where g is the gradient, m is the dimension of i-th, L is the function to be optimized, and $y^{(i)}$ is a batch data containing m new sample input. Numerical stability of the algorithm used for decimal division: the final parameter update quantity is obtained through the above equation. The convolution kernels of the mini4 convolutional neural network designed are all $3 * 3$ in size. Small convolution kernels are the development trend of the current convolutional neural network, which can reduce network parameters and reduce computation on the premise of maintaining accuracy. Firstly, there are two convolution layers with 32 convolution kernels. After extracting features from the two convolution layers, the maximum pooling layer is used to reduce dimension and compress features. It is followed by a convolution layer with 64 convolution kernels to continue the feature abstraction through the maximum pooling layer, and finally add the full connection layer. Features extracted from the full connection layer are classified by the softmax function. The gradient optimization diagram of the neural network is shown in Figure 6.

The function of the pooling layer is to further subsample the feature values extracted from the convolutional layer. The subsampling processing of the feature graph can further reduce the data scale, and it has local linear transformation invariance, which improves the generalization processing ability of the convolutional neural network. It can be used to compress images and reduce overwork. There are generally two methods of pooling layer operation: one is the maximum pooling function that takes the maximum value and the other is the average pooling function that takes the average value. After the feature graph is obtained by the convolution operation between data and the convolution kernel, if the linearity is transmitted to the next layer, the linear relationship will result in that no matter how many hidden layers there are in a neural network, the output is the input, and the hidden layer has no effect.

4. Experiments and Results

4.1. Model Training Experiment. Our dataset comes from the organizers of major domestic sports events in China, with a total of 100,000 pieces of data, 7750 pieces for both the test and validation sets, and the remainder for the training set. In the training process of the convolutional neural network, in order to maintain comparability, the same learning rate is set to 0.001, 32 samples are used as a batch, the impulse parameter is set to 0.9, and the dropout value is set to 0.5. The number of iterations is 20. The optimizer is selected as the batch random gradient descent method, and the cross-entropy loss function is selected as the loss function. The experimental environment of this article is as follows: the hardware environment is a Linux system, NVIDIA GTX 2080Ti; the software environment is Python3.5, sklearn0.20.3, and other toolkits. The model loss function diagram and accuracy diagram are shown in Figure 7.

After the model parameter training is completed, the model is saved and the model classification results are verified by the test set. The confusion matrix of convolutional neural network results is shown in Table 1.

As can be seen from the convolutional neural networks, the 4-layer mini4 convolutional neural network is shown in Table 1, and the classification effect is poor. Class L and R heartbeats are identified as more than class, so it is not discussed anymore. Network and improved network VGG-Connect are used as the evaluation objects in the following article. According to the above classification of confusion matrix, the classification model was evaluated using two indexes: sensitivity (Se) and positive predictivity (Pp). The index formula is as follows.

$$Se = \frac{TP}{TP + FN} \times 100\%,$$

$$Pp = \frac{TP}{TP + FP} \times 100\%.$$

(5)

The key to the construction of the evaluation index system of sports education lies in its feasibility in practical application. Through data recovery and statistical analysis,

the measured results are given, and the feasibility of the index system is preliminarily verified, which provides a reference for the evaluation of sports events in primary and secondary school. Indicators can reflect the situation between the real value and the predicted value of the classification results of the model, and they are used to evaluate the meanings of each part in the classification formula of the model, as shown in Table 2.

According to the identification of the test set, after statistics and calculation, each corresponding index is obtained and drawn as shown in Table 3. Combined with the previous research, analysis, and comparative experiments, the 22-layer deep convolution neural network with inception module is selected for training at this stage. The network performance is evaluated by ten groups of data of each type. Through the error matrix, it can be seen that the network has recognition errors in three categories, but overall, the

recognition accuracy is high, which can effectively identify a single data block in the data.

It can be seen from Table 3 that in the improved VGG convolutional neural network t, the average sensitivity of the classification results of five kinds of abnormalities is 96.74%, and the average positive detection rate is 96.96%. Sensitivity se represents the recall rate of abnormal classification. The higher se indicates the lower probability of missed diagnosis. The positive detection rate PP represents the accuracy rate of abnormal classification. The higher positive detection rate PP indicates the higher correct detection ability. The improved network VGG Connect improves the correct detection ability (average positive detection rate) by 0.35%.

4.2. Suggestions on Improvement Strategies of Sports Events. In the previous section, the evaluation score of the sports event mode is calculated. This chapter will analyze the evaluation results and put forward improvement suggestions. In 2017, more than 2000 sports events were broadcast live. Therefore, the specific analysis of the evaluation results of sports event mode is representative of the sports event live broadcasting platform according to the evaluation of sports business mode and puts forward improvement strategy suggestions for sports event mode, which is of practical significance for the improvement of Internet sports business mode. According to the evaluation results of sports event mode, we can find out the optimization order of sports event mode, that is, find out the places where the sports event mode needs to be improved most in order to improve the value of sports event mode in the shortest time. The calculation formula is as follows: difference value = weight $*$ (1-measure value), where measure value = index score/100. The difference value indicates the impact of the index on the sports event mode. The greater the difference value, the greater the impact of the index on the sports event mode. Therefore, the optimization order of the index can be sorted by the difference value. The calculation results of the difference value of the primary indicators of sports event mode evaluation are shown in Table 4.

By analyzing the characteristics of the actual sample data, it can be found that the classification effect is very stable in the complete data, the recognition accuracy decreases greatly, and the other two types have a large degree of dispersion in the error matrix. However, through in-depth learning of the commonly used top accuracy matrix

TABLE 2: Formula of meaning.

