries. As a result, arterial lumen becomes narrow or even completely occluded. The early MBTs can effectively promote the recovery of the blood flow of the peripheral arteries, expand the peripheral arteries, and even make them return to normal.

5. Conclusion

In the study, 114 patients with severely injured trauma were enrolled into MBT group (67 cases) and NBT group (47 cases) according to whether they accepted MBTs within 24 hours after the admission. They all had bedside ultrasound scanning. The results revealed that early MBTs can elevate survival rate and prognostic living quality and alleviate the atrophy degree of IVC, peripheral artery, and blood vessel of patients with severely injured trauma. Furthermore, bedside ultrasound scanning demonstrated superb capabilities in quantitatively displaying hemodynamics and outcomes of MBTs of patients with severely injured trauma. However, some limitations should be noted in the study. The sample size is relatively small, which may reduce the power and increase the margin of error of the study. A study with an expanded sample size is necessary to strengthen the findings. In summary, the results obtained provide a theoretical basis for the application of bedside ultrasound scanning in diagnosis of patients with severely injured trauma.

Academic Editor: Enas Abdulhay

This paper aimed to investigate the application of ultrasound image segmentation technology based on the back propagation neural network (BPNN) artificial intelligence algorithm in the diagnosis of breast cancer axillary lymph node metastasis, thereby providing a theoretical basis for clinical diagnosis. In this study, 90 breast cancer patients with axillary lymph node metastasis were selected as the research objects and rolled randomly into an experimental group and a control group. Besides, all of them were examined by ultrasound. The BPNN algorithm for the ultrasound image segmentation diagnosis method was applied to the patiens from the experimental group, while the control group was given routine ultrasound diagnosis. Thus, the value of this algorithm in ultrasonic diagnosis was compared and explored. The results showed that when the number of hidden layer nodes based on the BPNN artificial intelligence algorithm was 2, 3, 4, 5, 6, 7, and 8, the corresponding segmentation accuracy was 97.3%, 96.5%, 94.8%, 94.8%, and 94.1% in turn. Among them, the segmentation accuracy was the highest when the number of hidden layer nodes was 2. The correlation of independent variable bubble plot analysis showed that the presence or absence of capsules, the presence of crab feet or burrs in breast cancer lesions was critical influencing factors for the occurrence of axillary lymph node metastasis, and the standardized importance was 99.7% and 70.8%, respectively. Besides, the area under the two-dimensional receiver operating characteristic (ROC) curve of the BPNN artificial intelligence algorithm model classification was always greater than the area under the curve of manual segmentation, and the segmentation accuracy was 90.31%, 94.88%, 95.48%, 95.44%, and 97.65% in sequence. In addition, the segmentation specificity of different running times was higher than that of manual segmentation. In conclusion, the BPNN artificial intelligence algorithm had high accuracy, sensitivity, and specificity for ultrasound image segmentation, with a better segmentation effect. Therefore, it had a better diagnostic effect for breast cancer axillary lymph node metastasis.

1. Introduction

Breast cancer refers to the appearance of malignant tumors in the breast; that is, the cancer cells originate from the lobules of the ductal epithelium of the breast, and the breast cells grow out of control and are formed. Breast cancer can be divided into carcinoma in situ and invasive carcinoma based on histopathology. According to immunohistochemistry, it can also be divided into luminal A, luminal B, and triple-negative breast cancer [1]. The incidence of breast cancer is very high, ranking at the top of malignant tumors. In developed countries such as Europe and America, the incidence of breast cancer ranks first in malignant tumors [2]. According to the data released by the National Cancer Center, there were nearly 300,000 new cases of breast cancer and more than 700,000 deaths in China in 2018, with the highest incidence among women aged 45–74 years [3]. In the growth process of breast cancer, regional lymph node metastasis is prone to occur as the tumor infiltrates into the surrounding mammary gland tissues. The most common manifestation of lymph node metastasis of breast cancer is local lymph node enlargement, hardening, fusion, agglomeration, and fixation [4]. Lymph nodes, as an important filtration structure of the human body, are responsible for phagocytosis of killer cells and removal of degenerating and broken cells [5]. After cancerous transformation, the cancer cells fall off and enter the lymph node reflux, which is intercepted by the lymph nodes, so that the cancer cells stay in the lymph nodes. Due to immune and other reasons, the cancer cells cannot be killed by the lymph nodes and survive for a long time to form lymph node metastasis [6]. Generally, lymph node metastasis in superficial sites is easy to find and diagnose, while some deep lymph nodes (internal mammary lymph nodes, mediastinal lymph nodes, etc.) are not easy to find. Therefore, computed tomography (CT) and ultrasound imaging are needed for auxiliary diagnosis to improve the accuracy of diagnosis [7, 8]. However, current ultrasound is not diagnostic for some small or unformed nodules.

The back propagation neural network (BPNN) is a multilayer feedforward network trained according to the error BP algorithm, which is one of the most widely applied neural networks at present [9]. The human brain is composed of multiple neurons, and there is a certain connection between these neurons, which becomes the basic element of the brain to process information [10]. An artificial neural network is a technology that can optimize the process of calculation and judgment by imitating the structure of the human brain, to achieve functions that cannot be realized by current computers [11]. At present, BPNN is extensively used in disease auxiliary diagnosis and survival analysis, and it can be employed to screen breast cancer, cervical cancer, and diabetes [12, 13]. Medical image classification is a key point of current medical diagnosis and pattern recognition. Through image recognition and classification, the identification of diseased tissues in medical images (such as ultrasound and CT) can be realized, and information such as the location of the disease and the size and quantity of the disease can be determined [14, 15]. Studies have found that combining the texture features of medical images with BPNN, using the feature information of pixels as training samples to train the neural network, and using the trained neural network to classify and recognize images can effectively and accurately classify a given medical image [16].

To improve the accuracy of the diagnosis of breast cancer and other diseases, and to determine whether breast cancer has metastasis to lymph nodes and other parts, the clinical diagnosis is usually combined with CT, magnetic resonance, and ultrasound imaging examinations. Therefore, the BPNN algorithm model was established in this study and applied to the segmentation of ultrasound diagnostic images of patients with breast cancer axillary lymph node metastasis, to explore the application of ultrasound image segmentation technology based on artificial intelligence algorithms in the diagnosis of breast cancer axillary lymph node metastasis.

2. Materials and Methods

2.1. Research Objects and Grouping. 90 breast cancer patients with axillary lymph node metastasis were selected in this study, who were treated in hospital from January 2017 to September 2020. The cases included in this study were subjected to pathological examination and ultrasound diagnostic examination before surgical treatment. In this study, all breast cancer patients were grouped randomly into two groups and underwent ultrasound examinations. After the examination, the ultrasound images of the experimental group were processed by artificial intelligent-based ultrasound image segmentation technology to diagnose breast cancer axillary lymph nodes, while the control group was directly diagnosed by routine ultrasound images. The study had been approved by the medical ethics committee of the hospital, and the patients and their family members understood the content and methods of this study and agreed to sign the corresponding informed consent.

The criteria for inclusion were defined to include patients who were diagnosed with axillary lymph node metastasis of breast cancer by previous pathological diagnosis and imaging examination, did not receive other drugs or antibiotics in the recent research, did not receive radiotherapy or chemotherapy, and were conscious and in good mental state.

The criteria for exclusion were defined to include patients who were combined with psychiatric diseases or other system diseases, suffered from tumor metastasis to other systems and tissues other than lymph nodes, had incomplete clinical data and medical history information, did not receive treatment due to personal or other factors, and had axillary lymph nodes more than 30 mm in depth.

2.2. Patient Ultrasound Examination. The E-ultrasound equipment (French acoustic department Aixplorer type) and SL15-4 probe were adopted in this study, and the frequency range was 4–15 MHz. Then, each patient underwent B-type grayscale, energy Doppler, and AP examinations in sequence, and the imaging parameters of each mode and the size of the sampling box remained unchanged during the study. The operation was carried out by medical staff with about 10 years of breast ultrasound examination experience, and two full-time doctors would double-blindly read the images and record the reading results. If there was a disagreement, a third experienced physician would interpret the results.

2.3. BPNN Artificial Intelligence Algorithm Image Segmentation. BPNN includes three layers of feedforward network, namely, input layer, hidden layer, and output layer, and its topological structure is shown in Figure 1. The neurons of each layer are only fully connected with the neurons of the adjacent layer but not connected with the neurons of the same layer, and there is no feedback connection between the neurons of each layer, forming a feedforward neural network system with a hierarchical structure.

In the BPNN as shown in the figure, the input layer and the output layer contain a nodes and b nodes, so the neural network can be regarded as a mapping from an a-dimensional vector to a b-dimensional vector. According to the nodes of the input layer and output layer, the number of nodes in the hidden layer of the network can be calculated as follows:

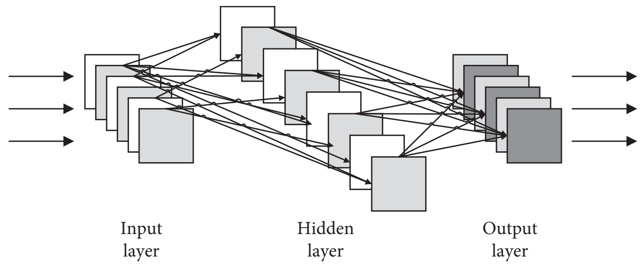

Figure 1: The structure of BPNN.

$$N = \sqrt{a+b} + C. \tag{1}$$

In (1), N stands for the number of nodes in the hidden layer, a means the number of nodes in the input layer, b represents the number of nodes in the output layer, and C expresses the adjustment constant. The relationship between the output and input of the artificial neural network can be expressed as follows:

$$\mathrm{net}_u = \sum_{v=1}^{b} Q_{uv} I_v - p, \tag{2}$$

$$O_u = A(\mathrm{net}_u). \tag{3}$$

In (2) and (3), I, Q, p, O, and A stand for the input signal from the neuron, the connection weight between neurons, the bias, the output of the neuron, and the activation function in turn, so the net is the net activation. Besides, v and u represent the number of neurons. Suppose there is an a-layer neural network and the sample m is added to the input layer, so the input sum of u neurons at layer n is S_u^n and the output is I_u^n. The weight coefficient from the v-th neuron in the $n-1$-th layer to the n-th neuron in the $n-1$-th layer is Q_{uv}, and the excitation function of each neuron is A:

$$A(m) = \frac{1}{1+\exp(-m)}. \tag{4}$$

In the above equation, m represents the number of samples. The relationship between each variable can be expressed as a mathematical relationship in

$$m_u^n = A(S_u^n), \tag{5}$$

$$S_u^n = \sum_v Q_{uv} m_v^{n-1}. \tag{6}$$

The BPNN algorithm is divided into two steps: forward propagation and back propagation. The forward propagation is carried out in the order of the input layer-hidden layer-output layer. What is more, the actual output is compared with the expected output. If there is a difference between the two, it enters BP. Then, the error signal will be transmitted back in reverse according to the forward propagation path, and the weight coefficient of each neuron in each hidden layer will be modified to minimize the error signal. The propagation process is shown in Figure 2.

The BP error function is defined as (7), and its gradient is determined as (8):

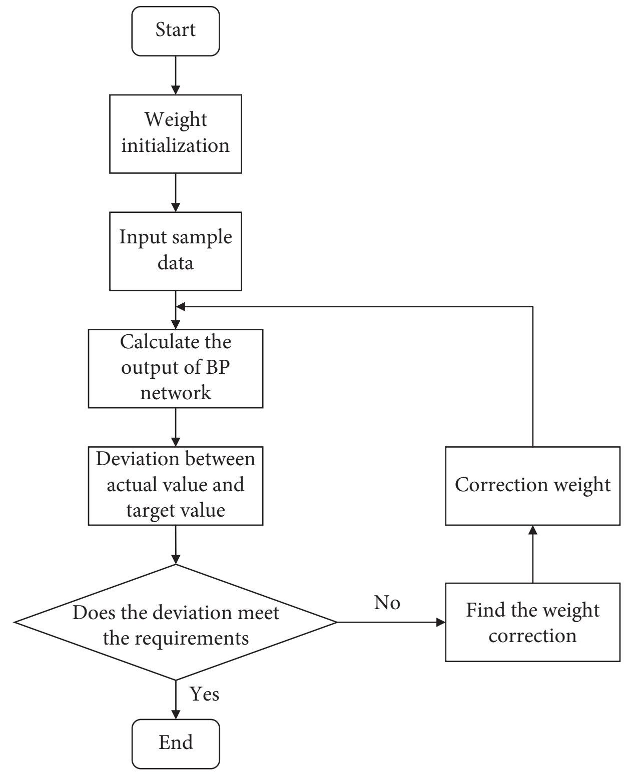

Figure 2: BPNN workflow chart.

$$r = \frac{1}{2}\sum_u \left(I_u^a - O_u\right)^2, \tag{7}$$

$$\frac{\partial r}{\partial Q_{uv}} = \frac{\partial r}{\partial S_u^n} \cdot \frac{\partial S_u^n}{\partial Q_{uv}}. \tag{8}$$

Among them, r represents the BP error, Q indicates the weight, and Ou means the output of the neuron u. If $d_u^n = \partial r/\partial S_u^n$, the following equation can be obtained:

$$\frac{\partial r}{\partial S_u^n} = \frac{\partial r}{\partial I_u^n} \cdot \frac{\partial I_u^n}{\partial S_u^n}. \tag{9}$$

In (9), I_u represents the input of neuron u, S_u^n stands for the total input of neuron u in the n-th layer, and $\partial I_u^n/\partial S_u^n = A'(S_u^n)$; $A'(S_u^n) = (1/1+\exp(-S_u^n))'$; $(1/1+\exp(-S_u^n))' = I_u^n(1-I_u^n)$. Besides, $\partial r/\partial I_u^n = \partial r/\partial I_u^a$ and $\partial r/\partial I_u^a = (I_u^a - O_u)$ when $n=a$, but $\partial r/\partial I_u^n = \sum_1 (\partial r/\partial S_1^{n+1}) \cdot (\partial S_1^{n+1}/\partial I_u^a)$ and $\sum_1 (\partial r/\partial S_1^{n+1}) \cdot (\partial S_1^{n+1}/\partial I_u^a) = \sum_1 Q_{Iu} \cdot d_1^{n+1}$ when $n < a$.

Therefore, the neural network weight modification equation is presented in

$$\Delta Q_{uv}(t+1) = \alpha \Delta Q_{uv}(t) - \theta \cdot d_1^n \cdot I_v^{n-1}. \tag{10}$$

If $I_u^n = e$, $d_1^n = I_u^n(1-I_u^n)\sum Q_{Iu} \cdot d_1^{n+1}$. In addition, Q, I, r, and a stand for the weight, the input, the propagation error, and the number of nodes in the input layer, respectively.

2.4. Evaluation Indicators. In this study, specificity (Spe), sensitivity (Sen), and accuracy (Acc) were employed to quantitatively evaluate the performance of the processing model. The calculation method of Spe was displayed in (11), which represented the proportion of correctly classified samples in all negative samples; the calculation method of Sen is shown in (12), which indicated the proportion of samples that were correctly classified in all positive samples; Acc could be calculated in (13), which represented the proportion of training positive samples in all predicted positive samples:

$$\mathrm{Spe} = \frac{\mathrm{TN}}{\mathrm{TN} + \mathrm{FP}}, \tag{11}$$

$$\mathrm{Sen} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}}, \tag{12}$$

$$\mathrm{Acc} = \frac{\mathrm{TN} + \mathrm{TP}}{\mathrm{TN} + \mathrm{TP} + \mathrm{FP} + \mathrm{FN}}. \tag{13}$$

In the above equations, TN stood for the number of true negative samples, representing the number of actual negative samples classified as negative samples; FP was the number of false positive samples, expressing the number of actual negative samples classified as true samples; TP was the number of true samples, which represented the number of actual positive samples classified as true samples; FN meant the number of false negative samples, which expressed the number of actual positive samples classified into negative samples.

BPNN has three or more layers of the forward network, the number of layers mainly depends on the number of hidden layers, and any continuous function in a closed interval can be approached by a single hidden layer of BPNN. Therefore, a three-layer BPNN can complete the mapping from the n dimension to the m dimension. In a neural network, the determination of the number of hidden layer nodes is the most important link in the determination of the whole network structure. In this study, through a simple cross-validation method, the number of potential hidden layer nodes was tested from 2 to 8, to explore the influence of neural network structure of different hidden layer node number models on the segmentation accuracy of ultrasonic images.

2.5. Statistical Methods. The data processing in this study was analyzed by SPSS 19.0 version statistical software, the measurement data were expressed as the mean ± standard deviation (□$x \pm s$), and the count data were represented by the percentage (%). The analysis of variance was used for pairwise comparison. In addition, $P < 0.05$ indicated that the difference was statistically substantial.

3. Results

3.1. Ultrasound Images of Breast Cancer Axillary Lymph Node Metastasis. Figure 3 shows the ultrasonographic images of breast cancer patients with axillary lymph node metastasis. It was found that most lymph nodes of breast cancer patients were oval, and the ultrasonographic images included the outer hypoechoic cortex and the inner hyperechoic medulla. In Figures 3(d)–3(f), the structure of lymph node metastasis was destroyed, the skin and medulla structure were not clear, and the local cortex showed obvious uneven thickening, with localized protrusion and eccentricity thickening (the thickness of one end of the cortex was about twice that of the other end).

3.2. Diagnosis Accuracy Rate of Different Hidden Layer Nodes. The average accuracy of different hidden layer nodes was compared, and the results are presented in Figure 4. When the number of hidden layer nodes was 2, 3, 4, 5, 6, 7, and 8, the corresponding segmentation accuracy was 97.3%, 96.5%, 94.8%, 94.8%, and 94.1%, respectively. In other words, the segmentation accuracy was the highest (97.3%) when the number of nodes in the hidden layer is 2. With the increase of the number of nodes in the hidden layer, the segmentation accuracy of ultrasonic images decreased continuously.

3.3. Analysis of the Importance of Ultrasound Manifestations and Pathological Results of Independent Variables. Figure 5 indicates the pathological findings of axillary lymph node metastasis in patients with breast cancer. The ultrasound imaging data of the patients included in the study were analyzed, and the pathological examination results of breast cancer patients with axillary lymph node metastasis were classified, including morphological regularity, echo intensity, and presence or absence of sand-like microcalcification. Different imaging features were used as independent variables, patient age was used as a covariate, and the occurrence of axillary lymph node metastasis was used as a dependent variable to establish an analysis model. According to the correlation analysis of the independent variable bubble chart (Figure 5), the presence or absence of the capsule and the presence or absence of crab feet or burrs in breast cancer lesions were important influencing factors for the occurrence of axillary lymph node metastasis, and the standardization importance was 99.7% and 70.8%, respectively.

3.4. Sensitivity Curve of the Algorithm Model. To determine the classification sensitivity of the BPNN model in this study, a two-dimensional ROC was drawn, and the area under the ROC curves segmented by artificial segmentation and the BPNN artificial intelligence algorithm were compared. Thus, there was an investigation on the sensitivity of the BPNN artificial intelligence algorithm to segment ultrasound images, and the results are shown in Figure 6. The area under the ROC curve classified by the BPNN artificial intelligence algorithm model was always larger than the area under the artificial segmentation curve. In other words, the BPNN artificial intelligence algorithm model had a better classification effect and high sensitivity.

3.5. Analysis of the Accuracy of the Algorithm Model. Figure 7 shows the accuracy analysis results of ultrasound images of breast cancer axillary lymph node metastasis by

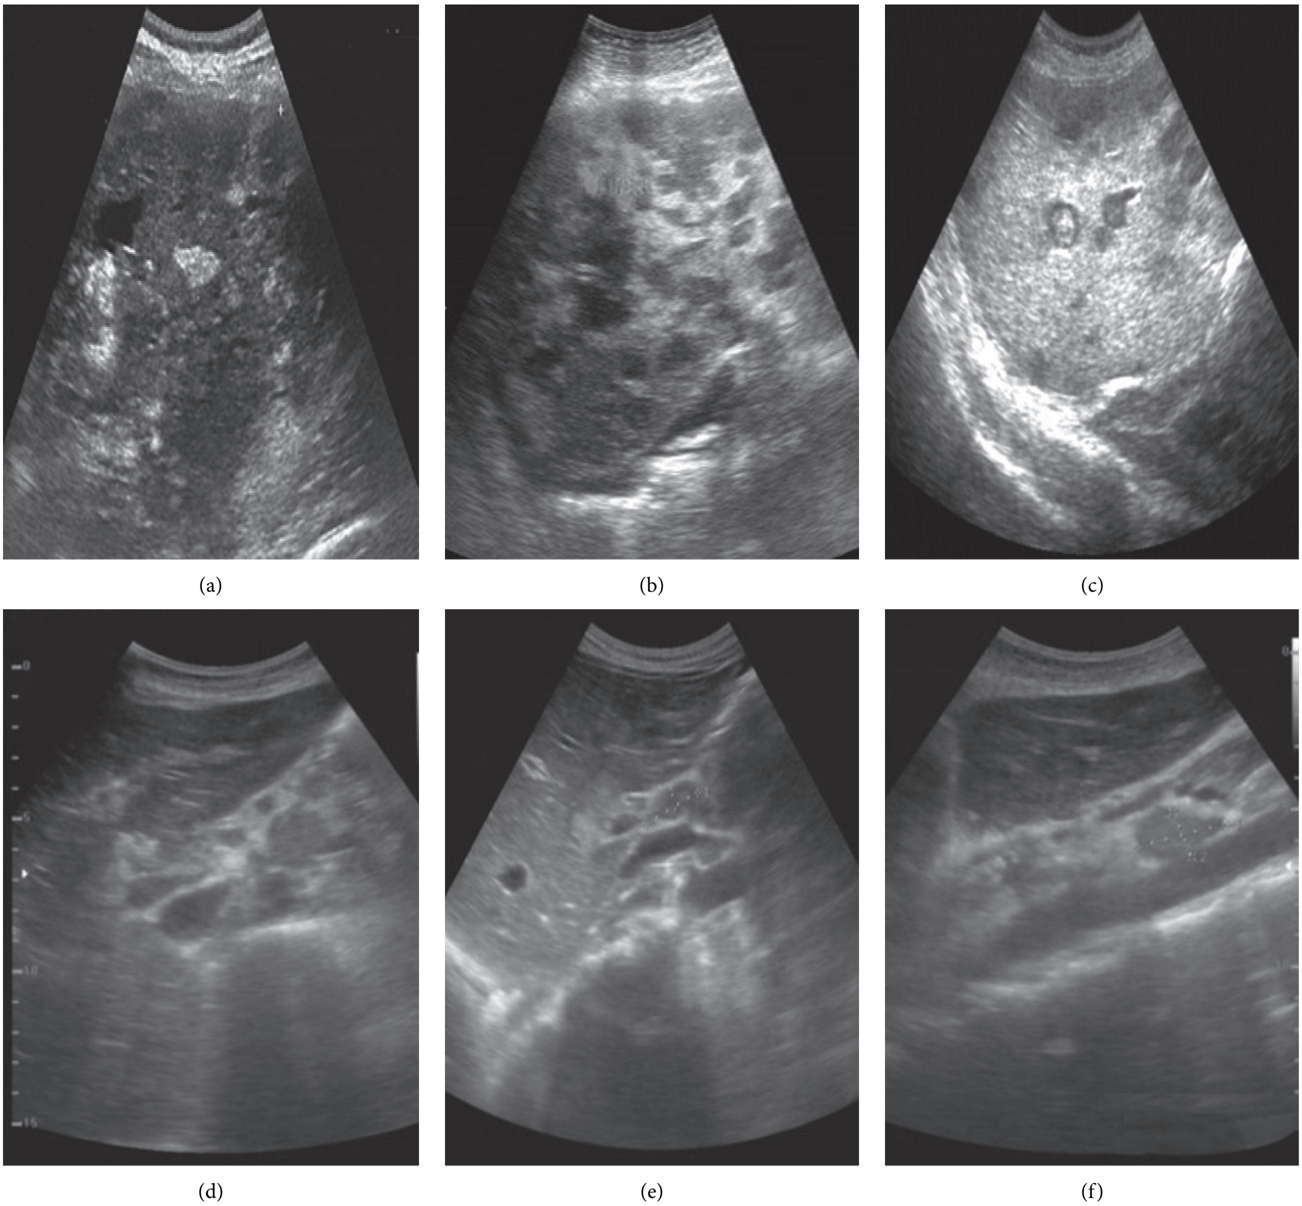

Figure 3: Ultrasound images of breast cancer axillary lymph node metastasis (note: (a–c) were left axillary lymph nodes; (d–f) were right axillary lymph nodes).

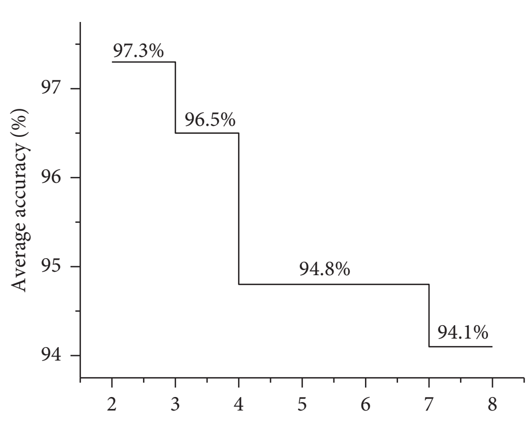

Figure 4: The average correct rate of different hidden layer nodes.

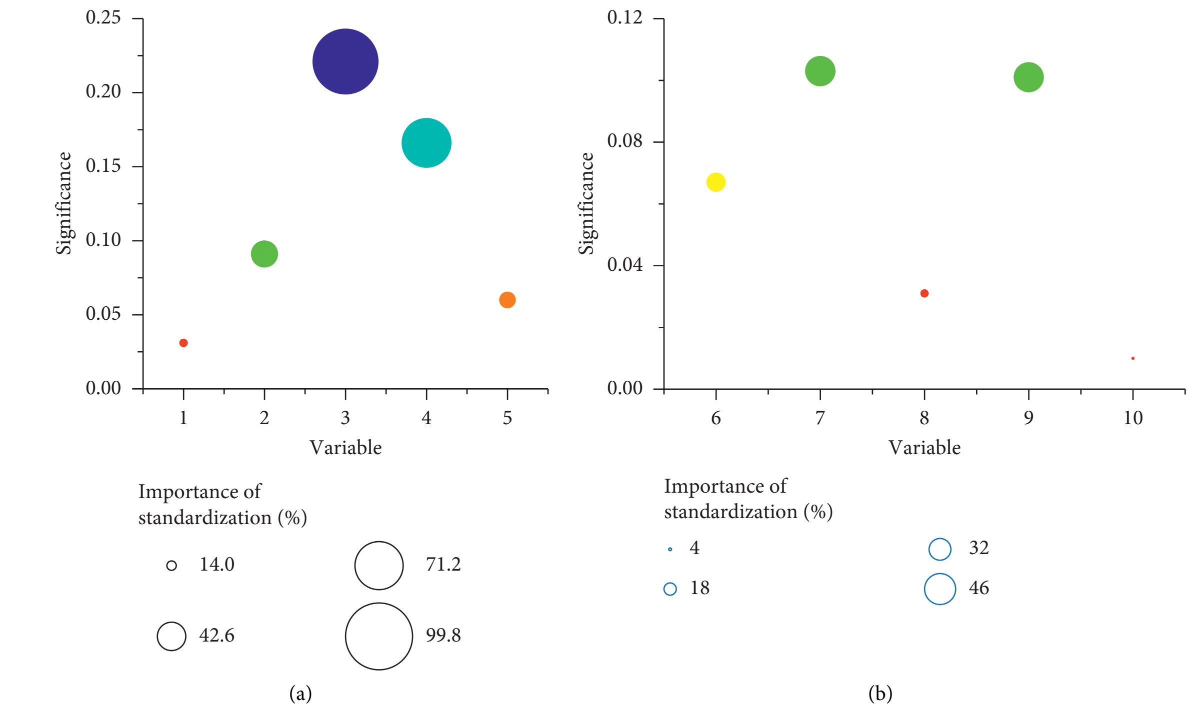

Figure 5: Comparison of the importance of the pathological results of independent variables (the independent variables 1–10 in the above figures represented the tumor shape, boundary, capsule, crab feet or burrs, internal echo, whether the echo was uniform, posterior echo, sand-like microcalcification, blood flow, and axillary lymph nodes).

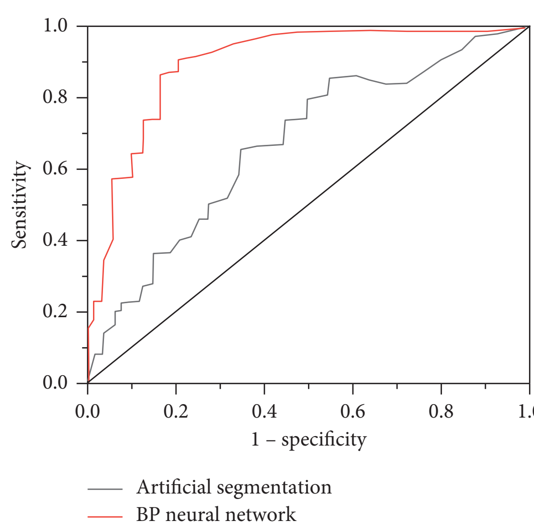

Figure 6: ROC curve of BPNN.

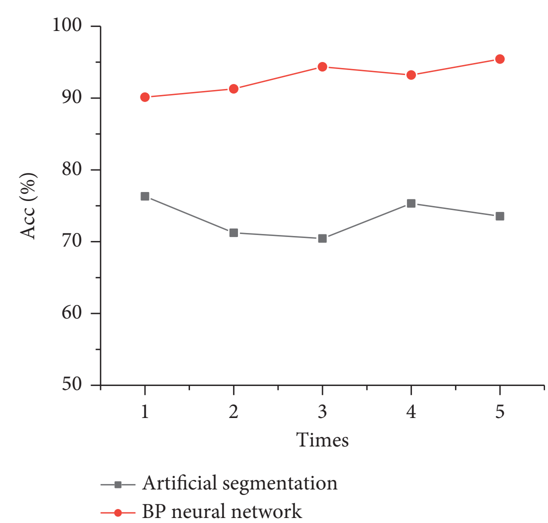

Figure 7: Algorithm segmentation accuracy analysis.

artificial segmentation and BPNN artificial intelligence algorithm. When the running times were 1, 2, 3, 4, and 5, the segmentation accuracy of the BPNN artificial intelligence algorithm model was 90.12%, 91.28%, 94.35%, 93.21%, and 95.43%, respectively. Furthermore, the accuracy was high.

3.6. Analysis of the Specificity of the Algorithm Model. The accuracy results of ultrasound images of breast cancer axillary lymph node metastasis by artificial segmentation and BPNN artificial intelligence algorithm were analyzed, as shown in Figure 8. When the number of running times was 1, 2, 3, 4, and 5, the segmentation accuracy of the BPNN artificial intelligence algorithm model was 90.31%, 94.88%, 95.48%, 95.44%, and 97.65% in turn. Therefore, the segmentation specificity of different running times was all higher than the manual segmentation method.

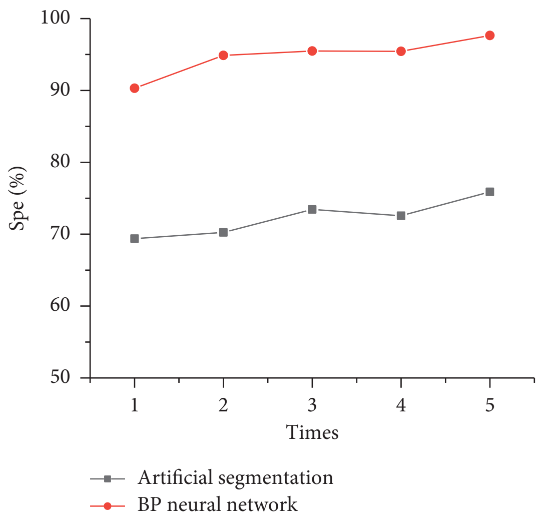

Figure 8: Algorithm segmentation specificity analysis.

4. Discussion

The lymphatic system is a crucial defensive system in the human body, which is distributed throughout the body, and the lymph nodes are an important part of the lymphatic system, mostly located in the armpits, groin, neck, etc. [17]. The presence or absence of breast cancer with axillary lymph node metastasis not only affects the choice of treatment options, but also has important implications for prognostic evaluation. Chien et al. [18] found that about 60% of breast cancer patients had regional lymph node metastasis (axillary, internal breast, and supraclavicular), and 40% of them had axillary lymph node metastasis, and most of them were sentinel lymph node metastasis. What is more, the 10-year survival rate of patients without axillary lymph node metastasis was higher than the rate of patients with axillary lymph node metastasis. Therefore, the noninvasive examination of axillary lymph node metastasis for early diagnosis has become a critical issue worthy of attention in clinical work. The scope of breast cancer surgery includes breast and axillary lymph nodes [19], and breast surgery includes enlarged tumor resection and total mastectomy. Sentinel lymph node biopsy and axillary lymph node dissection are available for axillary lymph nodes, and axillary lymph node status is required except for carcinoma in situ. The choice of surgical procedure should consider the clinical stage of the tumor and the patient's physical condition. In this study, patients with breast cancer axillary lymph node metastasis were selected as the research objects. The patients were diagnosed by ultrasound and the images were segmented by artificial segmentation and BPNN artificial intelligence algorithm, and the accuracy, specificity, and sensitivity of the two segmentation methods were compared, so as to investigate the application of ultrasonic image segmentation technology based on artificial intelligence algorithm in the diagnosis of breast cancer axillary lymph node metastasis. As a result, when the number of hidden layer nodes was 2, 3, 4, 5, 6, 7, and 8, the corresponding segmentation accuracy rates were 97.3%, 96.5%, 94.8%, 94.8%, and 94.1%, respectively. It showed that the segmentation accuracy rate was the highest when the number of hidden layer nodes was 2 in the algorithm model constructed by this research, so the optimal number of hidden layer nodes for this model was 2. According to the correlation analysis of the independent variable bubble chart, the presence or absence of the capsule and the presence or absence of crab feet or burrs in breast cancer lesions were important influencing factors for the occurrence of axillary lymph node metastasis, and the standardization importance was 99.7% and 70.8%, respectively. It indicated that tumor metastasis was affected greatly by the presence or absence of the capsule and the presence or absence of crab feet or burrs in the tumor lesion. The area under the ROC curve classified by the BPNN artificial intelligence algorithm model was always greater than the area under the artificial segmentation curve, namely, the BPNN artificial intelligence algorithm model had a better classification effect and high sensitivity; the algorithm's segmentation accuracy was 90.31%, 94.88%, 95.48%, 95.44%, and 97.65% in turn, suggesting that the segmentation specificity after different running times was higher than the manual segmentation method. This was similar to the research findings of Yang et al. [20], which disclosed that the BPNN artificial intelligence algorithm had high accuracy, sensitivity, and specificity for ultrasound image segmentation, and the segmentation effect was better. Moreover, it also had a better diagnostic effect for breast cancer axillary lymph node metastasis.

5. Conclusion

In this study, the BPNN artificial intelligence algorithm model was constructed and applied to the ultrasound images of breast cancer lymph node metastasis, and the images were segmented, so as to explore its application value in the diagnosis of breast cancer axillary lymph node metastasis. The results showed that the BPNN artificial intelligence algorithm had high accuracy, sensitivity, and specificity for ultrasound image segmentation, with better segmentation effect, which also had a better diagnostic effect for breast cancer axillary lymph node metastasis. However, the selected case samples in this study are small, which may have a certain impact on the experimental results. In addition, it lacks a comparison with other intelligent algorithm segmentation effects, and the representativeness is low. Therefore, the sample size will be increased in subsequent experiments, thereby further analyzing the application of ultrasound segmentation technology based on artificial intelligence algorithm in the diagnosis of breast cancer axillary lymph node metastasis. All in all, the results of this study can provide data support and theoretical basis for clinical diagnosis of breast cancer lymph node metastasis and other diseases.

Objective. This study uses PET imaging to observe the uptake and metabolism of 18F-fluorodeoxyglucose (^{18}F-FDG) in the multibrain areas of the emotional control loop in patients with generalized anxiety disorder (GAD) and investigate the brain of GAD patient's functional abnormality mechanism. *Methods*. The thesis clinically collected 20 GAD patients and 20 healthy subjects. Dynamic PET-CT scans were used. At the same time, ^{18}F-FDG whole-brain uptake and metabolism data were collected. Image fusion and semiquantitative analysis were used to measure emotional control loops. The maximum standard uptake value (SUVmax) and dynamic uptake and metabolic changes of 11 time points in the brain area at 150 min were measured. *Results*. Compared with the healthy control group, the peak uptake of the bilateral prefrontal cortex and the average uptake rate before the peak in GAD patients were significantly reduced ($P < 0.05$), and the average metabolic rate after the peak was significantly increased ($P < 0.05$). The peak uptake of the left striatum and the left hippocampus, the average uptake rate before the peak, and the average metabolic rate after the peak were all significantly reduced ($P < 0.05$); There were no obvious changes in the three indexes of the right striatum and the right hippocampus. *Conclusion*. There are ^{18}F-FDG uptake and metabolic disorders in multiple brain areas of the affective control loop of GAD patients. The abnormal peak and rate of uptake may be related to the pathogenesis of GAD.

1. Introduction

Generalized Anxiety Disorder (GAD) is a common mental illness. Patients have emotional disorders such as anxiety, tension, and fear, which often seriously affect normal life. Research on the pathogenesis of GAD is currently mostly focused on the fields of neurotransmitter and brain structure and function, and there are few studies from the level of molecular imaging. 18F-Fluorodeoxyglucose (^{18}F-FDG) PET-CT imaging is a technology that has been gradually used in clinical work in recent years. It can reflect the degree of somatic cell activity from the side, especially in the research of central nervous disease. The level reflects the function of nerve cells. At present, it has been well used in many fields such as stroke, brain tumor, and Alzheimer's disease and can accurately determine the distribution, range, and degree of nerve cell activity [1, 2]. There are many abnormalities in GAD, such as atrophy of gray matter nuclei in the brain area of the affect-regulated brain area, functional link disorder of the brain area, and neurotransmitter imbalance. These abnormal changes affect and interact with each other, and the pathogenesis is very complicated. Based on whole-brain imaging, this study dynamically observed the ^{18}F-FDG uptake and metabolism characteristics of nerve cells in the brain area of the emotional control loop and provided an objective basis for abnormal information interaction feedback and regulatory disorders in each brain area to supplement and improve the pathogenesis of GAD.

2. Materials and Methods

2.1. Clinical Data. The thesis collected 20 GAD patients in the neurology clinic of our hospital. All patients included 9 males and 11 females, aged 21 to 58 years, with an average of 33.9 ± 3.4 years; the patient's years of education were 9–16 (14.5 ± 3.5) years; height was 150 ~ 179 (155 ± 12) cm; weight

47 ~ 82 (60 ± 11) kg; and all patients were right handed [3, 4]. Conditions for patients to enter the group: (1) they all met the GAD diagnostic criteria of the Chinese Classification and Diagnostic Criteria for Mental Disorders 3rd Edition (CCMD3) and Hamilton Anxiety Scale (HAMA) score ≥ 14 points; (2) head MRI excludes brain organic diseases or development abnormality; (3) clinical-scale evaluation excludes depression, schizophrenia, and other mental diseases; and (4) not recently (within 3 months) taking hormones, antianxiety, and other psychotropic drugs that affect glucose intake.

Taking the staff of the hospital and their families as sources, this study collected a total of 20 cases in the healthy control group. There were 9 males and 11 females in the healthy group, aged 23 to 60 years, with an average of 35.3 ± 3.7 years; the years of education in the group were 9–19 (15.4 ± 2.7) years; height was 155–180 (160 ± 10) cm; weight was 41–79 (56 ± 9) kg; and all were right handed. Inclusion criteria: (1) clinical-scale evaluation to exclude any mental illness; (2) head MRI to exclude brain organic diseases or developmental abnormalities; and (3) recently (within 3 months), no drugs that affect glucose uptake have been taken.

2.2. PET-CT Image Acquisition. Preparations before and during the scan: the subject started smoking and alcohol prohibition 1 day before the examination, avoiding the intake of drinks such as coffee, strong tea, and sugar water, sitting still for half an hour before the scan, closing the eyes during the scan, and trying to keep calm breathing. The study used a SIEMENS52 ring 128-layer high-resolution PET-CT scanner; the imaging agent ^{18}F-FDG was produced by Canada's EBCOTR19 medical cyclotron, with radiochemical purity >95%. The data collection method is as follows: after the subject's measured blood glucose reaches the target, they will be injected with ^{18}F-FDG intravenously, the total amount of injection = body weight (kg) × 0.1 mCi, and keep calm for 10 minutes. All of them first performed CT head scan for anatomical positioning and then used the dynamic list mode to collect PET data at 11 time points at an interval of 15 minutes [5]. The data are reconstructed by the iterative method after attenuation correction and processed in the syngo True DVE12A workstation to obtain multiplanar reconstruction images.

2.3. A Semiquantitative Analysis of the Region of Interest of ^{18}F-FDG Uptake in the Emotional Regulation Brain Area. Because the CT anatomy of the brain tissue is fuzzy and the accuracy is not good, the subjects in this study have been examined by the head MRI before being enrolled. Based on the 3D-T1WI sequence of the same subject, a multiresolution nonparametric density model was used (MRNDM), image fusion method, which transforms the RGB space of the source multimodal medical image registration into a generalized intensity-hue-saturation space (GIHS). Then, the MRI brain image of the patient is decomposed into low- and high-frequency components using nonsubsampled contour transformation (NSCT), and the fusion image is constructed by inverse operation of the NSCT operation of all composite coefficients. This method effectively overcomes the problem of model mismatch and can provide an accurate anatomical positioning basis for the outline of the region of interest [6]. The outline of the region of interest based on the ALL template and the anatomical landmark points of each brain area proposed by Ax macher, respectively, outlines the prefrontal cortex, striatum, hippocampus, and thalamus in the emotional control brain area. After the region of interest is delineated, the highest dynamic standard uptake value (SUVmax value, unit of Bq/cc) of ^{18}F-FDG in the region is measured, and the data are automatically generated by the PET workstation software. The data of each point of 11 time points measured in each brain area were measured 3 times and averaged. Since ^{18}F-FDG uptake and metabolism in the cerebellar region are recognized as relatively stable, the SUVmax value of the ipsilateral cerebellar structure of the same subject was standardized based on SUVmax (standardized) = SUVmax (brain area of interest)/SUVmax (same as the lateral cerebellum). The ^{18}F-FDG peak value (the highest value of SUVmax in all time points), the average uptake rate before the peak, and the average metabolic rate after the peak of the brain area of interest were recorded. Average uptake rate before peak = [SUVmax peak − SUVmax (time starting point)]/peak time and average metabolic rate after peak = [SUVmax peak − SUVmax (time end point)]/postpeak time were recorded. Finally, Graph Pad Prism software was used to draw the time dynamic curve.

2.4. Statistical Analysis. Using SPSS11.0 software for statistical analysis, the data obtained in the experiment accord with the normal distribution, and the measurement data are expressed as mean ± standard deviation. A two-sample t-test was used to compare the two groups, and $P < 0.05$ indicated that the difference was statistically significant [7].

Context Awareness (CA) is a visual saliency model based on the contrast method. It uses LAB color space features to calculate the distance between two pixel blocks and define dissimilarity and then calculate the contrast of the 64 nearest neighbors of the current block; finally, feature maps such as color and distance are merged, and context correction and enhancement are performed to obtain a saliency map. The context-aware model follows the four criteria of bottom-level features, global features, organizational rules, and high-level elements. Among them, the first three points are calculated by color mode difference, global feature universality, and the relative concentration of salient feature pixels to calculate the salient area [8]. Finally, this paper adds feature elements to postprocess the salient map. The specific steps and calculation formula are as follows.

We divide the target image into $n \times n$ blocks and calculate the Euclidean color distance and the Euclidean space distance of the two pixel blocks in the LAB space, denoted by $d_{\text{color}}(p_i, p_j)$ and $d_{\text{position}}(p_i, p_j)$, respectively. Among them, p_i and p_j represent pixel block i and pixel block j. The saliency of a pixel block is jointly determined by $d_{\text{color}}(p_i, p_j)$ and $d_{\text{position}}(p_i, p_j)$. The larger the color distance and the smaller the position distance, the greater the difference between the two pixel blocks. The pixel block dissimilarity calculation formula is

$$D\left(p_i, p_j\right) = \frac{d_{\text{color}}\left(p_i, p_j\right)}{1 + c \times d_{\text{position}}\left(p_i, p_j\right)}. \quad (1)$$

Here, c is a constant. Taking the saliency value of the pixel block pi as an example, the greater the difference between p_i and the surrounding pixel blocks, the higher the saliency. The reference set is $\{q_k\}_{k=1}^{K}$. $K = 64$ is the number of selected pixel blocks, calculated as

$$S_i^r = 1 - \exp\left\{-\frac{1}{K}\sum_{k=1}^{K} d\left(p_i^r, q_k^r\right)\right\}. \quad (2)$$

Equation (2) can be used improve the contrast between the salient area and the insignificant area by taking the average value. The calculation formula is

$$S_i^r = 1 - \exp\left\{-\frac{1}{K}\sum_{k=1}^{K} d\left(p_i^r, q_k^{rk}\right)\right\}. \quad (3)$$

The range of saliency value is $[0, 1]$; the larger the two pixel blocks, the higher the saliency and the smaller the less significant for pixels around salient points. The paper needs to add context for correction, by setting the saliency threshold and calculating the Euclidean distance weighted value between the salient point and the surrounding pixels to obtain the saliency value of the information [9]. After the thesis is revised, the saliency value of the salient area is enhanced. The context correction calculation method is shown as follows:

$$\widehat{S}_i = \overline{S}_i\left(1 - d_{\text{foci}}(i)\right), \quad \overline{S}_i = \frac{1}{M}\sum_{r\in R} S_i^r. \quad (4)$$

After the target image is processed as mentioned above, a two-dimensional saliency map with the same size as the original image is obtained, as shown in Figure 1.

Grab cut characterizes the probability distribution of color information by estimating the Gaussian Mixture Model (GMM) of the target area and the background area. On the RGB space color image, the pixel GMM Gaussian component is allocated, the parameters are optimized, and the segmentation prediction is iterated to converge to obtain the foreground area. Finally, the paper uses the smoothest boundary of the foreground area to improve the edge accuracy of the segmented image [10].

The Grab Cut algorithm requires user initialization to divide the target image into a background area and possible target areas. The pixels in the two areas are initialized to 0 and 1, respectively [11]. The pixel point set $a = (a_1, \ldots a_n, \ldots, a_N), a_n \in \{0, 1\}$ corresponds to the pixel point label set $K = (k_1, \ldots k_n, \ldots, k_N)$. Among them, N is the number of pixels; θ is the color probability distribution model of the target area and the background area; and K is the number of Gaussian distribution ($K = 5$). The problem is described as follows:

$$a = \arg\min_{a} E(a, \theta). \quad (5)$$

The Gibbs energy used by Grab Cut on the RGB space color image is

$$E\left(\underline{a}, k, \underline{\theta}, z\right) = U\left(\underline{a}, k, \underline{\theta}, z\right) + V\left(\underline{a}, z\right). \quad (6)$$

Here, E is the Gibbs energy, U is the data item, V is the smooth item, and z is the image gray value array, $z = (z_1, \ldots z_n, \ldots, z_N)$. The parameters of the Gaussian mixture model are

$$\underline{\theta} = \left\{\pi(a, z), u(a, k), \sum(a, k)\right\}. \quad (7)$$

Here, $a = 0, k = 1, \ldots, K$. The boundary energy term V is solved using the Euclidean distance formula in the RGB space:

$$V\left(\underline{a}, z\right) = y\sum_{(m,n)\in C}\left[a_n \neq a_m\right]\exp - \beta\left\|z_m - z_n\right\|^2. \quad (8)$$

Here, m and n represent two neighborhood pixels; the value of parameter β is inversely proportional to the contrast of the image, so that the boundary energy term V can be applied to high-contrast and low-contrast images; and the constant γ is obtained from image training. This paper uses this method to obtain a segmentation curve with smooth edges, as shown in Figure 2.

3. Results

3.1. The Distribution of Abnormal Uptake in the Emotional Control Loop. F-FDGPET-CT imaging showed that the whole-brain uptake distribution of the GAD group and healthy control group was clear. Compared with the healthy control group, the peak uptake of the bilateral prefrontal cortex and the average uptake rate before the peak in the GAD group were significantly reduced ($P < 0.05$), and the average metabolic rate after the peak was significantly increased ($P < 0.05$); the peak uptake in the lateral striatum and the left hippocampus, the average uptake rate before the peak, and the average metabolic rate after the peak were all significantly reduced ($P < 0.05$); the peak uptake in the left thalamus, the average uptake rate before the peak, and the peak average metabolic rate after the peak increased significantly ($P < 0.05$); and the peak uptake in the right thalamus and the average uptake rate before the peak increased significantly ($P < 0.05$), and there was no significant difference in the average metabolic rate after the peak [12]. There were no obvious changes in the three indexes of the right striatum and the right hippocampus. The specific data in the paper are shown in Tables 1–3.

3.2. Dynamic Characteristics of Abnormal Uptake in the Brain Area of the Emotional Control Loop. Compared with the healthy control group, during the ^{18}F-FDG imaging process, the GAD group showed slow advancement and faster delivery and decreased total amount on both sides of the prefrontal cortex; the left striatum showed slow advancement and slow exit and decreased total amount. There was

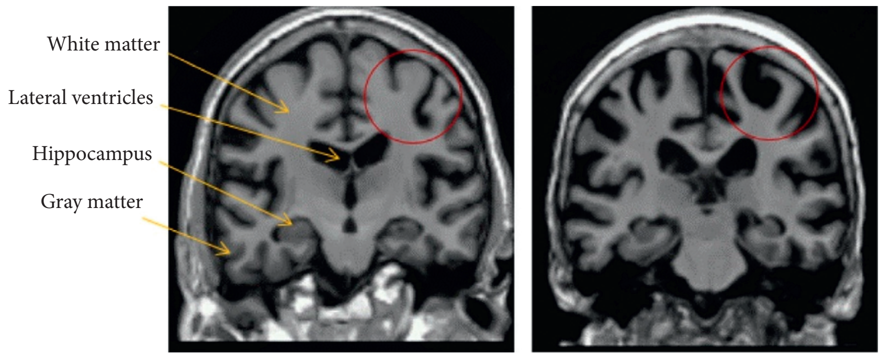

Figure 1: Two-dimensional saliency map of brain PET.

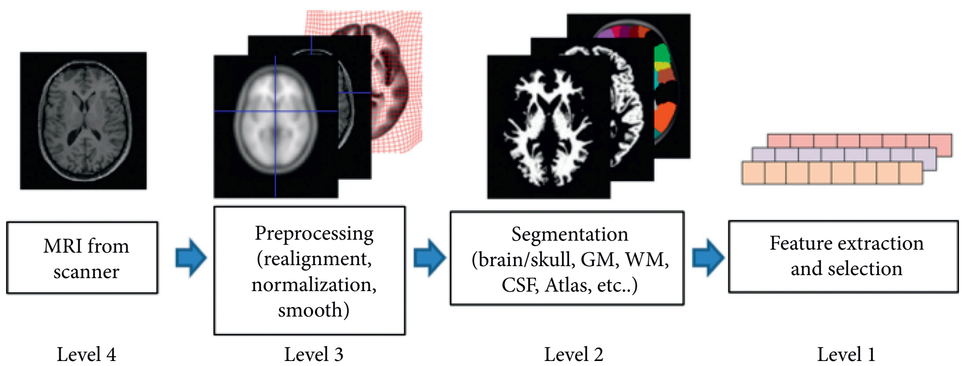

Figure 2: Segmentation curve with smooth edges.

Table 1: The difference of the peak uptake of the two groups of emotional control loops in multiple brain regions (Bq/cc).

Grouping	Left prefrontal cortex	Right prefrontal cortex	Left striatum	Right striatum	Left hippocampus	Right hippocampus	Left thalamus	Right thalamus
Healthy control group	2.41 ± 0.21	2.52 ± 0.24	1.95 ± 0.17	1.97 ± 0.22	1.65 ± 0.20	1.63 ± 0.19	1.71 ± 0.17	1.69 ± 0.15
GAD group	2.04 ± 0.20	2.06 ± 0.18	1.41 ± 0.19	1.97 ± 0.18	1.16 ± 0.15	1.63 ± 0.16	2.13 ± 0.24	2.08 ± 0.20

P value	<0.05	<0.05	<0.05	>0.05	<0.05	>0.05	<0.05	<0.05

no significant difference in changes in the lateral striatum; the left hippocampus showed slow entry and slow exit, and the total amount decreased, and the right hippocampus showed no significant difference; the left thalamus showed fast forward and faster exit, and the total amount increased, the right thalamus showed fast in and out, and the total volume increases performance [13] (see Figures 3 and 4).

4. Discussion

GAD has a number of functional abnormalities in brain structures, and the dysfunction of the affect regulation loop is a key factor leading to the disease. Structural magnetic resonance studies have shown that the prefrontal cortex, striatum, hippocampus, and thalamus contained in this loop have varying degrees of morphological abnormalities. The main manifestations are the reduction of brain volume and the reduction of gray matter thickness; functional magnetic resonance is here on the basis of this, and it is further confirmed that there are abnormal functional linkages between multiple brain areas of the emotional control loop. For example, there is an increase in the activation of the thalamus and the hippocampus, the prefrontal cortex, and the decrease of the activation of the hippocampus and the prefrontal cortex while the brain structure is atrophy [14]. Conventional MRI technology can certainly observe and explore the mechanism of GAD imaging performance to a certain extent, but due to differences in data collection, correction, and normalization steps, there are still many differences and controversies in the final results, and MRI lacks dynamic brain function. Technical means of change observation.

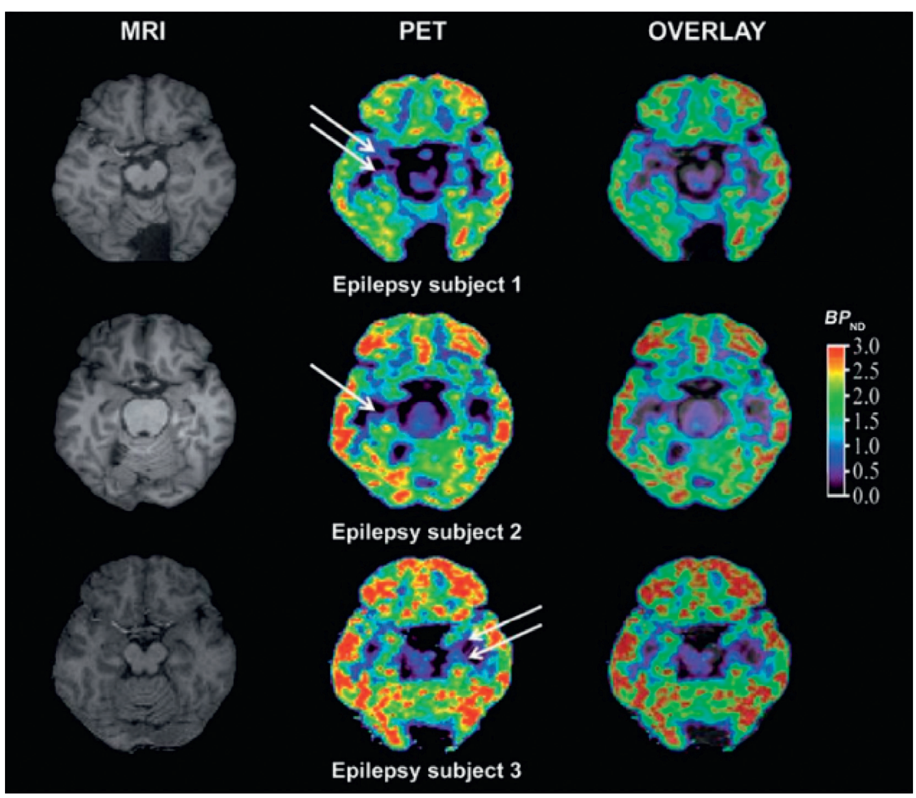

Figure 3: ^{18}F-FDG imaging of the bilateral prefrontal cortex showed slow advance and fast exit, and the total amount decreased.

F-FDGPET-CT, as a new technology for observing changes in brain nerve cell function in recent years, can clearly visualize the glucose uptake and metabolism process of nerve cells. This technology presents brain function changes in image data through the dynamic acquisition mode, which can compensate for MRI observation of the cell metabolism process that is difficult to achieve in brain function research, realizing the real molecular imaging level

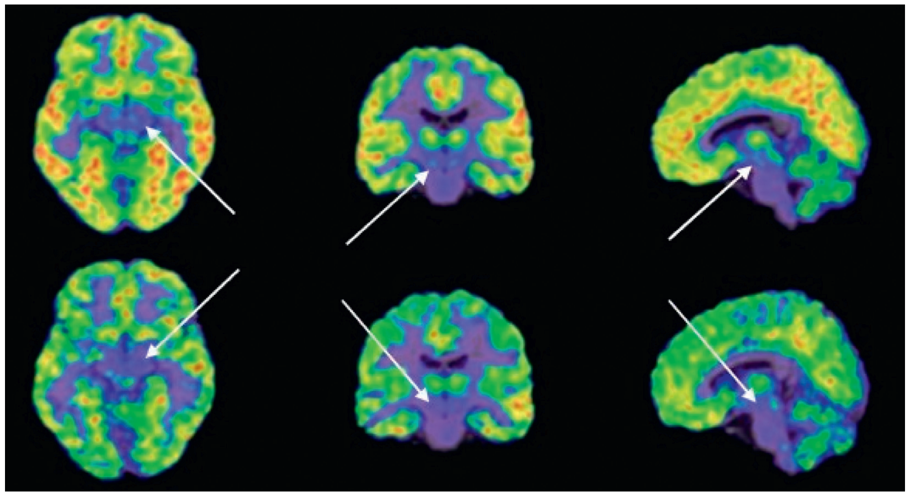

Figure 4: The left striatum of ^{18}F-FDG showed slow in and slow out, and the total amount decreased.

research. GAD patients have significant mental disorders such as anxiety, tension, and fear, and the nerve cells in the brain area of the emotional control loop have a significantly different demand for glucose energy from healthy people [15].

The results of this study showed that the peak uptake of the bilateral prefrontal cortex in GAD patients decreased and the average uptake rate before the peak decreased, which was consistent with the results of PET experiments in rat models of other scholars, but the time gradient results suggested that the brain area was average after the peak. The metabolic rate is significantly accelerated; the peak uptake of the hippocampus and striatum on the left side decreases, and the average postpeak metabolic rate slows down, similar to the results of the literature; our results also show that the peak uptake of the bilateral thalamus increases, reaching the prepeak The average uptake rate increases, and the average metabolic rate after the left thalamic peak increases [16]. Dynamic analysis of abnormal ^{18}F-FDG uptake in various brain regions shows that, in the emotional regulation loop of GAD patients, the thalamus structure, which is a rough information processing area, has a significant increase in the demand for glucose energy and the use of conversion rate is accelerated, as a fine information adjustment transmission The hippocampus and striatum in the central part of the hippocampus and striatum have a significant insufficient demand for glucose energy and a tendency to stagnate conversion. The prefrontal cortex, which has information executive functions, has insufficient demand for glucose energy but uses it to transform too quickly [17]. The possible mechanism for the occurrence of this misaligned energy demand and application inequality is that, with the continuous increase in external stress events, sensitive individuals absorb too many negative stimuli, resulting in a certain degree of regulatory transmission dysfunction.There are insufficient executive functions, unable to adapt and deal with too many adverse events, and there are also obstacles to the feedback implementation of benign regulation, which are prone to anxiety and fear-like behaviors and eventually lead to the occurrence of GAD. For the right emotional regulation loop, the study only shows abnormalities in the thalamus and prefrontal cortex, and the intermediate regulatory transmission center is not affected. In addition to the theory of the dominant hemisphere of the brain, the thesis needs to further study its mechanism.

5. Conclusions

To sum up, there are abnormalities in ^{18}F-FDG uptake and metabolism in multiple brain regions in the nutriregulation circuit of GAD patients. Abnormal uptake peaks and rates may be related to the onset of GAD. Dynamic observation of its changes can help reveal deeper the pathogenesis of GAD.

This paper aimed to study the application of local anesthetics combined with transversus abdominis plane (TAP) block in gynecological laparoscopy (GLS) surgery during perioperative period under the guidance of ultrasound image enhanced by the wavelet transform image enhancement (WTIE) algorithm. 56 patients who underwent GLS surgery in hospital were selected and classified as the infiltrating group and block group. The puncture needle was guided by ultrasound images under WTIE algorithm, and 0.375% ropivacaine was adopted to block TAP. The results showed that the dosage of propofol in the infiltrating group (313.23 ± 19.67 mg) was remarkably inferior to the infiltrating group (377.67 ± 21.56 mg) ($P < 0.05$). The hospitalization time of patients in the infiltrating group (2.14 ± 0.18 days) was obviously shorter than that of the infiltrating group (3.23 ± 0.27 days) ($P < 0.05$). 3 h, 6 h, and 12 h after the operation, the visual analogue scores (3.82 ± 1.58 points, 2.97 ± 1.53 points, and 1.38 ± 0.57 points) of the patients in the infiltration group were considerably higher than the infiltrating group (2.31 ± 1.46 points, 1.06 ± 1.28 points, and 0.95 ± 0.43 points) ($P < 0.05$). 3 h, 6 h, and 12 h after the operation, the number of patients in the infiltrating group who used tramadol for salvage analgesia (2 cases, 1 case, and 1 case) was notably less than that in the infiltration group (9 cases, 7 cases, and 3 cases) ($P < 0.05$). In short, local anesthetics combined with TAP block can reduce postoperative VAS score and postoperative nausea and vomiting (PONV) score, which also reduced the incidence of postoperative analgesia.

1. Introduction

Gynecological laparoscopy has been widely adopted in clinical treatment because of its advantages of small trauma, light pain, and quick recovery [1]. However, due to the different physiques of the patients, the pain is still unbearable. After GLS, patient-controlled intravenous analgesia is commonly adopted, and the analgesic effect is very significant. Due to general anesthesia, it causes more side effects, and it is prone to adverse symptoms such as respiratory depression, nausea, vomiting, and skin itching [2]. Transversus abdominis plane (TAP) block refers to injecting anesthetics into the neurofascial layer between the internal oblique muscle and the transversus abdominis muscle, to block the relevant nerve sensory conduction. Therefore, the pain of the skin, muscles, and peritoneum of the front abdomen is weakened, and a relatively ideal abdominal wall analgesic effect is achieved [3]. In recent years, the application of TAP block in postoperative analgesia has gradually increased. Ping-Chen et al. [4] found that different drug concentrations had a greater impact on laparoscopic surgery, so it was urgent to determine the optimal drug concentration.

With the rapid development of computer image processing technology, its application in medical imaging has been gradually extensive [5]. Ultrasound imaging medicine is one of the important tools for clinicopathological diagnosis, which can improve the efficiency of clinical diagnosis by locating and recognizing ultrasonic images and extracting graphic features. On the premise of feature extraction, image segmentation, image enhancement, and edge features of ultrasonic images, abnormal feature points are extracted from ultrasonic images to enhance the judgment ability of ultrasonic images [6]. Abraham et al. [7] proposed a small porter feature decomposition for the extraction of abnormal feature points in ultrasonic images and decomposed the edge contour features of ultrasonic images. Then, according to the decomposition results, the adaptive information fusion was enhanced to improve the detection of ultrasonic images. Sadek et al. [8] proposed an ultrasonic image localization of correlation characteristics and conducted batch processing of ultrasonic image edges. Based on the above reports, this work proposed an ultrasonic image localization technique based on WTIE algorithm. Firstly, edge feature fusion method was adopted for contour detection of ultrasonic images, color gradient decomposition was carried out in the region, and the ultrasonic image region was fused and filtered. Then, the wavelet transform method was combined to perform feature decomposition and scale template matching on the ultrasound image and process the color feature decomposition value of the ultrasound image, so that the region of the image was equalized. According to the color and texture features of ultrasonic images, the abnormal feature points of the image were located and monitored. Finally, the simulation experiment was utilized for analysis, and the conclusion was reached [9].

In this work, WTIE algorithm was applied to the ultrasound images of 56 patients undergoing GLS. The purpose was to explore the analgesic effect of different concentrations of ropivacaine combined with TAP block on the perioperative period of GLS and provide good clinical adoption reference in the analgesic aspect of GLS.

2. Materials and Methods

2.1. Selection of Research Subjects. 56 patients who were admitted to the hospital from October 17, 2018, to November 19, 2019, that underwent GLS were selected. The average age was 40.32 ± 1.24 years old. All patients were classified as grade I and grade II according to American Society of Anesthesiologists (ASA). The random number table method was utilized to divide the patients into the infiltrating group ($n = 28$) and block group ($n = 28$). The study had been approved by the Medical Ethics Committee of Hospital, and the patients and their families understood the situation of the study and signed the informed consent forms.

Inclusion criteria: (1) patients aged 20–60 years; (2) patients underwent surgery including hysterectomy, ectopic tubal pregnancy removal, and ovarian cyst removal; and (3) patients with clear consciousness and could receive normal examinations.

Exclusion criteria: (1) patients with mental illness; (2) patients with surgery time greater than 3 hours; (3) patients allergic to local anesthetics and drugs during surgery; (4) patients who withdrew from the experiment due to their own reasons; (5) patients with coagulopathy or peptic ulcer.

2.2. Observation Indicators. The clinical data of the patients were collected, and various examination indicators of the patient were detected, including blood routine, cardiac color Doppler ultrasound, lung ventilation function, blood biochemical results, infectious disease examinations, electrocardiogram, and chest radiograph. The presurgery inspections were performed in time, to fully understand the diagnosis process. Communications with the attending physician about surgery method and surgery time should be made in time. The patient's mental outlook was observed, to understand the patient's physical condition and take medication. ASA classification: before the anesthesia, the American Society of Anesthesiologists clearly categorized the risk of the upcoming surgery based on the patient's physical condition, which was divided into six levels. VAS score of pain: 0 meant no pain, less than 4 meant slight pain, 5 to 6 indicated moderate pain that can be tolerated, and a score of 7 to 10 indicated severe pain that was unbearable. PONV score: 0 meant no nausea and vomiting, 4 points or less meant slight nausea and vomiting, a score of 5 to 6 indicated moderate nausea and vomiting, and a score of 7 to 10 indicated severe nausea and vomiting. The patient needed to fast for 4 hours before the surgery.

General information of patients including average age, average height, and average weight of ASA classification was counted. The TAP blocking effect was measured after half an hour using the alcohol method to measure the patient's sensation, and the final data were recorded. The amount of anesthesia used was recorded, especially the amount of propofol used during surgery. The analgesic effect of the patients after surgery was recorded, and the VAS score of pain and PONV score were recorded 3 h, 6 h, and 12 h after the surgery. After the surgery, the number of patients using tramadol was recorded at 3 h, 6 h, and 12 h. Finally, the length of stay of all patients was recorded.

2.3. TAP Block Method. For TAP block guided by ultrasonic images, TAP localization should be performed first. Firstly, the ultrasonic probe (5.5~12 MHz) was placed under the xiphoid process to locate the rectus abdominis and the linea alba, and the probe was rotated to move along the costal margin. In the section position, it could be seen that the TAP was located between the rectus abdominis and the transverse abdominis. If TAP was not observed at the sectionals, it was because the transabdominal muscle terminated at the side of the rectus abdominis in some patients. If the probe was then moved along the costal margin to the position of the semilunar line at the lateral margin of the rectus abdominis, the three layers of the abdominal wall can be clearly identified, which were transverse abdominis, internal oblique, and external oblique from inside to outside, respectively. The probe was continuously moved to the midaxillary line, which was moved up and down between the costal margin and the iliac crest, so that the three bases can be clearly seen. The patient was told to lie on the opposite side, and the probe was moved to the direction of the posterior axillary line. It could be seen that the internal oblique muscle and the transverse abdominis were fused into a layer of fascia, which was called the pectoralis lumbar fascia, and was connected with the outer edge of the quadratus psoas. TAP was located between the transverse abdominis muscle and the internal oblique and was connected with the pectoralis lumbar fascia. A slightly mobile ultrasound probe scanned the ideal position, the area around the puncture site was disinfected with Jill iodine, and the ultrasound probe was wrapped in a sterile protective sleeve. The in-plane technique was adopted, and the nerve blocker was inserted from the medial side to the lateral side. When the puncture needle reached the TAP close to the quadratus psoas, if there was no blood loss during the withdrawal, 0.375% ropivacaine 20 mL would be injected, the ultrasonic image would be utilized to observe the diffusion of local anesthetics, and the step of the nerve blocking needle would be adjusted to continue the injection. 30 minutes after the TAP block, the block plane was detected by alcohol method. If the block scope covered T9~T12, the block effect was considered to be ideal; but if the block effect was not good, the patient would be withdrawn from the study.

Before surgery, patients in the block group were deflated in the abdominal cavity and sutured four holes. On each of the abdominal wall, a hole was made and injected with 5 mL of 0.375% ropivacaine, a total of 20 mL, for infiltration. The infiltrating group received local anesthetics combined with TAP block method for treatment.

2.4. Anesthesia Process and Surgical Method. After the TAP block was over, the patient was anesthetized. Both groups of patients were given intravenous anesthesia, and it was necessary to inject etomidate and sufentanil into the patient's veins. After the muscles were fully relaxed, the patient was put on a ventilator, and the working mode, tidal volume, respiratory rate, and respiratory ratio were determined. During surgery, it was necessary to continue to inject propofol for anesthesia and continue to add atracurium according to the actual surgery. The GLS surgery adopted the laparoscopic four-hole method. The specific positions of the four holes were the upper edge of the umbilical chakra, the right McBurney point, two fingers above the attachment between the left umbilical foramen and the left anterior superior spine of the ilium, and site with no blood vessels in the middle and lower abdomen. After surgery, the patients were transferred to the anesthesia recovery room for postoperative observation, and when they recovered consciousness, they were transferred to the general ward.

2.5. WTIE Algorithm. Wavelet transform is based on the frequency localization idea of Fourier transform. It is an analysis method in which the window size is fixed, but the shape, time window, and frequency window can be changed, and the local characteristics of the signal can be characterized in the time domain and frequency domain.

If the function $\phi(s)$ has finite energy, then, $\phi(s) \in M^2(T)$. The Fourier transform should be conducted on it, and $\phi(s)$ satisfies the following equation:

$$B_\phi = \int_T \frac{|\phi(\alpha)|^2}{|\alpha|} d\alpha < \infty. \tag{1}$$

In equation (1), B_ϕ represents the coefficient of the wavelet function, and then $\phi(s)$ is called the mother wavelet. After it is scaled and translated, the wavelet sequence $\phi_{a,b}(s)$ can be obtained, and equation is as follows:

$$\phi_{a,b}(s) = \frac{1}{\sqrt{|u|}}\phi\left(\frac{s-v}{u}\right) \quad u, v \in T;\ u \neq 0. \tag{2}$$

In equation (2), u represents the scaling factor, which corresponds to frequency information and v represents the translation factor, which corresponds to space-time information. For continuous wavelet transform of function $g(s) \in M^2(T)$, the calculation is shown as follows:

$$A_g(u, v) = \frac{1}{\sqrt{|u|}}\int_T g(s)\phi\left(\frac{t-v}{u}\right) ds. \tag{3}$$

In equation (3), $A_g(u, v)$ represents the wavelet coefficient. The wavelet function is reconstructed, and the equation is as follows:

$$g(s) = \frac{1}{B_\phi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{1}{u^2}A_g(u, v)\phi\left(\frac{s-u}{v}\right) du dv. \tag{4}$$

In equation (4), $g(s)$ represents the wavelet transform function. Since the continuous wavelet transform function is mainly utilized in theoretical analysis, the continuous wavelet and transform should be discretized in the actual application process. Discretizing the scaling factor u and the translation factor v as $u = u_0^j$ and $v = ku_0^j v_0$, respectively, the time variable is unchanged, and the discrete wavelet function of the continuous wavelet function is as follows:

$$\phi_{j,k}(s) = u^{-j/2}\phi\left(\frac{s - ku_0^j v_0}{u_0^j}\right). \tag{5}$$

Therefore, the discretized wavelet coefficient is calculated as follows:

$$B_{i,j} = \int_{-\infty}^{\infty} g(s)\phi_{j,k}^{\circ}(s) ds. \tag{6}$$

The inverse wavelet transform for discretization is as follows:

$$g(s) = b\sum_{j=-\infty}^{\infty}\sum_{k=-\infty}^{\infty} b_{j,k}\phi_{j,k}(s). \tag{7}$$

In equation (7), b is a constant. It can be seen that the smaller the u_0 and v_0, the higher the signal reconstruction accuracy.

Infrared image is a two-dimensional discrete image $A(u, v)$, which can be regarded as a two-dimensional matrix and subjected to two-dimensional wavelet transformation. Then, it is decomposed into low-frequency components PP1, PQ1, QP1, and QQ1 at each resolution of each layer, and high-frequency components PP2, PQ2, QP2, and QQ2 in the three directions of horizontal, vertical, and diagonal. The schematic diagram of wavelet transform is shown in Figure 1, and the image reconstruction process is just the opposite.

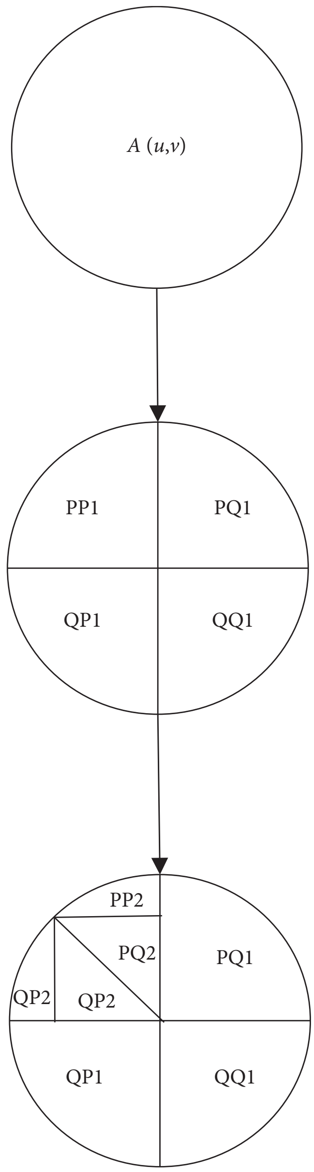

Figure 1: Schematic diagram of two-dimensional wavelet transform.

A threshold function is adopted to modify the positive wavelet coefficients. Commonly utilized threshold functions include hard threshold functions and soft threshold functions. It is assumed that A is a wavelet function, and A_S is threshold-treated wavelet coefficient, where S is the threshold. The hard threshold function means that when the absolute value of the wavelet coefficient is less than the threshold, it is equal to 0, and when it is greater than or equal to the threshold, it remains unchanged. The equation is as follows:

$$A_s = \begin{cases} A, & |A| \geq S \\ 0, & |A| < S \end{cases}. \tag{8}$$

The hard threshold function means that when the absolute value of the wavelet function is less than the threshold, it is equal to 0, and when it is greater than or equal to the threshold, the threshold is subtracted. The equation is as follows:

$$A_s = \begin{cases} \operatorname{sign}(A)(|A| - S) & |A| \geq S \\ 0 & |A| < S \end{cases}. \tag{9}$$

The key point of threshold denoising is the choice of threshold. If the choice of threshold is too large, it is possible to delete a lot of important information, and if the threshold is too small, it may affect the denoising effect. The VisuShrink threshold and the universal unified threshold is adopted. The calculation equation of the threshold S is as follows:

$$S = \sigma_m \sqrt{2 \ln M}. \tag{10}$$

In equation (10), σ_m represents the standard deviation of noise and M represents the length of the signal. Moreover, for the details of high-frequency components, the adoption of coefficient transformation can improve the contrast of the image and enhance the visual effect. The equation is as follows:

$$S_{\mathrm{OUT}} = H(S_A + f). \tag{11}$$

In equation (11), S_{OUT} represents the wavelet function after detail enhancement, S_A represents the wavelet function after threshold processing, H represents the gain factor, and f represents the offset.

2.6. Statistical Methods. Data processing adopted SPSS19.0 version statistical software analysis, measurement data conformed to normal distribution were recorded in the form of mean ± standard deviation ($\overline{x} \pm s$), and count data were recorded as percentage (%). The surgery time, length of stay, dosage, pain VAS score, and PONV scores of two groups were all analyzed by variance. The difference was considerable at $P < 0.05$.

3. Results

3.1. Statistics of General Information of Patients. There was no considerable difference in the average age, average weight, average height, and ASA classification results between the two groups ($P > 0.05$) (Figure 2). The GLS surgery received by the two groups of patients included ovarian cyst removal, hysteromyoma removal, and subtotal hysterectomy. Among them, of the majority of patients undergoing ovarian cyst removal, no notable difference was shown within or between groups ($P > 0.05$) (Figure 3).

3.2. Ultrasound Image of Gynecological Abdominal Cavity during Perioperative Period. There was a huge cystic mass in the peritoneal cavity of the ovarian cyst, with multiple compartments and compartments inside, large intra-atrial sound transmission difference, and dense spot echo. Other parts showed multiple vesicle-like aggregation. Ultrasonography showed a large amount of effusion in the abdominal cavity, with poor sound transmission, which was manifested as dense punctate echo. Original abdominal mass

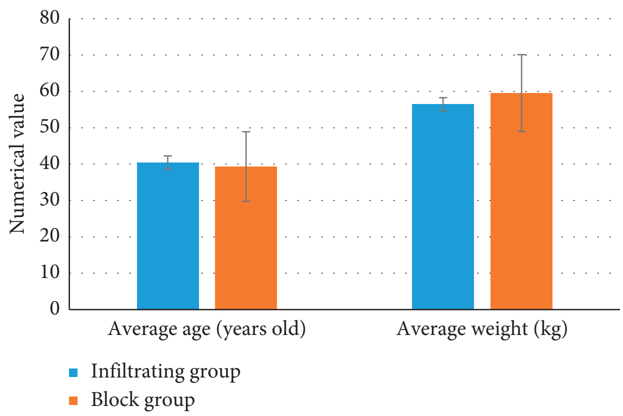

Figure 2: Contrast of general conditions of the two groups of patients.

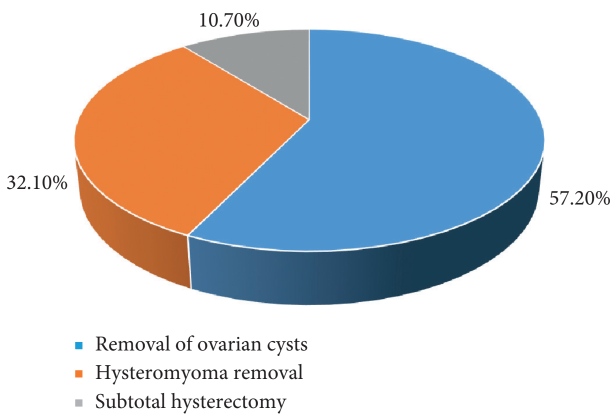

Figure 3: The proportion of ovarian cyst removal, hysteromyoma removal, and subtotal hysterectomy.

and whole volume manifestation were confined to the lower abdomen and pelvic cavity (Figure 4).

Uterine fibroids showed that the original lesion still had an echo mass with a diameter similar to that of the original lesion. This was the result of inflammatory response edema in local tissues after lesion coagulation. When ultrasound imaging was adopted for inspection, it can be seen that the original lesion still had echogenic light mass, and the diameter of the echogenic light group was generally significantly smaller than that of the original lesion, with irregular boundary and blood vessels piercing into it. This was the result of solidification of a fibroid or adenomyoma into scar tissue, which was a normal phenomenon (Figure 5).

3.3. Distribution of Blocking Planes. The anterior abdominal skin, muscles, and parietal peritoneum were innervated by T9~L1 anterior spinal nerves. After these spinal nerves left the intervertebral foramen, the anterior branch passed through the lateral abdominal wall muscles and run along the transverse abdominal muscle plane to innervate the anterior abdominal muscles and skin. The T9~T12 anterior branch entered the TAP layer from the inside of the anterior

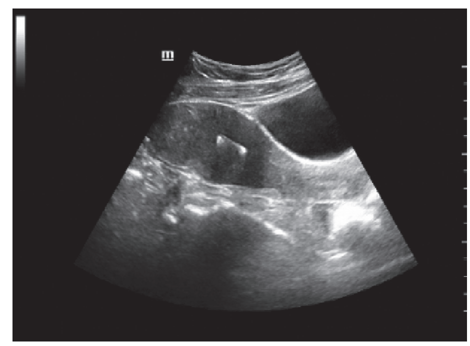

Figure 5: Ultrasound image of uterine fibroids of a female patient who underwent GLS (35 years old).

axillary line. Local anesthetics combined with TAP block were received by the two groups of patients, and no considerable difference in the block distribution was found after half an hour of surgery, as shown in Figure 6 ($P > 0.05$), and the block effect of the two groups was ideal.

3.4. Propofol Dosage during Surgery. The dosage of propofol in the block group (313.23 ± 19.67 mg) was substantially lower than that of the infiltration group (377.67 ± 21.56 mg) ($P < 0.05$) (Figure 7). In terms of surgery time, no evident differences between the two groups were found ($P > 0.05$) (Figure 8). The hospitalization time of patients in the block group (2.14 ± 0.18 days) was significantly shorter relative to the infiltrating group (3.23 ± 0.27 days) ($P < 0.05$) (Figure 9).

3.5. VAS Score and PONV Score for Postoperative Pain. 3 h, 6 h, and 12 h after the operation, the VAS scores (3.82 ± 1.58 points, 2.97 ± 1.53 points, and 1.38 ± 0.57 points) of the infiltrating group were greatly superior to the block group (2.31 ± 1.46 points, 1.06 ± 1.28 points, and 0.95 ± 0.43 points) ($P < 0.05$) (Figure 10); PONV score of the infiltrating group (1.84 ± 0.65, 1.53 ± 0.82, and 1.16 ± 0.36) was notably less than the block group (2.37 ± 0.46, 1.94 ± 0.52, and 1.57 ± 0.42) ($P < 0.05$) (Figure 11).

3.6. Tramadol Used for Postoperative Salvage Analgesia. 3 hours after the operation, 2 patients in the block group used tramadol for salvage analgesia. 6 hours after the operation, 1

patient in the block group used tramadol. 12 hours after the operation, one patient in the block group was treated with tramadol. 3 hours after the operation, 9 patients in the infiltration group used tramadol. 6 hours after the operation, 7 patients in the infiltration group used tramadol. 12 hours after the operation, 3 patients in the infiltration group received tramadol. The difference between the two groups at each time point was obvious ($P < 0.05$) (Figure 12).

4. Discussion

Pain after laparoscopic gynecological surgery includes pain at the incision site of abdominal surgery, pain in internal organs around organs, pain caused by phrenic nerve stimulation, and pain caused by tissue inflammation caused by surgery. Blanco et al. [10] deemed that the utilization of

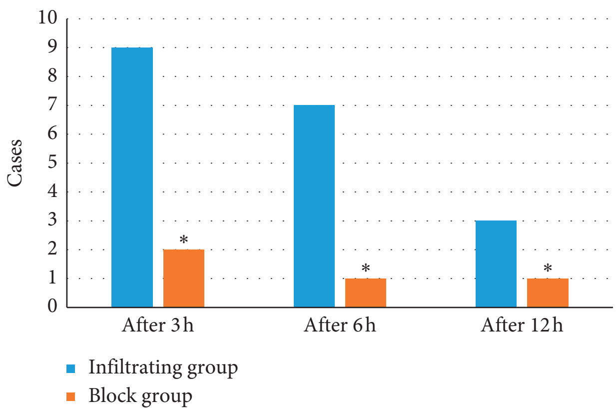

Figure 12: Contrast of the number of cases using tramadol in the two groups. Note: * meant $P < 0.05$ versus infiltrating group.

posterior approach for TAP block had a certain relief effect on peripheral visceral pain. Öksüz et al. [11] pointed out that the TAP block method can reduce the pain in the front of the abdomen, but it cannot reduce the pain in the internal organs. Studies have reported that intravenous injection of propofol before surgery can prevent the synthesis of cyclooxygenase and reduce the prostatic hormone content of the surgical site, thereby achieving the purpose of analgesia [12]. This work revealed that when patients received propofol combined with TAP block, in contrast to the infiltrating group, the dose of propofol used in the block group was greatly reduced during surgery, which can significantly reduce the pain VAS score after surgery, and the results were consistent with the above research results.

Previous studies have pointed out that local anesthetics combined with nerve block can reduce the dosage of opioid analgesics [13]. The results showed that the VAS scores and PONV scores of patients with TAP block decreased evidently at 3 h, 6 h, and 12 h after surgery, and the number of patients who used tramadol for analgesic remedy after surgery was reduced, which greatly improved patient satisfaction. The results were consistent with those of Zhang et al. [14].

TAP block adopted the water separation method to separate and diffuse local anesthetics and utilized local anesthetics to infiltrate the blocked nerves. The low concentration of local anesthetics will make the analgesic effect insignificant, while the high concentration will increase the drug concentration in plasma. Therefore, TAP block requires the adoption of appropriate drug concentration and dosage [14]. In this work, 20 mL of 0.375% ropivacaine was used to observe the block plane distribution between the two groups within 30 minutes after the TAP block, and the difference was not considerable ($P < 0.05$). Sun et al. [15] performed GLS on women after TAP block, and the concentrations of ropivacaine were 0.25%, 0.40%, and 0.45%, respectively, and the dosage was 40 mL. Plasma levels of ropivacaine in each group were measured after TAP block. The results showed that the maximum blood concentration changed with the injection. Adverse reactions to local anesthetics generally occurred within 10 minutes after completion of TAP block. The results of this work were different from those of the above studies, which may be related to the cases of the patients in this work, and it should further determine the concentration of ropivacaine in the blood.

5. Conclusion

Wavelet transform was adopted to enhance the ultrasound images, and it was revealed that the algorithm can enhance the image contrast, and the denoising effect was very strong. Ultrasound imaging technology was utilized to intuitively guide the direction of needle insertion during puncture, and it was proved that 0.375% ropivacaine can accurately enter the TAP, maximizing the analgesic effect. It also reduced the VAS score and PONV score of patients after surgery and reduced the incidence of postoperative analgesia. Moreover, the amounts of opioid analgesics during the GLS perioperative period and the occurrence of malignant reactions were also reduced. In contrast to the previous intravenous analgesia treatment, it greatly improved the comfort and satisfaction of patients after surgery. The limitation of this study is that only the clinical effects of the two groups of patients were compared, yet the concentration of ropivacaine in the blood was not further measured. In conclusion, local anesthetic combined with TAP block was used in this work, which provided a good reference for clinical GLS perioperative period.

In order to explore the efficacy of using artificial intelligence (AI) algorithm-based ultrasound images to diagnose iliac vein compression syndrome (IVCS) and assist clinicians in the diagnosis of diseases, the characteristics of vein imaging in patients with IVCS were summarized. After ultrasound image acquisition, the image data were preprocessed to construct a deep learning model to realize the position detection of venous compression and the recognition of benign and malignant lesions. In addition, a dataset was built for model evaluation. The data came from patients with thrombotic chronic venous disease (CVD) and deep vein thrombosis (DVT) in hospital. The image feature group of IVCS extracted by cavity convolution was the artificial intelligence algorithm imaging group, and the ultrasound images were directly taken as the control group without processing. Digital subtraction angiography (DSA) was performed to check the patient's veins one week in advance. Then, the patients were rolled into the AI algorithm imaging group and control group, and the correlation between May–Thurner syndrome (MTS) and AI algorithm imaging was analyzed based on DSA and ultrasound results. Satisfaction of intestinal venous stenosis (or occlusion) or formation of collateral circulation was used as a diagnostic index for MTS. Ultrasound showed that the AI algorithm imaging group had a higher percentage of good treatment effects than that of the control group. The call-up rate of the DMRF-convolutional neural network (CNN), precision, and accuracy were all superior to those of the control group. In addition, the degree of venous swelling of patients in the artificial intelligence algorithm imaging group was weak, the degree of pain relief was high after treatment, and the difference between the artificial intelligence algorithm imaging group and control group was statistically considerable ($p < 0.005$). Through grouped experiments, it was found that the construction of the AI imaging model was effective for the detection and recognition of lower extremity vein lesions in ultrasound images. To sum up, the ultrasound image evaluation and analysis using AI algorithm during MTS treatment was accurate and efficient, which laid a good foundation for future research, diagnosis, and treatment.

1. Introduction

Iliac vein compression syndrome (IVCS) is called Cockett syndrome and May–Thurner syndrome. It is a disease of physiological changes such as changes in the venous pressure of the lower extremities and venous return disorders caused by continuous compression of the iliac veins, which is also a common disease in clinical vascular disease [1]. In the early 1957, May and Thurner first proposed the anatomical basis of IVCS through autopsy research. Since the position of the iliac vein is different from the usual anatomy, the left common iliac vein receives the pressure of the bone and the stimulation of the blood vessels from the right common iliac artery and the lumbar spine. Compression of the left common iliac vein is the most common clinical case [2–4]. In addition, other general factors such as abdominal aorta, bladder disease, local kidney, pelvic tumor, and other high branches would also put pressure on the iliac vein [5–7]. The most important methods for detecting IVCS include ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) [8–11]. To save time and money, ultrasound has become the first choice for IVCS. However, the iliac vein compression point is combined with the surrounding mechanism in the ultrasound image of IVCS, which is difficult to distinguish with the naked eye. Due to the various experiences of doctors, needle biopsy, ablation, and other surgical treatment methods are used for various diagnostic results. Sometimes when surgery is not needed, it will bring unnecessary worry to the patient. Therefore, the correct detection and diagnosis of iliac vein disease is very important [12].