Names	Meaning
TP	The number of numbers that are predicted to be true and actually true
FP	The number of numbers that the model predicts to be true and are actually false
FN	The model predicts false, and the actual number is true

(see Table 5), the classification accuracy still has traces to follow.

The top accuracy error matrix is formed by arranging the soft classification membership degrees of a group of data in descending order. It can be found that although there is a recognition deviation in the item with the highest membership degree, the network can still recognize the correct classification in the two items with the highest membership degree, even in the case of wrong judgment. At this stage, the recognition performance of a deep learning correlation network for data classification is difficult to achieve a completely reliable classification accuracy. Therefore, in the actual accuracy evaluation process, smooth interpolation is made for the two soft classification items with the highest membership as a joint reference to modify the final recognition method.

5. Conclusion

Based on the principles of sports event evaluation and school sports theory, combined with the actual situation of China's current sports event development, through field investigation and interview, this article puts forward the theoretical framework of establishing sports event evaluation index system. Focusing on the goal of sports event evaluation, this article analyzes the situation of

sports events from four aspects: basic conditions of sports events, organization, and management of sports events, benefits of sports events, and sports culture. Based on new technologies such as convolution neural network with deep structure, the construction of an automatic evaluation technology system has great theoretical and practical significance. Based on this, this article proposes a sports event evaluation and classification method based on deep neural network. Starting from the convolution neural network, combined with the existing technical basis, this article analyzes the applicability of this method through comparative experiments and makes targeted fine-tuning and construction from the network model. Combined with the data characteristics, the dataset suitable for network training and the preprocessing strategy suitable for network evaluation are constructed. The convolution neural network technology is effectively combined with the event evaluation method. The experimental results show that the proposed model has high classification accuracy.

This model can be used for the horizontal comparison of sports events in different parts of the country, looking for their shortcomings, and understanding the development of sports events in different parts of the country. It can also be used to compare various indicators and find

problems so as to better improve the infrastructure construction of sports events, standardize the organization and management of sports events, and improve the benefits of sports events.

However, this method also shows some deficiencies. The following combs and prospects some deficiencies of this article. Many methods involved in this paper are realized automatically by the program. With the deepening of research in the future and combined with the existing research foundation, it is expected to form a relatively complete set of automatic detection software. In the future, we plan to develop cross-modal learning applications based on natural language processing and deep vision for the evaluation and classification of large-scale sports events.

With the continuous development of e-commerce, the logistics industry is thriving, and logistics delays have become an issue that deserves more and more attention. Genetic EM algorithm is a genetic EM algorithm that is an iterative optimization strategy algorithm that can be used to solve the high-quality algorithm of travel problems with many nodes. Bayesian network (BN) is a network model based on probabilistic uncertainty. This article aims to study the probability of many factors that cause logistics delays to construct an algorithm model to control or reduce logistics delays. This paper constructs an EY model (That is the abbreviation of BN model based on genetic EM algorithm) based on the genetic EM algorithm, and conducts related simulation experiments based on the model to verify the accuracy and feasibility of the model. The experimental results of this paper show that the calculation efficiency of the EY model is significantly improved, and the actuarial accuracy is as high as 98%, which can effectively control logistics delays.

1. Introduction

1.1. Background and Significance. The concept of "logistics" varies from country to country and time to time. Generally speaking, logistics means the circulation of goods. The earliest logistic activity was recorded in the UK. The purpose at that time was to deliver the products to wholesalers, retailers and users nationwide in a timely manner. During World War II, the United States took military needs as the starting point and first adopted the term "logistics management" to refer to the supply of weapons during the war. In today's e-commerce era, the global logistics industry is experiencing new developments. The central goal of modern logistics services is to meet customer needs with the lowest comprehensive cost in the entire logistics process. However, with the rapid development of e-commerce, online shopping users' complaints about logistics delays have increased year by year. After analyzing the reasons in detail, it is found that the current solution to logistics delays is an urgent and resource-intensive emergency solution. This plan is incompatible with the normalization and globalization of e-commerce logistics packages. Therefore, it is necessary to have a deep understanding of e-commerce logistics, and formulate accurate measures based on scientific law analysis.

With the popularization of e-commerce now, logistics not only brings a lot of inconvenience to transportation, but once it is delayed, it will be subject to complaints from many customers and even large claims from partners. Studying how to control logistics delays and effectively avoid losses caused by logistics can not only reduce the complaint rate and improve customer satisfaction but also gain the trust of partners and win more cooperation opportunities, which is of great commercial significance.

1.2. Related Work. With the continuous development of the Internet of Things technology and the continuous prosperity of the logistics industry, more and more adults have conducted relevant research and exploration on logistics delays. With the development of the logistics industry, road traffic has become more and more congested. Due to the continuous changes in road conditions, the unstructured traffic