With the rapid expansion of AI's core technology, the in-depth learning model in the field of medical image diagnosis has been improved. A deep learning mode was established in the recognition of iliac vein compression points based on ultrasound images to realize the classification of the severity of various lesions and automatically identify the disease and effectively help doctors to diagnose and treat it. Due to different compression point sizes, shapes, and textures, the establishment of an accurate and effective recognition model is of specific research value and clinical application value. Since the application of AI in medical treatment, especially the development of deep learning in images, many deep learning methods have been applied to medical image processing. The convolutional neural network (CNN) is the most common network model in image extraction. All effective networks include networks that provide excellent results for daily graphics, including the residual neural network, dense convolutional neural network (DenseNet), Mobile Net, and the top-ranked ImageNet network [13]. However, vein ultrasound images have higher noise and higher volatility compared with ordinary images, and the imaging of the vein end is not obvious. The common network limits the extraction of edges and textures. In addition, the resolution of the traditional convolution kernel gradually decreases as the number of layers increases, which can reduce the acquisition of more detailed position information [14–16]. Hole convolution has a wider field of view under the same convolution kernel size compared with traditional convolution.

A dense multireceptive field convolutional neural network based on AI was proposed in this research. It can detect iliac vein compression lesions efficiently and accurately and can evaluate the effectiveness of contrast-enhanced ultrasound in the diagnosis of iliac vein compression by different methods. In addition, a model that can automatically identify compression points was constructed based on deep learning methods to reduce the workload of clinicians.

2. Methods

2.1. Research Objects. A total of 280 CVD and DVT inpatients (363 affected limbs) in the hospital from January 2017 to January 2021 were selected as the research objects. There were 194 patients with nonthrombotic CVD (265 limbs), including 126 males and 68 females, aged from 25 to 80 years, with an average age of 40.7 ± 11.24 years. There were 90 patients with DVT (98 limbs), including 45 males and 45 females, aged from 25 to 80 years, with an average age of 60.23 ± 12.15 years. The patient's general information, clinical symptoms, history of intravenous treatment, and thrombus cases were recorded.

Inclusion criteria: (i) clinical inpatients diagnosed with CVD or DVT after vascular surgery and (ii) ultrasound and DSA examination of the iliac vein were performed before surgery or surgical treatment, and no venous related treatment was performed.

Exclusion criteria: (i) other diseases may lead to varicose veins (such as Budd–Chiari syndrome), right heart failure, pelvic tumors, pregnancy, and other lower limb venous insufficiency; (ii) diseases affecting the amount of blood in large amounts of chest, ascites, and hypoproteinemia; and (iii) patients who were allergic to contrast media and cannot be tested with DSA.

Patients were randomly rolled into the AI algorithm imaging group and control group according to ultrasound diagnosis results.

In this study, a total of 284 patients with IVCS met the above inclusion criteria and exclusion criteria. This study had been approved by the medical ethics committee of the hospital, and the families of the patients included in the study had all signed informed consent.

2.2. Data Acquisition and Image Analysis

2.2.1. Ultrasonic Data Acquisition. The patient needed to fast for more than eight hours before the ultrasound examination of the iliac vein. The patient was in a supine position with his lower extremities slightly eversion. Two-dimensional ultrasonic imaging (2D-US), color Doppler flow imaging (CDFI), and color Doppler energy imaging (CDE) were performed to analyze the energy imaging, vascular enhancement technology (VET), and pulse wave (PW). The abnormal echo of the iliac vein cavity, stenosis, or dilation was observed, so did the formation of collateral blood circulation, the reflux and abnormal echo of the internal bowel veins, and the expansion of the venous cavity of the lower extremities.

2.2.2. Equipment. A 52000 type Doppler ultrasonic diagnostic device was used. The 4c1 convex array detection frequency was 14 mHz, and the 9l4 linear array detection frequency was 4×9 mHz. Philips FD2.0 digital subtraction angiography machine was employed.

2.3. Experimental Environment

2.3.1. Convolutional Layer Model Construction. CNN realizes image point extraction through convolutional layers. The convolutional layer requires fewer parameters compared with the fully connected layer (the number of weights does not change with the size of the image). In the convolutional layer, the image convolution operation shares the weight of the network. Therefore, the model does not require separate detectors for the same object, and the network translation is consistent with the input result. The convolution operation is between the first layer and the second layer, and the complete connection operation is between the third layer and the fourth layer. Figure 1 shows a schematic diagram of a convolutional layer and a fully connected layer. The dense multireceptive field CNN (DMRF-CNN) was utilized to extract features from ultrasound images of thyroid nodules. The method of multiporosity convolution and dense connection was used to extract the features of the nodules and transfer the features. "d-x-conv-y" represents the feature map obtained after this kind of hole convolution, x represents the size of the hole rate ($x \in \{2, 3, 4\}$), and y represents the number of convolutional layers. "conv" represents the feature map after the traditional convolution kernel convolution, that is, the convolution kernel with a hole rate of 1, which is equivalent to "d1conv-y." "Cx" represents different cross-layer connections, and different colors represent the feature maps obtained after convolution kernels with different void ratios. This model realizes the fusion of multiple receptive fields with the help of four convolution kernel fusion methods with different void ratios, which can not only achieve the goal but also reduce the parameters and prevent overfitting to a certain extent. In addition, for each dilated convolution module (Dilated Conv), the convolution module of the 0Darknet network was used. A 3×3 convolution kernel was utilized, and then, a batch normalization layer was employed to normalize the feature map to prevent the gradient from disappearing, and finally, the LeakyReLU activation function was used. In the DMRF-CNN, information between various layers is exchanged through dense cross-layer connections. The fusion of deep-level feature maps with shallow-level feature maps can make edge features well recognized.

2.3.2. R-CNN. Figure 2 shows the flowchart of the R-CNN (Region-CNN), which is classified into three stages: generating regions of interest, feature extraction based on convolutional neural networks, and classification and positioning.

Since the R-CNN uses a selective search method to generate about 2,000 regional feature points for each image, accurate data points can be selected and the search space can be reduced in target detection. Therefore, the AlexNet CNN is used to extract the features of the image. Because of the automatic AI of the network, it can learn data processing and gradually improves the accuracy.

2.3.3. Dataset and Evaluation Criteria. The dataset from the hospital physical examination center was utilized to conduct the experiment, and finally, 699 vein images were selected, among which each image contained at least one lesion point. Venous compression images of 34 men and 177 women were extracted. The sample underwent data expansion, and the process included color dithering, changing saturation, exposure, and color. In particular, the aspect ratio of the lesion point may interfere with the judgment of the disease, so the random angle change was not used in this experiment. After zooming in, 10,377 images were obtained. Figure 3 shows the detailed number of training sets and test sets.

2.3.4. Deep Learning Mode. In this experiment, the compression site of the vein was first obtained, and then, the vein ultrasonic image was edited out with the same size, i.e., 240×240. Different models were used to categorize data graphs. In the experiment, the probability gradient descent algorithm was used to upgrade the quality and efficiency. The learning efficiency at the beginning of the experiment was 0.01, the number of iterations was 600, and the final training time of the model was about 4 hours. In addition, the rate of Jitter was set to 0.3 during data amplification. The ultrasonic image was edited and randomly inverted at a rate of 0.3. The chroma and exposure was set to 2.5 and the hue to 0.1 to represent the random generation of the image in the range of 0.05–0.12 tones. A 3070 graphics card (13G memory), 8-core CPU, and 16G memory were used to implement the model and Kersa architecture for training as the experimental environment.

2.4. Treatment Methods

2.4.1. Treatment Measures. The patient's physical data and the lower extremity venous ultrasound results were recorded. A lateral thigh artery puncture was performed by the Seldinger method in the supine position, depending on the polymortem level, which was through the affected vein in advance of B ultrasound. The sheath of 6F was inserted. The degree, location, extent, and collateral circulation of iliac vein stenosis were determined by angiography. If the skeleton has severe narrowing in the vein or occlusion of the vein, adjuvant treatment can be done through the spinal canal at the occlusion site. Reconfirming of the angiogram in the inferior great vein was carried out, and severe stenosis or occlusion can be found in images with small openings in the lumen. To open the narrow part of the iliac vein, the loach guide wire was inserted. A V-18 guide wire was used to pass through the occlusion without opening. With the majority of the orbital catheter, the majority of the lesions were detected. After balloon dilation, the lesion segment of angiogram intestinal venous stenosis was less than 50%, the vascular elasticity recovery was reduced to 1/3, or the balloon dilation was performed after peripheral collateral circulation was greatly reduced.

2.4.2. Anticoagulation Therapy and Compression Therapy. To prevent puncture bleeding after intracavitary treatment, sterile gauze and elastic bandage should be used for pressure protection of puncture site and 12 h clinical observation. Anticoagulant therapy referred to a subcutaneous injection of low molecular weight heparin (LMWH) with oral administration of Beritol 10 mg twice daily for three months. For patients with high thrombosis risk factors, this may be extended to six months. Patients needed to wear stretch socks for six months after discharge.

2.4.3. Diagnostic Criteria and Cure Indicators. Ultrasonic diagnostic criteria were as follows. During CT venography of completely obstructed thrombosis, this segment of blood

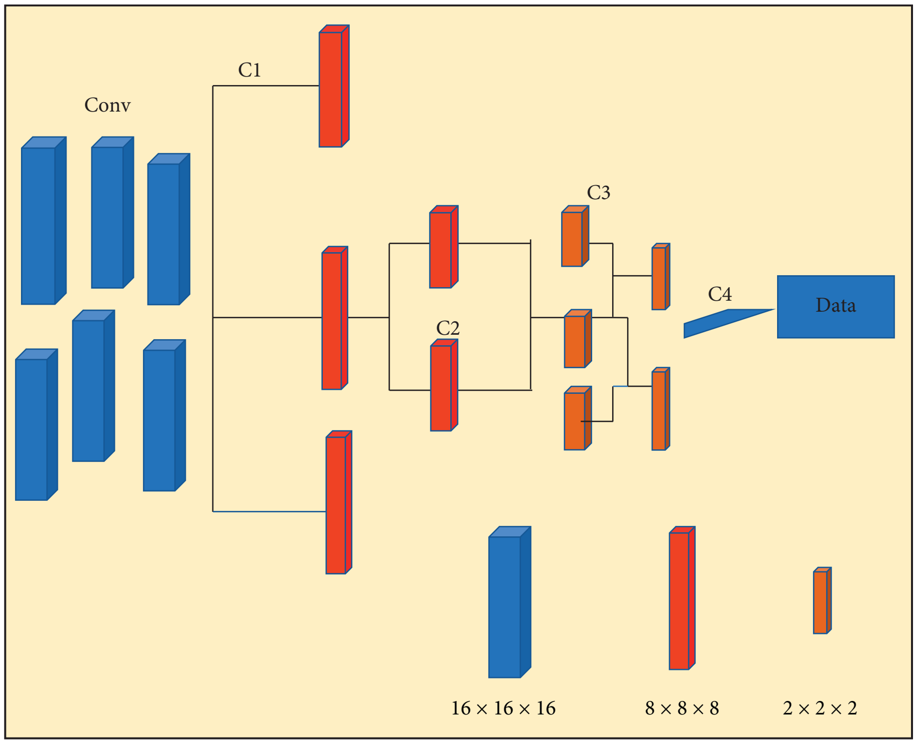

Figure 1: Schematic diagram of the convolutional layer and fully connected layer.

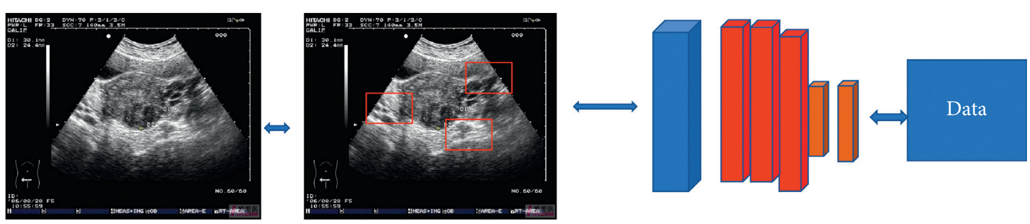

Figure 2: Flowcharts of the R-CNN.

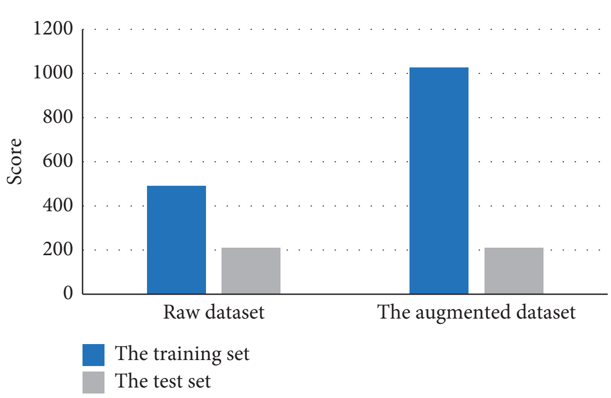

Figure 3: Detailed number of the training set and test set.

vessel did not develop at all or showed signs of sudden interruption of contrast medium at a certain level. For incomplete obstructed thrombosis, CT venography showed cylindrical or low-density contrast areas with different lengths in the venous lumen, and the edge of the venous lumen may have orbit disease caused by the contrast agent alignment. After mechanization and recanalization, CT venography showed that the venous lumen was irregular, narrow, and multibranched, partly dilated, or even twisted. Collateral circulation was established, and CT venography showed irregular collateral vein development around the obstructed vessel. Physical examination of the affected limb was implemented to assess relief of symptoms associated with venous hypertension in the lower extremity with a venous clinical severity score (VCSS). The VCSS scale includes ten clinical symptoms, such as, pain, varicose veins, venous edema, pigmentation, inflammation, sclerosis, number of ulcers, duration of ulcers, diameter of ulcers, and compression treatment. According to the classification of none, light, medium, and heavy, the corresponding score is 0, 1, 2, and 3. The patency rate of the stent was examined by color Doppler ultrasonography or venography to evaluate the patency of the venous outflow tract.

2.4.4. Follow-Up after Treatment. Hospitalization or telephone appointments were made at 3 months, 6 months, and 1 year. Patients were required to wear stretch socks and take anticoagulants. To assess the VCSS for reducing symptoms associated with venous hypertension of the lower extremities, physical examinations of the limbs were performed. The VCSS included ten clinical symptoms, such as varicose veins, edema of veins, pain, pigmentation, inflammation, sclerosis, number of ulcers, duration of ulcers, and diameter of ulcers. The patency rate of the stent was examined by color Doppler ultrasound or venography, and the smoothness of the venous outflow path was assessed.

2.5. Statistical Processing. SPSS 20.0 was employed for statistical analysis. The data were expressed as n, and the chi-square test was used for comparison in the same group. The measurement data were expressed as positive and negative standard deviations, and the normality test and the variance homogeneity test were performed before the analysis of the two sets of measurement data. The t-test was used for the comparison of the average between the normal groups, and the rank sum test was used to compare the mean between groups for normality. When $p < 0.005$, the difference was statistically significant.

3. Results

3.1. Evaluation of Hole Convolution. Figure 4 shows the difference comparison of the feature extraction effect of the hole convolution with four different kinds of hole ratios. When the hole ratio was two, the effect was ideal. In addition, the accuracy of vein compression image recognition can be improved to a certain extent by introducing the hole ratio. Figure 5 shows the segmentation and lesion identification of venous compression ultrasound images.

3.2. Comparison between Different Models. Figure 6 shows the segmentation comparison between different models. In the traditional feature extraction method, the recall rate was very high and the accuracy was very low. The deep learning methods improved accuracy compared with traditional feature extraction methods. However, the recall rate and accuracy of these methods had changed a lot, and the stability of model recognition was not good. The recall rate and accuracy of the DMRF-CNN were not significantly different. Therefore, the DMRF-CNN had good stability for identifying venous compression points and achieved good accuracy. Figure 7 shows the efficiency graph compared with other feature extraction methods.

3.3. Technical Success Rate. Sixty-six patients in the two groups successfully completed endovascular treatment for iliac vein stenosis or occlusion. After endovascular treatment, angiography confirmed different degrees of intestinal vein stenosis or occlusion, and the pelvic side blood circulation was significantly reduced. Twenty-three patients with venous flow received a second treatment in the observation group. Figure 8 shows that there was no statistical difference in the ratio of venous flow between the two groups.

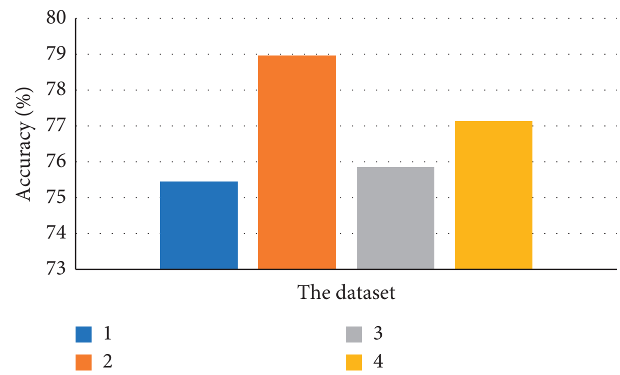

Figure 4: The influence of four kinds of hole convolutions on the feature extraction effect (1, 2, 3, and 4 represent four kinds of hole rate labels).

3.4. Relief of Intravenous Clinical Symptoms. The analgesic rate of 66 patients in the angiographic group was 88.42% and that in the control group was 86.3%. Most of the symptoms of limb swelling disappeared, and the patients' pain significantly reduced. The swelling rate of the angiographic group was 91.1%, and the swelling rate of the control group was 89.72%. Among patients with compound ulcers, the ulcer cure rate in the observation group was 83.20% in groups with different improvement and cure degrees. The average VCSS score at 3 months after treatment was 11.37 ± 3.12 points, that at 6 months after treatment was 7.98 ± 3.66, that at 12 months after treatment was 7.33 ± 2.12, that at 24 months after treatment was 15.15 ± 4.57, and that at 36 months after treatment was 14.33 ± 2.13. The average VCSS score of each follow-up point was 6.53 ± 2.33, which was lower than that before treatment, and there were statistical differences before and after treatment ($p < 0.005$). Therefore, the treatment method of the angiography group was effective. Figure 9 shows the comparison of pain relief rates between the two groups.

Comparison of VCSS scores before treatment, 3 months after treatment, and 6 months after treatment between the two groups showed that $p > 0.005$. There was no difference in the severity of intravenous clinical symptoms between the two groups before treatment. The curative effect was equivalent within 6 months. The average score of VCSS at 12 months after treatment, 24 months after treatment, and 36 months after treatment was compared, and there were statistical differences, $p < 0.005$. The average VCSS score of the angiographic group was significantly lower than that of the control group, indicating that the angiographic group had a more significant clinical effect than the control group in the midterm effect at 12, 24, and 36 months. Figure 10 shows the comparison of VCSS scores between the two groups at 3, 6, 12, 24, and 36 months after treatment.

The VCSS scores before treatment, 3 months after treatment, and 6 months after treatment were compared, and $p > 0.05$. The severity of intravenous clinical symptoms was compared between the two groups within 6 months, and there was no difference between the two groups. The average VCSS score at 12 months after treatment, 24 months after treatment, and 36 months after treatment was compared,

and the results showed statistical differences, $p < 0.005$. The average VCSS score of the control group was significantly lower than that of the angiographic group. Significant effects were achieved within 12, 24, and 36 months. Figure 10 shows the comparison of the VCSS scores of the two groups at 3, 6, 12, 24, and 36 months after treatment.

4. Discussion

IVCS is caused by a series of clinical symptoms of pelvic or venous return disorders due to venous pressure and/or an unusual bonding structure. The main manifestations are lower extremity skin pigmentation, lower extremity vein collapse, and spermatic vein flow [17]. MTS was thought to be a rare disease in the past. With the development of imaging techniques and improved understanding of MTS, it has been applied to a variety of lesions; however, the extent of its use is now overrated. Compression of the right common iliac vein is rare and is related to anatomical differences between the bony veins of the two intestines. The high rate of MTS in young women may be related to the

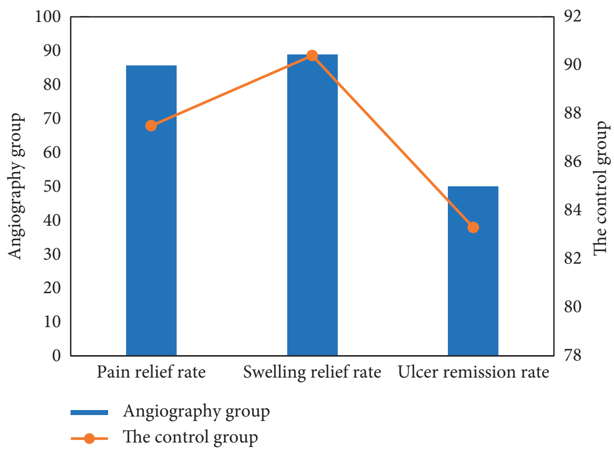

Figure 9: Comparison of pain relief rates between the two groups.

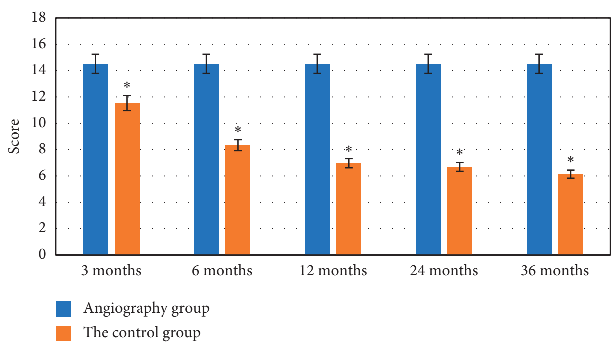

Figure 10: Comparison of VCSS scores between the two groups at 3, 6, 12, 24, and 3 months after treatment. *Significance of the difference.

obvious lumbar vertebra physiology of women and the long-term use of contraceptives in young women. The extent of enteric venous compression stenosis is not well defined. Collateral circulation may be observed by imaging [18].

With the improvement of people's living standard and the progress of medical technology, many people can get a physical examination at a very low cost. Intravenous compression examination is one of the most common items of physical examination. This has also led to an increase in the detection rate of venous compression syndrome. In addition, the same compression site can be identified with different results, depending on the clinician's clinical judgment. In addition, the gap between urban and rural medical level also makes it difficult for the county hospitals to distinguish compression lesions. Experience is likely to lead to overtreatment of patients [19]. It brings unnecessary pain and burden to patients. To solve this problem, an effective deep learning framework was proposed in this research to help doctors identify and judge the disease.

The general structure flowchart of this method was proposed and compared with other backbone networks based on YOLOV3. The dataset for comparison was from our hospital, and 699 ultrasound images of thyroid nodules were eventually collected. The graph features on the test set and detection time were used to evaluate the validity of the model. Then, YOLOV3-DMRF was verified to have the best detection performance. The graph features reached 91.77% in the dataset collected by myself, and the detection time was 4.2 seconds. In the open dataset, the mapping reached 94.72%, and the detection time was 2.3 seconds. To prove the feature extraction effect of the DMRF-CNN, the classification performance of the DMRF-CNN was compared with that of other AI networks. Finally, it was proved that the DMRF-CNN was superior to other CNNs in classification performance based on different evaluation criteria.

5. Conclusion

The contrast-enhanced ultrasound images were used in the treatment of venous compression syndrome. Compared with the lesion site manually delineated by the doctor on the angiography image, the method proposed in this study had little difference in both the therapeutic effect and the convenience of operation. This method significantly shortened the time needed for outlining compared with traditional manual segmentation. In the future, it needs to verify the performance of our model in more centers, CEUS models, and more disease types. In addition, to study various parameters of image formation based on this method, its clinical diagnosis and prognosis prediction need to be further studied.

To analyze the brain CT imaging data of children with cerebral palsy (CP), deep learning-based electronic computed tomography (CT) imaging information characteristics were used, thereby providing help for the rehabilitation analysis of children with CP and comorbid epilepsy. The brain CT imaging data of 73 children with CP were collected, who were outpatients or inpatients in our hospital. The images were randomly divided into two groups. One group was the artificial intelligence image group, and hybrid segmentation network (HSN) model was employed to analyze brain images to help the treatment. The other group was the control group, and original images were used to help diagnosis and treatment. The deep learning-based HSN was used to segment the CT image of the head of patients and was compared with other CNN methods. It was found that HSN had the highest Dice score (DSC) among all models. After treatment, six cases in the artificial intelligence image group returned to normal (20.7%), and the artificial intelligence image group was significantly higher than the control group ($X^2 = 335191$, $P < 0.001$). The cerebral hemodynamic changes were obviously different in the two groups of children before and after treatment. The VP of the cerebral artery in the child was (139.68 ± 15.66) cm/s after treatment, which was significantly faster than (131.84 ± 15.93) cm/s before treatment, $P < 0.05$. To sum up, the deep learning model can effectively segment the CP area, which can measure and assist the diagnosis of future clinical cases of children with CP. It can also improve medical efficiency and accurately identify the patient's focus area, which had great application potential in helping to identify the rehabilitation training results of children with CP.

1. Introduction

Cerebral palsy (CP) is one of the common causes of disability in children. It is the brain tissue damage caused by the immature brain (fetal period to within one year of life) due to congenital malformations or hypoxia, trauma, infection, and other factors after birth, which further causes a group of neurological syndromes in children with nonprogressive movement abnormalities and postural abnormalities as the main manifestations, accompanied by cognition, sensory, and communication disorders and other complications [1]. With the continuous development of perinatal medicine and neonatal life support technology and the improvement of rescue technology, more and more ultrapremature babies are able to survive. These premature babies are extremely immature and face severe challenge such as breathing, nutrition, metabolism, and infection. Their brain damage easily occurs, CP is caused, and the risk of disability is increased [2, 3]. Neuroimaging examination is an important auxiliary examination for central nervous system damage, which can provide objective basis for changes in tissue morphology for clinical diagnosis and treatment. The traditional cranial CT has been widely used in the cranial imaging examination of children with CP and has accumulated certain experience [4]. The other functional imaging examinations developed based on traditional techniques such as magnetic resonance imaging (MRI), ultrasound (US), positron emission tomography (PET), and other devices can assess the function of brain tissue through local blood flow changes, water molecular activity, and metabolic status. The lesions associated with the occurrence of CP were mapped in more detail to provide evidence of functional and metabolic abnormalities for some lesions with insignificant morphological changes. Up to now, medical imaging is an indispensable part of the clinic, and it plays an irreplaceable role in diagnosis and treatment. However, the workload of doctors is huge. Studies showed that, in some cases, general radiologists must make a diagnosis every three to four seconds in an 8-hour working day to meet the needs of the workload [5]. The accuracy of doctors' diagnosis results will be greatly affected by such a large work intensity, and misdiagnosis and missed diagnosis will be caused. However, there are also obvious problems in the current study. (I) The commonly used brain images have millimeter resolution. However, some diseases do not cause significant structural changes and require high resolution and small-scale brain imaging techniques. (II) The sample data only contains a certain kind of special diseases and health data. In actual diagnosis, the patient may suffer from ten related diseases. (III) The excessive number of extracted features consumes a large amount of storage space and at the same time greatly increases the computational complexity and leads to dimensional disaster. (IV) The classification accuracy should be further improved to meet the requirements of practical use. (V) The generalization performance of the classifier is poor, and the prediction effect of the new samples is obviously lower than that of the training samples.

With the development of artificial intelligence (AI), people began to try to use computer technology to assist doctors in diagnosis, which produced a computer-aided diagnosis (CAD) [6]. Taking the most widely used mammography CAD screening as an example, more than 74% of mammograms in the United States were performed with the aid of the CAD system by 2010 [7]. However, the advantages of CAD were questionable; several large trials concluded that there was little benefit from CAD. The accuracy of radiologists' diagnoses was reduced; thus high biopsy rates were caused. To eliminate the false alarms generated by these systems, the diagnostic process becomes more complex [8]. At present, diagnosis based on medical imaging mainly relies on radiologists' manual review of images and manual analysis of radiological images. This is a very time-consuming work, requiring radiologists to consult hundreds of sections and multiple lesions through three-dimensional CT scanning equipment [9]. For early detection, detecting lesions that are "too small to characterize" is particularly important, which requires time and effort on the part of the radiologist. In addition, the increasing huge amount of image data also brings great challenges for image reading. To effectively improve the efficiency of medical image reading, reduce the error rate of diagnosis, and provide effective auxiliary information for imaging physicians, the auxiliary diagnostic technology based on intelligent image analysis is becoming more and more important. In recent years, computer-aided diagnosis based on intelligent image analysis has gradually become a research hotspot in the medical field. Artificial intelligence algorithms have been used in the field of medical image data analysis and processing. By integrating these algorithms into clinical practice, effective and accurate diagnostic results are obtained. The traditional method of intelligent imaging diagnosis compares the automatically labeled or segmented area with the predefined benchmark template, but it still needs the imaging expert to give the final diagnosis result. In the application of disease diagnosis, abdominal CT imaging is the most important imaging means in the clinical diagnosis and follow-up of tumor diseases, which is widely used in the detection, segmentation, and diagnosis of lesions. Since different types of lesions correspond to different characteristics, how to separate the lesion area from the image is the key to the success of the high-precision diagnosis system [10]. To improve the accuracy of the automatic diagnosis system, the medical image assisted diagnosis system based on artificial intelligence mainly includes four aspects as follows: (I) image preprocessing, which improves the image quality and enhances the contrast of lesions; (II) detection and segmentation of the region of interest (ROI), which reduces the influence of interference background on the system; (III) feature extraction, selection, and classification, which improve the characterization ability of the target; (IV) the semantic segmentation of tumor, which can obtain the semantic features of lesions and improve the accuracy of recognition. The extraction of efficient features in the four key steps of the auxiliary diagnosis system is the core technology of the system. At present, the performance of medical image aided diagnosis system based on shallow learning completely depends on the characterization ability of features and the generalization performance of classification diagnosis model.

In short, the development of AI technology has provided new ideas to solve such medical problems. In particular, multidisciplinary knowledge such as radiology and computer science was integrated by imaging omics. High-throughput features can be mined from medical images and modeled and analyzed to provide clinical decision support for rehabilitation training for children with CP.

2. Methods

2.1. Research Object. Children with CP who were outpatient or hospitalized in our hospital from June 2017 to June 2020 were taken as research subjects. A total of 73 cases met the requirements; 44 were males and 29 were females. The age range was 1 to 14 years and the average age was 47.7 ± 37.2 months.

The classification was carried out according to the gross motor function classification system (GMFCS) [11]. There were 8 cases of GMFCS I (4 males, 4 females), 21 cases of GMFCS II (12 males, 9 females), 23 cases of GMFCS III (13 males, 10 females), 11 cases of GMFCS IV (8 males, 3 females), and 10 cases of GMFCS V (7 males, 3 females).

2.1.1. Inclusion Criteria. The abovementioned children met the diagnostic criteria for CP and must meet the following four necessary conditions: (a) nonprogressive aggravating dysfunction that persisted, which was caused by central nervous system damage; children with complications such as muscle damage and joint deformation as the course of CP was prolonged; (b) children with deviations in motor development and abnormal postures (motor development was included or not included); (c) the original reflex not disappearing or the erection reflex and balance response delayed or absent, which may be accompanied by a positive pathological reflex; (d) children with abnormal muscle tone and strength. In addition, there were two reference conditions whether it met the diagnosis of CP: (a) children with a history or risk factors that cause CP; (b) children with cranial imaging evidence.

2.1.2. Exclusion Criteria. The exclusion criteria included (a) the diagnosis of abnormal motor development in children that was consistent with general developmental retardation and developmental coordination disorder; (b) children with induced epileptic seizures caused by acute ketoacidosis, water and electrolyte disorders, acute brain injury, febrile convulsions, hypoglycemia, and drug poisoning, etc.; (c) children with metal implants or other contraindications for CT examination; (d) children with abnormal motor function caused by other genetic metabolic reasons; (e) children with motor dysfunction and epileptic seizures caused by tumors, peripheral neuropathy, and genetic metabolic diseases, etc.

A total of 73 children with CP met the above inclusion criteria and were included in the research. The research had been approved by the medical ethics committee of *X* hospital, and the informed consent form had been signed by the families of the children involved in the research.

2.2. Experimental Equipment. 74 contrast-enhanced CT samples constituted the dataset of the research. The Philips Brilliance 1281 CT scanner (Philips Healthcare, Amsterdam, Netherlands) was used. The tube voltage and current were 120 kV and 220 mA, respectively, the size of the collimator was 64×0.625 mm, and the Fov was 20×20 cm. The 512×512 size imaging matrix was used, the pixel size range was 0.58 to 0.98 mm, and the reconstruction interval was 5 mm. All scans were manually segmented by two radiologists using Itk snap software (version 3.4; http://www.itksnap.org), and the segmentation differences were resolved through discussion until a consensus was reached. The data set was randomly divided into three subsets, and 84, 20, and 30 samples were included for training, verification, and testing, respectively.

2.3. Experimental Environment

2.3.1. CNN Model. The proposed CNN model is shown in Figure 1, which was similar to 3D U-NET. The image features can be extracted layer by layer by the encoder, and the segmentation map can be generated by the decoder. The 3D U-Net was modified to be suitable for this task. In the original 3D U-Net, there were two $3 \times 3 \times 3$ convolutions included in each level, which was replaced by two modules. To reduce the size of the feature map, the step S3D convolution was used to replace the pooling operation. The goal of the decoder was generating high resolution feature maps. First, the feature graph was upsampled, and then the upsampled feature graph was cascaded with the feature graph from the corresponding level of the encoder. After cascading, the MSC module was used to adjust the number of feature graphs. The lightweight 3D CNN had fewer parameters and computational costs compared to the original 3D U-NET.

2.3.2. Deep Learning Mode. The Python deep learning framework was used to write code, which was trained on NVIDIA GeForce GTX 1080TIGPU. There were 100 training cycles and the training time was about 12 hours. The Adam optimizer was used with an initial learning rate of 0.001. The GDL loss function similar to the previous chapter was used to optimize network parameters. If the validation set loss was not decreased in the last 20 training cycles, the learning rate was reduced to 1/5 of the original. The rotation, scaling, deformation, mirroring, and other data were not used to enhance technology to focus on the impact of network structure. The LeakyReLU was used as the activation function. The negative part of the feature information can be retained by LeakyReLU to prevent falling into a local minimum compared with the standard ReLU. For 2D CNN, batch normalization was used to reduce internal covariant offset problems. For 3D CNN, a number of criteria were calculated using instance normalization as performance indicators to quantify the segmentation results, including DSC, sensitivity, and positive predictive value (PPV).

2.4. Comparative Test with 3DCNN Method. Compared with the 3D CNN method, each CT was first resampled to $256 \times 256 \times 64$ to maximize the utilization of 11 GB of GPU memory. In the decoder, each layer was composed of a trilinear upsampling layer with a factor of two, followed by two $3 \times 3 \times 3$ convolutions, and instance normalization and LeakyReLU were used to activate each layer. The jump connection was used to provide the decoder with spatial information from the encoder. Finally, the nearest neighbor sampling was used to upsample the segmentation result to the size of $512 \times 512 \times 64$.

2.5. Treatment Methods. The physical therapy (PT), occupational therapy (OT), and speech therapy (ST) were used as the main treatment methods. The selected method was Bobath's method to suppress the abnormal posture, abnormal posture reflex, and abnormal movement patterns of children with CP. The facilitating techniques were used to promote cervical erection, sitting erection, standing erection, and static and dynamic balance in children with CP. The German Voyt method was selected to perform reflex movement of the body to promote normal motor development and induce training with reflex turning over and reflex abdominal crawling. According to the child's condition, one-to-one rehabilitation training was carried out by

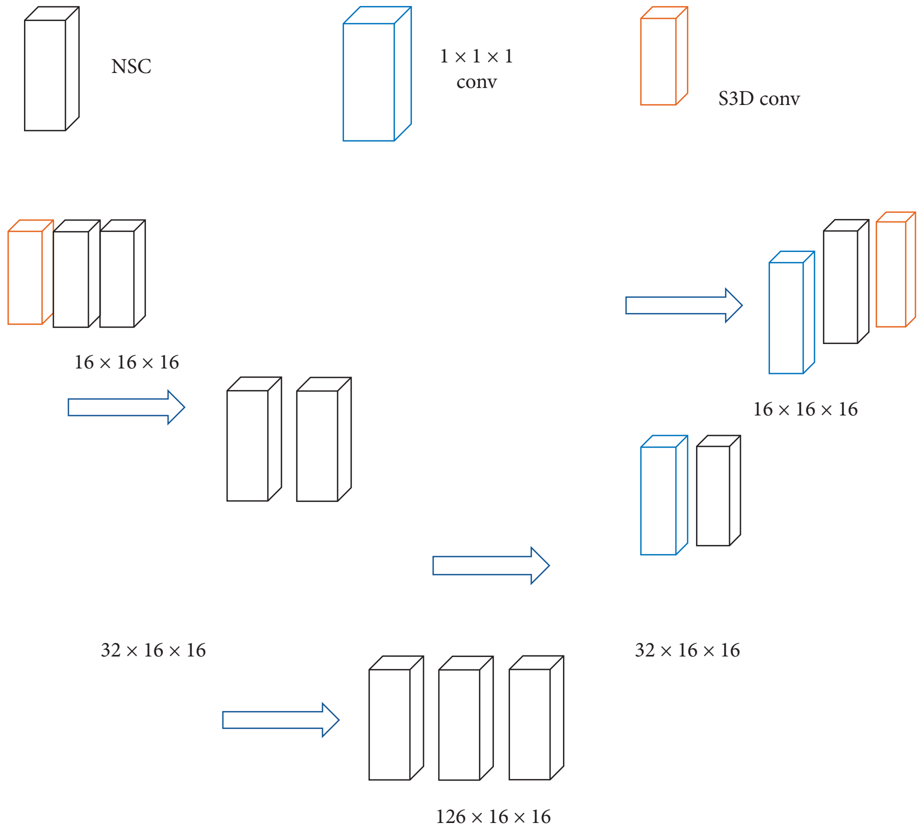

Figure 1: CNN model.

the rehabilitation therapist. The training was one to two hours a day, and 90 days was a course of treatment. The rehabilitation training for children with mild CP was one to two courses, and the rehabilitation training for children with severe CP was three to four courses.

2.6. Observation Indicators. Before and after treatment, the cerebral artery blood flow velocity (VP) and the vascular pulse index (PI) of the children in both groups were examined by Libong CBC-II transcranial doppler (TCD) cerebrovascular ultrasound to understand the recovery of cerebral blood circulation. The routine EEG and single photon emission cranial computed tomography (SPELT) were performed before and after treatment to assess cerebral perfusion and neuronal functional status. The CT scans of the head were performed after three to six months of treatment to observe the morphological and structural recovery of the brain. The development quotient (DQ) of the children was assessed using the Geisel method to assess the children's social adaptability, personal social ability, language ability, general motor, and fine motor recovery before and after treatment.

2.7. Statistical Analysis. SPSS 20.0 was used for statistical analysis of the data. Measurement data such as body weight and scores were expressed as mean ± standard deviation, and *t*-test was used to compare the data of normal distribution between the two groups. When three groups or more were compared, analysis of variance was carried out first, and then pairwise comparison was made. Enumeration data were expressed as percentage (%), and comparison between two groups was performed by χ^2 test or corrected χ^2 test. $P < 0.05$ was considered statistically significant.

3. Results

3.1. Comparative Test with 2DCNN Method. It was compared with 2D CNN method. The 2D models allowed larger images as input than 3D models (Figure 2). Therefore, full-resolution CT slices were used to collect detailed contextual information. The 2D CNN similar to 3D CNN was constructed, and the difference was that 3D convolution was replaced with 2D convolution. The 3D trilinear upsampling layer was replaced with 2D bilinear upsampling layer, and batch normalization was used in convolution.

3.2. Segmentation Results in Different Ways. Figures 3 and 4 show the segmentation results of 2D CNN and 3DCNN on the test set, respectively. The blue represented the gold standard for segmentation, and the red represented the result of automatic segmentation. These segmentation results indicated that 3D CNN can segment cancer regions more accurately than 2DCNN.

3.3. Comparative Experiment of Loss Correspondence Teaching. The choice of loss function was crucial to obtain accurate segmentation results when dealing with serious

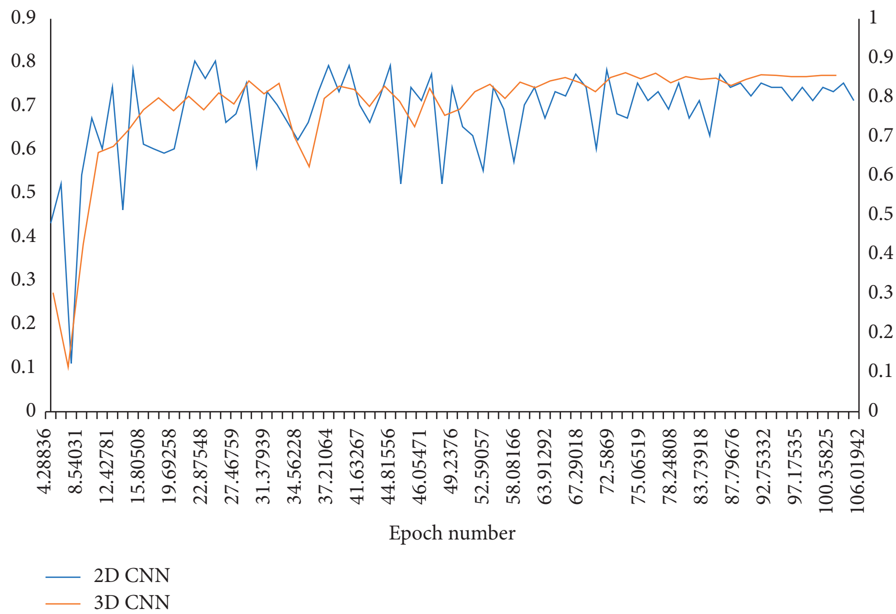

Figure 2: The average validation set DSC of 2D CNN and 3D CNN in 100 training cycles.

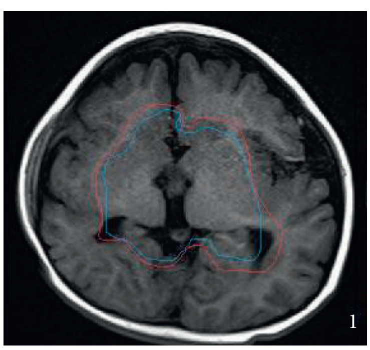

Figure 3: 2D CNN.

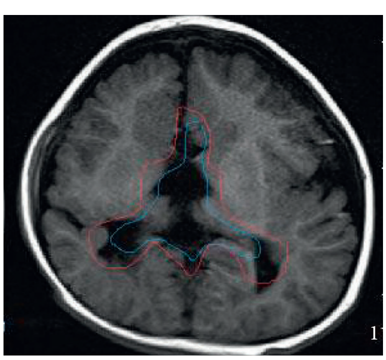

Figure 4: 3D CNN.

category imbalance. The GDL loss function was used to solve the class imbalance problem in CT images. Since many works proved that Dice loss can obtain more reliable results than cross-direction loss, there was a performance difference between Dice loss and GDL loss. Figures 5 and 6 show the average DSC on the validation set, and the loss of the model trained with GDL was smaller than the loss of the model trained with Dice. The DSC curve of the model's validation set was smoother when GDL was used for training, which indicated that GDL was more stable for CT image segmentation.

3.4. Quantitative Results of the Test Set. Figure 7 shows the quantitative results of the test set. The model with Dice loss training had lower DSC, lower PPV, and higher sensitivity compared with HSN, but all the deviations were large. The results showed that the problem of category imbalance can be effectively solved by GDL.

3.5. Spatial Convolution Contrast Experiment. The goal of 2D CNN was providing fine-grained semantic information about smaller and less salient objects for accurate segmentation. Therefore, the high spatial resolution must be retained in the output feature map. A simple reduction of the pooled or stepped convolution layer resulted in a reduction of the receptive field. Therefore, the cavity convolution was proposed to enlarge the receptive field and the resolution of the feature map was maintained. To study whether the hole convolution helped to learn fine-grained semantic information, it was compared with the standard 2D convolution version (HSN-N). The standard 2D convolution version (HSN-N) had the same architecture as HSN, but all 2D convolution layers did not use hole convolution. The convolution kernels with large void ratios may be too sparse to capture local features, which led to the "grid problem." To investigate the effect of large void rate on segmentation performance, another HSN model (2D HSN-L) with larger void rate was evaluated. The void rate of the original HSN was increased from three to five by this model. Figure 8 shows the qualitative segmentation results of different experiments on the test set. The blue represented the gold standard, and red represented the result of automatic

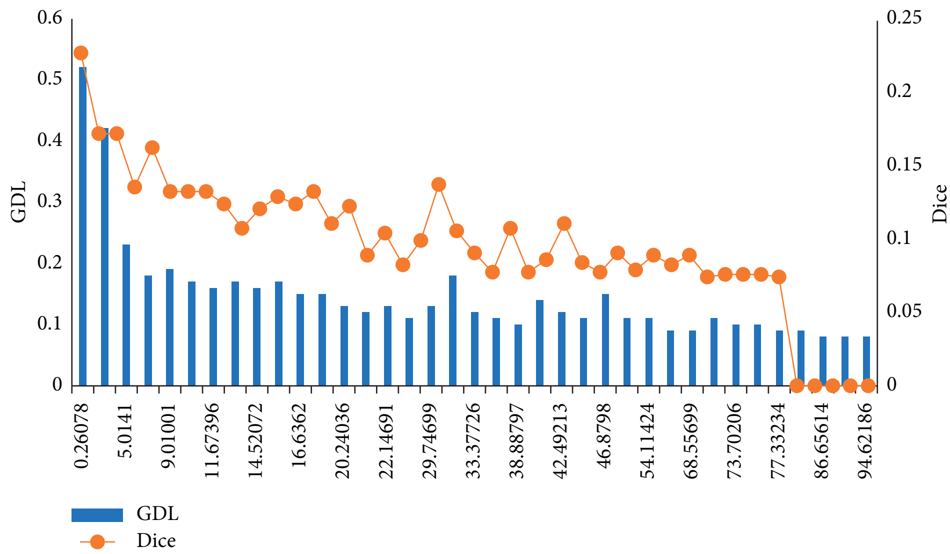

Figure 5: Training process of different loss function.

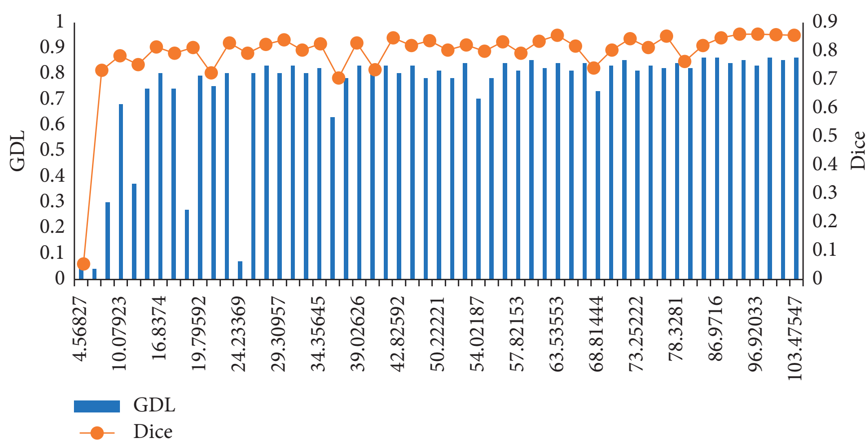

Figure 6: The average DSC of the verification set of different loss functions.

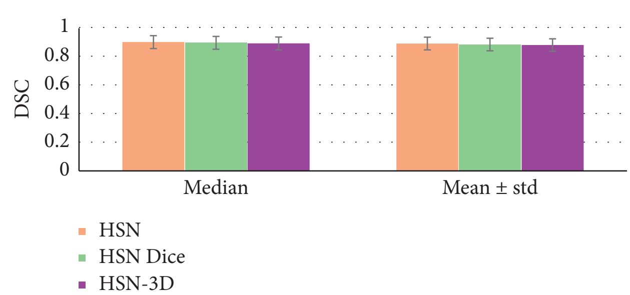

Figure 7: Quantitative results of the test set.

segmentation. These segmentation results showed that HSN performed well in segmenting lung cancer even in a small area. This was because the model can learn remote 3D context information and fine-grained 2D semantic information.

3.6. Results of Children's Rehabilitation Data. The SPECT examination showed hypoperfusion of cerebral blood flow and decreased functional activity of neurons in the treatment group before treatment, and 27 cases returned to normal after treatment (96.4%). There were 29 cases of

(a) (b) (c)

Figure 8: Qualitative segmentation results of different experiments on the test set (red was the artificial segmentation area, and blue was the model segmentation area). (a) HSN; (b) HSN-Dice; (c) HSN-S3D.

hypoperfusion of cerebral blood flow and decreased functional activity of neurons in the control group before treatment, and 6 cases returned to normal after treatment (20.7%). The return to normal rate of SPECT in the treatment group was significantly higher than that in the control group (XPINGFANG = 33 5191, $P < 0.001$). The cerebral hemodynamic changes of the two groups of children before and after treatment showed that VP of the cerebral artery in children was (139.68 ± 15.66) cm/s after treatment, which was significantly faster than that before treatment (131.84 ± 15.93) cm/s, $P < 0.05$. The cerebral artery PI of the children was 0.91 ± 0.19 after treatment, which was significantly lower than that of 1.18 ± 0.24 before treatment, $P < 0.05$. However, in the control group, the cerebral artery VP and PI of the children had no significant difference before and after treatment, $P > 0.5$. After treatment, there were significant differences in VP and PI between groups ($P < 0.05$). The changes in DQ of the two groups of children before and after treatment are shown in Figure 9. The difference of GM FM scale scores before and after treatment in the two groups of children is shown in Figure 10.

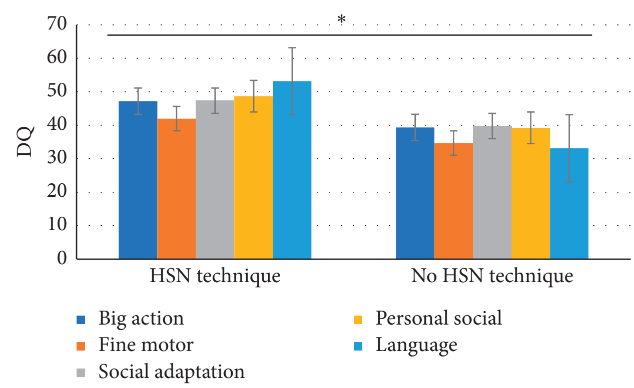

Figure 9: Changes in DQ of the two groups of children before and after treatment (*indicated significant difference.).

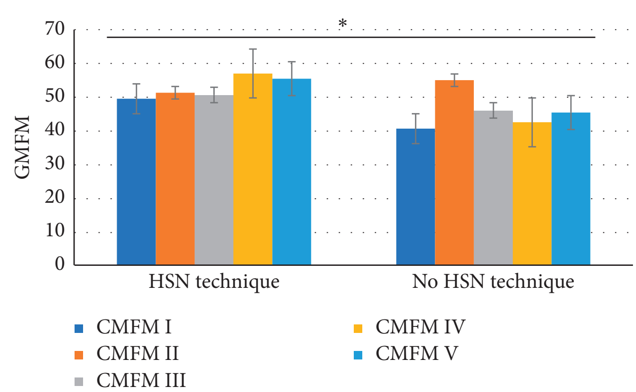

Figure 10: Difference of GM FM scale scores before and after treatment in the two groups of children (*indicated significant difference).

4. Discussion

A large amount of image data was generated in the process of diagnosis and treatment of CP lesions. These data were usually subjectively evaluated by doctors based on experience, and then the corresponding diagnosis and treatment plan were made. However, the features observed by doctors with only naked eyes from image data were very limited, and the potential of image data was often not fully utilized. For many years, the quantitative information that was not available to the human eye was extracted by many scholars with the help of complex mathematical and statistical algorithms, based on which the corresponding diagnosis and treatment plan were carried out, and even the progress of the disease was predicted. The image omics came into being with the development of AI technology. The machine learning algorithms were used to mine high-throughput features from medical images and perform modeling analysis [12]. More and more evidence showed that imaging omics can be used for the quantitative characterization of CP lesions for the diagnosis, treatment planning, and prognosis of the disease. Thus, an important research direction of AI technology in the field of medical applications was constituted [13–17].

In recent years, with the rise of deep learning technology and computer vision technology, it has become more and more urgent to develop automatic segmentation algorithms with high accuracy and high stability [9]. The problem of CT image segmentation was studied based on the brain MRI and lung CT images and the use of deep learning technology. In addition, for the grading of brain lesions, the impact of deep learning segmentation results and manual segmentation results on imaging omics research was compared in the research. For the prediction of chemotherapy outcomes in patients with CP, imaging omics models were also constructed and analyzed in combination with clinical features. The reproducibility of imaging omics research was still an unresolved problem, and the clinical application of imaging omics was greatly affected by this problem. Studies showed that more than 90% of research had not undergone rigorous external verification and lacked multicenter diversity data [18, 19]. A hybrid segmentation network based on deep learning (HSN) was used for CT brain image segmentation and the accuracy of image analysis of brain cell function in children with CP can be improved. The language function, motor function, cognitive function, language quotient, great motor development quotient, fine motor development quotient, personal social, and social adaptation development of the brain of children with CP in the HSN group were significantly improved after treatment compared to before treatment.

In this research, a hybrid segmentation network HSN based on deep learning was proposed for CT brain tissue image segmentation. CT images often have higher resolution than MRI images. How to segment CT images effectively is always a difficult problem. HSN can effectively solve this problem. HSN includes a lightweight 3D CNN and a refined 2D CNN. 3D CNN uses desampled images and spatio-temporal separable 3D convolution to reduce memory requirements and computational costs. 2D CNN can learn fine-grained semantic information while maintaining a high spatial resolution. A hybrid feature fusion module was proposed to effectively integrate 2D and 3D features. This network structure combines the advantages of 3D CNN learning long-range contextual information and 2D CNN learning semantic information. The results showed that this model can segment CP lesion area accurately on CT images. The development of deep learning and imaging omics has promoted the progress of medical imaging. Radiology using artificial intelligence can automate certain clinical tasks to some extent. In addition, it can reduce the heavy workload of doctors and improve the diagnostic efficiency, so as to optimize the allocation of social medical resources. However, there are still some shortcomings, which need to be further strengthened in the future. For example, traditional image omics feature extraction methods have certain limitations without adoption of deep learning in feature extraction. Deep learning methods, especially CNNs, can learn rich texture information from medical images in a hierarchical manner. Deep features have a more powerful feature representation than hand-designed features. In the future work, we will carry out related studies on feature extraction based on deep learning to further explore the potential of image data.

5. Conclusion

In this study, a hybrid segmentation network HSN based on deep learning was proposed for CT brain tissue image segmentation. After treatment, six patients in the artificial intelligence group returned to normal (20.7%), which was significantly higher than the control group ($X^2 = 335191$, $P < 0.001$). Cerebral hemodynamic changes were obvious in both groups before and after treatment. VP of the cerebral artery was (139.68 ± 15.66) cm/s after treatment, which was greatly faster than that before treatment (131.84 ± 15.93) cm/s, $P < 0.05$. In general, the deep learning model can effectively segment the CP area and assist in the clinical case measurement and diagnosis of future CP children. In addition, the deep learning model can improve medical efficiency and accurately identify patients' focal areas, which has great application potential in helping to identify the rehabilitation training results of children with CP.

The objective of this study was to explore the diagnosis of severe sepsis complicated with acute kidney injury (AKI) by ultrasonic image information based on the artificial intelligence pulse coupled neural network (PCNN) algorithm. In this study, an algorithm of ultrasonic image information enhancement based on the artificial intelligence PCNN was constructed and compared with the histogram equalization algorithm and linear transformation algorithm. After that, it was applied to the ultrasonic image diagnosis of 20 cases of severe sepsis combined with AKI in hospital. The condition of each patient was diagnosed by ultrasound image performance, change of renal resistance index (RRI), ultrasound score, and receiver operator characteristic curve (ROC) analysis. It was found that the histogram distribution of this algorithm was relatively uniform, and the information of each gray level was obviously retained and enhanced, which had the best effect in this algorithm; there was a marked individual difference in the values of RRI. Overall, the values of RRI showed a slight upward trend after admission to the intensive care unit (ICU). The RRI was taken as the dependent variable, time as the fixed-effect model, and patients as the random effect; the parameter value of time was between 0.012 and 0.015, $p = 0.000 < 0.05$. Besides, there was no huge difference in the ultrasonic score among different time measurements ($t = 1.348$ and $p = 0.128 > 0.05$). The area under the ROC curve of the RRI for the diagnosis of AKI at the 2nd day, 4th day, and 6th day was 0.758, 0.841, and 0.856, respectively, which was all greater than 0.5 ($p < 0.05$). In conclusion, the proposed algorithm in this study could significantly enhance the amount of information in ultrasound images. In addition, the change of RRI values measured by ultrasound images based on the artificial intelligence PCNN was associated with AKI.

1. Introduction

Acute kidney injury (AKI) refers to a clinical syndrome caused by a rapid decline in renal function within a short period that led to various etiologies. It can occur in people without previous kidney disease or in patients with existing chronic kidney disease [1]. AKI is a common emergency and critical illness, and its prevalence in ordinary hospitalized patients is 3–5%. Moreover, the prevalence of AKI is as high as 30–50% in the intensive care unit (ICU) [2]. Although blood purification technology is constantly being updated, the mortality rate of patients with AKI has not been markedly reduced, which is an acute and critical disease in kidney disease [3]. The early course of AKI is reversible, but its treatment window is narrow. Once the injury period is entered, the incidence of death or uremia will exceed 30% [4]. Therefore, the early diagnosis of AKI, the improvement of the treatment effect of AKI, and the reduction of the mortality rate of AKI have a very critical scientific value and clinical significance.

In patients with AKI, Doppler ultrasound (DU) is often adopted to determine the renal resistance index (RRI) of the renal interlobular artery [5]. Bragato et al. [6] reported that RRI could assess the renal function of patients with AKI. Most importantly, RRI is correlated with renal vascular resistance, renal vascular compliance, renal blood flow, oxygen partial pressure, renal interstitial pressure, and other aspects, most of which are risk factors for AKI, so it can be used to effectively evaluate AKI [7]. In recent years, Kim et al. [8] have shown that DU can be used for the early diagnosis of kidney injury in patients with severe sepsis. DU can evaluate the ultrasound score of patients in a semiquantitative manner, and the operation is simple. However, there are few reports on the application of DU to evaluate the renal function of patients with severe sepsis and AKI [9].

The artificial intelligence pulse coupled neural network (PCNN) algorithm can construct neuron mapping into a phase-based model, which carries information not only the pulse frequency but also a sign of the transmission channel [10]. The artificial intelligence PCNN makes the way of selecting communication routes and the construction of computers simpler and more effective. Compared with other neural network models, the PCNN is more practical. The artificial intelligence PCNN uses a single-layer neural network model, which can be directly applied to image segmentation, pattern recognition, and image fusion without training [11]. Lotfinejad et al. [12] have adopted the artificial intelligence PCNN to image processing, finding that the PCNN had the advantages of constant signal strength, constant rotation, and constant scale under weak connection conditions.

In this study, the artificial intelligence PCNN algorithm was compared with the histogram equalization algorithm and linear transformation algorithm. Then, they were applied to the ultrasound images of 20 patients with severe sepsis combined with AKI, aiming to explore the ultrasound image characteristics of severe sepsis combined with AKI. Therefore, it could provide a reliable reference basis for early diagnosis and early treatment of clinical AKI patients.

2. Materials and Methods

2.1. Research Objects. In this study, 20 patients diagnosed with severe sepsis and AKI in the hospital from December 2018 to October 2019 were selected as the research objects. Besides, all of them underwent ultrasound examinations. There were 13 males and 7 females, with an average age of 48.69 ± 12.47 years. This study had been approved by the ethics committee of the hospital, and the research objects included in this study and their family members signed the informed consent forms.

The criteria for inclusion were defined to include patients who met the diagnostic criteria for severe sepsis, with tissue hypoperfusion and renal dysfunction caused by sepsis, can undergo the assisted breathing treatment through a ventilator, and were 18–75 years old.

The criteria for exclusion were defined to include patients who were younger than 18 years old, were in the recovery period of AKI, were accompanied with obstructive renal failure, intraabdominal hypertension, arrhythmia, and other diseases that would affect the value of RRI, suffered from chronic renal insufficiency, and were combined with heart, spleen, and cardiovascular and cerebrovascular diseases.

2.2. Construction of Ultrasound Images Based on Artificial Intelligence Pulse Coupled Neural Network Algorithm. Figure 1 shows the artificial intelligence PCNN algorithm model. When the PCNN processed the images, it was a single-layer two-dimensional network. The number of neurons was consistent with the number of pixels in the output image. The pixel intensity of the gray-scale image was the excitation condition of the neuron. The surrounding input neurons connected with each output neuron to form an image processing system based on the PCNN algorithm. In this study, a threshold $F_{i,j}$ was constructed to represent the Mach band effect. The Laplacian operator $L = \begin{bmatrix} -1 & -1 & -1 \\ -1 & 6 & -1 \\ -1 & -1 & -1 \end{bmatrix}$ was convolved with the gray-scale image of the input excitation, so that the size of the threshold $F_{i,j}$ was redefined as follows.

$$F_{i,j}(0) = \mathrm{BPG} - \mathrm{CPG}_{i,j}. \tag{1}$$

In equation (1), BPG represents the gray value of the brightest pixel of the original image input, and $\mathrm{CPG}_{i,j}$ represents the gray value of the neuron (i, j) point image after convolution processing. The network output of the PCNN was transformed into the gray-scale excitation value perceived by the network to obtain the final enhanced image. Besides, the equation was as follows.

$$\mathrm{EIG} = \mathrm{In}(\mathrm{BPG}) - \tau (S(i, j) - 1). \tag{2}$$

In equation (2), EIG represents the gray value of the enhanced image, BPG represents the brightest pixel gray value of the original image input, $S(i, j)$ represents the ignition timing of the neuron (i, j), and τ represents the attenuation constant.

The specific steps of the PCNN algorithm included the following.

Step 1: first, the parameters of the PCNN were set, and the number of cycles was set as M, so that all neurons were in the inhibited state. The gray value of the PCNN algorithm image was calculated to construct the matrix S of neuron ignition time and determine the threshold $F_{i,j}$. The specific algorithm flow steps were expressed in the following equations.

$$F_{i,j}[m] = S_{i,j}[m], \tag{3}$$

$$R_{i,j}[m] = W_L \sum VY[m], \tag{4}$$

$$U[m] = F_{i.j}[m]\left(1 + \alpha R_{i,j}[m]\right), \tag{5}$$

$$Y_{i,j}[m] = 1, \quad \text{if } U[m] > F_{i,j}[m] \text{ or otherwise}, \tag{6}$$

$$F_{i,j}[m] = \exp(-\tau) \times F(i, j) + W_E \times Y(i, j). \tag{7}$$

In the above equations, the PCNN parameters $\alpha = 0.2, \tau = 0.7, W_L = 1, W_F = 278$, $F_{i,j}$ represents the dynamic threshold, m represents the number of

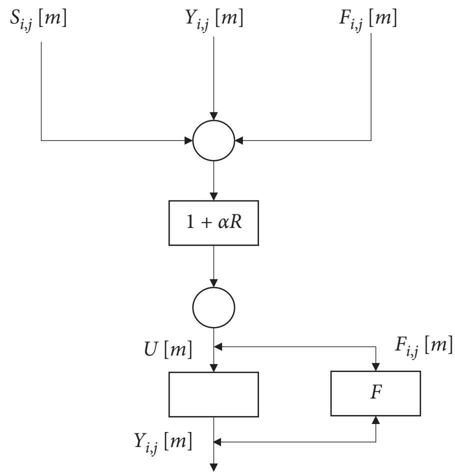

Figure 1: Artificial intelligence PCNN algorithm model.

iterations, $S(i, j)$ represents the ignition timing of the neuron (i, j), $R_{i,j}[m]$ represents the feedback input of the neuron (i, j)'s m^{th} iteration, $Y_{i,j}[m]$ represents the feedback output of the neuron (i, j)'s m^{th} iteration, α represents the strength constant of links between synapses, $U[m]$ represents the internal activity item, W_L represents the amplitude constant of $F_{i,j}[m]$, and W_F represents the threshold decay time coefficient.

Step 2: the neuron ignited at a certain moment and could output a pulse to record the ignition moment in S. The threshold of the neuron was taken as the maximum value to inhibit the occurrence of reignition. What is more, the equations are given as follows:

$$S_{i,j}[m] = m, \quad \text{if } E_{i,j}[m] = 1, \text{mark}_{i,j}[m] = 0, \tag{8}$$

$$\text{mark}_{i,j}[m] = \infty i, \quad \text{if } E_{i,j}[m] = 1, \text{ otherwise } 0, \tag{9}$$

$$E_{i,j}[m] = \infty, \quad \text{if } Y_{i,j}[m] = 1. \tag{10}$$

Step 3: if one of the neurons ignited, the final output value was 1, and the gray value of the image could be enhanced according to equation (2).

Step 4: all gray values were processed, so it would be ended; otherwise, return to Step 2.

2.3. Ultrasound Scoring Standards for Severe Sepsis Patients Combined with Kidney Injury. The diagnostic criteria of severe sepsis combined with AKI in this study referred to the diagnostic criteria of severe sepsis in the 2012 Scientific Steering Committee (SSC) guidelines [13]. The patients received the DU examinations, and their ultrasound images were saved in ultrasound equipment, which was scored (DU scoring) by 3 physicians who were specially trained in emergency and critical ultrasound. Using a 0–3 semi-quantitative scoring standard, the ultrasound scoring was as follows. 0 point indicated that no renal blood vessels could be detected, 1 point meant that a few blood vessels could be observed in the renal hilum, 2 points showed that interlobular blood vessels could be observed in the renal parenchyma, and 3 points presented that the renal arcuate artery level could be found in the kidney.

2.4. Renal Ultrasound Examination. Within 24 hours of entering ICU, each patient was given with renal ultrasound examination when the hemodynamics was stable. The patients were detected through ultrasound once a day for 7 consecutive days until they left the ICU. Besides, the ultrasound examinations were conducted by the physicians who were specially trained in emergency and critical ultrasound and were not involved in the treatment. The Vivid i portable Doppler ultrasound (produced by GE, USA) was employed to explore the kidneys on both sides of the patient, and a 5 Hz ultrasound probe was adopted to observe whether the kidneys had contusions or hematomas and whether there was damage to the bilateral renal arteries. Finally, RRI was measured, first on the right kidney and then on the left.

The measurement of RRI was as follows. First, the protruding probe was used for the detection of the patient's abdomen, and the long axial section of the kidney was intercepted from the posterolateral position of the two-dimensional ultrasound. Doppler was applied to identify the renal vessels to locate an interlobular artery. Then, the minimum Doppler sampling gate 3–6 mm and minimum pulse repetition frequency (PRF) where graphics did not overlap were set to obtain 4–6 consecutive similar spectra. Moreover, statistical measurements of the peak systolic velocity (SV) and the minimum diastolic velocity (DV) were made to calculate the RRI of each spectrum. In addition, the RRI for each spectrum could be calculated by the following equation.

$$\text{RRI} = \frac{(\text{SV} - \text{DV})}{\text{SV}}. \tag{11}$$

In equation (11), SV represents the peak flow velocity in the systolic period and DV represents the lowest diastolic flow rate. Furthermore, the average value of the RRI was taken after 4–6 measurements.

2.5. Statistical Methods. The test data processing was carried out using SPSS20.0 statistical software. The measurement data were expressed as the mean ± standard deviation ($\overline{x} \pm s$), and the t-test was used for the comparison of the average values between each group. The count data were represented by the percentage (%), and the χ^2 test was used. The RRI at different time points was used as the diagnostic evaluation test to draw the ROC and determine the optimal critical value of RRI for the diagnosis of AKI. What is more, the AUC of ROC was compared between each time point. In addition, $p < 0.05$ indicated that the difference was statistically substantial.

3. Results

3.1. Ultrasound Image Quality Evaluation Results Based on Artificial Intelligence Pulse Coupled Neural Network Algorithm. Figure 2 shows the ultrasound images of

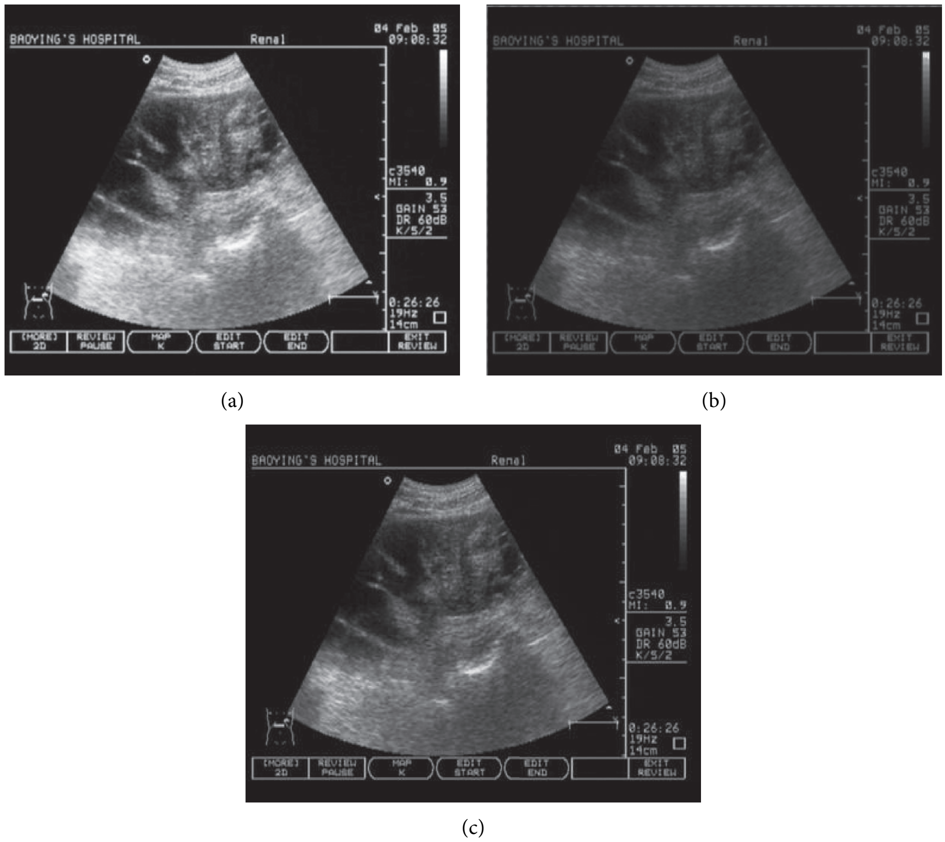

Figure 2: The ultrasound images of (a) histogram equalization, (b) linear transformation algorithm, and (c) artificial intelligence PCNN algorithm.

equalization, linear transformation algorithm, and artificial intelligence PCNN algorithm. The results showed that histogram equalization was a global image enhancement algorithm that could extend the gray scale of low-brightness ultrasound images, and eventually, over-enhancement occurred. The transformation function adopted by the linear transformation algorithm was relatively simple, and the final imaging effect was not ideal. The artificial intelligence PCNN algorithm proposed in this study not only considered the global information but also enhanced the local information. After enhancement, the gray value of the ultrasound image was evenly distributed near the gray value sensitive to the human eye, and the overall image effect was suitable for direct observation with naked eyes.

The histograms of AKI, histogram equalization, linear transformation algorithm, and artificial intelligence PCNN algorithm are shown in Figure 3. To verify the effectiveness of the artificial intelligence PCNN algorithm, it was compared with the equalization method and the linear transformation algorithm. It was found that the histogram of the equalization method was mainly concentrated in a large area and the distribution was relatively uniform, but there was the enhancement after the image was enhanced, and the overall image effect was not very good. The linear transformation algorithm was mainly concentrated in the darker area, the enhancement was not obvious, and the overall effect was not good. The histogram of the artificial intelligence PCNN algorithm was relatively evenly distributed, and each gray level was retained, with significantly enhanced ultrasound image information, which was convenient for the medical diagnosis of AKI. Therefore, it showed that the artificial intelligence PCNN algorithm was the best among the three algorithms in enhancing the information content of the ultrasonic images.

3.2. General Information of Patients with Severe Sepsis Combined with Acute Kidney Injury. Figure 4 shows the general data of patients with severe sepsis combined with AKI. In this study, there were a total of 20 severe sepsis patients with AKI, including 13 males (65%) and 7 females (35%), with an average age of 48.69 ± 12.47 years. The patient's injury severity score (ISS) was 32.5 ± 8.9 points, and the acute physiology and chronic health status score II (APACHE II score) was 16.2 ± 9.4 points. Among them, 7 cases (35%) were injured by road traffic accidents, followed by 4 cases (20%) injured by falling from a height, 3 cases (15%) injured by heavy objects, 2 cases (10%) injured by beatings, 3 cases (15%) with machine strangulation injuries, and 1 case (5%) with explosion injury. Finally, 3 cases died, 1 case died of hemorrhage at the trauma site, 1 case died of severe sepsis, and 1 case died of multiple organ failure after severe head injury.

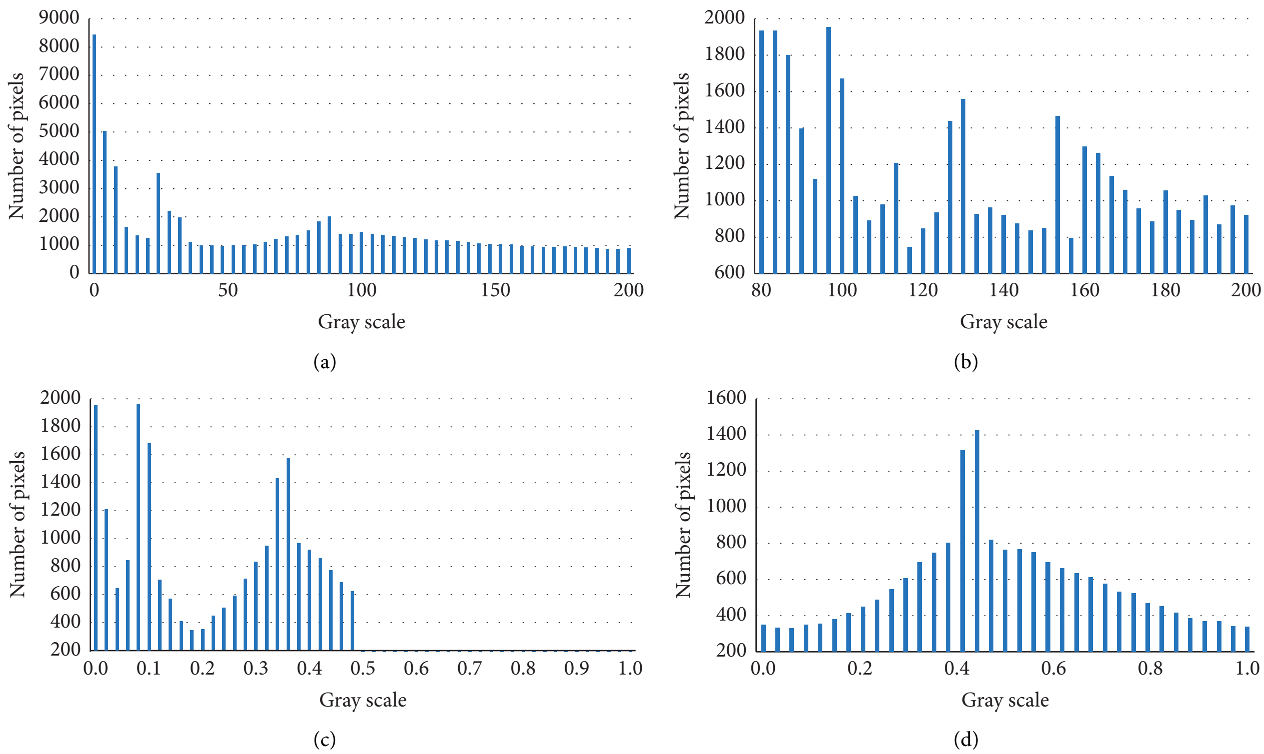

Figure 3: The histograms of (a) severe sepsis with AKI, (b) histogram equalization, (c) linear transformation method, and (d) artificial intelligence PCNN algorithm.

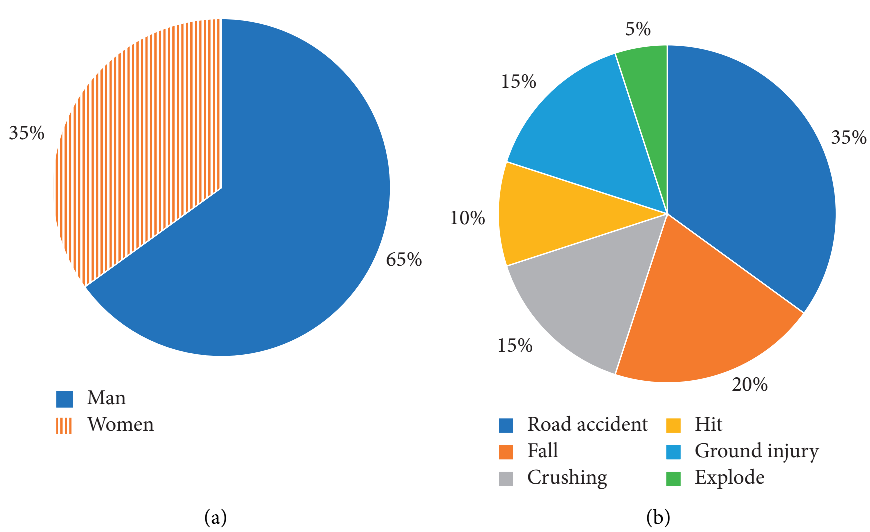

Figure 4: General data of patients with severe sepsis combined with AKI. (a) Ratio of male to female in severe sepsis patients with AKI. (b) Types of injury in severe sepsis patients with AKI.

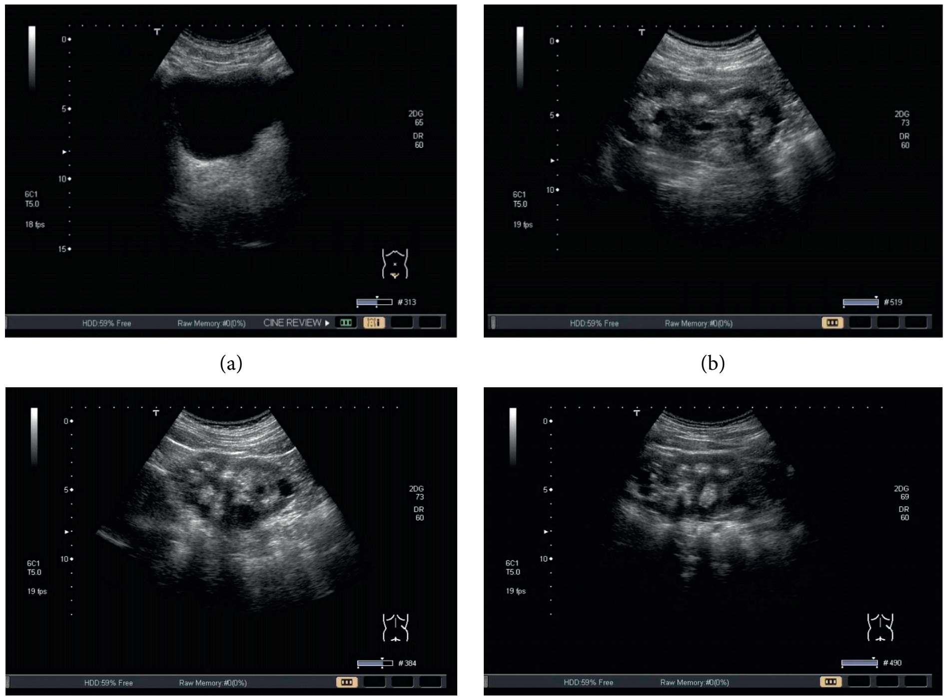
3.3. Ultrasound Image Performance Characteristics Based on Artificial Intelligence Pulse Coupled Neural Network Algorithm. The ultrasound images based on the artificial intelligence PCNN algorithm are shown in Figure 5. Ultrasound is an important method for diagnosing AKI and judging the prognosis. Whether it was glomerular sclerosis, renal tubular atrophy, interstitial fibrosis, or inflammation, ultrasound imaging showed enhanced cortical echo. The cortex became thinner and the echo was enhanced; the renal cortex and the medulla echo were not demarcated; the focal cortex was thinned; the echo was enhanced, with the uniform structure, and the renal parenchyma and the renal sinus could not be distinguished by naked eyes; the cortical echo was enhanced, and the upper pole of the kidney was



(a) (b) (c) (d)

Figure 5: Ultrasound images based on artificial intelligence PCNN algorithm. (a) Ultrasound image of renal cortex thinning and echo enhancement. (b) Ultrasound image of renal cortex and medulla echo being unclear. (c) Cortical echo enhancement and an ultrasound image of renal enlargement. (d) Ultrasound image of renal inferior pole laceration and subcapsular effusion.

unclear; the cortex echoes enhanced, and the kidneys enlarged; the lower pole of the kidney was lacerated, and the subcapsular fluid was accumulated.

3.4. Changes in Ultrasound Renal Resistance Index in Severe Sepsis Patients Combined with Acute Kidney Injury. Figure 6 includes the two graphs showing the changing trend of ultrasound RRI in patients with severe sepsis combined with AKI. According to the changing trend in the figure, there were obvious individual differences in RRI; on the whole, RRI indicated a slight upward trend after the patient entered ICU.

The analysis results of the linear mixed model of RRI and time are presented in Table 1. The RRI was used as the dependent variable, time was used as a fixed-effect model, and the patient was treated as a random effect. The parameter value of time was 0.012–0.015, $p < 0.001$, which verified that RRI would increase over time. Among them, 2 patients had AKI after entering ICU, 1 patient had a marked increase in RRI after AKI, and 1 patient showed a significant downward trend.

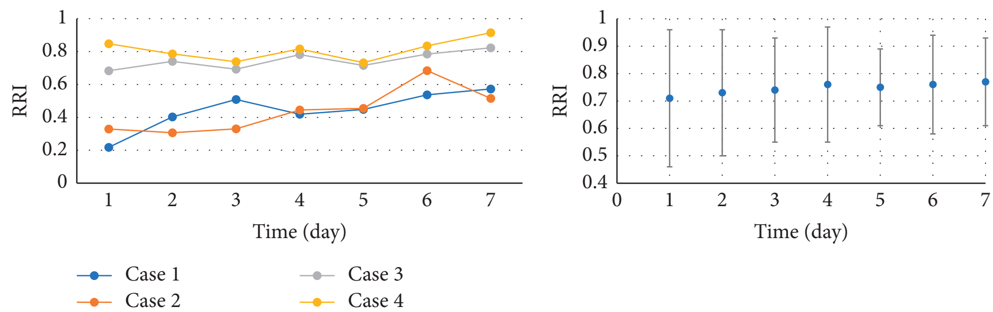
3.5. Ultrasound Scores of Severe Sepsis Patients Combined with Acute Kidney Injury. The ultrasound scores of patients with severe sepsis and AKI are shown in Figure 7. Over time, the ultrasound scores of patients with severe sepsis and AKI were mainly distributed in 2 points.

Table 2 reveals the analysis results of the linear mixed model of RRI and time. The ultrasound score was used as the dependent variable, time was a fixed-effect, patient time was used as a fixed-effect model, and the patient was taken as a random effect. The parameter value of time was 0.001–0.015, $p = 0.128 > 0.05$, indicating that there was no substantial difference in the ultrasound scores of patients with severe sepsis complicated with AKI ($t = 1.348$ and $p = 0.128 > 0.05$).

3.6. ROC Curve Analysis of Renal Resistance Index at Different Time Points in the Diagnosis of Severe Sepsis with Acute Kidney Injury. Figure 8 shows the ROC curves of the RRI for the diagnosis of AKI on the 2^{nd} day, 4^{th} day, and 6^{th} day after entering the ICU. Besides, the AUC values of ROC for RRI diagnosis of AKI at different time points were analyzed, and the analysis results are given in Table 3. The patient with AKI was defined as a positive index as 1, and the ROC of RRI on the 2^{nd} day, 4^{th} day, and 6^{th} day after entering ICU was drawn to the diagnosis of AKI. Furthermore, the values of AUC were 0.758, 0.841, and 0.856 in turn, which were all greater than 0.5 ($p < 0.05$).

4. Discussion

AKI is a complication of traumatic diseases, and the common risk factors for its occurrence include the severity of the trauma, the degree of bleeding, shock, traumatic inflammation, and severe sepsis [14]. In this study, 20 patients with severe sepsis combined with AKI were included, and there were no marked differences in gender, age, and ISS.



(a) (b)

FIGURE 6: Trend chart of ultrasound RRI changes in severe sepsis patients combined with AKI. (a) The changing trend of RRI of randomly selected cases. (b) The changing trend of average RRI of patients on ultrasound.

TABLE 1: Analysis of the linear mixed model of RRI and time effect.

Parameters	Standard error	95% CI	t	P
Time	0.002	0.012–0.015	12.348	<0.001
Intercept	0.007	0.638–0.758	64.854	<0.001

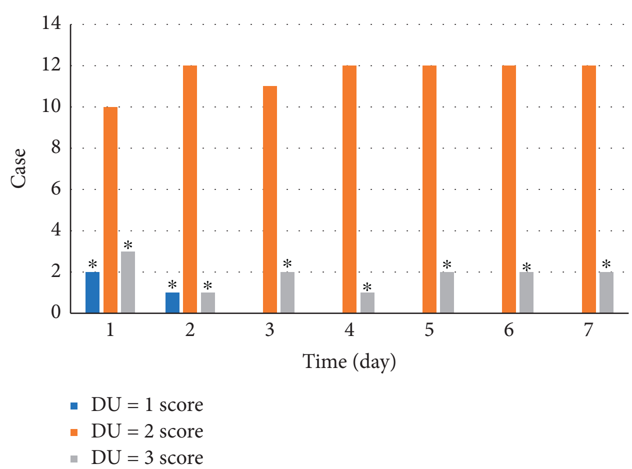


FIGURE 7: Ultrasound scores of severe sepsis patients combined with AKI. *Compared to DU = 2 points, $p < 0.05$.

TABLE 2: Linear mixed model analysis of ultrasound scores and time effect.

Parameters	Standard error	95% CI	t	P
Time	0.003	0.001–0.015	1.348	0.128
Intercept	1.225	1.126–2.154	13.238	<0.001

DU has the advantages of high reproducibility and noninvasiveness, which is extensively applied in the field of acute and critical illness and has shown a good diagnostic value in the assessment of renal trauma [15–17]. DU can quantitatively determine the resistance index of renal interlobular arteries. Xia et al. [18] confirmed that RRI could predict the occurrence of AKI in the state of severe sepsis. According to the changing trend of the RRI within 1–7 days

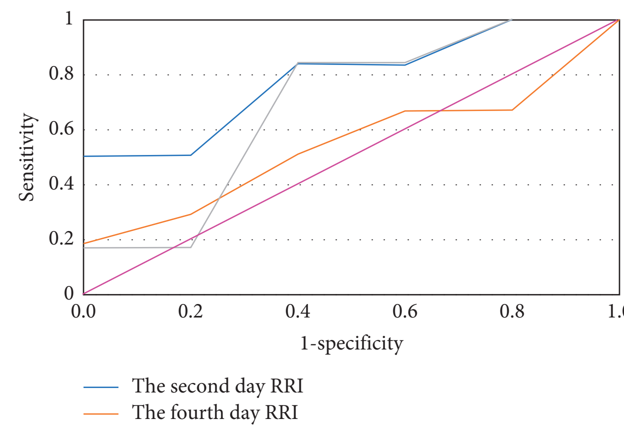

FIGURE 8: The ROC curves of the RRI on the 2^{nd} day, 4^{th} day, and 6^{th} day after entering the ICU for the diagnosis of AKI. The AUC values were 0.758, 0.841, and 0.856, respectively, which were all greater than 0.5 ($p < 0.05$).

TABLE 3: Analysis of the AUC of the ROC curves of RRI at different time points in the diagnosis of AKI.

Time	AUC	95% CI	Standard error	P value
The 2^{nd} day	0.758	0.526–0.974	0.148	1.241
The 4^{th} day	0.841	0.540–0.985	0.134	1.126
The 6^{th} day	0.8526	0.623–1.000	0.012	1.364

Note. The P value was compared with the value of AUC (0.5).

after entering the ICU, there were obvious individual differences in RRI [19]. On the whole, the RRI had a slight upward trend after entering the ICU. The RRI, time, and the patient were taken as the dependent variable, a fixed-effect model, and a random effect, respectively. The parameter value of time was 0.012–0.015, $p < 0.001$, verifying that RRI would rise over time.