chaos, the lack of lane discipline, and the wide variety of vehicles, there is a special need to develop a new type of traffic monitoring system. Chaudhary S uses dynamic BN to learn the pattern of road conditions and predict future road traffic conditions within a specific time delay. The predicted road condition information can be used for traffic planning. The method proposed by Chaudhary et al. is computationally lightweight, but very powerful and efficient. The algorithm has also been tested against various weather conditions. Chaudhary et al. uses Synchro Studio simulator (a traffic simulation software) to verify the algorithm, the average accuracy rate is 95.7%, for real-time video, the experimental accuracy rate is 84% [1]. Subjective detection is a natural language processing task designed to remove "facts" or "neutral" content from online product reviews, or objective text that does not contain opinions. Chaturvedi extends the extreme learning machine (ELM is a type of machine learning system or method based on feedforward neural network, suitable for supervised learning and unsupervised learning problems) paradigm to a new framework that uses the features of Bayesian and fuzzy recurrent neural networks to perform subjective detection. In particular, BN is used in the traditional ELM configuration to establish a network of connections between hidden neurons. The experimental results of Chaturvedi et al. verified the ability of the proposed framework to deal with standard subjective detection problems, and proved its ability to solve the portability between languages in translation tasks [2]. The multidimensional BN classifier is a topology-constrained BN, specifically used to classify data instances into multidimensional. Bolt and van der Gaag introduces the concept of balanced sensitivity function, in which multiple parameters are related in function by the odds ratio of the original value and the new value. These functions provide appropriate inspiration for adjusting the multidimensional classifier (It is a classification model that describes the dependency between class variables and class variables, class variables and attribute variables, and attribute variables and attribute variables) and output probability. The practical application of Bolt's classifier in the veterinary field proves the practicality of the heuristic method [3]. In ship reliability engineering, reliability evaluation is an important step to determine whether a ship has an acceptable level of reliability. Current reliability assessment methods are based on static logic. However, warships are typical power systems, and reliability cannot be evaluated by the above methods. Liang et al. proposed a new reliability evaluation method based on dynamic BN and numerical simulation. It overcomes the limitations of analysis methods and multi-level integration methods, and provides an effective means for evaluating ship reliability [4]. Based on dynamic BN with incomplete time slices and mixed Gaussian output, Zhang et al. proposed a data-driven method for predicting process failures with unknown models. According to the requirements of failure prediction, this method constructs an incomplete time slice BN of unknown future observation node. The method proposed by Zhang et al. is suitable for continuous stirred tank reactor system. The results show that even if some measured values are lost, the method proposed

by Zhang et al. can effectively predict and identify faults and estimate the remaining service life of the process [5]. The original BN model did not have the expected variable hierarchy. When modeling the relationship between product sales in the retail industry, it is best to consider the hierarchy of items. Kawabe et al. proposed a hierarchical BN model based on the maximum and minimum hill climbing learning algorithm and a new learning method. The method proposed by Kawabe et al. focuses on the product hierarchy and allows the construction of a lower layer that considers the causality of the upper layer. In addition, Kawabe et al. investigated case studies using actual hierarchical data of consumer purchases and demonstrated the proposed model using simulation analysis [6]. Legal scholars have put forward examples of reasoning problems such as the twin problem and the poison paradox (that is, both the idea of drinking medicine and the cancellation of the idea of drinking medicine must be generated, which violates the law of contradiction) to prove the limitations of probability theory in legal reasoning. Specifically, such questions are intended to show that the use of probability theory may lead to legal paradoxes. Therefore, these problems have seriously affected the application of probability theory in law, especially Bayes' theorem. If various related hypotheses and evidence are correctly described in BN, the paradox disappears. Jacob demonstrated this with examples of food trays, the abuse paradox, and the murder problem in small towns. The resulting BN provides a powerful framework for legal reasoning [7]. However, the above research either lacks actual testing, or the calculation process is too complicated or even accurate, and it is currently difficult to pass.

1.3. Innovation. (1) The use of genetic EM algorithm can perform convergence calculations (it refers to the solution that has been numerically calculated, and if it continues to iterate, the result will not change) on unknown parameters, which can reduce logistics delay time. (2) Using BN to represent the graphical model of the connection probability of a set of variables, it provides a method for calculating logistics delays. (3) The EY model combined with the genetic EM algorithm and BN can greatly reduce the calculation error. (4) Comparing the EY model in this article with the traditional calculation model can better reflect the advantages of this model.

2. BN Model Based on Genetic EM Algorithm

2.1. Genetic EM Algorithm

(1) The concept of genetic EM algorithm. The full name of genetic EM algorithm is Electromagnetic-like Algorithm, which is similar to electromagnetic mechanism algorithm. This algorithm is a new global improvement algorithm based on the meta-heuristic of group randomness. The earliest inspiration for this algorithm comes from the movement of point charges and Coulomb force in physics, as shown in. The genetic EM algorithm formulates criteria such as total force calculation between strokes, stroke power

calculation, stroke motion, local search, etc., so that each stroke in the population moves in the direction of the optimal stroke, which can be obtained after repeated several times. The optimal solution of the optimization problem can be used as an independent algorithm to solve the global optimization problem. It can also be integrated with other algorithms to form a new global optimization algorithm (global optimization algorithm, also known as modern heuristic algorithm, is an algorithm with global optimization performance, strong versatility and suitable for parallel processing) [8].

(2) Genetic EM algorithm classification. Because the genetic EM algorithm is a relatively new algorithm, domestic scholars have done very little research on the genetic EM algorithm, and the application of this method to the field of logistics distribution route optimization is still a blank. Fortunately, many researchers have done a lot of research on other optimization algorithms, including more advanced algorithms such as ant colony algorithm (it is a probabilistic algorithm used to find an optimal path, which comes from the behavior of ants finding paths in the process of looking for food) and genetic algorithm. Some scholars also apply these algorithms to the optimization problem selection of vehicle distribution routes, and have achieved certain results [9, 10].

(3) The principle of genetic EM algorithm. Genetic EM algorithm is an iterative optimization strategy. The genetic EM algorithm is affected by the idea of data loss. It was originally to solve the problem of parameter estimation in the case of missing data. The basis and convergence of the algorithm are effective. The basic idea is as follows: first, estimate the value of the model parameters based on the given observation data. Then estimate the value of the missing data based on the parameter value estimated in the previous step, and then add the missing data previously estimated based on the estimated missing data. Re-estimate the parameter values from the observed data, and iterate repeatedly until the final convergence, and the iteration ends. Taking the question in this article as an example, assuming that the logistics has to pass through k nodes, then there are $(k-1)!$ ways to move, so how to make the logistics journey the shortest?

First, Figure 1 randomly selects a point from the known feasible region as the initial stroke, calculate the objective function $G(x)$ of each stroke in a initial stroke, and calculate the optimal stroke $S^?$ of the objective function as the current optimal journey. Then set the local search parameters. Local search refers to an improved solution for searching the current population within a single travel range. According to the set local search parameters, calculate the various dimensions of the stroke, obtain the movement direction of the stroke and the maximum feasible step length, and perform a local search along this direction until a better
Figure 1: Schematic diagram of EM algorithm.

solution is found. After the local search is completed, the population is updated once, the objective function value of each trip after the population update is recalculated, and the optimal trip of the objective function is updated. Then calculate the charge of each stroke according to the value of the objective function of each stroke, and then calculate the resultant force of each stroke through the formula of simulating electromagnetic field force and the principle of superposition. In the process of calculating the resultant force, the value of the objective function of each stroke is greater than the value of the objective function of the other two strokes. In this case, the (good) stroke with a small objective function value absorbs the stroke with a large objective function value, and the stroke with a large objective function value (bad) rejects the stroke with a small objective function value. The final stroke moves in the direction of the resultant force, and the feasible step length of each step of the stroke can be calculated by the following formula. At this time, the position of each stroke is updated, and the iteration of similar electromagnetic algorithms is completed [11, 12].

2.2. Bayesian Network

(1) *Concept.* Bayesian network (BN), also known as causal probability network and belief network, is a network model for reasoning based on probabilistic uncertainty, as shown in. The basis of BN is Bayes' theorem (A theorem about the conditional probability of random events A and B, where $P(A|B)$ is the probability that A will occur if B occurs). BN is a network composed of nodes representing variables (including child nodes and parent nodes) and directed edges connecting these nodes. Random variables are represented by nodes, and the directed edges between each node represent nodes. The strength of the relationship is determined by the conditional probability. If there is no parent node, the information is represented by a priori

probability. BN is a directed graphic description based on the network structure. This is a graphic model used to express the connection probability of a set of variables. It is suitable for expressing and analyzing uncertain and probabilistic things. It cannot be incomplete or uncertain, and must be based on knowledge and information. BN is a directed acyclic graph (A directed acyclic graph refers to a directed graph without a loop. If there is a non-directed acyclic graph, and starting from point A to B via C, it can return to A, forming a ring. Changing the edge direction from C to A from A to C becomes a directed acyclic graph. The number of spanning trees of a directed acyclic graph is equal to the in-degree product of nodes with non-zero in-degree.), and the acyclic graph (DAG) is composed of variable nodes and directed edges connecting these nodes [13, 14].

BN is a mathematical model based on random reasoning, as shown in Figure 2. The emergence of BN is to solve the problem of imperfection and uncertainty. This method helps to solve the uncertainty and correlation of complex equipment, and has great benefits for reducing risks. Probability theory is the theoretical basis of BN and an accurate solution to problems in probability theory. The BN theoretical system often uses some basic probability formulas, such as conditional probability, probability law, total probability, Bayesian formula, etc. [15].

(2) *Features.* BN can qualitatively express complex causal or random relationships between events in a concise graphical way. With some prior information, these relationships can also be expressed quantitatively. The topology of the network is usually determined based on specific survey topics and questions. One of the current research hotspots of BN is how to automatically determine and optimize the network topology through learning [16].

(3) *Bayesian Formula.* In order to solve the joint probability problem, there are usually different calculation methods for different probability events. The following are several common probability calculation formulas, in which the probability value is represented by p.

(i) *Multiplication Formula.* If X and Y are two of the basic probability events of event Z, and the probability of any of these events is not 0, the calculation formula:

$$p(XY) = p(X)p(Y|X),\qquad(1)$$

$$p(XY) = p(Y)p(X|Y).\qquad(2)$$

(ii) *Conditional Probability.* If X and Y are two of the basic probability events of event Z, there is a conditional relationship between the occurrence of event X and event Y, and the probabilities affect each other. If event X occurs and the
Figure 2: BN model.

probability is not 0, then the probability of event Y occurs:

$$p(Y|X) = \frac{p(XY)}{p(X)}.\qquad(3)$$

Similarly, if event Y occurs and the probability is not 0, then the probability of event X: Figure 2.

$$p(X|Y) = \frac{p(XY)}{p(Y)}.\qquad(4)$$

(iii) Using the multiplication formula and the conditional probability formula to generalize the total probability formula of the big event Z, assuming that $K_1, K_2, \ldots, K_n$ are the sub-events of event Z, and the probability of occurrence of the event is not 0, then the total probability formula of event Z can be expressed as:

$$p(Z) = \sum_{i=1}^{n} p(K_i)p(Z|K_i).\qquad(5)$$

From this, the conditional probability formula of the event K_i can be scored:

$$p(Z|K_i) = \frac{p(Z)}{\sum_{i=1}^{n} p(K_i)}.\qquad(6)$$

(iv) *Bayesian Formula.* Assuming that $K_1, K_2, \ldots, K_n$ are the sub-event groups of event Z, the probability is not 0, and the event X is any event among them, and the probability is not 0, then the above generalization can be obtained:

$$p(K_i|X) = \frac{p(K_i)p(X|K_i)}{\sum_{j=1}^{n} p(K_j)p(X|K_j)}.\qquad(7)$$

(4) *BN Mathematical Model.* BN modeling is a relatively complicated process, which requires patience and care. When modeling, the first thing to do is to determine the nodes, use the nodes to build the topology, then calculate the conditional probability distribution of each node, and finally test to determine the model. shows the basic model building process [17, 18].