The AUC of ROC for the diagnosis of AKI was drawn on the 2^{nd} day, 4^{th} day, and 6^{th} day of entering the ICU [20]. The patient with AKI was defined as a positive index as 1, and the ROC curves of RRI on the 2^{nd} day, 4^{th} day, and 6^{th} day after entering the ICU were drawn to the diagnosis of AKI. What is more, the values of AUC were 0.758, 0.841, and 0.856 in sequence, all greater than 0.5 ($p < 0.05$), suggesting that the AUC of ROC drawn in this study had high accuracy. Thus, RRI could be used as a predictive index of AKI.

5. Conclusion

The artificial intelligence PCNN algorithm in this study was compared with histogram equalization algorithm and linear transformation algorithm, which were adopted for the ultrasound images of 20 patients with severe sepsis and AKI. The results disclosed that the artificial intelligence PCNN algorithm proposed in this study not only considered the global information of ultrasound images but also enhanced the local information of ultrasound images. In addition, the changes in RRI measured by ultrasound images were related to AKI. The shortcomings of this study are that the time is limited, the number of samples collected is small, and the patient observation time is only about 1 week. It is impossible to observe the changes of RRI before and after kidney injury and during the recovery period of AKI. Further research is needed in the later period. All in all, the artificial intelligence PCNN algorithm has a significant effect on ultrasound image enhancement, thereby providing a reference theoretical basis for the diagnosis of severe sepsis with AKI.

Retracted: The Effect of lncRNA SNHG3 Overexpression on Lung Adenocarcinoma by Regulating the Expression of miR-890

Journal of Healthcare Engineering

Received 8 August 2023; Accepted 8 August 2023; Published 9 August 2023

This article has been retracted by Hindawi following an investigation undertaken by the publisher [1]. This investigation has uncovered evidence of one or more of the following indicators of systematic manipulation of the publication process:

(1) Discrepancies in scope
(2) Discrepancies in the description of the research reported
(3) Discrepancies between the availability of data and the research described
(4) Inappropriate citations
(5) Incoherent, meaningless and/or irrelevant content included in the article
(6) Peer-review manipulation

The presence of these indicators undermines our confidence in the integrity of the article's content and we cannot, therefore, vouch for its reliability. Please note that this notice is intended solely to alert readers that the content of this article is unreliable. We have not investigated whether authors were aware of or involved in the systematic manipulation of the publication process.

Wiley and Hindawi regrets that the usual quality checks did not identify these issues before publication and have since put additional measures in place to safeguard research integrity.

We wish to credit our own Research Integrity and Research Publishing teams and anonymous and named external researchers and research integrity experts for contributing to this investigation.

The corresponding author, as the representative of all authors, has been given the opportunity to register their agreement or disagreement to this retraction. We have kept a record of any response received.

Academic Editor: Enas Abdulhay

The lncRNA small nucleolar host gene 3 (SNHG3) was discovered to play an important role in the occurrence and development of lung adenocarcinoma (LUAD). However, the underlying molecular mechanism of SNHG3 in LUAD remains unclear. In the present study, SNHG3 expression levels in LUAD tissues and cell lines were analyzed using reverse transcription-quantitative PCR. The effects of SNHG3 on the proliferation, apoptosis, migration, and invasion of LUAD cells were determined using Cell Counting Kit-8, colony formation, flow cytometry, wound healing, and Transwell chamber assays, respectively. The specific underlying mechanism of SNHG3 in LUAD was investigated using bioinformatics analysis and a dual luciferase reporter assay. The results revealed that SNHG3 expression levels were downregulated in LUAD tissues and cell lines. Functionally, SNHG3 overexpression suppressed the proliferation, migration, and invasion of LUAD cells, while promoting apoptosis. Mechanistically, microRNA- (miR-) 890 was identified as a potential target of SNHG3, and its expression was negatively regulated by SNHG3. Notably, SNHG3 was found to promote LUAD progression by targeting miR-890. In conclusion, the findings of the present study revealed that lncRNA SNHG3 promoted the occurrence and progression of LUAD by regulating miR-890 expression.

1. Introduction

Lung cancer is a common type of cancer with high incidence and mortality rates worldwide [1]. Non-small-cell lung cancer (NSCLC) represents ~85% of all lung cancer types and has a mortality rate of ~50%. Lung adenocarcinoma (LUAD), a leading cause of cancer-related mortality, accounts for ~40% of NSCLCs and has a 5-year survival rate of only 15% [2]. At present, patients with LUAD are usually diagnosed at the terminal stage or following metastasis due to the lack of effective biomarkers and obvious early symptoms [3, 4]. For more than half a century, even with the significant progress and development made in molecular biology, oncology, and medicinal technology, the treatment of LUAD has been and remains ineffective [5]. In addition, although a large number of molecular biology studies have focused on investigating the mechanisms underlying LUAD, the exact molecular mechanism of LUAD remains unclear. Thus, further investigations to identify LUAD-associated pathogenic genes and the underlying molecular mechanisms of LUAD are required.

Long noncoding RNAs (lncRNAs), which are functional transcripts of >200 nucleotides in length, have been discovered to serve important roles in modulating the pathological and physiological progression of numerous cancer types [6–9]. Accumulating studies have reported that the abnormal expression of lncRNAs was associated with the progression of different malignant tumor types, including breast cancer [9], prostate cancer [10], liver cancer [11], and LUAD [12, 13]. Numerous lncRNAs, such as metastasis-associated lung adenocarcinoma transcript 1 [12], long intergenic non-protein-coding RNA 1512 [13], MIR31 host gene [14], FEZ family zinc finger 1 antisense RNA 1 [15], and urothelial cancer associated 1 [16], were found to be closely associated with LUAD occurrence and development. In addition, the lncRNA DiGeorge syndrome critical region gene 5 was reported to promote the progression of LUAD by downregulating microRNA- (miRNA/miR-) 22-3p expression [17]. The lncRNA small nucleolar host gene 3(SNHG3) is a long noncoding RNA. At present, its potential role and mechanism in lung adenocarcinoma have not been reported. SNHG3, also known as the host gene of U17 (U17HG), is located in band 6 in region 3 of the short arm of chromosome 1. The lncRNA small nucleolar host gene 3 (SNHG3) has been demonstrated to serve a role in multiple types of cancer. In fact, an increasing number of studies have revealed that the expression levels of SNHG3 were upregulated in numerous tumor types, and SNHG3 upregulation markedly promoted tumor cell proliferation, migration, and invasion, thereby indicating that SNHG3 may represent a novel oncogenic lncRNA [18]. For example, SNHG3 promoted the migration and invasion of osteosarcoma cells by regulating the miR-151a-3p/RAB22A, member RAS oncogene family axis [19]. In NSCLC, SNHG3 promoted the proliferation, migration, and invasion of NSCLC cells by activating the TGF-β and IL-6/JAK2/STAT3 signaling pathways [20]. These studies suggested that SNHG3 may serve a role as a novel oncogene in numerous cancer types. Nevertheless, the specific regulatory mechanism of SNHG3 in LUAD requires further study.

The current study hypothesized that SNHG3 may promote LUAD occurrence and development by targeting miR-890 expression. Thus, the expression levels of SNHG3 and miR-890 in LUAD tissues and cell lines were analyzed. The potential functions of SNHG3 and its association with miR-890 were also investigated *in vitro*. The results of the present study may provide a novel insight into potential targets for the treatment of LUAD.

2. Materials and Methods

2.1. Patient Studies. LUAD and adjacent normal tissues were obtained from 66 patients with LUAD (men and women account for 50%, respectively) who were diagnosed at Weifang Yidu Central Hospital (China). Included patients had neither received surgery nor chemotherapy prior to sample collection. The present study was approved by the Ethics Committee of Weifang Yidu Central Hospital, and all enrolled patients provided written informed consent. All tissues were stored at −80°C before use.

2.2. Cell Lines and Culture. The human normal lung epithelial cell line, 16HBE, and human LUAD cell lines (A549, H1299, and H1975) were obtained from the Cell Bank of Type Culture Collection of the Chinese Academy of Sciences. All cells were cultured in DMEM (Nanjing KeyGen Biotech Co., Ltd.) and maintained in a humidified atmosphere with 5% CO_2 at 37°C.

2.3. Cell Transfection. The pcDNA 3.1 and pcDNA3.1 SNHG3 plasmids, negative control (NC) inhibitor, miR-890 inhibitor, NC mimic, and miR-890 mimic were purchased from Invitrogen; Thermo Fisher Scientific, Inc. The synthetic oligonucleotides or plasmids were transfected into cells using Lipofectamine® 2000 (Invitrogen; Thermo Fisher Scientific, Inc.).

2.4. Cell Counting Kit-8 (CCK-8) Assay. The cells were gently seeded at a density of 1 × 106 cells/well into 96-well plates by the experimenter. Following 24, 48, 72, 96, or 120 h of culture, the CCK-8 reagent (Beyotime Institute of Biotechnology) was added to each well. The cell density was measured at a wavelength of 450 nm.

2.5. Colony Formation Assay. The transfected cells were seeded into a 6-well plate and cultured for 14 days; during this process, the medium was replaced every 2 days. Following the incubation, the formed colonies were fixed with 4% formaldehyde and stained with crystal violet (Sangon Biotech Co., Ltd.) for 3 min to visualize the colonies, which were defined as >50 cells. The colony formation rate was calculated using the following equation: colony formation rate (%) = (number of colonies/number of seeded cells) × 100.

2.6. Reverse Transcription-Quantitative PCR (RT-qPCR). Total RNA was extracted from LUAD cell lines and tissues using TRIzol® reagent (Invitrogen; Thermo Fisher Scientific, Inc.). Total RNA was reverse transcribed into cDNA using a PrimeScript RT reagent kit (Qiagen, Inc.). qPCR was subsequently performed using SYBR Green (Takara Bio, Inc.), with U6 as the control gene. The following primer pairs were used for the qPCR: SNHG3 forward, 5′-TTCAAGCGATTCTCGTGCC-3′ and reverse, 5′-AAGATTGTCAAACCCTCCCTGT-3′; miR-890 forward, 5′-CGGCTTCCTGTGCTAAGCGT-3′ and reverse, 5′- AACGCTTCACGAATTTGCGT-3′; and U6 forward, 5′-CTCGCTTTCGGCAGCACA-3′ and reverse, 5′-AACGCTTCACGAAATTTGCGT-3′.

2.7. Cell Apoptosis Assay. Following trypsinization and centrifugation, 1×10^6 cells were collected and incubated with 500 μl buffering agent containing Annexin V-FITC and PI in the dark for 30 min. The cell apoptotic rate was analyzed using flow cytometry (Beckman Coulter, Inc.).

2.8. Wound Healing Assay. The migratory ability of LUAD cells was analyzed using a wound healing assay. Briefly, 1×10^6 transfected cells were cultured for 24 h, and upon reaching confluence, a straight line was scratched into the cell monolayer to generate an artificial wound. The area of the scratch was visualized under a microscope at 0 and 48 h and analyzed using an image analysis and detection system.

2.9. Cell Invasion Assay. The invasive ability of LUAD cells was measured using Transwell plates (8.0 μm pores; Nanjing KeyGen Biotech Co., Ltd.). Briefly, 1×10^6 cells/well were seeded into the upper chamber of the Transwell plates. Following 48 h of incubation, the invasive cells were fixed and stained with crystal violet. Stained cells were visualized and semiquantified using a microscope (Nikon Corporation).

2.10. Dual Luciferase Reporter Assay. Wild-type (WT) or mutant (Mut) SNHG3 3′-untranslated region (UTR) fragments containing the miR-890 binding sites were synthesized and inserted into the pGL3-basic plasmid (Promega Corporation) to construct SNHG3-WT or SNHG3-Mut reporter vectors, respectively. LUAD cells were cotransfected with the aforementioned reporter vectors and miR-890 inhibitor or NC inhibitor. Following 48 h of transfection, the relative luciferase activity was measured using a Dual Luciferase Reporter assay system (Promega Corporation).

2.11. Statistical Analysis. Statistical analysis was performed using SPSS 19.0 software (IBM Corp.), and data are presented as the mean ± SD. Statistical differences between two or more groups were performed using Student's *t*-test or one-way ANOVA, respectively. Kaplan–Meier survival analysis was used to evaluate the association between the overall survival of patients with LUAD and SNHG3 expression levels. The Gene Expression Profiling Interactive Analysis (GEPIA) database was used to analyze the survival of patients with either low or high expression of SNHG3. $P < 0.05$ was considered to indicate a statistically significant difference.

3. Results

3.1. SNHG3 Expression Levels Are Downregulated in LUAD Tissues and Cell Lines. To determine the potential regulatory roles of SNHG3 in LUAD, RT-qPCR analysis was performed. The clinicopathological characteristics of patients are shown in Table 1. SNHG3 expression levels were downregulated in LUAD tissues compared with adjacent normal tissues (Figure 1(a)). The results of the Kaplan–Meier analysis revealed that patients with low SNHG3 expression levels had a shorter overall survival compared with those with high SNHG3 expression levels (Figure 1(b)). Similar to the patient studies, SNHG3 expression levels were also found to be markedly downregulated in LUAD cell lines (A549, H1299, and H1975) compared with 16HBE cells (Figure 1(c)). The expression levels of SNHG3 were downregulated to the greatest extent in A549 and H1299 cells; therefore, these two cell lines were selected for use in subsequent experiments. These results indicated that SNHG3 expression levels may be significantly downregulated in LUAD tissues and cells.

3.2. SNHG3 Overexpression Inhibits the Proliferation, Migration, and Invasion, and Promotes the Apoptosis, of LUAD Cells. To determine the function of SNHG3 in LUAD, pcDNA3.1 SNHG3 vectors were transfected into A549 and H1299 cells. Following transfection, SNHG3 expression levels were markedly upregulated (Figure 2(a)). The results of the CCK-8 and colony formation assays demonstrated that SNHG3 overexpression inhibited the proliferation of LUAD cells (Figures 2(b) and 2(c)). In addition, flow cytometric analysis found that SNHG3 overexpression induced the apoptosis of LUAD cells (Figure 2(d)). To investigate the effects of SNHG3 on the migration and invasion of A549 and H1299 cells, wound healing and Transwell invasion assays were performed. The results of the wound healing assay revealed that the migration was decreased following the overexpression of SNHG3 in LUAD cells (Figure 2(e)). Similarly, the results of the Transwell assay demonstrated that SNHG3 overexpression inhibited the invasive abilities of LUAD cells (Figure 2(f)). These findings suggested that SNHG3 overexpression may inhibit the proliferation, migration, and invasion and promote the apoptosis of LUAD cells.

3.3. SNHG3 Directly Binds to miR-890 and Downregulates miR-890 Expression. To identify specific miRNAs modulated by SNHG3 in LUAD, downstream genes of SNHG3 were searched for using bioinformatics analysis. Data from The Cancer Genome Atlas database identified a potential binding site between SNHG3 and miR-890 (Figure 3(a)). Furthermore, a dual luciferase reporter assay was performed, and the results found that the cotransfection with the miR-890 inhibitor increased the relative luciferase activity of the SNHG3-Wt reporter vector compared with the cotransfection with the NC inhibitor. However, no significant differences were observed in the relative luciferase activity of the SNHG3-Mut reporter vectors between cells cotransfected with the miR-890 inhibitor or NC inhibitor (Figure 3(b)). In addition, SNHG3 overexpression was found to downregulate miR-890 expression (Figure 3(c)). Thus, the expression levels of miR-890 in LUAD tissues and cell lines were further analyzed. RT-qPCR analysis revealed that the expression levels of miR-890 were upregulated in LUAD tissues and cell lines (Figures 3(d) and 3(e)). These results indicated that miR-890 may be a target of SNHG3 and be negatively regulated by SNHG3.

3.4. SNHG3 Exerts Its Effects in LUAD by Regulating miR-890 Expression. To determine whether miR-890 was involved in promoting the effects of SNHG3 in LUAD, a miR-890 mimic was transfected into A549 and H1299 cells following the overexpression of SNHG3. The transfection efficiencies of the miR-890 mimic transfection and cotransfection of the miR-890 mimic and SNHG3 overexpression plasmid are presented in Figure 4(a). The expression levels of miR-890 were upregulated following the overexpression of miR-890, while the expression levels of miR-890 were downregulated following the overexpression of SNHG3. The results of the CCK-8 and colony formation assays demonstrated that miR-890 overexpression increased the proliferation of LUAD cells, while the SNHG3-overexpression-induced inhibition of LUAD cell proliferation was impaired following miR-890 overexpression (Figures 4(b) and 4(c)). Flow cytometric analysis showed that miR-890 overexpression inhibited the apoptosis of LUAD cells. Conversely, the increased apoptotic rate following SNHG3 overexpression was weakened following miR-890 overexpression (Figure 4(d)). The results of the wound healing and Transwell chamber assays showed that the migratory and invasive abilities of LUAD cells were increased following the overexpression of miR-890, while the inhibitory effects of SNHG3 overexpression on migration and invasion were partially antagonized by miR-890

Table 1: The expression of SNHG3 and clinicopathological features in 66 lung adenocarcinoma. *P values are calculated with the chi-square test.

Clinicopathological features	Cases ($n = 66$)	SNHG3 expression 38 high (%)	SNHG3 expression 28 low (%)	P value*
Gender				
Male	34	20 (58.8)	14 (41.2)	0.833
Female	32	18 (56.3)	14 (43.8)	
Age (years)				
≤60	33	17 (51.5)	16 (48.5)	0.319
>60	33	21 (63.6)	12 (36.4)	
Tumor size (mm)				
≤5.0	39	24 (61.5)	15 (38.5)	0.434
>5.0	27	14 (51.9)	13 (48.1)	
TNM stage				
I-II	38	27 (71.1)	11 (28.9)	0.010*
III-IV	28	11 (39.3)	17 (60.7)	
Lymph node metastasis				
0–2	41	29 (70.7)	12 (29.3)	0.014*
>2	25	11 (40.7)	16 (59.3)	

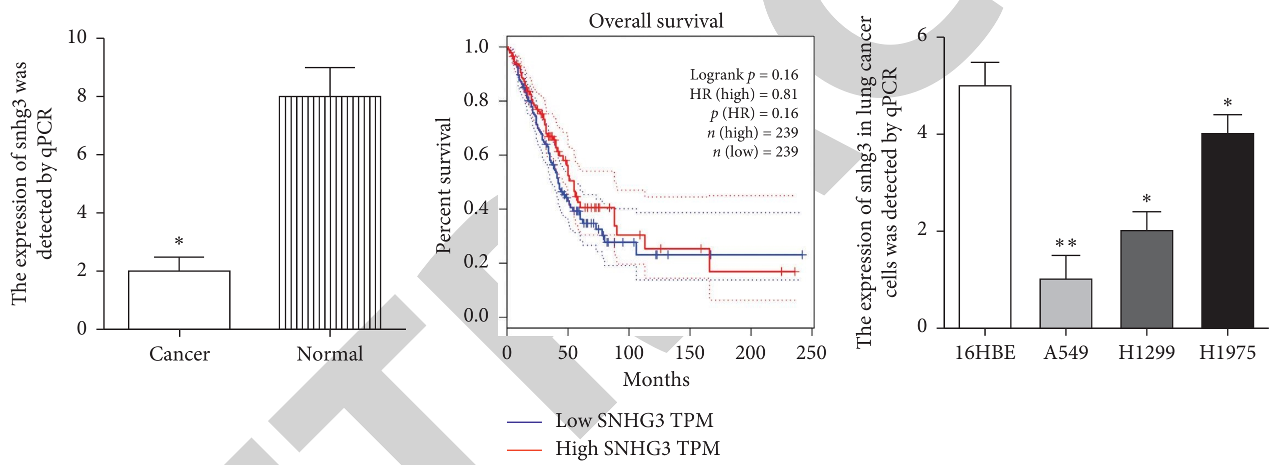

Figure 1: The SNHG3 expression is downregulated in LUAD tissues and cell lines. (a) Relative expression levels of lncRNA SNHG3 in LUAD tissues and normal tissues were detected by RT-qPCR. *$P < 0.05$ vs. the normal tissue. (b) The GEPIA database was used to evaluate the relationship between SNHG3 expression and the prognosis of LUAD patients with overall survival (OS). (c) Relative expression levels of lncRNA SNHG3 in different LUAD cell lines were detected by RT-qPCR. *$P < 0.05$, **$P < 0.01$ vs. the normal tissue the 16HBE cell line.

overexpression (Figures 4(e) and 4(f)). Therefore, miR-890 overexpression promoted the progression of LUAD. SNHG3 activated LUAD progression by regulating miR-890.

4. Discussion

LUAD is one of the most common types of malignancy worldwide, accounting for high mortality rates [1, 2]. Therefore, determining the specific underlying mechanisms of LUAD remains a priority for the development of effective treatments for patients with LUAD. Currently, numerous studies have reported roles for and determined the underlying mechanisms of lncRNAs in LUAD [12–17]. In particular, the lncRNA SNHG3 was discovered to serve as a competing endogenous RNA to regulate the progression of various cancer types [18–20]. For example, SNHG3 promoted hepatocellular tumorigenesis by regulating miR-326 expression [21], and SNHG3 modulated the miR-384/WEE1 G_2 checkpoint kinase axis to regulate laryngeal carcinoma cell proliferation and migration [22]. In addition, the lncRNA SNHG3 was reported to play a vital role in LUAD progression [23, 24]. However, to the best of our knowledge, the tumorigenic properties and underlying mechanism of action of SNHG3 in LUAD progression remain to the determined. The present study characterized the expression pattern and molecular mechanism of SNHG3 in LUAD. The expression levels of SNHG3 were found to be downregulated in both clinical samples from patients with LUAD and LUAD cell lines. Furthermore, SNHG3 overexpression inhibited the proliferation, migration, and invasion and promoted the apoptosis of LUAD cells, which indicated that SNHG3 may regulate the malignant behavior of LUAD cells by serving as an oncogene in LUAD. Mechanistically,

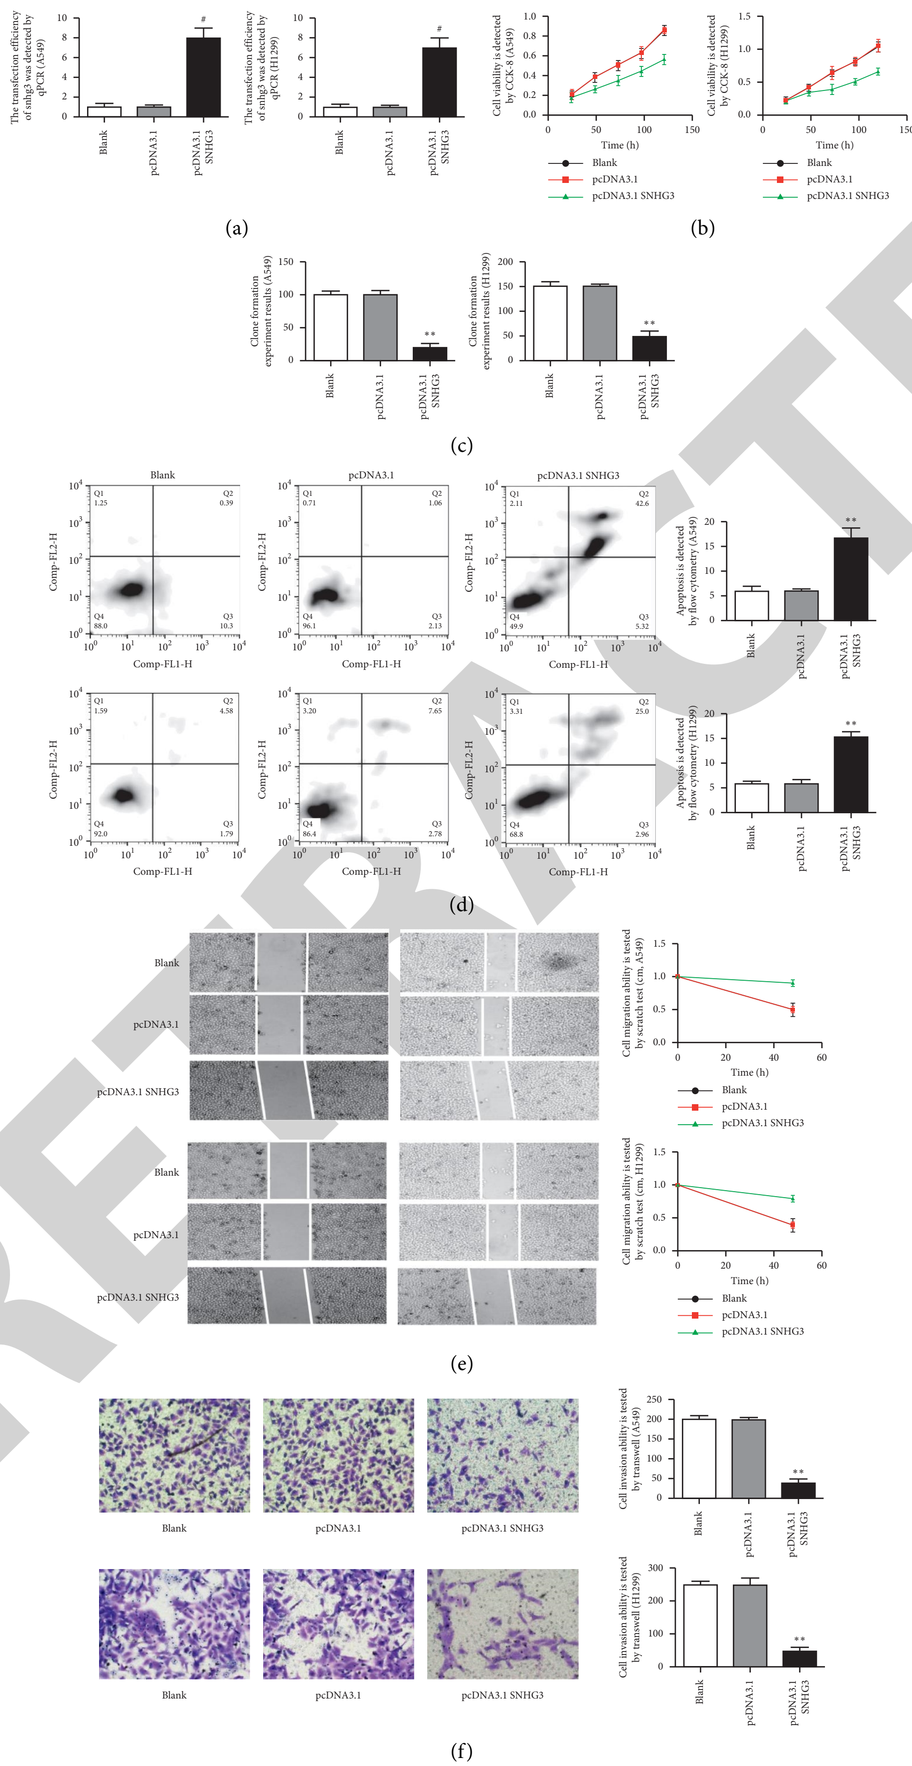

Figure 2: SNHG3 overexpression inhibits the progression of LUAD cells. (a) The transfection efficiency of pcDNA3.1 SNHG3 was verified by RT-qPCR assay. (b) Cell viability was detected by CCK-8 assay. (c) Cell proliferation was detected by clone formation assay. (d) Cell apoptosis was determined by flow cytometry assay. (e) Cell migration was detected by wound scratch assay. (b) Cell viability was detected by CCK-8 assay. (c) Cell proliferation was detected by clone formation assay. (d) Cell apoptosis was determined by flow cytometry assay. (e) Cell migration was determined by wound healing assay. (f) Cell invasion was determined by transwell chamber assay. $^{*}P < 0.05$, $^{**}P < 0.01$ vs. blank and NC mimic.

SNHG3 promoted LUAD progression by regulating miR-890 expression.

An increasing number of studies have demonstrated that miRNAs exert both tumor suppressive and oncogenic roles in tumorigenesis, and the expression of lncRNAs can regulate the activities of miRNAs [25, 26]. Therefore, miRNAs have shown promise as potential clinical biomarkers and therapeutic targets for the treatment of patients with LUAD [27–29]. To date, numerous studies have revealed that miR-890 was associated with the progression of a large number of cancer types [30, 31]. For instance, miR-890 repressed the proliferation and invasion and induced apoptosis in breast cancer cells by regulating CD147 expression [32]. Nevertheless, to the best of our knowledge, the functional role of miR-890 in the evaluation of LUAD status remains unclear. Based on the results of a previous study, the present study further investigated the function of miR-890 in LUAD development. Using bioinformatics analysis and a dual luciferase reporter assay, SNHG3 was predicted to directly bind to miR-890. Moreover, miR-890 expression was negatively regulated by SNHG3, and miR-890 expression levels were found to be upregulated in both LUAD tissues and cell lines. In addition, miR-890 overexpression promoted the proliferation, migration, and invasion and inhibited the apoptosis of LUAD cells. Thus, miR-890 overexpression abrogated the effects of SNHG3 overexpression on LUAD cells. Thus, it is suggested that SNHG3 may promote the occurrence and progression of LUAD by regulating miR-890 expression.

Nonetheless, there are several limitations to the present study. First, although there are a large number of lncRNAs, the current study only determined the role of lncRNA SNHG3 and miR-890 in LUAD. Second, the study did not investigate the association between other lncRNAs and lung cancer and any other potential interactions between genes. Therefore, future studies will focus on the interactions between lncRNAs.

In conclusion, to the best of our knowledge, the current study was the first to report the function and regulatory mechanism of the lncRNA SNHG3 in LUAD. The findings suggested that SNHG3 may function as an oncogene in LUAD by modulating the expression levels of miR-890. Therefore, lncRNA SNHG3 and miR-890 may serve as novel biomarkers or potential targets for the treatment of LUAD.

In order to provide theoretical support for clinical diagnosis, the diagnostic value of the optimized fuzzy C-means (FCM) algorithm combined with coronal magnetic resonance imaging (MRI) scan was investigated in the diagnosis of tracheal foreign bodies in children. The anisotropic filtering was applied to optimize the traditional FCM algorithm, so as to construct a new MRI image segmentation algorithm, namely, AFFCM algorithm. Then, the traditional FCM algorithm, the FCM algorithm based on the kernel function (KFCM), and the FCM algorithm based on the spatial neighborhood information (RFCM) were introduced for comparison with the AFFCM. 28 children diagnosed with foreign bodies in the trachea were selected for MRI diagnosis, and AFFCM was used for segmentation. The partition coefficient, segmentation entropy, and the correlation degree between classes after fuzzy division of the four algorithms were recorded, and the location and distribution of foreign bodies in the trachea and the types of foreign bodies were also collected. Besides, the MRI scanning and chest X-rays of the children with foreign bodies in the trachea should also be recorded in terms of the positive rate, diagnosis rate, and indirect signs. The class division coefficient and interclass correlation degree after fuzzy division of AFFCM were markedly greater than those of FCM, KFCM, and RFCM ($P < 0.05$), while the segmentation entropy of AFFCM was less sharp than the entropies of FCM, KFCM, and RFCM ($P < 0.05$). Among the 28 children, there were 5 cases with foreign bodies in the trachea (17.86%), 10 cases in the left bronchus (35.71%), and 13 cases in the right bronchus (46.43%). Among the foreign body types, there were 10 cases of melon seeds (35.71%), 6 cases of peanuts (21.43%), and 5 cases of beans (17.86%). The positive rate (89.29%) and diagnosis rate (96.43%) of MRI for bronchial foreign bodies increased obviously in contrast to the rates of X-ray chest radiographs (57.14% and 67.86%) ($P < 0.05$). Therefore, it was indicated that AFFCM showed higher partition coefficient value, lower segmentation entropy, larger similarity among classes, and better image segmentation effect. Furthermore, AFFCM-based coronal MRI scan had a higher positive rate and diagnosis rate for children's tracheal foreign bodies, and the main signs were emphysema and atelectasis.

1. Introduction

Tracheal foreign bodies in children refer to foreign bodies entering the airway, causing airway blockage. In mild cases, it can result in lung damage, and, in severe cases, suffocation death is more common in children below 5 years of age [1]. The most common manifestations of foreign bodies in the trachea of children are severe coughing, suffocation, nausea, excessive phlegm, and difficulty breathing [2]. If it is not treated in time, it will easily lead to suffocation, atelectasis, recurrent pneumonia, which will not heal for a long time, and even death in severe cases. Therefore, timely diagnosis of foreign bodies in the trachea of children is necessary. The clinical diagnosis methods for foreign bodies in the trachea of children mainly include X-ray, ordinary computed tomography (CT), and multislice spiral CT [3, 4]. When diagnosing atypical foreign bodies in the trachea of infants and young children, it is necessary to use X-rays for chest plain radiographs and fluoroscopy to determine the presence of foreign bodies through indirect signs. However, when the imaging manifestations such as pulmonary obstruction, pulmonary block shadows, and atelectasis occur, it is easy to be misdiagnosed as bronchial pneumonia, bronchial lung cancer, bronchial asthma, and other diseases, and the misdiagnosis rate is high [5]. Ordinary CT axial images increase the detection rate of foreign bodies, and the display clarity of indirect lung signs is better than X-ray, but it has the disadvantages of slow scanning speed, only presenting axial images, and easy to miss small foreign bodies. Multislice spiral CT is developed based on common CT technology, which greatly shortens the scanning time, and has higher resolution and image clarity, but it does not perform well in soft tissue display and needs further improvement. MRI examination is an auxiliary examination method that is extensively applied in clinical practice. It is different from X-ray film, CT, and other methods, which can accurately locate the lesion and make qualitative diagnosis of the lesion. It is mainly suitable for soft tissues, bones and joints, nervous system, and chest and abdomen [6, 7].

Due to the uncertainty of the gray scale and geometric shape of the digital image, it is quite difficult to use the digital image. Therefore, it is necessary to apply fuzzy theory and robust algorithm to process these digital images [8]. Among them, fuzzy C-means (FCM) is the most widely used objective function-based fuzzy clustering method in daily life applications. It occupies a key position in the field of image segmentation and can be used for gray image or color image segmentation [9]. FCM can obtain the minimum value of the objective function through an iterative optimization method, thereby updating the membership of the elements in the sample set and finally obtaining the optimal cluster center [10, 11]. However, FCM also has some inherent shortcomings. For example, FCM will become very sensitive and affect the accuracy of the segmentation results when some sample images with natural noise are encountered. Based on this, the introduction of anisotropic filtering was considered in this study to optimize the FCM algorithm and apply it to the sagittal MRI image processing of pediatric bronchial foreign bodies.

To sum up, the application of mathematical algorithms and magnetic resonance imaging (MRI) images in the field of medical diagnosis is the focus of the current research. On this basis, anisotropic filtering was employed to optimize the traditional fuzzy clustering method, and a new MRI image segmentation algorithm was constructed in this study. In addition, the traditional fuzzy clustering algorithm, the FCM algorithm based on the kernel function (KFCM), and the rough FCM (RFCM) were also introduced, which were compared with the fuzzy clustering algorithm. 28 pediatric patients diagnosed with foreign bodies in the trachea were selected for MRI diagnosis, and AFFCM was used for segmentation to comprehensively evaluate the diagnostic value of modified FCM combined with coronal MRI scanning in children with foreign bodies in the trachea.

2. Materials and Methods

2.1. Research Objects. 28 child patients, who were hospitalized with foreign bodies in the trachea in the hospital from October 2019 to November 2020, were selected as the research objects in this study. There were 17 males and 11 females, with the age ranging from 5 months to 10 years, and the history of foreign body inhalation ranged from 5 hours to 32 days. This study had been approved by the ethics committee of the hospital, and the family members of the child patients included in the study were known and signed the informed consent forms.

The inclusion criteria were defined to include child patients who were diagnosed with foreign bodies in the trachea, signed the informed consent forms, and had no contraindications to MRI scanning.

The exclusion criteria were defined to include child patients who had received relevant treatment, withdrew from the experiment halfway, and had other lung diseases.

2.2. Coronary MRI and X-Ray Scanning. The requirements of MRI scanning were as follows: A 3.0 T superconducting magnetic resonance MAGNETOM Skyra imaging system (produced by Siemens, Germany) was adopted in this study to scan the child patients. First, each child patient was placed in a supine position and underwent the cross-sectional and sagittal positioning scanning. Besides, a coronal scanning was performed with the child's trachea and bronchus bifurcation as the center to obtain the coronal T1-weighted imagining (T1WI) of the self-cyclotron wave sequence. The scanning parameters included repetition time (TR) of 400 ms, echo time (TE) of 15 ms, and layer thickness of 5 mm.

The requirements of chest X-ray were shown in the following. In this study, PHILIPS DR machine (produced by Royal Philips, Netherlands) was used for X-ray examination, and each child patient was placed in a supine position, inhaled, and taken X-ray after the chest was in the center.

2.3. FCM Based on Anisotropic Filtering Optimization. FCM can minimize the objective function through the iterative calculation of the membership matrix and clustering center, and then the data sample set is partitioned by defuzzing operation according to the membership matrix [4]. When FCM is applied to image segmentation, all pixels on the image to be segmented are the sample set of data, and its objective function can be expressed as follows:

$$G_\alpha(W, Z) = \sum_{i=1}^{n} \sum_{j=1}^{s} \left(w_{ji}\right)^\alpha l^2(x_i, z), \tag{1}$$

$$\sum_{j=1}^{s} \left(w_{ji}\right) = 1. \tag{2}$$

In equations (1) and (2), s represents the number of clusters, n stands for the number of pixels, W expresses the value of the membership function, $S = (w_{ji})_{s\times n}$, Z indicates the central value of all clusters, $Z = (z_1, z_2, \ldots z_n)$, x_i means the gray value of the image pixel, α represents the fuzzy weighted index, and $l^2(x_i, z)$ indicates the square of the error within the class. Then, the Lagrangian multiplier method is introduced to solve equations (1) and (2):

$$H = \sum_{j=1}^{s} \left(w_{ji}\right)^{\alpha} l_{ji}^{2} + \beta\left(1 - \sum_{j=1}^{s} w_{ji}\right). \tag{3}$$

In equation (3), H represents the Lagrangian multiplier solution, and α and β stand for the parameters. Then, the necessary conditions for the optimization of the Lagrangian equation should be the following:

$$\frac{\partial H}{\partial \beta} = 1 - \sum_{j=1}^{s} w_{ji} = 0, \tag{4}$$

$$\frac{\partial H}{\partial w_{ji}} = \alpha\left(w_{ji}\right)^{\alpha-1}\left(l_{ji}\right)^{2} - \beta = 0. \tag{5}$$

From equation (4), the following equation can be obtained:

$$w_{ji} = \left[\frac{\beta}{\alpha\left(l_{ji}\right)^{2}}\right]^{(1/\alpha-1)}. \tag{6}$$

Equation (5) is substituted into equation (2), so as to obtain the two following equations:

$$\sum_{j=1}^{s} w_{ji} = \left(\frac{\beta}{\alpha}\right)^{1/\alpha-1}\left\{\sum_{j=1}^{s}\left[\frac{1}{\left(l_{ji}\right)^{2}}^{1/\alpha-1}\right]\right\} = 1, \tag{7}$$

$$\left(\frac{\beta}{\alpha}\right)^{1/\alpha-1} = \frac{1}{\sum_{j=1}^{s}\left[1/\left(l_{ji}\right)^{2}\right]^{1/\alpha-1}}. \tag{8}$$

Equation (9) can be obtained by substituting equation (8) into equation (5).

$$w_{ji} = \frac{1}{\sum_{p=1}^{s}\left[l_{ji}/l_{jp}\right]^{2/\alpha-1}}. \tag{9}$$

Then, $G_{\alpha}(W, Z)$ is made to be the minimum membership function value, which can be shown in the following equation:

$$w_{ji} = \left[\frac{\beta}{\alpha\left(l_{ji}\right)^{2}}\right]^{1/\alpha-1}. \tag{10}$$

In the same way, $G_{\alpha}(W, Z)$ is made to be the smallest cluster center value, as shown in the following equation:

$$Z_i = \frac{\sum_{i=1}^{n}\left(w_{ji}\right)^{\alpha} x_i}{\sum_{i=1}^{n}\left(w_{ji}\right)^{\alpha}}. \tag{11}$$

Therefore, the cluster center and the best classification matrix can be determined by equations (10) and (11) according to the number of cluster categories of the data sample set and the specified sample fuzzy weight. What is more, the defuzzy algorithm [12] is applied to operate the membership matrix to complete the partition effect of samples. However, the standard FCM algorithm does not consider the association of the neighboring pixels of each element when performing image segmentation, which makes the algorithm very sensitive to images with noise. Therefore, the anisotropic filtering method was introduced in this study to denoise the image by anisotropic filtering, and its objective function can be updated as follows:

$$\begin{aligned} G^{*} &= \sum_{j=1}^{s}\sum_{t=0}^{T-1} f_{x}(t) w_{jt}^{\alpha}\left\|\Phi\left(x_t\right) - \Phi\left(z_j\right)\right\|^{2} \\ &\quad + \kappa \sum_{j=1}^{s}\sum_{t=0}^{T-1} f_{y}(t) w_{jt}^{\alpha}\left\|\Phi\left(y_t\right) - \Phi\left(z_j\right)\right\|^{2}. \end{aligned} \tag{12}$$

In equation (12), t stands for the gray level in the image, T represents the highest gray level in the image, $f(t)$ means the gray domain histogram statistical function of the image before and after processing, κ indicates the coefficient of fuzzy weight correction, y represents the gray value of the postprocessing image, and $\Phi(x)$ represents the kernel function. $\Phi(x)$ is set as the Gaussian kernel function ([K]), so the following equations can be gotten:

$$\left\|\Phi\left(x_i\right) - \Phi\left(z_j\right)\right\|^{2} = K(x, x) + K(y, y) - 2K(x, y), \tag{13}$$

$$K(x, y) = \exp\left(-\frac{\|x - y\|^{2}}{\theta^{2}}\right). \tag{14}$$

From equations (13) and (14), the following equation can be obtained:

$$\left\|\Phi\left(x_i\right) - \Phi\left(z_j\right)\right\|^{2} = 2\left(1 - K\left(x_i, z_j\right)\right). \tag{15}$$

Thus, the objective function can be updated as follows:

$$\begin{aligned} G^{*} &= \sum_{j=1}^{s}\sum_{t=0}^{T-1} f_{x}(t) w_{jt}^{\alpha}\left(1 - K\left(x_i, z_j\right)\right) \\ &\quad + \kappa \sum_{j=1}^{s}\sum_{t=0}^{T-1} f_{y}(t) w_{jt}^{\alpha}\left(1 - K\left(y_i, z_j\right)\right). \end{aligned} \tag{16}$$

The same can be solved to make $G*(W, Z)$ the minimum membership function value and cluster center value, which can be expressed in the two following equations:

$$w_{ji} = \frac{\left[f_x(t)\left(1 - K\left(x_i, z_j\right)\right) + \beta f_y(t)\left(1 - K\left(y_i, z_j\right)\right)\right]^{1/\alpha - 1}}{\sum_{j=1}^{s}\left[f_x(t)\left(1 - K\left(x_i, z_j\right)\right) + \beta f_y(t)\left(1 - K\left(y_i, z_j\right)\right)^{1/\alpha - 1}\right]}, \tag{17}$$

$$Z_i = \frac{\sum_{t=0}^{T-1}\left[f_x(t)w_{jt}^{\alpha}K\left(x_i, z_j\right)x_t + \beta f_y(t)w_{jt}^{\alpha}K\left(y_i, z_j\right)y_t\right]}{\sum_{j=1}^{s}\left[f_x(t)w_{jt}^{\alpha}K\left(x_i, z_j\right) + \beta f_y(t)w_{jt}^{\alpha}K\left(y_i, z_j\right)\right]}. \tag{18}$$

Therefore, an optimized FCM algorithm based on anisotropic filtering can be obtained, which is set as AFFCM. The calculation process is shown in Figure 1. First, the FCM algorithm's parameters are initialized, the image is preprocessed by anisotropic filtering, and the histogram function of the original image and the filtered image is obtained. Then, the membership matrix and clustering center are calculated and updated. If $t \le T$, the algorithm ends. Otherwise, the above steps are repeated. Finally, the image is deblurred to judge the categories of image elements.