(i) Selection of nodes. Bayesian network node variables are various elements of the emergency

system. It is very important to determine the node variables as comprehensively as possible for the accuracy of situation assessment. There are several main types of nodes in Bayesian networks. The first is the target node. This node represents the final problem that the model needs to solve. The second is the evidence node (also called the parent node), which is the most basic parent node in the network and has a value similar to the following: the prerequisites for Bayesian network inference are provided directly from the database or provided by expert knowledge. The third is to realize a component of the integrity of the Bayesian network. After determining the connected role nodes, the value of each node needs to be further determined. The value of each node is independent of each other and does not contain each other [19].

Assuming that there are m nodes in BN, and each node is represented by N, then: Figure 3.

$$P(N) = P(N_1, ..., N_m). \tag{8}$$

Taking m equal to 4 as an example, suppose there are four nodes H, I, J, and K, as shown in Figure 4:

According to the previous probability formula, we can get:

$$P(H, I, J, K) = P(K|J)|P(I|H, J)|P(J|H)|P(H). \tag{9}$$

(ii) The establishment of BN topology. The purpose of BN structure learning is to extract specific data and build a structure with a higher degree of fit. According to the previous knowledge, when the number of nodes is m, the number of structures can be expressed as a function:

$$G(m) = \sum_{i=1}^{m} (-1)^{i+1} \left[\frac{m!}{i!(m-1)!} \right] 2^{i(m-1)} g(m-i). \tag{10}$$

Using the scoring search method to perform statistics, R represents random variables, and S represents data collection, then:

$$R = \arg\max P(R|S), \tag{11}$$

$$P(R|S) = \frac{P(S|R)|P(R)}{P(S)}. \tag{12}$$

According to formula (12), the logarithm of both sides can be obtained

$$\text{Log}P(R|S)| = \text{Log}P(S|R)| + \text{Log}P(R). \tag{13}$$

Formula (13) is the score of R. In fact, $P(R)$ is usually evenly distributed, for which one can obtain

$$P(S|R) = \int P(S|R, \delta)|P(\delta|R)|d\delta. \tag{14}$$

In the formula, δ represents the size of the node corresponding to R.

When the data set S is independent and identically distributed, and R is the corresponding BN structure, the evaluation function for BD is

$$G_{BD}(R, S) = \text{Log}P(R) + \sum_{i=1}^{m} \sum_{j=1}^{h_i} \left[\text{Log} \frac{\Gamma(x_{i,j})}{\Gamma(x_{ij*} + y_{ij*})} + \sum_{c=1}^{d_i} \frac{\Gamma(x_{ijc} + y_{ijc})}{\Gamma(x_{ijc})} \right]. \tag{15}$$

When the data set S is independent and identically distributed, and R is a BN structure of y variables, the evaluation function for K2D is

$$G_{K2}(R, S) = \text{Log}P(R) + \sum_{i=1}^{m} \sum_{j=1}^{h_i} \left[\text{Log} \frac{(d_i - 1)!}{(y_{ij} + d_i - 1)!} + \sum_{c=1}^{d_i} \text{Log}(y_{ijc}) \right]. \tag{16}$$

If the BN structure information is uniformly distributed, the evaluation function for BDe is

$$G_{B\,De}(R, S) = \text{Log}P(R) + \sum_{i=1}^{m} \sum_{j=1}^{h_i} \left[Log \frac{\Gamma(x/h_i)}{(\Gamma(x/h_i) + y_{ij*})} + \sum_{c=1}^{d_i} \frac{\Gamma((x/d_i h_i) + y_{ijc})}{\Gamma(x/d_i h_i)} \right]. \tag{17}$$

Or an evaluation function based on information theory, $LL(R|S)$ represents the logarithm of the likelihood of BN, then

$$G(R|S) = g(\delta)|R| - LL(R|S). \tag{18}$$

When $g(\delta) = 1$, there are

$$G_A(R|S) = |R| - LL(R|S). \tag{19}$$

When $g(\delta) = (1/2)\mathrm{Log}m$ represents the number of bytes

$$G_B(R|S) = \frac{1}{2}\mathrm{Log}|R| - LL(R|S). \qquad t \tag{20}$$

The selection of the evaluation function should be carried out according to the actual situation of the BN network, and the minimum evaluation function obtained by calculation can obtain the best parameters of BN [20, 21].

2.3. Plan to Control Logistics Delays

2.3.1. The Meaning of Logistics Delay.
The rapid development of e-commerce has brought more and more convenient online shopping services, and at the same time, it has also driven the rapid development of the logistics industry. shows the growth of online shopping users and the amount of online shopping transactions in the past five years.

It can be seen from Figure 5 that with the continuous development of e-commerce, the number of online shopping users has increased year by year, and the total amount of e-commerce transactions has also continued to increase. Due to the impact of the epidemic at the end of 2019, its online shopping transaction volume has declined, but online shopping users are still increasing, which also shows that during the epidemic, more and more people began to prefer online shopping. Figure 5.

However, there are also a lot of problems in the development process of the logistics industry. As a service-oriented industry, logistics is the most important thing to ensure the timely delivery of goods, so the problem of logistics delays is the most worthy of attention. Figure 6 shows the growth of the express delivery industry in recent years and the growth of the number of complaints about logistics delays by express users to the State Post Bureau.

It can be seen from Figure 6 that the number of complaints about logistics delays by express users to the State Post Bureau has been increasing year by year, and the number of express delivery delays accounted for more than 25% of the total number of complaints, such a serious delay has brought a lot of discomfort to e-commerce merchants, operators and users. For e-commerce merchants, delays in e-commerce logistics have brought them credibility and economic losses. Major e-commerce platforms regard logistics as an indicator for customers to evaluate their online stores. The poor experience of logistics delays will affect the reputation of the customer's store, damage the reputation of

(a)

(b)
FIGURE 5: The development of online shopping and express delivery in China in recent years. (a) Growth of online shopping users. (b) Growth of online shopping transactions.

FIGURE 6: The number of express complaints about logistics delays in recent years. (a) Growth in express delivery business. (b) Delay in express delivery complaints.

the store, and affect the decision of other potential customers whether to purchase the store's goods [22, 23].

2.3.2. Reasons for Logistics Delays. According to the direct personnel contacting the goods, it can be divided into corporate factors (including logistics company factors, provider factors, courier factors), customer factors and other factors. Logistics company factors include arranging logistics drivers for loading, transportation schedules and other factors; providers include delivery speed, packing speed, etc.; the courier includes the speed of handover, telephone notification to customers, etc.; customer factors include pickup speed, fuzzy receiving address, incorrect phone number, etc.; other factors include road traffic conditions, weather factors, emergencies, and so on. Table 1 shows the statistics of the proportions of various factors, among which the corporate factor is the most important factor.

2.3.3. Features. When e-commerce logistics is delayed at the starting node, the delay will spread downstream through online shopping products. Affected by this, e-commerce logistics continues to lag downstream neighboring nodes, and there is a continuous delay between this point and downstream neighboring nodes. Affected by interference factors, there is a complicated correlation between the initial delay in e-commerce logistics at the starting node and the adjacent delay in downstream adjacent nodes. Initial delays in commercial logistics can increase, pass on, or weaken the impact of adjacent delays. Delivery companies have different factors in e-commerce logistics delay management methods, leading to the introduction of corporate and customer factors. The degree of correlation between successive delays in e-commerce logistics caused by various factors varies. Figure 7 is a schematic diagram of the spread of logistics delays [24].

TABLE 1: Proportion of reasons for logistics delays.

Factor	Include	Proportion (%)
Company	Logistics company	56.2
	Enterprise store	27.9
Customer	Pickup speed	11.6
Other	Natural factors	4.3
FIGURE 7: Schematic diagram of the spread of logistics delays.

2.3.4. Control Measures for Logistics Delays. Based on the analysis of the causes of logistics delays, it can be carried out from the aspects of enterprises, customers, etc., and other factors can be avoided if they can be avoided. On the corporate side, improvements or optimizations can be made in terms of employees, equipment, management methods, etc., while on the customer side, communication with them can be strengthened, and logistics awareness can be promoted. In other aspects, such as sudden traffic jams, if the transportation cost is similar, the detour is faster if it can take a detour. In severe weather, it can choose a better logistics method. ① In terms of corporate employees, improving the working level of the staff not only guarantees the work quality of the courier, but also ensures that the behavior of the customer during the delivery process meets the requirements of the courier, and avoids the delay caused by the following reasons in e-commerce logistics: operation error. Human factors are now an important reason for e-commerce logistics delays. Improving the work level of personnel is the key to avoiding unreasonable delays and an important means to control the spread of delays. To improve staff credibility, it is necessary to strengthen the training and management of express company employees. The staff of courier companies need to have professional knowledge and skills to effectively avoid delays caused by seal errors, misdelivery, and failures in timely response. At the same time, having professional knowledge and a sense of responsibility is an important guarantee for the courier staff to correctly guide the delivery behavior of customers and avoid problems such as blurred addresses and telephone errors. ② Stability of working equipment. The failure of logistics operation equipment is an important factor causing delays in e-commerce logistics. By improving the reliability of logistics equipment, it can effectively reduce the possibility of logistics delays caused by corporate factors in e-commerce. For this reason, this section focuses on the maintenance and repair management of logistics equipment. Working and deploying the correct logistics equipment are two aspects of improving equipment reliability. One is the

regular maintenance and overhaul management of logistics equipment. The logistics company's regular maintenance and overhaul management of logistics equipment can effectively avoid delays caused by mechanical equipment failures, increase equipment reliability, reduce potential delays in the cradle, and provide guarantee for e-commerce logistics operation planning. The second is to introduce appropriate logistics equipment. The introduction of suitable logistics equipment by logistics companies can effectively improve the efficiency of logistics operations, reduce the actual operation time of e-commerce logistics, and increase the "slack time" in the logistics operation process. If there is a delay in e-commerce logistics, e-commerce logistics is one of the nodes. The longer the "relaxation time" between the two, the more helpful it is to absorb the delay time and reduce the spread of the delay. ③ Reasonably arrange the priority of logistics business. Due to corporate factors, enterprises have poor management of e-commerce logistics delays. The spillover effect of delays is mainly manifested in transmission, and the delay absorption rate is very low, which reduces customer satisfaction with carriers and shipments, and damages the company's reputation. If e-commerce logistics is delayed due to corporate factors, the company is fully responsible, and the company must have greater control over the increasingly serious logistics delay. This article recommends that companies adopt new business priority allocation to solve the problem of e-commerce logistics delays caused by corporate factors. That is, change the logistics route and choose the route with higher priority [25].