2.4. Evaluation Criteria for Image Segmentation. The traditional FCM algorithm, KFCM [13], and RFCM [14] were introduced for comparison with AFFCM constructed in this study. Moreover, the results of image segmentation were evaluated by using three indicators of correlation degree between classes after fuzzy, partition coefficient, and segmentation entropy, which could be calculated as follows:

$$Q_{pc} = \frac{\sum_{i=1}^{s}\sum_{j=1}^{n} w_{ij}^{2}}{n}. \tag{19}$$

$$Q_{pe} = -\frac{\sum_{i=1}^{s}\sum_{j=1}^{n}\left(w_{ij}\log w_{ij}\right)}{n}. \tag{20}$$

$$Q_{da} = -\frac{\sum_{j=1}^{s}\sum_{j=1}^{n} w_{ij}\left\|x_j - z_i\right\|^2}{n\left(\min i \ne k\left\|z_k - z_i\right\|\right)}. \tag{21}$$

In equations (19), (20), and (21), Q_{pc} represented the partition coefficient, Q_{pe} stood for the segmentation entropy, Q_{da} meant the correlation degree between classes after fuzzy, and the other letters had the same meaning as above. When performing image segmentation, the larger the value Q_{pc}, the better the segmentation effect; the smaller the value Q_{pe}, the better the segmentation effect; the smaller the value Q_{da}, the better the segmentation effect.

2.5. Observation Indicators. Three indicators of AFFCM, FCM, KFCM, and RFCM needed to be recorded, which were the partition coefficient, segmentation entropy, and the correlation degree between classes after fuzzy. Then, the location and distribution of foreign bodies in the trachea and the types of foreign bodies should be collected. MRI scanning and chest X-ray were recorded for the diagnosis of tracheal foreign body (positive and negative), and the positive rate of diagnosis was calculated. In addition, the indirect signs of tracheal foreign bodies in the children were recorded by MRI scanning and chest X-ray.

2.6. Statistical Methods. SPSS 19.0 statistical software was used for test data processing, the measurement data were expressed as the mean ± standard deviation ($\overline{x} \pm s$), the count data were represented by percentage (%), and the AFFCM, FCM, KFCM, and RFCM were compared by one-way analysis of variance (ANOVA). Furthermore, MRI scanning and X-ray chest radiographs adopted t-test to compare the positive rate and the diagnosis rate of tracheal foreign bodies in children, and $P < 0.05$ indicated that the difference was statistically marked.

3. Results

3.1. Comparison on the Segmentation Performance of Different Algorithms. Figure 2 reveals that the partition coefficient and the correlation degree between classes after fuzziness of AFFCM increased greatly in contrast to those of FCM, KFCM, and RFCM, with a statistically marked difference ($P < 0.05$). The segmentation entropy of AFFCM (0.137) was smaller steeply than the entropies of FCM (0.447), KFCM (0.322), and RFCM (0.275), and there was a statistically obvious difference ($P < 0.05$). The partition coefficient and the correlation degree between classes after fuzziness of KFCM (0.347) and RFCM (0.406) were markedly greater than those of FCM (0.288) ($P < 0.05$), while the segmentation entropies of KFCM and RFCM were both hugely smaller than that of FCM ($P < 0.05$).

Figure 3 shows the comparison of MRI images processed by different algorithms. It was found that the original image map had poor clarity and more artifacts and noises, and the observation of image features was not clear enough, with poor quality. After the four algorithms, the sharpness of the image was improved to a certain extent, and the noise was correspondingly reduced. Among them, the sharpness of the image processed by AFFCM was the highest, with less noise and artifacts, and the quality was improved hugely.

3.2. X-Ray and MRI Imaging Evaluation of One Child Patient. Figure 4 shows the X-ray and MRI image evaluation of one case (male, 2 years old). X-ray film revealed that the transmittance of the left lung field decreased, the mediastinum moved to the left, the transmittance of the right lung field increased, the air content rose, and there were obvious manifestations of emphysema. Considering the valve function of the foreign body, the volume of air inhaled was more than the volume of air exhaled, resulting in the increased volume of air in the right lung and emphysema, so he was diagnosed as a right bronchial foreign body. The right lung emphysema could be observed from the MRI image, the

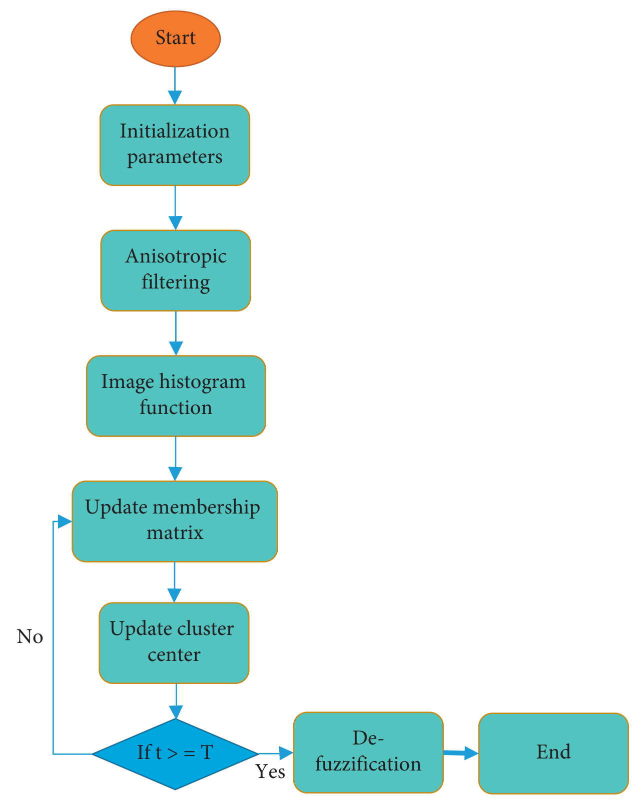

Figure 1: Algorithm's flow chart.

T1-weighted image was an iso-signal shadow, and the T2-weighted image was a high-intensity shadow. Thus, the diagnosis was a vegetative bronchial foreign body.

3.3. The Situation of Foreign Bodies in the Bronchus of 28 Child Patients. Figure 5 reveals that there were 5 cases of foreign bodies in the trachea (17.86%), 10 cases of foreign bodies in the left bronchus (35.71%), and 13 cases of foreign bodies in the right bronchus (46.43%) among the 28 child patients.

As for the types of foreign bodies, 10 cases were melon seeds (35.71%), 6 cases were peanuts (21.43%), 5 cases were beans (17.86%), 3 cases were pistachios (10.71%), 3 cases were plastic (10.71%), 1 case was fish bone (3.57%), most of which were plant-based foreign bodies, as shown in Figure 6.

3.4. Comparison on Positive Rate and Diagnosis Rate of MRI and X-Ray Diagnosis of Bronchial Foreign Bodies. Figure 7 discloses the comparison results of the positive rates of MRI and X-ray diagnosis of bronchial foreign bodies. It was found that MRI diagnosis of bronchial foreign bodies was positive in 25 cases and negative in 3 cases; chest X-ray diagnosis of bronchial foreign bodies was positive in 16 cases and negative in 12 cases. The positive rate of MRI diagnosis of bronchial foreign bodies (89.29%) rose substantially compared with X-ray chest radiograph (57.14%), and the difference was obvious ($P < 0.05$). Besides, the negative rate of MRI diagnosis of bronchial foreign bodies (10.71%) dropped sharply in contrast to the rate of X-ray chest radiograph (42.86%), showing a statistically huge difference ($P < 0.05$).

The diagnosis rates of MRI and X-ray diagnosis of tracheal foreign bodies were compared, and the results are presented in Figure 8. It shows that the diagnosis rate of tracheal foreign bodies diagnosed by MRI (96.43%) elevated obviously compared with chest X-ray (67.96%) ($P < 0.05$). However, the negative diagnosis rate of tracheal foreign bodies diagnosed by MRI (3.57%) reduced steeply in contrast to the rate of chest X-ray (32.14%) ($P < 0.05$).

3.5. MRI and X-Ray Diagnosis of Tracheal Foreign Body Signs. Figure 9 displays the signs of foreign bodies in trachea diagnosed by MRI and X-ray. It reveals that the X-ray diagnosis of bronchial foreign body signs included emphysema, atelectasis, limited obstruction, and mediastinal displacement. Among them, 21 child patients suffered from emphysema, 8 child patients had atelectasis, 1 child patient suffered from limited obstruction, and 2 child patients showed mediastinal displacement; thus emphysema > atelectasis > mediastinal displacement > limited obstruction. The bronchial foreign body signs diagnosed through MRI were emphysema, atelectasis, mediastinal swing, limited obstruction, mediastinal displacement, and pulmonary infection. Among them, there were 25 cases with emphysema, 22 cases with atelectasis, 17 cases with mediastinal swing, 10 cases with limited obstruction, 3 cases with mediastinal displacement, and 19 cases with pulmonary infection, so emphysema > atelectasis > pulmonary infection > mediastinal swing > limited obstruction > mediastinal displacement.

4. Discussion

Tracheal and bronchial foreign bodies refer to the symptoms of coughing, wheezing, and dyspnea caused by foreign bodies entering the respiratory tract through inhalation, ingestion, suffocation, and so forth. Kozaci et al. (2019) [15] found that when a foreign body entered the human airway, it would stimulate the airway mucosa and cause mucosal edema. If it stayed in the airway for too long, it would also lead to pneumonia and lung abscess. Therefore, it is necessary to choose an accurate way to diagnose and treat airway foreign bodies. MRI, as an imaging method extensively used in the field of medical diagnosis in recent years, has very prominent advantages, but it is rarely applied in the diagnosis of foreign bodies in the trachea. In this study, the traditional FCM algorithm was first optimized based on anisotropic filtering (AFFCM), which was compared with FCM, KFCM, and RFCM. The result indicated that the partition coefficient and the correlation degree between classes after fuzziness of AFFCM were hugely greater than those of FCM, KFCM, and RFCM, but the segmentation entropy of AFFCM was obviously smaller than those of FCM, KFCM, and RFCM ($P < 0.05$). This was similar to the research findings of Tamiru et al. (2012) [16], which showed that, compared with the traditional algorithm, the proposed algorithm AFFCM had higher segmentation coefficient value, lower segmentation entropy, higher similarity between classes, and better image segmentation effect [17].

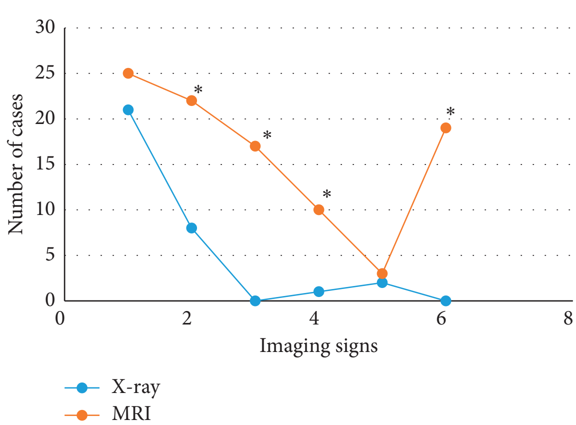

Figure 9: Comparison of the tracheal foreign body signs of MRI and X-ray diagnosis: $*$ indicates $P < 0.05$ compared with X-ray.

Based on the processed MRI images, AFFCM could overcome noise and improve image quality.

In this study, MRI and X-ray scanning based on AFFCM were performed on 28 children who were diagnosed with tracheal foreign bodies and admitted to the hospital from October 2019 to November 2020. It was found that there were 5 cases (17.86%) of tracheal foreign bodies, 10 cases (35.71%) of left bronchial foreign bodies, and 13 cases (46.43%) of right bronchial foreign bodies in the 28 children, which was consistent with previous studies, showing that the right bronchial foreign body was the most common site. Among the 28 cases of foreign bodies, 10 cases were melon seeds (35.71%), 6 cases were peanuts (21.43%), 5 cases were beans (17.86%), and other types were few, most of which were plant foreign bodies. This may be due to the fact that melon seeds are always available in every family. When children are frightened, crying, and naughty, and there are other predisposing factors, it is easy to accidentally choke into the airway [18]. The positive rate (89.29%) and diagnosis rate (96.43%) of bronchial foreign body diagnosed by MRI were substantially higher than the rates of chest X-ray (57.14% and 67.86%) ($P < 0.05$), which was similar to the research findings of Gao et al. (2015) [19], indicating that the diagnostic level of coronal MRI for airway foreign bodies was better than that of chest X-ray film. What is more, it could clearly show the size, shape, and type of foreign bodies as well as the complications caused to the lungs, and it was easier to identify the related diseases. The bronchial foreign body signs through MRI diagnosis were emphysema > atelectasis > lung infection > mediastinal swing > limited obstruction > mediastinal displacement, in which emphysema and atelectasis were the most common cases, suggesting that emphysema and atelectasis could be the main signs of bronchial foreign body in MRI diagnosis. In the X-ray diagnosis of bronchial foreign body signs, emphysema > atelectasis > mediastinal displacement > limited obstruction, where the number of emphysema cases was the largest, which indicated that emphysema could be used as the primary sign of X-ray diagnosis of bronchial foreign bodies.

5. Conclusion

In this study, the traditional FCM algorithm was optimized based on anisotropic filtering to obtain AFFCM, and it was compared with FCM, KFCM, and RFCM, which was also applied to 28 cases of pediatric tracheal foreign body MRI diagnosis. It was found that AFFCM had a relatively high partition coefficient value, a lower segmentation entropy, and a greater degree of similarity between classes, with better image segmentation effect. MRI based on AFFCM also had a higher positive rate and diagnosis rate for children with foreign bodies in the trachea, and the main signs were emphysema and atelectasis. However, the selection of children's samples is small in this study, and more detailed group discussions are not possible. Further consideration is given to the selection of more children to further explore the characteristics of tracheal foreign body in MRI images of child patients. All in all, the results of this study can provide a good theoretical basis for the clinical diagnosis of foreign bodies in the trachea of children.

Academic Editor: Enas Abdulhay

To study and explore the adoption value of magnetic resonance imaging (MRI) in the diagnosis of anterior cruciate ligament (ACL) injuries, a multimodal feature fusion model based on deep learning was proposed for MRI diagnosis. After the related performance of the proposed algorithm was evaluated, it was utilized in the diagnosis of knee joint injuries. Thirty patients with knee joint injuries who came to our hospital for treatment were selected, and all patients were diagnosed with MRI based on deep learning multimodal feature fusion model (MRI group) and arthroscopy (arthroscopy group). The results showed that deep learning-based MRI sagittal plane detection had a great advantage and a high accuracy of 96.28% in the prediction task of ACL tearing. The sensitivity, specificity, and accuracy of MRI in the diagnosis of ACL injury was 96.78%, 90.62%, and 92.17%, respectively, and there was no considerable difference in contrast to the results obtained through arthroscopy ($P > 0.05$). The positive rate of acute ACL patients with bone contusion and medial collateral ligament injury was substantially superior to that of chronic injury. Moreover, the incidence of chronic injury ACL injury with meniscus tear and cartilage injury was notably higher than that of acute injury, with remarkable differences ($P < 0.05$). In summary, MRI images based on deep learning improved the sensitivity, specificity, and accuracy of ACL injury diagnosis and can accurately determined the type of ACL injury. In addition, it can provide reference information for clinical treatment plan selection and surgery and can be applied and promoted in clinical diagnosis.

1. Introduction

The knee joint is a very important compound joint in the human body, which not only undertakes frequent and complex movements but also is the most important weight-bearing joint of the human body [1]. Therefore, knee injuries are inevitable in life. Most knee injuries are caused by high-intensity exercises, sports competitions, and falls from high altitudes. The most common knee injuries include anterior cruciate ligament (ACL) injury and meniscus injury, and the combination of the two injuries is also common. According to reports, the incidence of ACL injury with meniscus injury was more than 85%, which may cause joint swelling, pain, and movement inconvenience in patients, thus substantially affecting the life and work of patients [2, 3]. In the case of knee injury, timely and accurate assessment of ACL injury is helpful to select the best treatment plan and effectively evaluate the prognosis of patients. It is of great clinical significance for patients to recover the normal stability and normal motor function of knee joint and to avoid or reduce the secondary injury of other knee joint structures [4]. Clinically, complete tears and partial tears are often taken as the basis for judging ACL damage [5]. All in all, the early and correct diagnosis after ACL injury is of great significance for the choice of clinical treatment plan and prognosis [6, 7].

The commonly used methods for diagnosing ACL injury are roughly classified into three categories, clinical stability examinations, such as anterior drawer test and axis shift test, imaging examinations such as ultrasound diagnosis, CT diagnosis, and MRI diagnosis, and arthroscopy [8]. Ultrasound examination and CT examination require high operational experience of medical staff. Arthroscopic diagnosis is an effective standard for ACL injury, but the inspection method is limited to the case of trauma [9]. Therefore, clinical stability check is an important method for doctors to check ACL injury. Due to the good tissue resolution and high spatial resolution, MRI can not only objectively evaluate knee joint injuries but also evaluate knee joint injuries such as meniscus injuries and cartilage injuries [10].

Since MRI examinations show high clinical diagnosis accuracy of ACL tears and meniscus, knee MRI has become the first choice for the diagnosis of knee joint injuries in recent years. The deep learning approaches can automatically learn multilayer features, which are very suitable for the auxiliary diagnosis of medical images [11]. At present, deep learning approaches have surpassed traditional medical image analysis methods and have made great progress in the field of knee MRI. Mayo et al. [12] developed a fully automatic knee joint magnetic resonance cartilage damage detection system based on deep learning. The system consisted of two CNN networks. The first CNN network was utilized for the rapid segmentation of cartilage and bone, while the second CNN network evaluated the structural abnormalities of articular cartilage. The total accuracy of the experiment reached 98.37%. Therefore, the deep learning-based MRI cartilage injury detection system of the knee joint shows a high diagnostic accuracy, can quickly analyze images, significantly saves the diagnostic time, and improves the diagnostic efficiency. This diagnosis method is worthy of promotion and adoption.

In summary, the knee joint injury patients were taken as the research object in this research. MRI images of patients were optimized based on deep learning algorithms, which were then applied to the diagnosis of knee joint injury patients, and the adoption value of MRI image diagnosis in ACL injury was evaluated.

2. Materials and Methods

2.1. Research Objects and Grouping. Thirty patients with knee joint injuries diagnosed in our Hospital from May 2019 to March 2020 were selected as the research objects. All patients underwent MRI and the results were compared with those obtained by arthroscopy. There were 21 males and 9 females. The age range of the patients was 18–75 years, and the average age was (37.82 ± 5.18) years. The patients were rolled into two groups according to diagnosis methods. One group was MRI diagnose and the other group was arthroscopic diagnose, and they were compared within the groups. The experimental process had been approved by the ethics committee of the hospital, and all subjects included in the study had signed the informed consent forms.

Inclusion criteria: (i) clinical symptoms were joint pain, swelling, joint instability, etc.; (ii) physical examination methods (anterior drawer test, Lachman test, etc.) showed at least one positive sign; (iii) those who aged 18–75 years old.

Exclusion criteria: (i) patients with a previous history of knee joints, such as tuberculosis arthritis and rheumatoid arthritis; (ii) the patient's joints were found to have tumors or tumor-like lesions through examination; (iii) patients with a history of knee surgery; (iv) patients whose age was under 18.

2.2. MRI Examination. The patient's original image was sent to a postprocessing workstation. Three associate chief doctors with more than five years of experience in MRI diagnosis in the radiology department performed oblique coronal and cross-sectional multiplane recombination. The thickness was 0.4 mm, and there was no spacing between the layers. The three-dimensional reconstructed ACL and its surrounding structures were observed, and consensus was reached and recorded through consultation. At the same time, the MRI scan sequences (T2WI-SPAIR sagittal images, T2WI cross-sectional images, etc.) were observed and analyzed, and the corresponding diagnostic opinions were recorded. According to the characteristics, continuity, edge, shape, and signal of ACL damage, whether ACL was damaged and the extent of damage were judged. According to the comprehensive literature, MRI diagnostic criteria of ACL injury were established, and the MRI signs of ACL injury were classified into four categories [13] as follows. Grade 0: no abnormalities in initial profile, walk, and signal. Grade I: the ligament continuity was still good, the contour was still intact, the ligament was not thickened or slightly thickened and expanded, small patches or streaks of signal can be seen, and damage area was less than 50%. Grade II: ligamentous continuity was poor, but some continuous fibers were still visible; locally thickened or diffused ligaments were visible; incomplete or well-defined edges were at the site of ligament injury, or there were locally notched areas; abnormally high signal can be seen, with damage area greater than or equal to 50%. Grade III: there was intact rupture of the ligament, characterized by broken continuity of the ligament, displacement of the bent or broken end, clumpy ligament, increased signal, and unclear boundary.

After the patient's medical history and MRI results were provided, radiologists would observe and analyze the knee images of the patient to determine whether there was a tear in the ACL of the knee and the degree of the tear. If there was a difference of opinion, the three experts could reach a conclusion after consultation.

2.3. Arthroscopy Examination. Arthroscopy with a diameter of 4.0 mm and a wide angle of 30 degrees from Stryker and Smith & Nephew were utilized. The arthroscopy was performed by two joint surgeons. A detailed medical history was taken before surgery, and a physical examination was performed in combination with X-rays and MRI. The knee ACL was carefully examined during surgery. If there was a partial injury, a detailed examination with a probe was performed to avoid misdiagnosis. If a ligament injury was found arthroscopically, the physician could take further appropriate treatment and recorded the surgical plan and procedure. MRI findings and arthroscopic findings were studied and analyzed.

2.4. Deep Learning Model Construction Based on Multimodal Feature Fusion

2.4.1. Deep Feature Extraction. At present, convolutional neural networks are more and more widely used in the field of medical image diagnosis and have made good progress. The mechanism of convolutional neural network refers to automatically performing the feature extraction of the image through the convolution operation of the image, and such feature has advanced semantic information and is more robust [14]. Since the deep learning model can only achieve ideal results when trained on annotated images, transfer learning is adopted to directly use the second to fifth convolution blocks of the pretrained VGG16 [15]. The feature map of the last layer of each convolution block is extracted, which is $H(g)$, $g = 1, 2, 3, 4, 5$. After the up-sampling $K(g-1)$ of $H(g-1)$ was obtained, the result image after 2^*2 convolution processing is pixel fused, and then, 5^*5 convolution kernel is used again to correct the fused image, which can eliminate the aliasing effect used above and obtain a new feature map $H(g-1)$. The pyramid fusion equation is as follows:

$$\begin{aligned} K(g-1) &= y_{2\times 2}(H(g-1)), \\ H(g-1) &= y_{5\times 5}(H(g) + H(g-1)). \end{aligned} \tag{1}$$

After the last layer $H(2)$ is acquired, it passes through the batch normalization (BN) layer, the adaptive maximum pooling layer, and the fully connected layer in turn. The BN layer can speed up the convergence speed and classification effect of the model. $y^{(n)}$ is set as the nth dimension feature of $H(2)$, the BN layer is $H(2)$ introduced with the parameters $\partial^{(n)}$ and $D^{(n)}$, and the indifference estimation is conducted to output the nth dimension feature as follows:

$$y^{(n)} = \partial^{(n)}\overline{s}^{(n)} + D^{(n)}, \tag{2}$$

$$\begin{aligned} \overline{s_l} &= \frac{s_l - q}{\sqrt{w_x^2 + \vartheta}}, \\ q &= \frac{1}{e}\sum_{l=1}^{a} s_l, \end{aligned} \tag{3}$$

$$w_x^2 = \frac{1}{e}\sum_{l=1}^{a}(s_l - w_x). \tag{4}$$

In the above equation, equation (3) is the average value of batch size q, and equation (4) is the variance of batch size q.

When nonlinear factors are added to the ReLU layer, the expression ability of the increased model will be weakened. The activation function of ReLU is as follows:

$$f(m) = \max\{0, m\}. \tag{5}$$

The main difference between the adaptive maximum pooling layer and the standard Max Pooling is that the former will control the output size (Out) according to the input size (In), and stride and kernel size are as follows:

$$\begin{aligned} \text{stride} &= \text{floor}\left(\frac{\text{In}}{\text{Out}}\right), \\ \text{kernel size} &= \text{In} - (\text{Out} - 1) \times \text{stride}, \\ \text{Padding} &= 0. \end{aligned} \tag{6}$$

The fully connected layer can be regarded as the full-scale convolution of $s \times u$; s and u are the output size of the previous layer, and finally, 1026-dimensional features extracted by the convolutional neural network can be obtained:

$$h = (h_1, h_2, h_3, \ldots, h_{1026}). \tag{7}$$

2.4.2. Multimodal Feature Adaptive Fusion. Due to the different features of different modalities [16], a deep learning model of multimodal feature fusion is constructed to retain the correlation of multimodality. The model contains a hidden layer with a number of neurons less than the feature dimension and a Sigmoid layer. The entire network is trained by maximizing the energy proportion of the feature layer. The Sigmoid layer can map the feature interval after feature fusion to (0, 1), which is the prediction probability. The feature vector $m = (c, o)$, and the forward propagation equation is as follows:

$$p_e = (s_i + t_i)\vartheta_{ie} + \beta_e, \tag{8}$$

$$W = \partial\left(\sum_{l=1}^{a}(s_i + t_i)\vartheta_{ie} + \beta_e\right). \tag{9}$$

In the above equations, $\partial(k) = 1/1 + n^{-k}$, t_i is the deviation of the visible layer, β_e is the deviation of the hidden layer, and p_e is the hidden layer vector. To obtain the optimal fitting multimodal feature, the energy model is used to adjust the parameters, and the energy function is as follows:

$$H(x, y|\ell) = -\sum_{l=1}^{a} s_i t_i - \sum_{e=1}^{i} \beta_e p_e - \sum_{l=1}^{a}\sum_{e=1}^{i} t_i \vartheta_{ie} y_i. \tag{10}$$

In equation (9), $\ell = (t_i, \vartheta_{ie}, y_i)$, $H(x, y|\ell)$ represents the total energy of the module.

The marginal probability distribution is defined as follows:

$$p(x|\ell) = \frac{1}{Z(\ell)}\sum_{e} r^{-k(x,y|\ell)}, \tag{11}$$

$$p(y|\ell) = \frac{1}{Z(\ell)}\sum_{i} r^{-k(x,y|\ell)}. \tag{12}$$

In equations (10) and (11), $Z(\ell) = \sum_{il} r^{-k(x,y|\ell)}$, and the optimization function is defined as follows:

$$\ell_{nm} = \arg\max_{\ell}\sum_{j=1}^{o} \lg P\left(x_j|\ell\right). \tag{13}$$

In equation (12), o is the number of samples. When the function ℓ takes the maximum value, the energy proportion of the characteristic layer is high, and the energy of the hidden layer is small. When data is transmitted within the network, the direction of the data flow is also the direction of energy dissipation. After many iterations, the network energy shows a decay trend, the network tends to be ordered, or the probability distribution tends to be concentrated.

2.5. Evaluation Index. The performances of different models were quantitatively evaluated regarding the Accuracy, Recall, and AUC.

Accuracy refers to the proportion of the correct samples predicted by the model to the total samples, which is calculated as follows:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FN} + \text{TN} + \text{FP}},$$
$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}. \tag{14}$$

In the above equations, TP (true positive) means that the segmentation result and the gold standard result are both true, that is, true positive. FP (false positive) means that the segmentation result is false, and the gold standard results are all true. FN (false negative)) indicates that the segmentation result is true, and the gold standard results are all false.

The AUC value is defined as the area under the ROC curve enclosed by the coordinate axis. Since the ROC curve is generally above the line $y = x$, the value range of AUC is between 0.5 and 1. The closer the AUC is to 1.0, the higher the authenticity of the detection method is.

The observation of concomitant injury of ACL mainly included common combined injuries such as meniscus tear, bone contusion, medial and lateral collateral ligament injury, cartilage injury, and joint effusion.

2.6. Statistical Methods. SPSS 19.0 was employed for data statistics and analysis. Mean ± standard deviation ($\overline{x} \pm s$) was how measurement data were expressed, and the comparison of the mean between each group was performed by t test. Percentage (%) was how count data were expressed, and the χ^2 test was used. The difference was statistically considerable with $P < 0.05$.

3. Results

3.1. Analysis of the Results of ACL Damage Diagnosis Based on Deep Learning Algorithms. The results of ACL damage diagnosis based on deep learning algorithms were analyzed. Figure 1 showed that, after fusion of traditional features and deep learning features, the performance indicators of MRI were improved to a certain extent, especially in accuracy and AUC value. The accuracy was up to 90%, and the highest AUC value was 0.9726. The detection rate of this model for general positive samples was higher than 92%, and the detection rate for positive samples of ACL tear and meniscus tear was high, which was of great significance to assist physicians in diagnosing high-risk patients.

From the results in Figure 1, the sagittal plane detection had a great advantage and a high accuracy of 96.28% in the task of ACL tear prediction. The prediction accuracy of meniscus tear was low, which was 75.37% (Figure 1(a)). In the prediction of recall rate, the prediction of ACL tear was the best on the horizontal axis, the recall rate was 89.56% (Figure 1(b)), and the AUC value was 0.9726. In the prediction of meniscus tear, the sagittal plane was the best, with a recall rate of 90.57% and an AUC value of 0.923 (Figure 1(c)).

Since each prediction task had only two cases of positive and negative, the prediction probability of the model greater than or equal to 0.5 was deemed as a positive patient, and the prediction probability less than 0.5 was deemed as a negative patient, so as to better show the prediction effect of the model. The test results of ACL tear and meniscus tear were shown in Figure 2. The results showed that this prediction model had good performance for ACL tear and meniscus tear predictions, especially for ACL prediction accuracy and recall rate, and the maximum AUC value was above 0.96. It indicated that the prediction model based on deep learning used in this study can be used as a basis for diagnosing knee joint injuries and had certain value in clinical adoptions.

3.2. MRI Features of Patients with Knee Joint Injury Based on Deep Learning. Figure 3 was the schematic diagram of a 55-year-old male patient with bone contusion (axial displacement sign). In Figure 3(a), once the ACL was torn, the tibia would move forward relative to the femur, causing the lateral femoral condyle to collide with the outer and posterior tibia. Both sides had edema, and the degree of knee flexion determined the location of the femoral condyle. Figures 3(b) and 3(c) were images of ACL tears observed at different positions.

Figure 4 showed MRI images of some patients with knee injuries. Figure 4(a) showed ligament discontinuity. There was a low signal of the ligament, but the interruption was discontinuous, the path was low and flat, and the ligament was curled in a clumpy or wavy shape, which was generally seen in fresh injuries. In Figure 4(b), there was abnormal direction of ligament injury (ACL ptosis). There was a relatively intact ligament with low signal, but the direction was abnormal and pendulous, which was usually seen in the old injury of the femoral attachment, where the damaged ACL dropped and adhered to the PCL. In Figure 4(c), the ACL was absent. The intercondylar fossa was empty and there was no ligament signal. The symptoms were mainly present in prolonged injuries, where the damaged ACL tear was heavy and horse-tailed, did not enclose synovium, and was gradually corroded by enzymes in the joint.

In Figure 5(a), MRI T2WI showed a tear in the posterior horn of the medial meniscus of the knee. In Figure 5(b), MRI T2WI plain scan showed the high signal shadow within the low signal of the posterior cruciate ligament. The arrow indicated a partial rupture with hyperintensity bleeding around the rupture. The MRI diagnosis was an incomplete rupture of the right posterior cruciate ligament.

3.3. MRI Manifestations of ACL Injury. There are 60 knee joints in 30 patients with knee joint injury. In the examination results, the MRI examination showed that there were 34 cases of ACL grade III injury, 10 cases of grade II injury, 10 cases of grade I injury, and 6 cases of grade 0 injury.

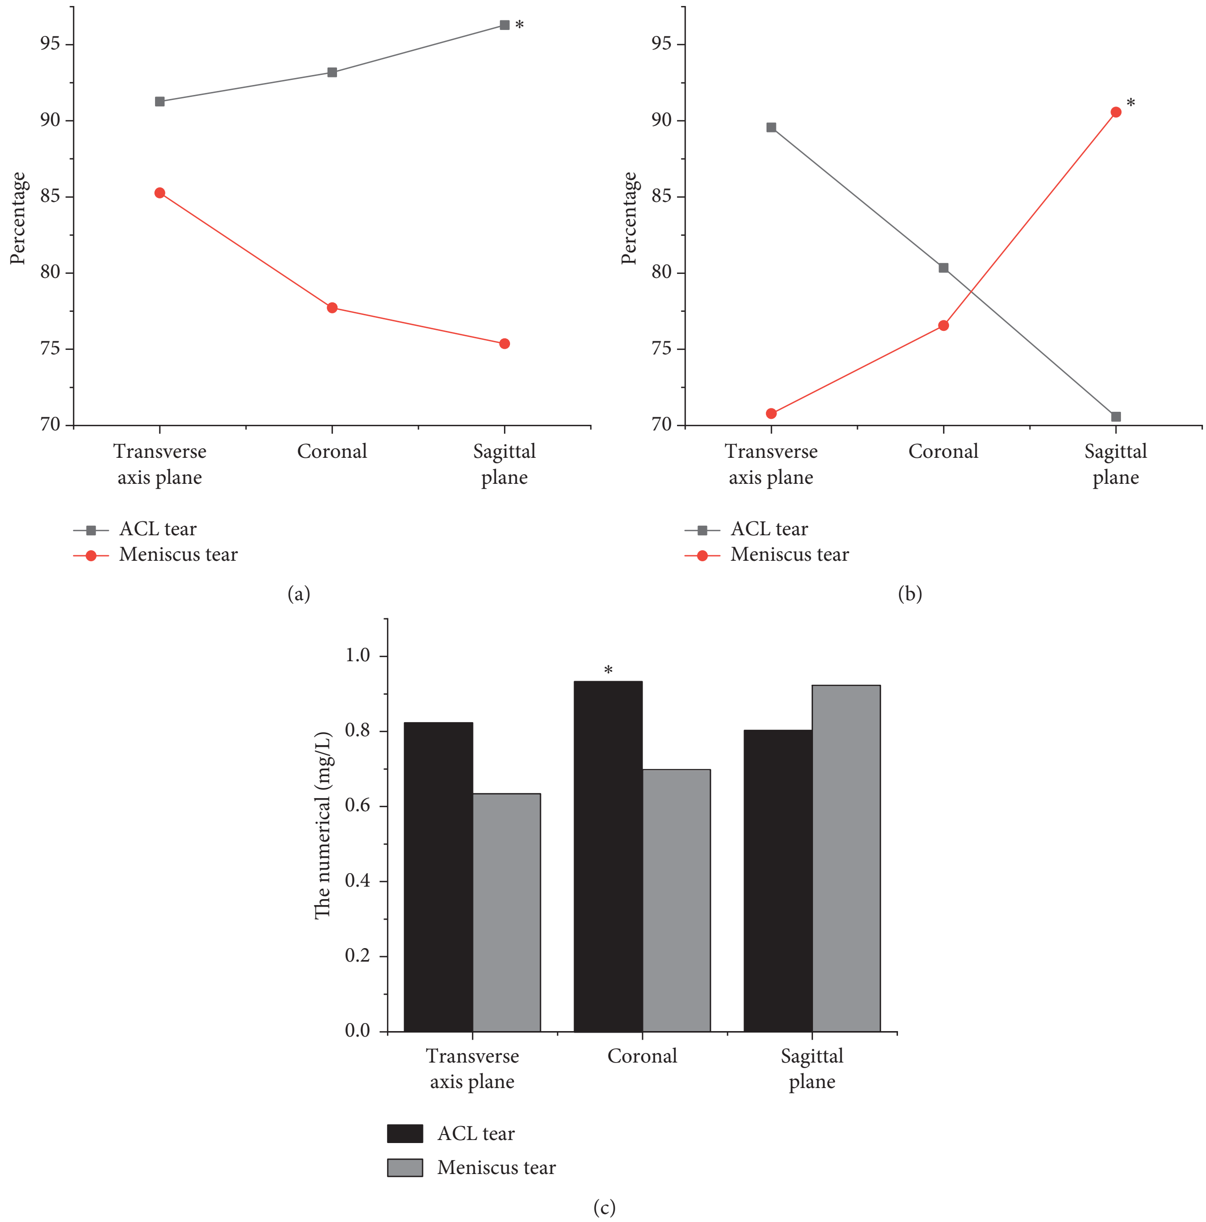

Figure 1: Analysis of diagnosis results of ACL injury based on deep learning algorithm. Accuracy comparison of transverse plane, coronal plane, and sagittal plane (a); recall rate comparison of transverse plane, coronal plane, and sagittal plane (b); AUC comparison of transverse plane, coronal plane, and sagittal plane (c). *indicated that the accuracy, recall rate, and AUC of ACL injury were statistically different from that of meniscus injury ($P < 0.05$).

Arthroscopy showed that there were 34 cases of ACL grade III injury, 13 cases of grade II injury, 11 cases of grade I injury, and 2 cases of grade 0 injury. Compared with the results of arthroscopy, 3 cases were misdiagnosed as intact ligaments, 3 cases were misdiagnosed as grade II ligament injuries, 1 case was misdiagnosed as grade I ligament injuries, 4 cases were misdiagnosed as grade 0 injuries, and 2 cases were missed (Figure 6).

Figure 7 showed that the sensitivity, specificity, and accuracy of MRI in the diagnosis of ACL injury was 96.78%, 90.62%, and 92.17%, respectively, with no substantial difference from the results of arthroscopy ($P < 0.05$), which showed that MRI can accurately diagnose ACL injury.

3.4. ACL Injury Classification and Concomitant Injury. In this research project, there were 34 cases of ACL grade III injury, including 10 cases of chronic injury and 24 cases of acute injury, 10 cases of grade II injury, 4 cases of chronic injury, and 6 cases of acute injury. Among grade I and grade 0 injuries, chronic injuries accounted for 3 cases and acute injuries accounted for 13 cases. There were 43 cases of acute injury and 17 cases of chronic injury.

Among the types of ACL injuries, there were meniscus tears, bone contusions, internal and external collateral ligament injuries, cartilage injuries, joint effusions, etc. The common concomitant injury was the torn meniscus. There were 30 patients with acute injury in concomitant injury and

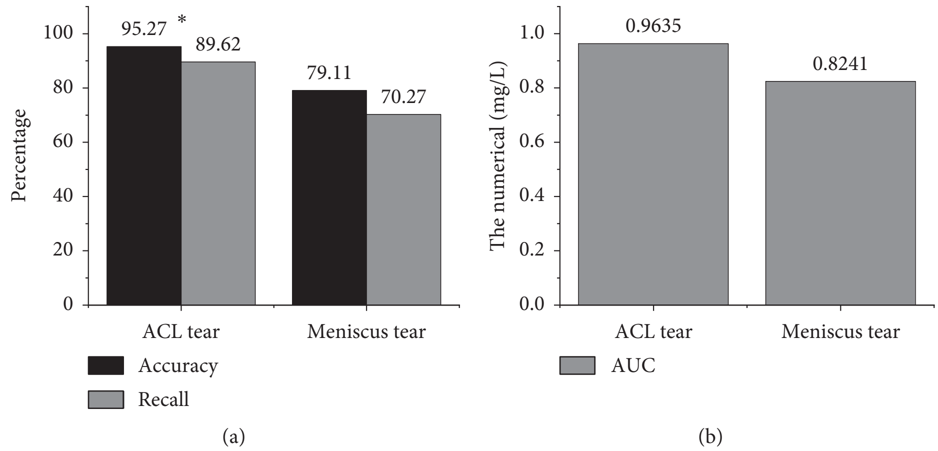

Figure 2: Performance comparison of regression models: (a) comparison of accuracy and recall rate of ACL and meniscus tear; (b) comparison of AUC of ACL and meniscus tear. *indicated that ACL injury was dramatically different versus meniscus injury ($P < 0.05$).

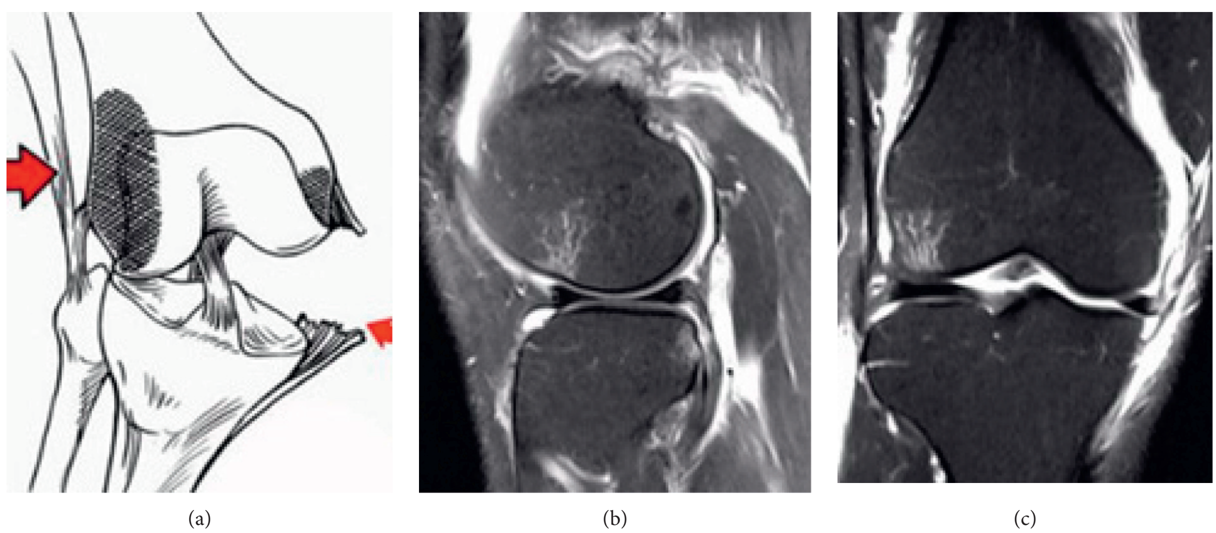

Figure 3: Schematic diagram of ACL injury. (a) The ACL tear, the arrow indicated the site of the ligament injury, (b) the coronal diagram of the ligament tear, and (c) the sagittal diagram of the ligament tear.

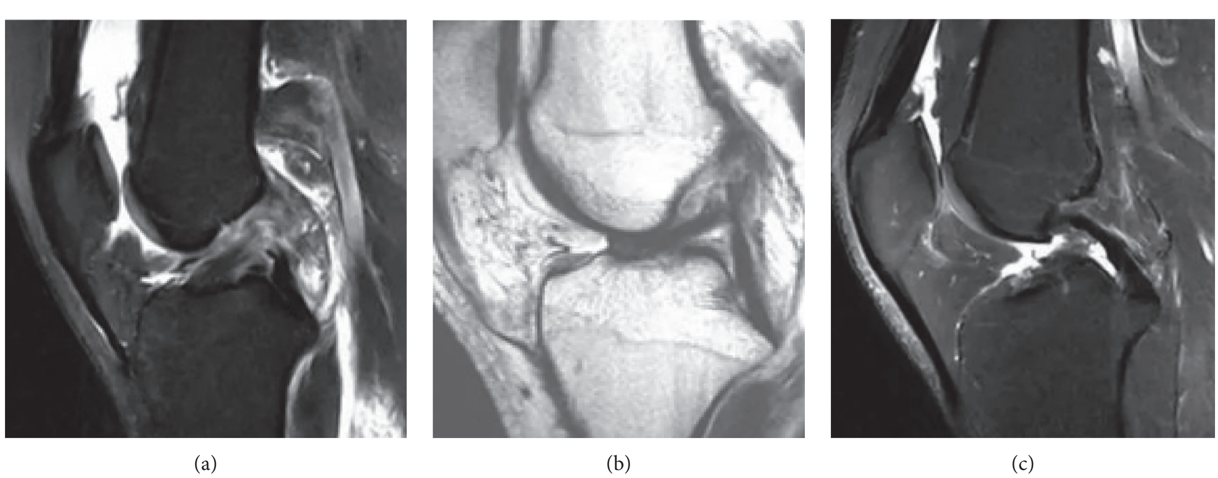

Figure 4: MRI images of the patients. (a) ACL discontinuity (49-year-old female patient), (b) ACL drooping sign (58-year-old male patient), and (c) ACL disappearance (55-year-old male patient).

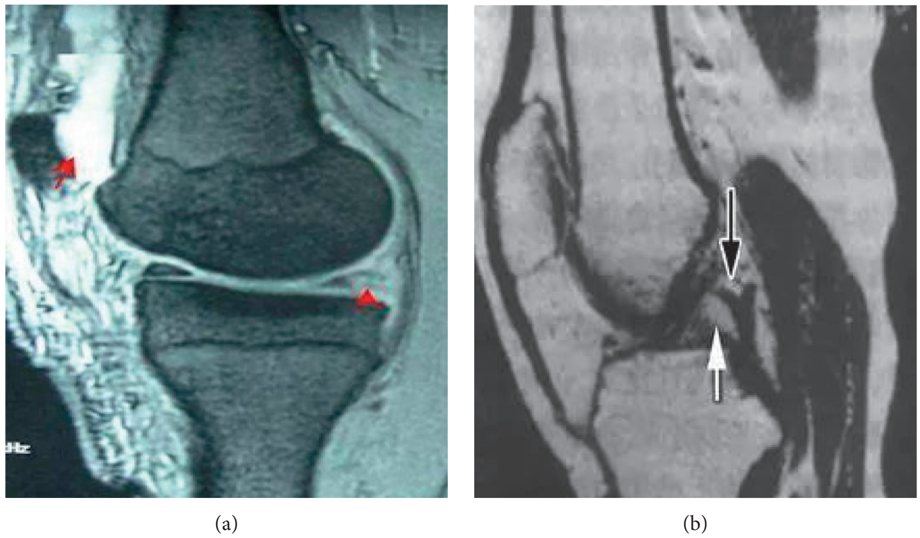

Figure 5: MRI T2WI images of the patients (male, 61 years old). (a) Tear of posterior corner of medial meniscus of knee joint (the arrow was the tear site); (b) MRI T2WI plain scan of posterior cruciate ligament (the arrow indicated a partial rupture of the ligament).