3. EY Model Logistics Delay Control Simulation Experiment

3.1. Design of EY Model

3.1.1. Design Ideas. According to the number m of nodes passed by the logistics, the delay of each node logistics will affect the logistics delay of the two goods before and after, as

shown in Figure 8, the entire logistics business process of online shopping from receipt to delivery is connected. The goods pass through x_1, x_2, ..., x_i, ..., x_m logistics nodes in sequence according to the logistics plan. i is a positive integer. The delay of online shopping at specific logistics nodes will inevitably affect the timeliness of subsequent logistics nodes. In the process of logistics business, there is "logistics slack" in online shopping products. For example, an online shopping product will stay at a specific logistics node for an hour, but in reality, the staff of the logistics node will complete half of the logistics transfer activities such as weighing, loading and unloading, and product handling. The remaining 30 minutes are "logistics slack," but "logistics slack" may not be enough to absorb the delay time of the product operation on the previous node, leading to the spread of delays. If the user suggests to the carrier that the delivery of online shopping goods from node x_i to node $x_i + 1$ is delayed, the goods will continue to pass through nodes x_i, $x_i + 1$...x_m to the preliminary planned route of subsequent logistics business activities. Assuming that in the process of sending online shopping products from node x_i to node $x_i + 1$, the delay cannot be fully absorbed due to the interference factor "logistics slack," then the arrival of online shopping products at node $x_i + 1$ will be delayed; if $x_i + 1$ is affected by the delay time of the node after receiving, "logistics slack" cannot fully absorb the remaining delay time in the processing of online shopping products from node $x_i + 1$ to node $x_i + 2$, online shopping arrival delay node $x_i + 2$ products will certainly continue to be delayed. This paper mainly studies the delay propagation of online shopping products from node $x_i + 1$ to delivery node x_n. Node $x_i + 1$ is defined as the starting node and node $x_i + 2$ is the adjacent node; the delay of online shopping products at the starting node is defined as the initial delay. The delay of online shopping products on adjacent nodes affected by the initial delay is defined as the adjacent delay. The delay of online shopping products affected by the initial delay is defined as the delay of the delivery node. The delay time of the online shopping product at the starting node is defined as the initial delay time, that is, the difference between the time when the online shopping product actually arrives at the starting node and the planned time. The node delay time when the online shopping product is adjacent is defined as the adjacent delay time, that is, the difference between the actual time and the planned time for the online shopping product to reach the adjacent node; the delay time of the online shopping product at the delivery node is defined as the total delay time. This is expressed as the difference between the actual time and the planned time for the online shopping product to arrive at the delivery node. Online shopping products are affected by initial delays in the distribution process, and online shopping products continue to reach downstream nodes. Delay nodes (except the start node) are defined as downstream delay nodes [26, 27].

Figures 7 and 8 original delay model is improved and simplified, and the EY model is obtained. The model comparison is shown in Figure 9. The numbers in the figure represent various causes of logistics delays. Figure (a) is the model before improvement, and figure (b) is the model after improvement.

3.1.2. The Characteristics of the Improved Model.

The streamlined model is smaller in scale, faster in calculation, and suitable for processing large data sets. The improved model combines related factors, its structure is clearer, the calculation path is clearer, there is no redundant calculation, the simplified model is smaller in scale, faster in calculation, and suitable for processing large data sets. In the logistics delay forecast, the effect is better and the accuracy rate is high.

3.2. Simulation Experiment of Logistics Delay Control Based on EY Model.

This article simulates the simulation experiment of logistics transportation route optimization, and the selected EY model is feasible and efficient. Collecting data before the experiment. Before the experiment, this article investigated the complaints, data management, delayed mediation, problem handling, etc. from many domestic express company users. The data includes the number of courier services and delay factors for online shopping products. The selected courier tracking number is one of the courier's working group, indicating that the delayed item was purchased online, or the logistics information of the delayed item indicates that the seller shipped it. This article collected 11,000 e-commerce logistics delay data, of which 8,500 valid data. The number of e-commerce logistics delays caused by corporate factors was 6,213; the number of delays caused by customer factors was 2,101; and the number of e-commerce logistics delays caused by other factors was 186. As shown in Table 2.

The experiment selected 18 logistics nodes where a logistics company is about to transport goods. The purpose is to calculate a more reasonable logistics distribution route to make the transportation mileage the shortest. The logistics node is represented by two-dimensional coordinates (i, j), as shown in Table 3.

According to the permutation and combination algorithm, there are a total of 18 paths, including more than 6,400 trillion ways. It is basically difficult to calculate. Using the model optimization algorithm designed in this paper, first select a node as the center node, the coordinate center point is (100, 100), because considering that the node closest to the coordinate center point is the node number 15, the center node coordinate is selected as the number 15 (126, 85). According to the previous formula, take m as 18. After iterative calculation, the better mileage shown in Table 4 is obtained, and the corresponding comparison is shown in Figure 10.

The experimental results found that the calculation of the optimal route for the total mileage of the logistics transportation route calculated by the EY model has high accuracy, few iterations of the calculation, and high calculation efficiency. The optimal route obtained after 9 calculations is 1106 km. Among them, the number of occurrences of the optimal route is 4 times, ranking first. The longest calculation is 1225 km, the distance error is less than 1.1%, and the calculation accuracy is as high as 98%.

4. Discussion

The electromagnetic-like mechanism of logistics transportation path optimization algorithm simulates the mechanism of charged particles in physics, so that the particles move to the optimal solution. Particle turbulence allows the local search mechanism to search better both locally and globally. In order to obtain the best solution, the goal of preventing the best solution from slipping through the network has been achieved.