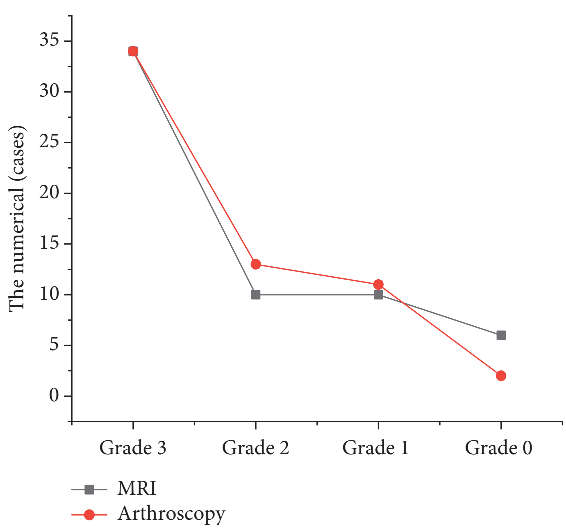

Figure 6: MRI diagnosis result of ACL injury.

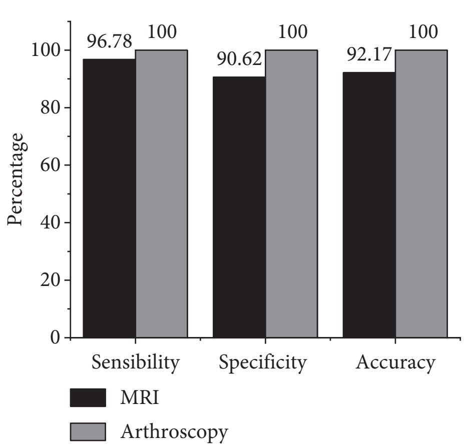

Figure 7: Contrast of MRI diagnosis performance of ACL injury.

meniscus injury. In addition, there were 20 patients with internal collateral ligament injury, 13 patients with lateral collateral ligament injury, 15 patients with cartilage injury, and 10 patients with bone contusion. Among chronic ACL injuries, 12 patients were accompanied by meniscus tears. In addition, there were 7 patients with collateral ligament injury, 5 patients with lateral collateral ligament injury, 7 patients with cartilage injury, and 3 patients with bone contusion. Figure 8 shows the positive rate of ACL concomitant injury. The positive rate of acute ACL patients with bone contusion and medial collateral ligament injury was considerably higher than that of the chronic patients. However, the incidence of ACL injury with meniscus tear and cartilage injury in the chronic group was substantially higher than that in the acute group, and there was a remarkable difference between the two ($P < 0.05$).

4. Discussion

The main function of the ACL is limiting the overdevelopment of the tibial plateau and the rotation of the knee joint. During the bending movement of the knee joint, the fiber bundles in the knee joint obtain the stability of the knee joint through various stretching modes. When the knee joint is straightened, the posterolateral branch (PLB) is in tension, and the anteromedial branch (AMB) is slightly relaxed. When the knee joint is bent, AMB is in tension and PLB is in a relaxed state. When an external force acts on the knee joint, resulting in excessive extension or rotation (for example, excessive internal and external rotation), it is easy to cause ACL damage or even fracture. MRI has become the most ideal examination method for the diagnosis of knee cruciate ligament injuries due to its advantages of high contrast, high resolution, noninvasive, and multipart imaging. MRI can not only clearly show the normal form of ACL but also show the location, extent, fracture, tear of meniscus, and other knee joint injuries of injured ACL. In this work, a

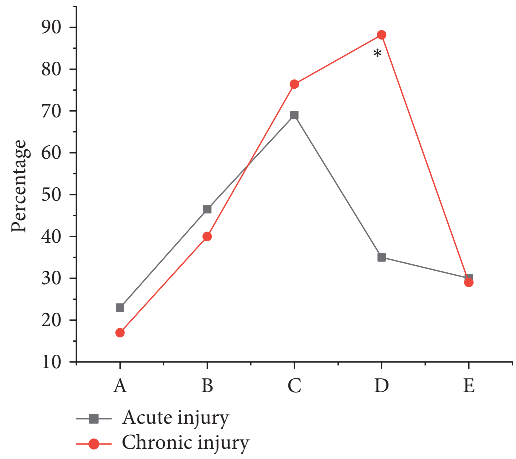

Figure 8: Contrast of positive rate of ACL concomitant injuries (A: bone contusion; B: medial collateral ligament injury; C: meniscus tear; D: cartilage injury; E: lateral collateral ligament injury) (*suggested remarkable differences in contrast to acute injury, $P < 0.05$).

multimodal feature fusion model based on deep learning was proposed for imaging diagnosis based on MRI. First, the knee joint MRI image was preprocessed, and the multimodal features of knee joint injury were extracted based on both traditional and deep learning. Then, the multilayer neural network was adopted to perform correlation fusion of the features. The results showed that the sagittal plane detection has a great advantage and a high accuracy rate of 96.28% in the task of ACL tear prediction. The prediction accuracy of meniscus tear was low, which was 75.37%. In the prediction of recall rate, the prediction of ACL tear was the best on the horizontal axis, the recall rate was 89.56%, and the AUC value was 0.9726. In the prediction of meniscus tear, the sagittal plane was the best, with a recall rate of 90.57% and an AUC value of 0.923. This prediction model showed good prediction performance for ACL tear and meniscus tear. In particular, the prediction accuracy and recall rate of ACL were relatively better, and the maximum AUC value was above 0.96. The results were similar to the conclusions of Miyaji et al. [17] and both showed that the prediction model based on deep learning used in this study can be used as a basis for diagnosing knee joint injuries and had certain value in clinical applications.

The model was applied to the MRI diagnosis of ACL injury. The MRI examination results showed that there were 34 cases of ACL grade III injury, 10 cases of grade II injury, 10 cases of grade I injury, and 6 cases of grade 0 injury. Arthroscopy showed that there were 34 cases of ACL grade III injury, 13 cases of grade II injury, 11 cases of grade I injury, and 2 cases of grade 0 injury. Compared with the results of arthroscopy, 3 cases were misdiagnosed as intact ligaments, 3 cases were misdiagnosed as grade II ligament injuries, 1 case was misdiagnosed as grade I ligament injuries, 4 cases were misdiagnosed as grade 0 injuries, and 2 cases were missed. The sensitivity, specificity, and accuracy of MRI in the diagnosis of ACL injury was 96.78%, 90.62%, and 92.17%, respectively, and there was no great difference from the results of arthroscopy ($P > 0.05$). Namiri et al. [18] found that the indirect signs of ACL tear had high specificity (91%~100%) and sensitivity in a retrospective study of the correlation between MRI imaging and arthroscopy in 100 patients. Therefore, these signs can determine whether the patient had an ACL tear, which was similar to the conclusion of this study, indicating that MRI can accurately diagnose ACL injury. The positive rate of acute ACL patients with bone contusion and medial collateral ligament injury was notably superior to the chronic group. However, the incidence of ACL injury with meniscus tear and cartilage injury in the chronic group was substantially higher than that in the acute group, with substantial differences ($P < 0.05$). Pedoia et al. [19] reported a high incidence of combined articular cartilage damage. However, the literature did not separate statistics on acute and chronic injuries. In this research topic, a clear analysis of the types of concomitant damage was carried out, and the results also provided a certain reference for the diagnosis of ACL concomitant damage.

5. Conclusion

A multimodal feature fusion deep learning model based on deep learning algorithms was established in this work and applied to the diagnosis of ACL injury patients, to explore the value of MRI based on deep learning in the diagnosis of ACL injury. The results revealed that deep learning-based MRI substantially improved the ability to diagnose ACL damage and increased the sensitivity, specificity, and accuracy of the diagnosis of ligament damage. However, this study still has some shortcomings. The number of patient samples selected is small, there is a lack of disease diversity research, and the scope of adoption of the research results has certain limitations. In the future work, the research area and research samples will be further expanded to ensure the universality of research results. In summary, the ability to diagnose ACL injuries in MRI images based on deep learning is improved, which provides a reference for the diagnosis and treatment of patients with knee joint injuries.

Prostatic cancer (PCa) is a prevalent form of malignancy based on its high associated levels of mortality and morbidity across the world. MicroRNAs (miRNAs) are significant in the advancement of prostatic cancer. The current study is aimed at exploring the potential roles of miR-373 in PCa. In turn, the study conducted a qRT-PCR test to determine the levels of mRNA. A western blot test was also executed in determining the protein level. The processes of transwell assay and wound healing were integrated in the detection of the potential for PCa cells to invade and migrate. The integration of dual luciferase reporter assay is critical in determining the levels of luciferase activity among prostatic cancer cells. Then, the results showed a net decrease of miR-373 within prostatic cancer cells and tissues. Upregulated miR-373 reduced the invasion and migration potential of PCa cells. Moreover, overexpressed miR-373 increased the levels of E-cadherin and FSP1 as epithelial cell markers. Similarly, the overregulation of miR-373 brought about the upregulation of mesenchymal markers (N-cadherin, Snail, and vimentin). The study predicted runt-related transcription factor 2 (RUNX2) to be a target of miR-373. The luciferase activity of PCa cells was decreased after the cotransfection with miR-373 mimics and RUNX2 3′ untranslated region (3′UTR) wild type (WT). Moreover, RUNX2 became upregulated in PCa cells and tissues. The upregulation of miR-373 decreased the mRNA and protein level of RUNX2. However, overexpressed RUNX2 abated the roles of miR-373 in the intrusion and migration of PCa cells and in regulating the expression of epithelial cell markers and mesenchymal markers. In short, miR-373 may regulate the EMT of PCa cells via targeting RUNX2. The miR-373/RUNX2 axis provides a therapeutic target for PCa.

1. Introduction

PCa, characterized with high mortality and morbidity, is one of the most malignant tumors worldwide [1, 2]. The past years saw an increase of morbidity and mortality of PCa patients [3, 4]. The PCa-related deaths in 2012 reached 300,000 [5]. Additionally, the mortality of PCa increased from 3/100,000 to 30/100,000 in Asia [6]. Although prestigious breakthroughs have been realized in the management of PCa, the overall rates of survival in PCa are still unsatisfactory. In part, the diagnosis of patients at advanced stages is responsible for the low survival rates. The average survival rate over 5 years is 90% at early stage, while it is no more than 15% at advanced metastatic stage [7]. Lymph node metastasis and bone metastasis are the main challenges in the treatment of prostate cancer [8]. Epithelial-mesenchymal transition (EMT) remodels cell-cell and cell-extracellular matrix interactions, which induces the initiation and metastasis of cancer [9]. Therefore, to suppress the metastasis of PCa may be a promising therapy for the management of PCa.

MicroRNAs (miRNAs) are small endogenous noncoding RNAs, which play a crucial role in post-transcription [10].

Besides, miRNAs degrade gene level through their potential to bind to the 3′ untranslated region (3′UTR) within the target genes [11]. Intensive bodies of evidence have reported that miRNAs participate in multiple biological processes, including proliferation, cell differentiation, invasion, apoptosis, and migration, and epithelial-mesenchymal transition [12, 13]. Moreover, the aberrant expressed miRNAs are significant in facilitating the progression and emergence of cancer, including PCa. For instance, miR-373 is downregulated in non-small cell lung cancer (NSCLC), while overexpressed miR-373 suppresses EMT of NSCLC cells [14]. Upregulated miR-373 promotes EMT of tongue squamous cell carcinoma. MiR-373 is decreased in human epithelial ovarian cancer (EOC), while its overexpression suppresses the invasion and EMT of EOC cells [15]. MiR-373 inhibits the invasion of progression of PCa [16]. However, the underlying mechanisms is still unclear.

Still, RUNX2 is firstly reported to participate in the skeletal embryogenesis. In recent years, its oncogenic properties have been attracting increasing attention. RUNX2 is involved the initiation and progression of numerous cancers [17–19]. RUNX2 acts as an oncogene and regulates the apoptosis, migration, proliferation, invasion, and ETM of malignant cells via unchecked signaling pathways [18, 19]. In PCa, overexpressed RUNX2 is associated with high-grade prostatic intraepithelial neoplasia (HGPIN), cancerous lesions, and prostate tumorigenesis [20]. However, the possible roles of RUNX2 in EMT of PCa have not been elucidated.

In this study, transwell assay and wound healing were applied to examine the implications of overexpressed miR-373 on the processes of invasion and migration among PCa cells. The concept of luciferase assay has the potential of providing novel therapeutic target and was thus used in verifying whether RUNX2 was a target of miR-373. In summary, the study was based on the purpose of investigating the potential roles of miR-373 in the EMT of PCa and the underlying molecular mechanisms.

2. Methods

2.1. Clinical Samples. Tissue samples from the PCa as well as normal tissues in adjacent locations were selected from 30 patients diagnosed with PCa. Besides, the control population entailed patients that had benign prostatic hyperplasia (BPH) during August, 2017, to January, 2019, at The Affiliated Weihai Second Municipal Hospital of Qingdao University. The samples were immediately placed at a temperature of −80°C following the surgery. Besides, the participants have not received chemotherapy or radiotherapy prior to this study. The supervision of the research was conducted by the Institutional Review Board within the sponsoring institution. However, all participants were required to sign and provide informed consent.

2.2. Cell Culture. The researchers purchased their cell culture from ATCC and included normal prostate epithelia cell line alongside LNCaP, and DU145. Similarly, human PCa cell lines PC3 were also sourced from the cell culture in ATCC. Cells were incubated in a basal medium with 10% concentration of FBS and Penicillin-Streptomycin at 1%. Moreover, the temperature of the incubator was controlled at 37°C with 5% CO_2. The cells were subjected to a confluence of 80% through the process of being passaged.

2.3. Transfection. The transfection of PC3 cells was achieved using 50 nM of miR-373 mimics (Mimics) or miR-NC mimics (NC mimics) using Lipofectamine 2000 (Invitrogen, USA) for 48 h. pcDNA3.1 and pcDNA3.1-RUNX2 were synthesized and provided by GenePharma (Shanghai, China). The transfection of the cells was achieved using either pcDNA3.1-RUNX2 or pcDNA3.1 based on the manufacturer's protocols that use lipofectamine 2000.

2.4. qRT-PCR. The choice of reagent for isolating total RNA from the localized cells and tissues was TRIzol. The collected RNA was then transcribed into cDNA with PrimeScript RT kit (Takara, Japan) based on the manufacturer's instructions. The PCR was conducted using SYBR® Premix ExTaq™ II Kit (Takara, Japan) under the prescribed thermo cycling condition. Particularly, it was exposed to five minutes at 95°C, and 40 more cycles averaging 30 seconds at a temperature of 95°C. Finally, it was subjected to further cycles of 45 sec at 60°C. Then, a calculation of the expression level was made using $2^{-\Delta\Delta CT}$ method. In turn, U6 was regularized to the prescribed levels of miRNA and GAPDH to mRNA.

2.5. Western Blot. Cells or tissues were lysed. Total protein was collected with RIPA buffer (Sigma-Aldrich, USA). The concentration of the protein was calculated with BCA kit (Pierce, USA). Then, total protein was isolated with 12% SDS-PAGE. Afterwards, the protein was moved onto PVDF membranes, which was then blocked with milk that possessed nonfat attributes. The membranes would then be incubated over the night by relying on primary antibodies and being put in temperatures of 4°C in shade and then with secondary antibodies. Subsequently, the protein was visualized, and the relative protein level was calculated.

2.6. Wound Healing Assay. After 48 h transfection, cells became cultured with a 6-well plate (3 × 104 cells/well) overnight till the cells reached 80–90% confluency. Then, a pipette tip was applied to make a scratch. The cell movement was pictured and analyzed.

2.7. Transwell Assay. The cells were placed into a 24-well plate (2 × 103 cells/well) and then incubated in the upper chamber containing Matrigel and serum-free DMEM. Inherently, the bottom chamber was treated with 10% FBS. Within a day, the noninvasive cells were removed. Next, the invaded cells were corrected with 4% methanol while crystal violet was used for staining. Finally, the cells were captured before being calculated.

2.8. Dual Luciferase Reporter Assay. The online database across TargetScan 7.2 (https://www.targetscan.org/vert_72/) was utilized to forecast the target of miR-373. The 3′ untranslated region (3′UTR) sequences containing the potential target of miR-373 were synthesized and cloned into reporter gene plasmid vector pGL3 to build RUNX2 3′UTR wild type and RUNX2 3′UTR Mutant (MUT) plasmids. Then, the transfection of the cells is achieved using either miR-373 NC or the same variant with an accompanying Lipofectamine 2000 at 37°C with 5% CO_2. The determination of the cell luciferase activity was consistent with the Dual-Luciferase Reporter Assay System (Promega, USA).

2.9. Statistical Analysis. Data collected in the study was analyzed with SPSS22.0 software and represented through calculations of mean ± standard deviation (mean ± SD). The variances between the two groups were considered using Student's t-test, while the variances in multigroups were evaluated with one-way ANOVA. The statistical significance was set at $P < 0.05$.

3. Results

3.1. MiR-373 Is Downregulated in PCa Tissues. qRT-PCR was executed to identify the manifestation of miR-373 in PCa tissues as well as the normal tissues adjacent to the malignant cells. As shown in Figure 1, the expression of miR-373 was downregulated in PCa tissues relative to the normal tissues in adjacent locations, thereby suggesting that miR-373 may be an antitumor miRNA in PCa.

3.2. MiR-373 Is Decreased in PCa Cells. In exploring the roles of miR-373 in PCa, we also detected the expression of miR-373 in PCa cells. The findings also portrayed a decrease in the volume of miR-373 in PCa cell lines, such as PC3, LNCaP, and DU145, compared with prostate epithelial cell line RWPE-1, which was more potent in PC3 (Figure 2(a)). Then, PC3 cells were used in the following experiment. Moreover, the manifestation of miR-373 in PC3 cells that were transfected with miR-373 mimics was upregulated in comparison with control populations, which suggested PC3 were successfully transfected (Figure 2(b)).

3.3. MiR-373 Inhibits the EMT of PCa Cells. The processes of transwell assay and wound healing were executed to test the implications of miR-373 on the intrusion and migration of PCa cells. As shown in Figure 3(a), the scratch width of the miR-373 mimics transfected cells showed no significant difference. In turn, the healing rate was significantly decreased, suggesting that miR-373 inhibited the potential for PCa cells to migrate. Moreover, the ability of PCa cells to invade is significantly inhibited when transfected with miR-373 mimics, relative to the control group (Figure 3(b)). Meanwhile, overexpressed miR-373 downregulated N-cadherin, Snail, and vimentin and upregulated E-cadherin and FSP1, suggesting miR-373 played an inhibitory role in the EMT of PCa cells (Figure 3(c)).

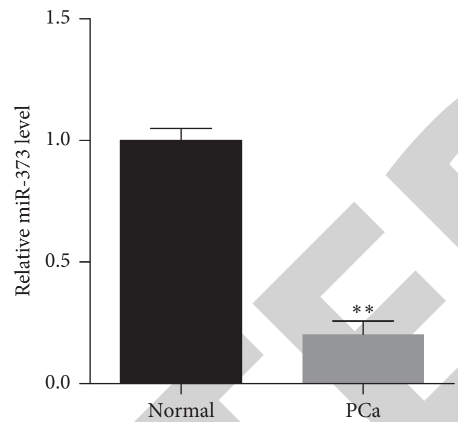

Figure 1: MiR-373 was downregulated in PCa tissues. The evidence of miR-373 was identified by qRT-PCR. $^{**}P < 0.01$ vs. normal tissues.

3.4. MiR-373 Directly Targets RUNX2. The research predicted RUNX2 as a target of miR-373 (https://www.targetscan.org/vert_72/). The binding locations between miR-373 and RUNX2 are shown in Figure 4(a). The findings from the luciferase assay portrayed the fact that the luciferase activity of PCa cells was transfected along with miR-373 mimics and RUNX 3′UTR WT was considerably decreased compared with NC mimics group (Figure 4(b)). The protein rates of RUNX2 were upregulated in PCa cells and tissues (Figures 4(c) and 4(d)). However, the mRNA of RUNX2 was also downregulated following its transfection with miR-373 mimics, which was paralleled with the protein level (Figures 4(e) and 4(f)).

3.5. Overexpressed RUNX2 Alleviates Inhibition of EMT Induced by MiR-373 Mimics in PCa. Rescue assay was performed to examine the roles of RUNX2 in the EMT of PCa cells. As shown in Figures 5(a) and 5(b), upregulated miR-373 reduced the potential for invasion and migration among PCa cells when compared with NC mimics, which was reversed by the overexpression of RUNX2. Moreover, the regulatory role of miR-373 in the depiction of EMT-related genes (such as N-cadherin, Snail, vimentin, E-cadherin and FSP1) was alleviated by RUNX2, where upregulated RUNX2 alleviated the effects of miR-373 on the EMT of PCa cells (Figure 5(c)).

4. Discussion

Augmenting bodies of evidence have revealed miRNAs have a significant role in the initiation and sustenance of PCa [16, 21, 22]. The aberrant expressed miRNAs suppress the identified tumors in PCa. For instance, downregulated miR-129-3p is associated with TNM staging, differentiation of PCA tumor, and lymph node metastasis, while its overexpression inhibited the spread and invasion of PCa cells [23]. miR-601 functions as an oncogene in PCa. As such, it alleviates the potential for migration, invasion, and progression of PCa cells [24]. Meanwhile, Qiu et al. demonstrated that the downregulation of miR-373-3p induces the

metastasis of PCa, and the silence of testicular nuclear receptor 4 (TR4) or the upregulation of miR-373-3p may be a likely target for PCa [25]. There was a reduction of miR-373 in PCa cells and tissues, thereby suggesting that miR-373 serves as an antitumor gene in PCa. These results are consistent with Qiu et al.'s study [25]. However, the possible mechanism that miR-373 regulated the progression of PCa is still unclear.

Epithelial-mesenchymal transition (EMT) is a complicated progress involved in the metastasis, stemness, and drug resistance of PCa [26]. EMT progresses with the loss of epithelial functions and acquisition of mesenchymal features [27]. This degradation from cuboidal to spindle-shaped in cell phenotype is accompanied with the downregulation of epithelial cell markers (E-cadherin, occludins, and FSP1). Similarly, mesenchymal markers such as vimentin and N-cadherin have been upregulated and further activating the master regulator of EMT, such as Snail and Twist [28, 29]. Thence, to explore the expected molecular mechanisms involved in the EMT of PCa cells to inhibit the metastasis is of vital importance. Still, miRNAs contribute to the initiation and sustenance of cancers via regulating multiple biological processes including EMT [12, 13]. In this study, upregulated miR-373 reduced the potential for invasion and migration among PCa cells. Moreover, its overexpression decreased the expression of mesenchymal markers (vimentin and N-cadherin) and the master regulator of EMT (Snail) and enhanced the manifestation of epithelial cell markers (E-cadherin and FSP1), which suggested the upregulation of miR-373 repressed the loss of epithelial functions and acquirement of mesenchymal features, and therefore inhibited the progression of EMT of PCa cells. However, the underlying mechanisms is still unknown.

miRNAs regulate biological functions through provision of bonds to the 3′UTR of the identified genes [11]. Runt-related transcription factor 2 (RUNX2) was predicted and proved to be a target of miR-373. Increasing studies have reported the upregulation of RUNX2 derived from epithelial tissues induces the progression of multitype cancers [17–19]. RUNX2, as a linage specific transcription factor, collectively participates in EMT and promotes the maturation of mesenchymal markers via interacting with specific pathways related to these pathophysiological processes [30, 31]. In PCa, the abnormal upregulation of RUNX2 contributes to EMT of PCa cells and PCa to bone metastasis [32]. In the current study, RUNX3 was upregulated in PCa cells and tissues. Interestingly, overexpressed RUNX2 reversed the alleviation of PCa invasion and migration and abrogated the upregulation of epithelial markers and the downregulation of mesenchymal markers in induced by miR-373. The findings suggested the regulatory role of miR-373 in PCa EMT was alleviated by RUNX2. Therefore, miR-373 may inhibit the EMT of PCa cells via targeting RUNX2.

In conclusion, miR-373 was downregulated in PCa cells and tissues. Overexpressed miR-373 inhibited the transition from epithelial to mesenchymal state for PCa through targeting PCa. In turn, the inhibition of this transition provides a significant strategy in the treatment of prostate cancer (PCa).

However, the present study has some limitations. Firstly, more patients are needed to make the results more convincing. Secondly, a miRNA may have more than one target, which may be targeted by various miRNAs. Therefore, the underlying mechanisms that miR-373 regulates the EMT of PCa need further research. Furthermore, this study needs to be combined with other hospitals for multicenter research in the future to promote the basic treatment of liver cancer.

Data Availability

The simulation experiment data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

The authors declare no conflicts of interest.

Authors' Contributions

Jianyi Pang drafted the paper and cooperated with Limei Dai to conduct the experiment, with Qinglei Zhang to collect the data, and with Chen Zhang to interpret the data. Qinglei Zhang designed this work.

Introduction. Health monitoring and remote diagnosis can be realized through Smart Healthcare. In view of the existing problems such as simple measurement parameters of wearable devices, huge computing pressure of cloud servers, and lack of individualization of diagnosis, a novel Cloud-Internet of Things (C-IOT) framework for medical monitoring is put forward. *Methods*. Smart phones are adopted as gateway devices to achieve data standardization and preprocess to generate health gray-scale map uploaded to the cloud server. The cloud server realizes the business logic processing and uses the deep learning model to carry out the gray-scale map calculation of health parameters. A deep learning model based on the convolution neural network (CNN) is constructed, in which six volunteers are selected to participate in the experiment, and their health data are marked by private doctors to generate initial data set. *Results*. Experimental results show the feasibility of the proposed framework. The test data set is used to test the CNN model after training; the forecast accuracy is over 77.6%. *Conclusion*. The CNN model performs well in the recognition of health status. Collectively, this Smart Healthcare System is expected to assist doctors by improving the diagnosis of health status in clinical practice.

1. Introduction

By the end of 2015, there were about 220 million people aged 60 or above in China, accounting for 16.1% of the total population. Among them, 140 million were over 65 years old, accounting for 10.5% of the total population. In this context, healthcare for the elderly has increasingly aroused social concern [1]. The rapid development of wearable devices, IOT, and cloud computing has brought about significant development opportunities and affected every aspect of people's lives. In the field of healthcare, the adoption of IOT can bring us health monitoring all the time [2]. With the popularity of smart phones, smart bracelets, and other devices, a variety of sensors can monitor health indicators timely and accurately [3–5]. Deep learning is an implementation method of machine learning, which is different from the traditional shallow models such as artificial neural network. Deep learning usually has a deeper model structure with five or six layers or even over ten layers or more hidden layers [6]. In addition, the importance of feature learning is highlighted [7, 8]. The feature representation of samples in the original space is transformed into a new feature space by means of feature transformation layer by layer. Deep learning is widely used in image and voice processing and develops rapidly in the medical and health field [8–10]. The study in [11] proposed a human fall early warning algorithm based on RNN and compared it with traditional machine learning algorithms such as SVM to verify its excellent performance. The study in [12] compared and studied the application of CNN, RNN, LSTM, and other deep learning models in the evaluation of sleep quality.

With the increase of the number of IOT devices and sensors, medical IOT system also highlights more problems in the development process, mainly including the following:

(1) The measurement parameters of existing wearable health monitoring devices are relatively simple, such as pedometers and intelligent sphygmomanometers. The common pedometer devices can connect with

smart phones via Bluetooth and other communication means, and upload data to the cloud server, so it is possible to view data such as exercise amount and sports assessment report through the phone APPs. Various forms of wearable health monitoring devices fail to share data due to different manufacturers and communication protocols.

(2) Limited by memory capacity and computing power, wearable devices may upload the collected data to the cloud server through smart phones or home gateways. The cloud server needs to store and process a large amount of collected data. The server and network have great transmission pressure, which reduces the real-time processing capacity.

(3) At present, many telemedicine monitoring systems based on IOT carry out certain disease early warning according to a set of diagnostic schemes, and it is difficult to develop personalized diagnosis and treatment schemes according to individual physiological characteristics and historical parameter changes.

(4) Intelligent diagnosis methods based on the uploaded data of health monitoring devices mainly include system-based diagnosis methods of experts and intelligent diagnosis methods based on sample data. Back Propagation (BP) neural network algorithm [13] and Support Vector Machines (SVM) algorithm have been applied to the classification of diagnosis results. Although deep learning algorithm has been applied in sleep quality and other fields [12], the application of intelligent diagnosis algorithm based on deep learning is rarely seen.

In view of the above problems, a healthcare monitoring system based on Cloud-Internet of Things (C-IOT) and deep learning is proposed, and the major work includes the following aspects:

(1) A health data acquisition system is designed based on C-IOT and the acquisition of parameters such as human blood pressure, body temperature, body weight/fat, and exercise amount is realized. The shortcoming that the acquisition of simple physiological parameters fails to evaluate and diagnose the user's health effectively is avoided.

(2) Data preprocessing of each acquisition device is realized locally to eliminate noise interference. By communicating with the user's smart phones through Bluetooth, the smart phones may display the collected data in real time, preprocess the data of each device, and upload them to the cloud server. The processing and integration of local data can reduce the computing pressure of cloud server and transmission pressure of network.

(3) The private doctor evaluates the user's health condition according to the data on the cloud server and establishes the initial data set. The cloud server uses the deep learning algorithm (CNN) to train the user health evaluation model according to the initial data set. The newly uploaded data are calculated by a depth model to automatically give health assessment results. The model is a process of dynamic change. The private doctor will manually evaluate the user's health status and update the user data set on a regular basis as well as the parameter values of the depth model. The model can realize personalized health assessment.

2. Materials and Methods

2.1. System Architecture. Figure 1 indicates the architecture of health monitoring system based on C-IOT and deep learning proposed in this paper. It is improved from the traditional three-layer architecture of the IOT, and described from the perspective of system implementation and data flow, including data collection layer, data preprocessing and net layer, data processing, and application layer.

Data collection layer is responsible for the acquisition of physiological parameters of health, which is mainly composed of a number of Internet-connected or wearable devices. Temperature, body fat/weight, blood pressure parameters, and exercise parameters are measured. In general, data collection layer devices have small data storage capacity and low computing capacity [14–16]. In order to reduce data redundancy, network transmission pressure, and power consumption, the data denoising, digital filtering, and power management based on rules can be realized locally. High-frequency noise is eliminated by digital low-pass filter and band-pass filter. In addition, the special value in the collected data is removed based on rules. The data collection layer device may be connected to smart phones or other mobile intelligent terminals through Bluetooth.

The data preprocessing and net layer are mainly composed of smart phones and other intelligent mobile terminals. Smart phone devices not only serve as network layer devices to realize data communication function of medical IOT gateway, but also install application layer APP software to realize local data preprocessing, parameter display, and device control. The smart phone connects to the data collection layer device through Bluetooth to receive measurement information reported by the blood pressure meter, weight/fat meter, pedometer, thermometer, and other data acquisition devices, and display the real-time information on the mobile APPs. Preprocessing data are uploaded to the cloud server through Wifi, 4G, and other communication means. Data preprocessing includes data normalization, data dimension transformation, data fusion, and other functions to generate images of health parameters. In terms of data normalization, body weight, body temperature, and other measurement parameters are normalized according to the grade to the gray value ranging from 0 to 255. In terms of data dimension transformation, original measurement parameters are extended in dimension, such as heart rate, systolic pressure and diastolic blood pressure measured by sphygmomanometer extended to ambulatory pulse pressure (APP), mean arterial pressure (MAP), and ambulatory rate-pressure product (ARPP), which are often used to diagnose cardiovascular diseases more effectively. The application

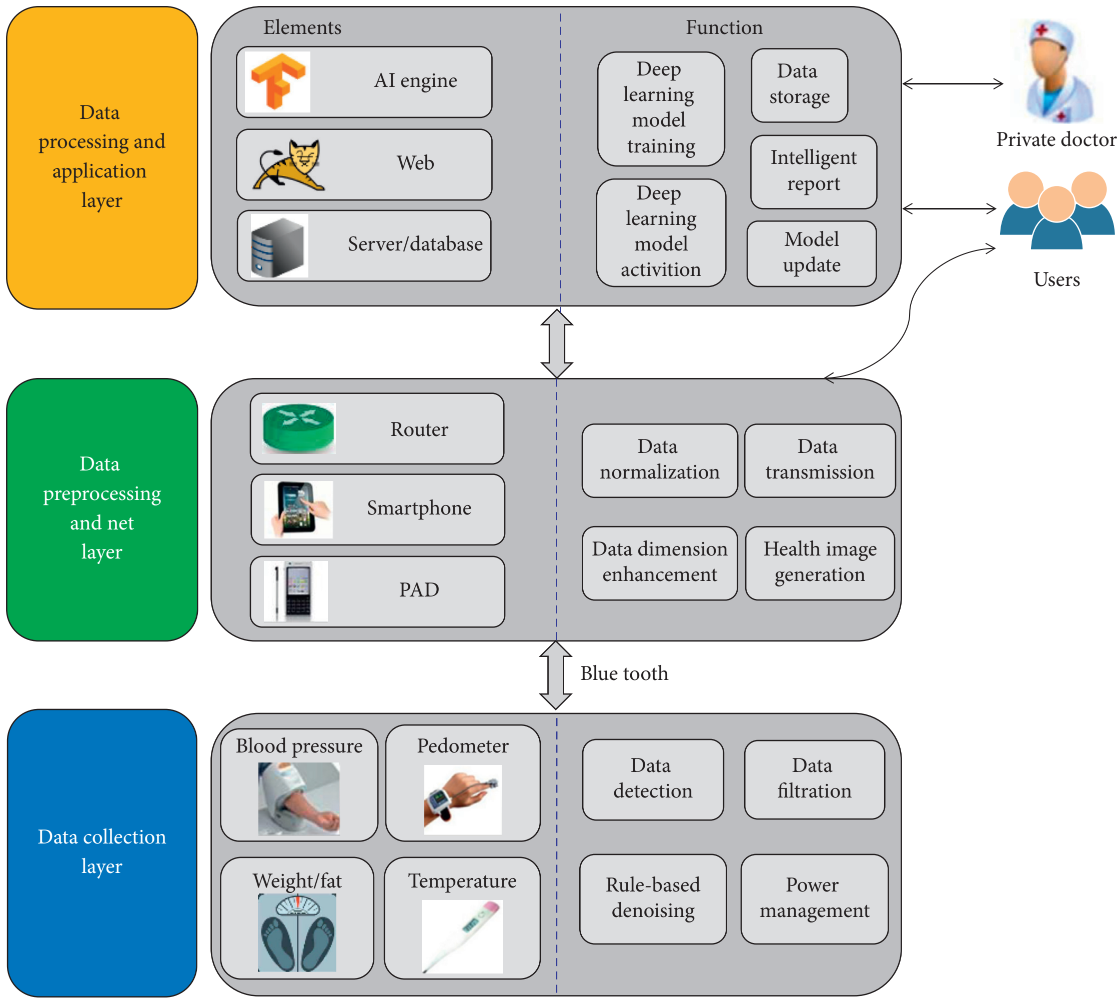

Figure 1: System architecture.

software of mobile phones can also fuse the physiological parameter measurement data after normalization of gray value and dimension expansion into the image of health parameters, upload them to the cloud server in the form of two-dimensional image, and use the deep learning model to solve the health parameter image to give the health index report. The users may receive and display the health report issued by the cloud server through smart phones. Making full use of the computing power of intelligent equipment for data preprocessing can effectively reduce the transmission pressure of database and network. With the rapid improvement of the computing power of intelligent terminal equipment, more and more data processing functions will be completed directly in the intelligent terminals.

The data processing and application layer mainly includes database and distributed server, web server, and deep learning model engine. The database stores and manages users' personal information/health monitoring data, personal doctor information, equipment information, etc., the distributed server realizes various business processing logic, and the web server provides users and personal doctors with friendly web interface for background operation. The deep learning model engine is used to train the deep learning model, and the trained deep learning model is used to solve the health parameter image. With the increase of user data, private doctors can annotate the data, enrich the personal health data set, and retrain and update the deep learning model.

2.2. Measurement of Blood Pressure. For blood pressure acquisition nodes, the oscillometric method is used to measure blood pressure [17], and the pressure value of the pressure sensor is filtered by low-pass filter and band-pass filter to obtain the static pressure value and the dynamic pressure value. In the measurement process, the dynamic pressure value amplitude increases gradually and then decreases. When the dynamic pressure value amplitude is multiplied by the normalized coefficients (Ks and Kd), the dynamic pressure value amplitude corresponding to the systolic pressure and the diastolic pressure can be obtained, respectively, and the human blood pressure value can be obtained by reverse check, as shown in Figure 2. According to the conclusions of Mauro's mathematical model, the normalized coefficient Ks was 0.46–0.64, and the normalized coefficient Kd was 0.43–0.73 [18]. In this paper, the amplitude coefficients commonly used in clinical medicine are $Ks = 0.48$ and $Kd = 0.58$ [19].

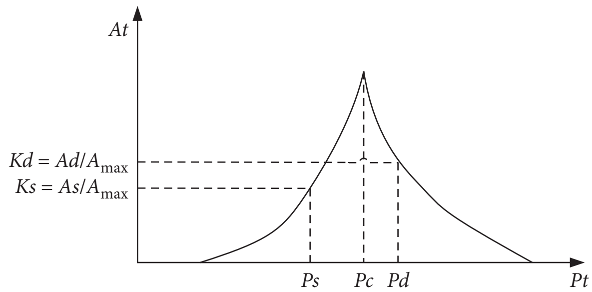

Figure 2: Blood pressure measurement method.

In order to obtain the optimal pulse oscillation amplitude envelope, Gaussian fitting method is used for data fitting: a set of sample data $(x_i, y_i)(i = 1, 2, 3 \ldots N)$ can be described by Gaussian functions as shown in the following equation:

$$y_i = y_{\max} * \exp\left[-\frac{(x_i - x_{\max})^2}{s}\right]. \quad (1)$$

Take the logarithm of both sides of this equation:

$$\ln y_i = \ln y_{\max} - \frac{(x_i - x_{\max})^2}{s} = \left(\ln y_{\max} - \frac{x_{\max}^2}{s}\right) + \frac{2x_i x_{\max}}{s} - \frac{x_i^2}{s}. \quad (2)$$

Assume

$$\begin{aligned} \ln y_i &= z_i, \\ \ln y_{\max} - \frac{x_{\max}^2}{s} &= b_0, \\ \frac{2x_{\max}}{s} &= b_1, \\ -\frac{1}{s} &= b_2. \end{aligned} \quad (3)$$

Taking all sample data into consideration, equation (2) is converted into a matrix as follows:

$$\begin{bmatrix} z_1 \\ z_2 \\ \vdots \\ z_n \end{bmatrix} = \begin{bmatrix} 1 & x_1 & x_1^2 \\ 1 & x_2 & x_2^2 \\ \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 \end{bmatrix} \begin{bmatrix} b_0 \\ b_1 \\ b_2 \end{bmatrix}. \quad (4)$$

It is simplified as

$$Z = XB. \quad (5)$$

According to the principle of least squares, the generalized solution of least squares for matrix B is

$$B = \left(X^T X\right)^{-1} X^T Z. \quad (6)$$

Then, the estimated parameters (b_0, b_1, b_2) are substituted into equation (1) to obtain the fitted Gaussian function. Both the measuring speed and accuracy are improved by using Gaussian fitting function.

2.3. Data Preprocessing. After the human physiological parameter monitoring equipment transmits the measurement results to a smart phone via Bluetooth, data preprocessing shall be conducted through the application software installed in the smart phone, which mainly includes dimensional transformation of data, data standardization, and generation of two-dimensional gray image for human health.

In order to optimize the input vector, the measurement data uploaded by monitoring equipment need to be transformed into a certain dimension. The measured data including heart rate (HR), systolic blood pressure (SP), and diastolic blood pressure (DP) are converted into three parameters, namely, mean arterial pressure (MAP), ambulatory pulse pressure (APP), and ambulatory rate-pressure product (ARPP).

$$\begin{aligned} \mathrm{APP} &= F1(\mathrm{SP}, \mathrm{DP}) = \mathrm{SP} - \mathrm{DP}, \\ \mathrm{MAP} &= F2(\mathrm{SP}, \mathrm{DP}) = \frac{\mathrm{DP} + (\mathrm{SP} - \mathrm{DP})}{3}, \\ \mathrm{ARPP} &= F3(\mathrm{HR}, \mathrm{SP}) = \mathrm{HR} * \mathrm{SP}. \end{aligned} \quad (7)$$

Step number, motion distance, fast motion time, fast motion distance, length of sleeping, and length of awakening are obtained according to the step number and time measured by the pedometer after dimension expansion. Data standardization converts the data of each index into the gray value ranged from 0 to 255 according to the scaling, so as to facilitate the synthesis of health status matrix for uploading to the cloud server for processing. The corresponding range relationship between the measured value of each index and the standardized value is shown in Table 1.

In this paper, the deep learning method is adopted to evaluate the human health status. The input data of the deep learning model are the measured values after the standardization of each physiological parameter of human body in a day. In order to better serve as the input of CNN, the standardized data need to be processed in two dimensions to generate the health status matrix. The health status matrix is

Table 1: Data standardization.

Index	Range of measurement value	Range of standard value
Weight	0–150 kg	0–255
Fat	0%–50%	0–255
SP	0–250 mmHg	0–255
DP	0–250 mmHg	0–255
HR	0–200 bpm	0–255
APP	0–200 mmHg	0–255
MAP	0–300 mmHg	0–255
ARPP	0–50000	0–255
Step num	0–30000	0–255
Distance	0–20 km	0–255
Fast motion time	0–24 h	0–255
Fast motion distance	0–20 km	0–255
Length of sleeping	0–24 h	0–255
Length of awakening	0–24 h	0–255
Body temperature	30–45°C	0–255

organized into 2D images. As required, the subjects shall have their blood pressure and body temperature measured once every morning and every evening, have their weight/fat measured once every day, and wear a pedometer 24 hours a day. On the smart phone side, 36-pixel 2D images of human health are generated every day, as shown in Table 2. Figure 3 is an example 2D image of health status matrix according to Table 2.

2.4. Collection of Data Set. The training of deep learning model shall be supported by a certain amount of labeled data set. In this study, the gray-scale chart of health monitoring parameters in one day is obtained by combining measurement and construction. Six volunteers are selected, including 3 males and 3 females (including 2 adolescents, 2 middle-aged, and 2 elderly). The volunteers are required to test the blood pressure each morning and evening, the body temperature once, and the weight/fat once. They are also required to wear a pedometer device for 24 hours and upload data to the cloud server at 6 o'clock each morning through the phone APP. Then, private doctors will grade their health status according to the uploaded data and user information such as age and gender and then divide them into three types: health, sub-health, and illness. The initial data set is generated by continuously tracking and annotating the user's data for 100 days. In addition, the initial data set of each user constructed and annotated by private doctors according to the user's historical data information is 3,000, and these three types account for 1/3. 80% of the extended initial data set is selected as the training sample to train the user's personalized deep learning model, and 20% is used as the test sample to test the model's performance.

2.5. Deep Learning Model. Deep learning model is constructed and trained in the cloud server, and CNN is the most commonly used deep learning model, which has been widely used in the field of image processing. The classic LeNet-5 [20] CNN model is adopted and modified to simplify a pooling layer. The CNN model constructed is shown in Figure 4, which contains two convolution layers, a pooling layer, and a full connection layer. The CNNs have 2×2 kernels for the convolutional layers with 3 and 9 filters, respectively, and a scaling of 2 for the max-pooling layers. The output layer outputs the health assessment results, including health, sub-health, and illness.

3. Results and Discussion

3.1. Measurement and Test of Blood Pressure. The method of using medical blood pressure meter and blood pressure measurement node at the same time for the same subject is used for comparative verification. A health monitor (PM-900S, Biocare Technology Co. Ltd., Shenzhen, China) is selected as the comparison device. The verification results are shown in Table 3, and the measurement results indicate that the relative error is within the range of 6%. Figure 5(a) is the photo of blood pressure measurement node device.

Also, the method of wearing commercial pedometer and step monitoring node is used for comparative verification. A sports bracelet (Honor 3, HUAWEI Technology Co. LTD, Shenzhen, China) is selected as the comparison experiment device. The test subjects wear sports bracelets and step monitoring nodes at the same time. The measured data of the previous day is read after the subjects get up at 6 o'clock in the morning. The verification results are shown in Table 4, and the measurement results indicate that the relative error is within the range of 9%. Figure 5(b) is the photo of step monitoring node.

3.2. Evaluation of Deep Learning Algorithm and Model. For each subject, the accuracy of average recognition of the three health states is studied. Apart from that, recall and precision and $F1$_score are used for model evaluation in respect of each category [21]. The data of test set in data set are used as model input. TP denotes number of true positive (labeled correctly). FP denotes number of false positive (other activity labeled as the sub-health and illness). Furthermore, TN denotes number of true negatives (correct rejection), and FN denotes number of false negatives (missed detections).

Figure 6 exhibits the accuracy of the average classification of each subject. Error bars display the standard deviation of the recognition accuracy of the three health categories for each subject. As can be seen from the figure, the results of different subjects are of obvious differences. The highest recognition accuracy of CNN model is 84.2% (S4) and the lowest is 68.5% (S3). The standard deviation of recognition accuracy is all within 15 and the maximum is 14.94 (S5). For 6 subjects, the average accuracy of CNN model is 77.61%.

Figure 7 indicates the confusion matrices of 6 subjects acquired by CNN model. It can be revealed that the recognition performance of the model for health categories is obviously superior to the other two categories. In 200 samples, the highest recognition accuracy is 182 (S6). The capability to recognize sub-health categories is relatively poor, and S5 can only recognize 110 out of 200 samples correctly.

Figure 8 shows the precision, recall, and $F1$-score of 6 subjects in three categories acquired by CNN model. It can be seen that CNN model boasts higher precision for disease recognition than other two categories, except S2. Nevertheless, the value of recall is higher than that of

precision except S2. $F1$_score is a comprehensive index reflecting the performance of the model. By observing the $F1$_score curve of 6 subjects, the recognition performance of the model for sub-health is worse than the other two categories, with a minimum of 61.8% (S5).

The current research suggests that it is feasible to recognize and intelligently diagnose the preprocessed data of the underlying devices of the medical Internet of Things with CNN model. In comparison with traditional machine learning methods such as SVM [22] and LDA

[23], the depth learning method for intelligent diagnosis does not require manual selection of data feature values. The depth model can automatically extract features and perform high-level abstraction. For different subjects, the optimal parameters of the model can be automatically acquired through training, which is more flexible and robust compared with traditional machine learning methods. The intelligent health management system architecture based on deep learning proposed in the current research can make the data set continuously grow under the condition of user data accumulation, and cooperate with doctors' manual annotation, and can optimize model training from time to time to achieve better recognition and diagnosis effects. Pretreatment of health data at the bottom layer of Internet of Things equipment enhances the robustness of data and can tremendously lower the computing pressure of servers.

For each subject, the accuracy of average recognition of the three health states is studied. Apart from that, recall and precision and $F1\_score$ are used for model evaluation in respect of each category.

4. Conclusions

In view of the existing problems in the existing IOT medical system, a new IOT architecture for medical monitoring is proposed in this paper, in which smart phones are used as gateway devices to realize data preprocessing of measurement node devices, thus greatly reducing the computing pressure of cloud servers and transmission pressure of network. Based on the data sets generated from such data annotated by private doctors, a CNN health recognition model is constructed to realize personalized diagnosis and treatment of human health. Six subjects are selected to wear wearable measuring devices for a long time and physiological parameters are measured as required. The test sample set is input into the deep learning model for identification, with a prediction accuracy of over 77%. In the future work, the measurement types of human health parameters will be added, such as ECG and EEG signals, etc. In addition, the scale of the data set will be expanded, and the training depth learning model will be updated continuously to improve the prediction accuracy.

Parkinson's disease (PD) is a neurodegenerative disorder characterized by progressive neuronal loss in different brain regions, including the dopaminergic (DA) neurons of the substantia nigra pars compacta (SNc). The aggregation of α-synuclein (α-Syn) plays an essential role in the progression of PD-related neuron toxicity. In this study, bioinformatic analysis was used to confirm differentially expressed genes between patients with PD and healthy donors. Immunofluorescence was used to study the aggregation of α-Syn. Flow cytometry was used to confirm the apoptosis of neurons. Western blot was used to investigate the underlying mechanism. Coimmunoprecipitation (co-IP) was used to verify the interaction between proteins. Luciferase activity assay was used to confirm the target gene of miRNA. In vitro protein ubiquitination assay was used to ascertain the role of S-phase kinase-associated protein 1 (SKP1) on the ubiquitination processes of polo-like kinase 2 (PLK2). The result indicated that miR-101-3p was overexpressed in the substantia nigra of the postmortem brains of patients with PD. The underlying role was investigated in the SH-SY5Y cell line. The overexpression of α-Syn did not result in toxicity or aggregation. However, the co-overexpression of miR-101-3p and α-Syn promoted aggregation and neuron toxicity. Luciferase activity assay indicated that SKP1 is a target gene of miR-101-3p. The co-IP experiment confirmed that SKP1 could directly interact with PLK2. In vitro protein ubiquitination assay confirmed that SKP1 could promote the ubiquitination and subsequent protein degradation of PLK2. We also observed that the cotransfection of short hairpin RNA that targets PLK2 and α-Syn overexpression plasmid results in the endoplasmic reticulum stress of neurons. Our results collectively provide evidence that miR-101-3p contributes to α-Syn aggregation in neurons through the miR-101-3p/SKP1/PLK2 pathway.

1. Introduction

PD is the most common severe movement disorder globally and affects about 1% of adults older than 60 years [1, 2]. The disease is attributed to the selective loss of neurons in the substantia nigra. Its cause is enigmatic in most individuals; PD is characterized by motor and nonmotor symptoms; patients with PD classically display rest tremor, rigidity, bradykinesia, and stooping posture [3–5]. PD can also be associated with neurobehavioral disorders (depression and anxiety), cognitive impairment (dementia), and autonomic dysfunction (e.g., orthostasis and hyperhidrosis) [6, 7]. α-Synuclein (α-Syn) plays a role in rare familial forms of PD and sporadic PD [8]. Human α-Syn is a protein with a molecular mass of ~14 kDa (containing 140 amino acid residues) and is highly expressed in the brain [8, 9]. The accelerated fibrillation of α-Syn may worsen the pathology of PD. Increased α-Syn protein levels in the neurons may facilitate its abnormal aggregation, which results in toxicity and diseased condition [10–12].

MicroRNAs (miRNAs) are small noncoding RNAs that are transcribed from miRNA genes and intronic sequences as primary miRNAs (pri-miRNAs) and stem-loop precursor miRNAs (pre-miRNAs), respectively [13]. The dysregulation of miRNAs may contribute to the development of various diseases, including brain disorder. Several studies have shown that miRNAs contribute to the progression or onset of PD [14].

A study showed that polo-like kinase 2 (PLK2) expression increased in aged monkeys. PLK2 might play an essential role in the modulation of α-Syn [15]. Abid Oueslati et al. reported that PLK2 could interact with α-Syn and subsequently promote the autophagic degradation of α-Syn [15, 16].

Ubiquitination, which is the process of tagging a protein with ubiquitin, is one of the most versatile cellular regulatory mechanisms [17]. Ubiquitination also participates in multiple cellular processes, including gene transcription and cell cycle progression; ubiquitin degrades protein via the ubiquitin-proteasome system or by selective autophagy [18, 19].

A comprehensive understanding of the association between PD and α-Syn is essential to prevent PD progression. In the present study, bioinformatic analysis was used to confirm the differential expression of miR-101-3p in patients with PD and healthy donors. The overexpression of α-Syn did not result in toxicity or aggregation, whereas the co-overexpression of miR-101-3p and α-Syn promoted aggregation and neuron toxicity. We also found that S-phase kinase-associated protein 1 (SKP1) is a target gene of miR-101-3p and could directly interact with PLK2. We also investigated the underlying mechanisms that contributed to these effects.

2. Materials and Methods

2.1. Cell Culture and Treatment. Cell line SH-SY5Y cells were purchased from American Type Culture Collection (Manassas, Virginia). The cells were incubated in RPMI-1640 medium (Thermo Fisher Scientific, Inc., Waltham, Massachusetts) supplemented with 10% fetal bovine serum (Gibco, USA) and 100 μg/mL penicillin-streptomycin (Sigma-Aldrich Co, St. Louis, Missouri) and cultured in a humidified atmosphere of 5% CO_2 in air at 37°C.

2.2. Transfection. Short hairpin RNAs (shRNAs) for PLK2 and SKP1, overexpression plasmids for PLK2 and α-Syn (pcDNA3.1-α-Syn), and corresponding negative controls were purchased from Shanghai GenePharma Co., Ltd. (Shanghai, China). miR-101-3p mimic, inhibitor, and negative control were purchased from RiboBio (Guangzhou, China). Transfection was conducted according to the instruction of the manufacturer.

2.3. Coimmunoprecipitation (Co-IP). Cells were lysed with lysis buffer. The lysates were centrifuged and purified by incubation with protein A/G magnetic beads at 4°C for 1 h. The precleared supernatant was then immunoprecipitated with the primary antibody Flag at 4°C overnight. The complexes were subjected to 1 h of incubation at 4°C using protein A/G magnetic beads and subsequently analyzed by Western blot. Of course, we repeated the experiment three times, and the results were recorded.

2.4. Western Blot. Western blot was carried out according to the standard protocols described previously. We used primary antibodies against GAPDH (1 : 500; Santa Cruz Biotechnology, CA, USA), α-Syn (1 : 1000; #2642), SKP1 (1 : 1000; # 2156S), PLK2 (1 : 1000; # 14812S), eIF2α (1 : 1000; #9722), P-eIF2α (1 : 1000; #9721), ERK (1 : 500), and P-ERK (1 : 500; Cell Signaling Technology, MA, USA). Goat anti-mouse and anti-rabbit antibodies conjugated with horseradish peroxidase were used as secondary antibodies (1 : 2000; Jackson ImmunoResearch, PA, USA). We detected the blots using enhanced chemiluminescence (Dura, Pierce, NJ, USA). We repeated the experiment three times.

2.5. Flow Cytometry. Cell apoptosis was measured by flow cytometry. The cells were harvested and washed with PBS after 24 h of incubation with 1-methyl-4-phenyl-pyridinium (MPP+). Then, the cells were resuspended and incubated with 5 μL of Annexin V-fluorescein isothiocyanate and 5 μL of propidium iodide (PI). Apoptosis percentage, including early apoptosis (Annexin V+/PI−) and late apoptosis (Annexin V+/PI+), was calculated. Experiments were repeated three times to ensure reproducibility. The labeled cells were analyzed using the BD FACSverse flow cytometer (BD, Bioscience), and the data were processed by the FlowJo software (Treestar).

2.6. Immunofluorescence Staining. SH-SY5Y cells were fixed with 4% paraformaldehyde for 10 min and permeabilized with PBS containing 0.1% Triton X-100 for 10 min after 72 h of transfection. The cells were blocked in 10% goat serum and incubated overnight with primary antibodies against α-Syn (1 : 500; Cell Signaling Technology, MA, USA) at 4°C. The cells were washed with PBS and incubated with fluorescent secondary antibody conjugated with Alexa Fluor®594 for 1 h. Subsequently, the cells were counterstained with 4',6-diamidino-2-phenylindole and imaged with a fluorescence microscope. Fluorescent intensities were measured using the ImageJ software.

2.7. Statistical Analysis. All statistical analyses in this study were performed using GraphPad Prism 5 for Windows. Data were expressed as mean ± standard deviation (SD) and were compared using a one-way analysis of variance (ANOVA) followed by Tukey's multiple-comparison test. The SPSS 21.0 software was used to analyze the experimental data. A value of $P < 0.05$ was considered statistically significant.

3. Results

3.1. miR-101-3p and α-Syn Co-Overexpression Promotes α-Syn Aggregation and Neurotoxicity. Initially, the Gene Expression Omnibus (GEO) database was used to predict the difference in the expression between patients with PD and healthy donors. Figures 1(a) and 1(b) show that the expression of 30 genes considerably changed. Among which, seven genes were upregulated and 24 genes were downregulated in patients with PD. miR-101-3p was the most considerably upregulated among the genes; therefore, miR-101-3p was used in the subsequent study.

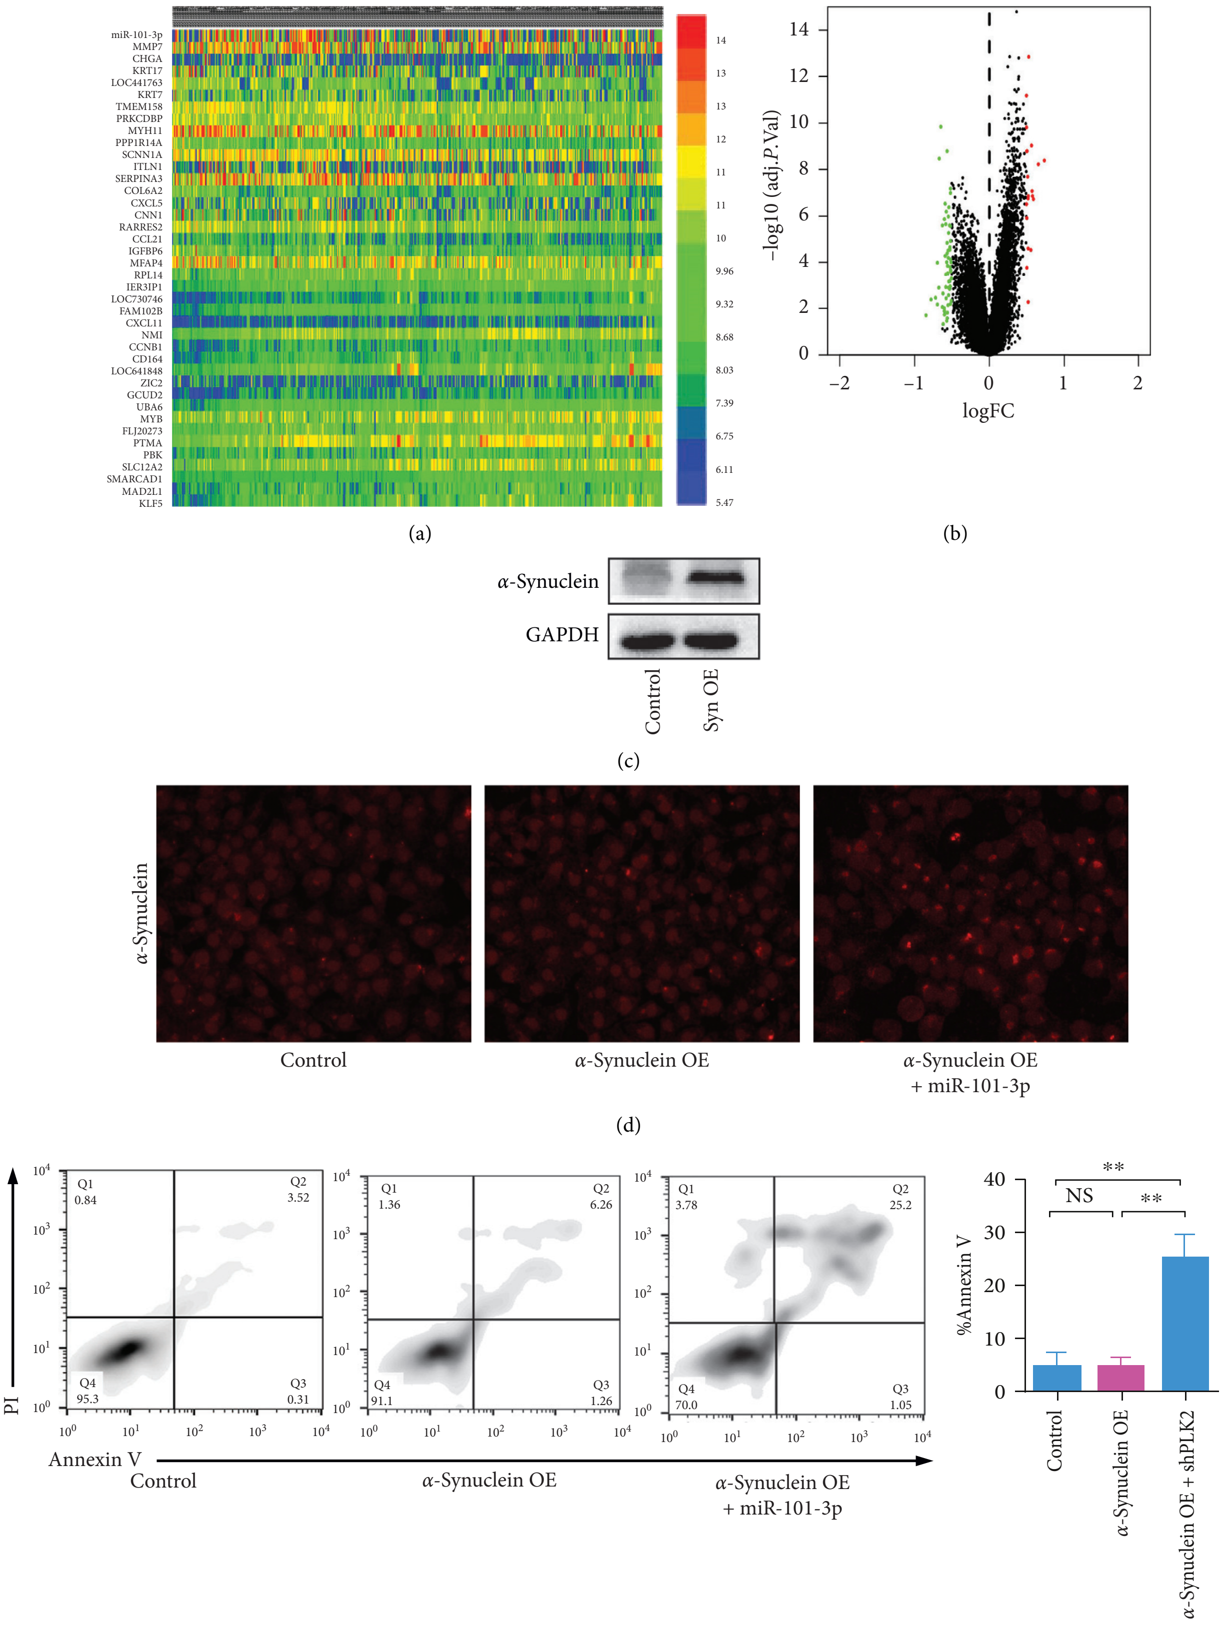

Figure 1: Co-overexpression of miR-101-3p and α-synuclein promotes α-Syn aggregation and neurotoxicity. (a) Heatmap of gene expression between substantia nigra from postmortem brains of patients with Parkinson's disease and health donors. (b) Volcano map of gene expression between substantia nigra from postmortem brains of patients with Parkinson's disease and health donors. (c) Western blot analysis of SH-SY5Y after transfection of α-synuclein overexpression plasmid. (d) Immunofluorescence of α-synuclein aggregation. (e) Flow cytometry analysis of cell apoptosis. Error bars represent mean ± SD. $^{**}P < 0.01$. n.s., not significant, by the paired two-sided Student's t-test.

The abnormal aggregation of α-Syn can promote PD progression and result in neuron toxicity. We confirmed this conclusion by constructing an α-Syn overexpression plasmid. The effect of the overexpression was confirmed by Western blot. As shown in Figure 1(c), α-Syn was overexpressed successfully. The impact of α-Syn overexpression on α-Syn aggregation was confirmed by immunofluorescence. Figure 1(c) demonstrates that no remarkable accumulation in SH-SY5Y cells after α-Syn was overexpressed. However, the cotransfection of miR-101-3p and α-Syn overexpression plasmid resulted in a considerable aggregation of α-Syn. Flow cytometry also confirmed that the cell apoptosis rate increased after the co-overexpression of miR-101-3p and α-Syn. This finding indicated that the co-overexpression caused substantial neurotoxicity.

Our result indicated that the co-overexpression of miR-101-3p and α-Syn promotes α-Syn aggregation and neurotoxicity.

3.2. miR-101-3p Binds to SKP1 mRNA and Suppresses SKP1 Expression. The public online dataset TargetScan was used to predict the possible target gene of miR-101-3p and confirm the downstream signal pathway of miR-101-3p. We found that SKP1 might serve as the target gene of miR-101-3p. Western blot was performed to confirm this prediction. As shown in Figure 2(a), SKP1 was downregulated after the transfection of miR-101-3p mimic and was upregulated after the transfection of the inhibitor. This result indicated that a regulation relationship might exist between SKP1 and miR-101-3p. Luciferase reporter assay was performed to further confirm their relationship. As shown in Figure 2(b), the 3'-untranslated regions (UTRs) in the predicted binding site of wild-type and mutated SKP1 were constructed, and cDNA was cloned into the luciferase reporter plasmid. The result confirmed that the transfection of miR-101-3p caused a substantial suppression of luciferase activity but did not substantially change the luciferase activity in the luciferase reporter plasmid with mutated UTR. This work demonstrated that miR-101-3p could directly bind to SKP1 mRNA and subsequently suppress SKP1 expression.

SKP1 is an essential component of the ubiquitin ligase complex. Therefore, the downstream signal of SKP1 was investigated. As shown in Figure 2(c), the STRING online dataset indicated that SKP1 could interact with PLK2. As shown in Figure 2(d), molecular docking confirmed that PLK2 might directly interact with SKP1. A co-IP experiment was performed based on the evidence. Figure 2(e) shows that PLK2 precipitated with SKP1; hence, PLK2 could directly interact with SKP1.

Our result confirmed that miR-101-3p targets SKP1 and SKP1 could interact with PLK2.

3.3. SKP1 Interacts with PLK2 and Promotes Ubiquitination of PLK2. SKP1 is an essential component of the ubiquitin ligase complex. Therefore, we speculated the interaction between SKP1 and PLK2 might influence the ubiquitination processes of PLK2. To confirm this hypothesis, shRNA targeting SKP1 was constructed, as shown in Figure 3(a); Western blot demonstrated that SKP1 was knocked down successfully, and we select shRNA#3 for subsequent study, as shown in Figure 3(b), after treatment of cycloheximide, a protein synthesis inhibitor, the half-life of PLK1 study. The result confirmed that after downregulation of SKP1, the half-life of PLK2 significantly increased, indicating that downregulation of SKP1 stabilized PLK2 and suppressed the protein degradation processes of PLK2.

To confirm whether SKP1 can influence the ubiquitination processes of PLK2, in vitro protein ubiquitination assay was performed. As shown in Figure 3(c), ubiquitination of PLK2 was enhanced significantly after overexpression of SKP1.

We next investigated the role played by PLK2 in neurotoxicity. To answer this question, PLK2 overexpression vector was constructed, as shown in Figure 3(d); Western blot indicated that PLK2 was overexpressed successfully after transfection of PLK2 overexpression vector.

Neurotoxin MPP+ is a classical neurotoxin that is used to generate a cell model of Parkinson's disease. As shown in Figure 3(e), the apoptosis rate increased after MPP+ treated neuron cells. However, the apoptosis rate was partly reduced after overexpression of PLK2. The result confirmed that PLK2 could partially alleviate neurotoxicity.

Our result confirmed that SKP1 interacts with PLK2 and promotes ubiquitination of PLK2, and PLK2 can partly alleviate neurotoxicity.

3.4. The Cotransfection of PLK2-Targeting shRNA and α-Syn Overexpression Plasmid Promotes Endoplasmic Reticulum (ER) Stress in Nerve Cells. PLK2 can interact with α-Syn and subsequently promote the autophagic degradation of α-Syn. Co-IP was performed to confirm this conclusion. Figure 4(a) shows that PLK2 could interact with α-Syn. To further investigate the role played by PLK2 in aggregation processes of α-syn, shRNA targeting PLK2 was constructed, as shown in Figure 4(b); Western blot indicated that PLK2 was knocked down successfully, and we select shRNA#1 for subsequently study. As shown in Figure 4(c), after cotransfection of PLK2-targeted shRNA and α-synuclein overexpression plasmid, P-ERK and eIF2α were overexpressed significantly, indicating that cotransfection of PLK2-targeted shRNA and α-synuclein overexpression plasmid promotes ER stress.

Flow cytometry was used to confirm our conclusion further. As shown in Figure 4(d), α-synuclein overexpression alone does not increase the apoptosis rate. However, cotransfection of PLK2-targeted shRNA and α-synuclein overexpression plasmid significantly enhanced apoptosis rate.

Taken together, our result confirmed that cotransfection of PLK2-targeted shRNA and α-synuclein overexpression plasmid promotes ER stress in nerve cells.

4. Discussion

PD is a severe neurological disease that results from the progressive degeneration of dopaminergic neurons located in the substantia nigra. PD influences about seven million

people worldwide and occur among older adults; its prevalence increases from 1% in people aged more than 60 to 4% in those older than 80 [20–22].

MiRNAs with vast regulatory potential have been recently proposed as biomarkers or possible therapeutic targets for PD. MiRNAs are small (about 20–24 nucleotides long), endogenous noncoding RNAs that play a profound role in numerous biological processes in health and disease. Most miRNAs suppress gene expression through the promotion of mRNA degradation and translation inhibition [23]. Previous studies have revealed that miRNAs are implicated in neurodegeneration, and miRNA pathways are affected in almost all neurodegenerative disorders. In this study, the GEO database was used to predict the difference in expression between patients with PD and healthy donors [24]. We found that the expression of 30 genes considerably changed. Among which, seven genes were upregulated and 24 genes were downregulated in patients with PD. miR-101-3p was the most upregulated among the miRNAs. Therefore, miR-101-3p was used for subsequent study [25].

α-Syn is a 140-residue natively unfolded protein that is abundantly expressed at the presynaptic terminals. α-Syn participates in the regulation of synaptic transmission and dopamine biosynthesis; the overexpression and misfolding of α-Syn play an essential role in the progression of neurodegenerative disorders [26, 27]. In the present study, immunofluorescence was used to confirm α-Syn aggregation. No remarkable accumulation was observed in SH-SY5Y cells after α-Syn was overexpressed [28]. However, the cotransfection of miR-101-3p and α-Syn overexpression plasmid resulted in substantial α-Syn aggregation. Flow cytometry also confirmed that cell apoptosis rate increased after the co-overexpression of miR-101-3p and α-Syn. The results indicated that the co-overexpression caused considerable neurotoxicity.

SKP1 is an essential component of the ubiquitin ligase complex. In this study, we confirmed that SKP1 can bind to PLK2 and subsequently promote the ubiquitination of PLK2.

PLK2 can bind directly to α-Syn and regulate α-Syn clearance [29–31]. In the current study, we confirmed that α-Syn could directly interact with PLK2, and the overexpression of PLK2 can partly alleviate the neurotoxicity induced by MPP+. The binding between PLK2 and α-Syn is needed for α-Syn clearance.

Based on our result, miR-101-3p overexpression in neurons may suppress the expression of SKP1. SKP1 downregulation limited the clearance of α-Syn and subsequently caused the abnormal accumulation and aggregation of α-Syn.

Our result provides evidence that miR-101-3p contributes to α-Syn aggregation in neurons through the miR-101-3p/SKP1/PLK2 pathway.

Background. Portal vein (PV) thrombosis (PVT) is a common complication of liver cirrhosis and can refer to thrombosis within the PV that can extend to its left or right branches and in some cases to the superior mesenteric vein or the splenic vein (Chawla and Bodh, 2015). For severe PVT patients, there are possibilities of increasing PV resistance and reduction of the blood flow though PV towards liver, which exacerbate liver function damage meanwhile elevating the gastrointestinal variceal bleeding risk. Endoscopic Variceal band ligation (EVL) is often used to prevent esophageal variceal bleeding; postoperative complications such as severe gastrointestinal bleeding and bleeding-related death, fever, retrosternal pain, and esophageal stenosis may appear. There was absence of the research which evaluated the impact of PVT in liver cirrhosis on the complication of endoscopic Variceal band ligation for now. We herein aimed to compare cirrhosis patients with and without PVT of recent complications after EVL. *Method*. We established the retrospective investigation on 144 consecutive cirrhosis patients (excluding patients with hepatocellular carcinoma and who received portal vein-systemic circulation devascularization or shunt surgery, splenectomy, hepatectomy, liver transplantation, transjugular intrahepatic portal vein stent shunt (TIPS), endoscopic varices Variceal ligation, or sclerotherapy before) who have received first endoscopic esophageal varices band ligation in Gastrointestinal Endoscopy Center of the First Affiliated Hospital, College of Medicine, ZheJiang University, between January 2014 and December 2017. Portal vein Doppler ultrasonography, liver computerized tomography (CT), and angiography or liver-enhanced magnetic resonance imaging (MRI) were applied to evaluate the portal vein thrombosis of each patient before EVL. There were 18 patients confirmed with portal vein thrombosis while the other 126 patients without PVT. The primary end point for this research is the upper gastrointestinal hemorrhage and related death occurred from the date of ligation until leaving hospital, and the secondary end point is the appearance of postoperative fever and retrosternal pain. *Results*. There are no significant differences of gastrointestinal bleeding, bleeding-related death, fever, or retrosternal pain after EVL and the length of hospital stays between cirrhotic patients with or without PVT ($P = 0.34, 0.51, 0.58, 0.61, 0.88$). *Conclusion*. Liver cirrhosis with portal vein thrombosis did not increase incidence of recent complications of the endoscopic Variceal band ligation.

1. Introduction

The studies of the epidemiology of portal vein thrombosis (PVT) in cirrhosis are mainly established on liver transplant patients [1]. One study evaluated 41 indexes of the secondary PVT for liver transplant patients and finally reported that the prevalence of PVT is about 10% (2%–23%). A prospective cross section study established by 43 Italian research centers found that the prevalence of PVT for liver transplant patients is 7% [2]. According to the reports, PVT affects 0.6%–26% of liver cirrhosis patients, while the prevalence of PVT in healthy people is ~0.7–1/100000 [3].

As we know, different factors can drive risk of thrombosis including endothelial injury, hypercoagulability, and static blood flow from the PH [4]. Routine ultrasound is the most common means of incidentally detecting PVT in cirrhosis. The majority of the thrombus of portal vein is asymptomatic and chronic, but patients with acute PVT and hepatic decompensation may suffer from pain in the abdomen and/or worsening ascites. Follow-up imaging is generally necessary after ultrasound in order to confirm PVT diagnosis and exclude the possibility of tumor-related thrombosis, with MRI and CT being the primary imaging modalities used for this purpose.

The classification of PVT in early stage is mainly according to the anatomy position of thrombus. In 2002, a widespread application of classification standard raised by Yerdel and other scholars [5] has four different types and only defined by the anatomy position. The classification standard in the most recent guidance (from European Association for the Study of the Liver, EASL, and American Association for the Study of Liver Diseases, AASLD) has comprehensively gathered the past nomenclature (such as "acute" and "chronic"). At present, another "Anatomical-Functional Classification System"(Supplementary Table 1) has been indicated, which combined the anatomy position of thrombus, the duration of thrombosis formation, and the relationship with clinical outcomes [6]; this classification system is more capable to describe the disparity of different PVT types and provided a good standard for further clinical study.

The common treatments of PVT are anticoagulation, intravenous thrombolysis, and TIPS. However, considering the risk of gastrointestinal bleeding, the anticoagulant using is still controversial.

Endoscopic Variceal band ligation (EVL) is a frequently used treatment for the esophageal variceal bleeding, which is recommended by the Chinese guidance of the prevention and treatment of gastroesophageal variceal bleeding [7] and also 2016 Practice Guidance by AASLD as primary prevention for moderate to severe esophageal varices and secondary prevention for all severity of esophageal varices [8]. Common postoperative complications include ulcer-related bleeding after the ligation (which can cause fatal haemorrhage), fever, and retrosternal pain.

There was absence of the research which evaluated the impact of PVT in liver cirrhosis on the complication of endoscopic Variceal band ligation for now. Alessandra et al. made a retrospective research to assess the impact of PVT in the eradication effect of endoscopic ligation for esophageal varices. The results showed that the portal vein thrombosis will not elevate the incidence of gastrointestinal bleeding events of the group of PVT patients who received EVL during follow-up [9]. However, they did not evaluate the other complications of EVL. Therefore, we designed a retrospective cohort study, with detailed instruction as follows.

2. Method

2.1. Patients. We established retrospective investigation on 144 consecutive cirrhotic patients receiving endoscopic Variceal band ligation (EVL) in first time in Gastrointestinal Endoscopy Center of the First Affiliated Hospital, College of Medicine, Zhejiang University, from January 2014 to December 2017. This study was approved by the First Affiliated Hospital Ethics Committee of Zhejiang University College of Medicine.

Inclusion Criteria. First, the diagnosis of liver cirrhosis is based on the clinical history, laboratory inspection, and imageological examination. The etiology is separated into viral, alcoholic, and other reasons. Second, endoscopic esophageal varices were diagnosed by upper gastrointestinal endoscopy; meanwhile, the severity of esophageal varices was classified according to the endoscopic behaviors. Based on the form of the varices and whether had red signs with high risk of bleeding, the severity was separated into 3 types as follows: mild (G1): the appearance of endoscopic esophageal varices is linear or slightly tortuous and no red signs; moderate (G2): the appearance of endoscopic esophageal varices is linear or slightly tortuous and red sign appears or the appearance of endoscopic esophageal varices is serpentine, tortuously uplifted; severe (G3): the appearance of endoscopic esophageal varices is serpentine, tortuously uplifted along with red signs or the appearance of endoscopic esophageal varices is bead, nodular, or tuberculiform (no matter the red signs appeared or not).

Exclusion Criteria. First, patients who combined with hepatocellular carcinoma or once had hepatocellular carcinoma and treated by surgery are excluded. Second, patients who received endoscopic Variceal band ligation or sclerotherapy, TIPS, portal vein-systemic circulation devascularization or shunt surgery, splenectomy, and liver transplantation due to esophageal variceal bleeding are excluded. Patients selection is as shown in Figure 1.

2.2. Clinical Data Collection. Age, gender, etiology of liver cirrhosis, hemoglobin (HGB, g/dL), blood platelet count (PLT, 1000/mm3), serum total bilirubin (mg/dl), prothrombin time (PT, s), serum creatinine (mg/dl), international normalized ratio (INR), D-dimmer (μg/L), serum albumin (g/dL), severity of ascites, severity of hepatic encephalopathy, and status of portal thrombosis are collected retrospectively.

The Child-Pugh-Turcotte score (Table 1) and classification of patients and grade the model for end-stage liver disease (MELD) are calculated.

For primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC) patients, serum total bilirubin (umol/L) should be modified as follows: 17–68 as 1 point, 68–170 as 2 points, and > 170 as 3 points.

Child-Pugh-Turcotte classification is as follows:

(i) Class A： 5-6 points, low risk, the best prognosis
(ii) Class B： 7–9 points, moderate risk
(iii) Class C： ≥10 points, high risk, the worst prognosis

Computational formula of MELD score is as follows:
$R = 3.8\ln$ [bilirubin (mg/dl)] + 11.2ln (INR) + 9.6ln [creatinine (mg/dl)] + 6.4 (etiology: biliary or alcoholic = 0, others = 1). (Results in round numbers).

2.3. The Diagnosis and Evaluation Method for Portal Vein Thrombosis. Portal vein Doppler ultrasound is implemented for preliminary screening for all patients, the diagnosis is confirmed through liver-enhanced CT scan or liver CT angiography or liver-enhanced MRI, and the range of

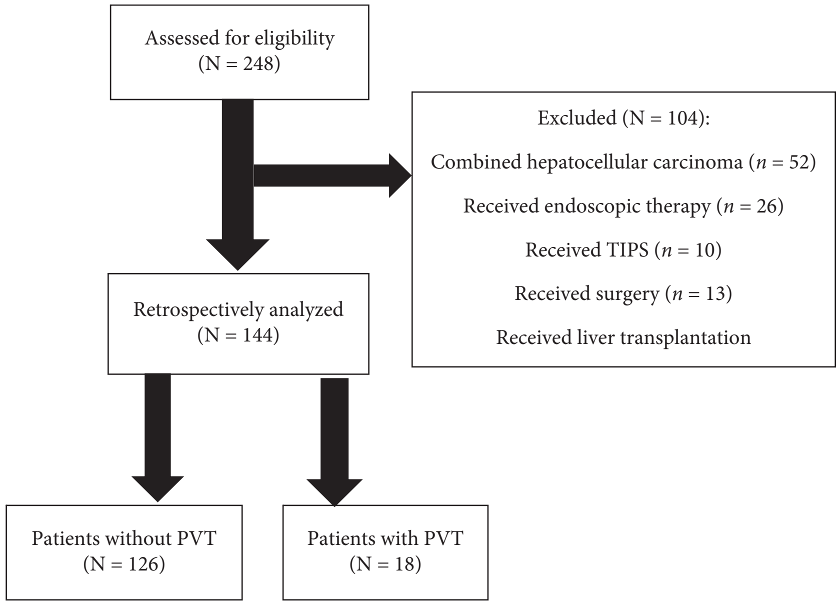

Figure 1: Patients enrollment and screening.

Table 1: The standards of Child-Pugh-Turcotte score.

Clinical biochemical indicators	1 point	2 points	3 points
Hepatic encephalopathy (stage)	Non	1–2	3–4
Ascites	Non	Mild	Moderate or severe
Serum total bilirubin (umol/L)	< 34	34–51	> 51
Serum albumin (g/L)	> 35	28–35	< 28
Prolonged PT (s)	< 4	4–6	> 6

thrombus, portal vein occlusion degree, and whether portal vein cavernous transformation appeared are evaluated.

2.4. The Implementation and Used Equipment of Endoscopic Variceal Band Ligation (EVL). All the endoscopic esophageal varices ligation (EVL) was operated by senior gastroenterologist. Type of applied endoscopy is as follows: Gif-Q260 J, Olympus Corporation, Japan. Type of ligation device is as follows: MBL-6-F, Wilson Cook Medical, America (Six Shooter Saeed Multi-Band Ligator, Wilson Cook Medical Inc. Winston-Salem, NC).

2.5. Endpoints

(a) Post-EVL gastrointestinal bleeding: hematemesis, melena, or HGB reduction greater than 2 g/dL during the period after EVL until patient leaving hospital

(b) Bleeding-related death: death caused by massive gastrointestinal hemorrhage after the EVL, which are judged by the clinician

(c) Post-EVL fever: body temperature greater than 37.5°C after the EVL

(d) Post-EVL retrosternal pain: pain behind the sternum after the EVL

2.6. Data Collection and Analyze. Data are analyzed with SPSS 17.0 software; statistical methods such as chi-square test or one-way analysis of variance will be implemented for analyzing influence factor of interblock or intraclass. P value less than 0.05 will be admitted as statistical significance.

3. Results

3.1. Baseline Characteristics. 144 patients were enrolled in the study in total, 67.46% men with the mean age of 54.79 ± 11.15 years. Study population characteristics are counted statistically. There were no significant difference between cirrhotic patients with or without PVT of etiology, prophylaxis level, Child-Pugh class, Child-Pugh score, MELD score, severity of esophageal varices, hemoglobin, platelets count, creatinine, PT, INR, albumin, bilirubin, and NSBB use. The D-dimer level of the PVT group is significantly higher than that of non-PVT group ($P < 0.001$)(Table 2).

We made a further analysis of the 18 cirrhosis patients with PVT classified by the anatomical-functional classification of PVT (Table 3). All the patients' portal vein thrombus is asymptomatic chronic thrombus, including 8 (44.4%) cases of Type 1, 3 (16.7%) cases of Type 2, and 7 (38.9%) cases of Type 3. There are 5 (27.8%) cases with superior mesenteric vein thrombosis and 2 (11.1%) cases with splenic vein thrombosis. Only 1 (5.6%) case was occlusive with cavernous transformation of portal vein, while the other 17 (94.4%) cases were nonocclusive. The chi-square test shows that the site of portal vein thrombus is significantly correlated to the severity of esophageal varices ($P = 0.004$). It seems that the trunk of portal vein involved patients has more severe esophageal varices. Besides, there

None of the patients with PVT are given anticoagulant therapy. PVT: portal vein thrombosis; MELD: the model for end-stage liver disease; NSBB: nonselective beta blockers; PT: prothrombin time; INR: international normalized ratio.

Table 3: The classification of PVT.

Site + extent	Frequency (N)	Percentage (%)
Type 1	6	33.3
Type 1+M	1	5.6
Type 1+S	1	5.6
Type 2	3	16.7
Type 3	2	11.1
Type 3+M	4	22.2
Type 3+S	1	5.6
Total	18	100.0
Degree		
NO	17	94.4
O	1	5.6
Total	18	100.0

All cases accord with symptomatic chronic thrombus. O: occlusive; NO: nonocclusive; S: splenic vein; M: mesenteric vein.

are no significant correlation between extension or degree of PVT and the severity of esophageal varices ($P = 0.49, 0.72$) (Table 4).

3.2. Primary End Points: Gastrointestinal Bleeding after EVL and Bleeding-Related Death. The chi-square test shows that the prevalence of gastrointestinal bleeding and bleeding-related death of the cirrhosis patients with or without PVT has no significant difference (0/18 versus 6/126, $P = 0.34$; 0/18 versus 3/126, $P = 0.51$) (Table 5).

3.3. Secondary End Points: Post-EVL Fever and Retrosternal Pain. The chi-square test shows that the prevalence of post-EVL fever and retrosternal pain of the cirrhosis patients with or without PVT has no significant difference (1/18 versus 12/126, $P = 0.58$; 1/18 versus 4/126, $P = 0.61$). One-way analysis of variance shows that the length of hospital stays of the two groups has no significant differences (20.61 ± 6.66 versus 20.87 ± 6.82; $P = 0.88$) (Table 5).

4. Discussion

Endoscopic ligation is often employed for treating patients with high risk of bleeding or rebleeding from esophageal varices, and its possible complications include gastrointestinal bleeding, fever, and retrosternal pain after ligation. PVT can worsen portal vein hypertension, can result in esophageal varices aggravated, and may finally raise the risk of gastrointestinal bleeding after ligation. Past studies have assessed the impact of PVT in the eradication effect of endoscopic ligation for esophageal varices. The results showed that the portal vein thrombosis will delay the time to eradicate esophageal varices but not increase the incidence

Table 4: The site\extension\degree of PVT with esophageal varices.

PVT: portal vein thrombosis; EVL: endoscopic Variceal band ligation.

of recurrence of esophageal varices. The gastrointestinal bleeding events of the group of PVT patients during follow-up had not significantly increased [9]. This study aimed to evaluate the impact of cirrhosis with PVT on postoperative complications of endoscopic Variceal band ligation.

Despite the past study suggested the anticoagulant therapy in cirrhotic patients with PVT is safe [10], as all the PVT cases were clinically asymptomatic chronic thrombosis, according to the American association of liver disease recommendations [11], meanwhile, considering the risk of GI bleeding after EVL, none of the patients with PVT were given anticoagulant therapy.

The results of our study revealed no significant differences in postoperative gastrointestinal bleeding events, bleeding-related death events, fever, and retrosternal pain in cirrhotic patients with PVT compared with those without PVT. It suggests that endoscopic band ligation is still a safe treatment option for cirrhotic patients with PVT. Further analysis of the patients in the PVT group showed that the site of PVT was significantly associated with the severity of esophageal varices ($P = 0.004$), among which the degree of esophageal varices in the patients with the trunk of portal vein involvement was more serious, while the extension site and the degree of obstruction were not significantly correlated with the severity of esophageal varices. This result reveals the importance of classification of PVT, and further attention should be paid to the effect of different types of PVT on patient prognosis and endoscopic treatment in clinical practice and future studies. Considering this is a retrospective study, it has certain limitations. For one, inclusion bias cannot be ruled out since people experienced death threatening gastrointestinal bleeding may choose TIPS or surgery as the first treatment option rather than EVL, leaving only low-risk patients in the study cohort, such as Child-Pugh class A or class B patients. Second, this study included a limited number of cirrhotic patients with PVT, which might not be enough for statistical purposes. Hence, caution is required to interpret these conclusions, and we are looking forward a further scale up prospective research which could confirm the impact of PVT on EVL. Third, considering the risk of gastrointestinal hemorrhage, none of the patients with PVT were treated with anticoagulants; thus, we could not evaluate the impact of anticoagulants on PVT and EVL. Fourth, there was absence of the data of follow-up because of the poor treatment compliance of the patients. We are forward to promote prospective cohort study and find out a best strategy for the prevention of esophageal variceal bleeding of the cirrhotic patients with PVT.

In summary, endoscopic band ligation is an effective and safe treatment for cirrhotic patients without or with PVT. The incidence of GI bleeding and bleeding-related death after EVL is relatively low and does not get impacted by the presence of PVT and so does the incidence of fever and retrosternal pain after EVL.