5. Conclusions

The EM algorithm proposed in this paper has made a certain breakthrough in solving the problem of logistics transportation route optimization. However, there is still room for further research on this issue. This article only conducted simulations with careful consideration of distance and calculation of increased vehicle restrictions and vehicle capacity restrictions. Road congestion is frequent in logistics and transportation, and short-distance routes will waste a lot of time due to congestion, resulting in reduced transportation efficiency. Therefore, in future research, it is necessary to increase congestion parameters and time parameters, comprehensively consider the length of the trip and the time of the trip, and obtain an algorithm that matches the actual logistics road conditions.

With the global industrial integration, trade exchanges between countries are becoming more and more frequent and the competition for related international trade logistics is becoming more and more intense. This paper aims to study the optimization design of international trade logistics based on Internet of Things technology. For this reason, this paper proposes an RFID method, through which it is possible to master a journey in the actual international trade logistics process. And it optimizes and improves its related paths, shortens the time delayed on the road, and achieves the purpose of mentioning the carrying capacity. And for the actual use effect, the relevant experiments and analysis parts are designed to simulate it. The experimental results of this paper show that the improved and optimized international trade logistics shortens the carrying time by 28.6% and increases the carrying capacity by 34.2%, which greatly promotes the development of the relevant international trade logistics industry.

1. Introduction

The continuous development of the contemporary world economy toward integration has greatly promoted the development of international trade and international shipping, and logistics has played an increasingly powerful role in the development of the regional economy. After realizing the importance of logistics, all parts of the world are actively developing the logistics economy, and the competition among logistics is becoming more and more fierce, which makes the development of logistics more inclined to the specialization of functions, large-scale scale, modernization of technology, and scientific management. These changes make the competitive environment among logistics more cruel, but at the same time promote the rapid development of logistics in a better and more efficient direction.

Through the analysis of the construction of the existing international trade logistics platform, the development of international trade logistics has accelerated the operation of enterprise logistics, and it is also beneficial to the development of international trade. On the one hand, it can improve the loading and unloading processes, reduce the production cost, and improve the economic benefits of international trade,

which is beneficial to the long-term development of international trade; on the other hand, it enhances the expansion function of international trade, extends the basic function of international trade, and provides a new economic growth point for the development of international trade, thereby reducing the operational risk of international trade. From the perspective of international competition, the development of international trade logistics can help to establish an international trade logistics center and improve the comprehensive benefits of international trade logistics.

The innovation of this paper lies in the use of the key technology of the Internet of Things, that is, RFID radio frequency technology. And the technology is optimized so that the improved RFID technology can be better applied to the research topic of this paper. And the relevant national trade logistics is also analyzed and researched, and its memory is optimized and improved to a certain extent.

2. Related Work

With the development of economy and the expansion of globalization and internationalization, international trade logistics does not meet the basic functions of simple loading

and unloading, warehousing, and so on. How to adapt international trade logistics to the requirements of modern development, how to promote the sustainable development of economy and trade, and how to promote the regional development of surrounding areas have become one of the urgent problems to be solved. Lai M proposes a vehicle initial path optimization model considering uncertainty, considering vehicle capacity, customer time window, maximum travel distance, and road capacity [1]. The model proposed by Zhang et al. is formulated as a two-layer formula in which the upper layer determines the optimal choice of logistics infrastructure investment and green transportation mode subsidies to maximize the benefit-cost ratio of the entire logistics system [2]. Based on the relationship between suppliers, transit warehouses, and sellers in the collaborative logistics network, Xu et al. established a two-level programming model with random constraints considering the uncertainty of time. He proposed a genetic simulated annealing mixed intelligence algorithm to solve it. Numerical examples show that the method has strong robustness and convergence, and it can realize the rationalization and optimization of resource allocation in collaborative logistics network [3]. Aiming at the common distribution methods of urban logistics in the e-commerce environment, Yang considers the dynamic uncertainty of the urban road network based on the optimization of the distribution path [4]. Liu et al. proposed a stochastic model of postdisaster relief logistics to guide the tactical design of mobilizing relief material levels, planning initial helicopter deployments, and creating transport. He introduced a robust optimization method to deal with these uncertainties and derived a robust counterpart of the proposed stochastic model [5]. Rajasekar et al. reconsidered the problem of conflicting optimization goals, focusing on low inventory levels and short throughput times. It generates conversions of some performance metrics (such as delivery time and latency) to penalties. When manufacturing is the main economic activity of an industry, changes in production patterns pose challenges to the logistics system, forcing manufacturers to optimize the logistics system [6]. Dossou and Vermersch defined a study based on a cocreation approach that integrates all stakeholders (local authorities, companies, and citizens) to develop alternative solutions for road transport. It is used for the architecture and development of decision aids for simulating and optimizing alternative solutions to road traffic [7]. Malladi and Sowlatti proposed that biomass logistics was reviewed in a previous study aimed at classifying logistics operations, but the inherent issues and complexities and how they were incorporated into mathematical models were not discussed in detail. Their aim is to review the important features of biomass logistics operations, discuss how to incorporate them into mathematical optimization models, and explain new trends in biomass logistics optimization [8]. The above-mentioned literature is very good for the relevant logistics optimization ideas, and the relevant technical explanations are all in place. The proposed model is also studied in detail. However, the Internet of Things technology is not used in a certain combination, and the introduction of the relevant experimental process is not detailed enough.

3. International Trade Logistics Optimization Method

3.1. IoT Technology

3.1.1. Concept of Internet of Things. At present, there is still no authoritative definition of the Internet of Things. From the technical field, the Internet of Things refers to the integration of various technologies (sensors, wireless sensors, smart embedded, Internet, RFID, smart processing, nano, etc.), and through the Internet of Things, the interconnection of all things can be realized. It has the characteristics of precise control, reliable transmission, and comprehensive processing intelligence and perception. Figure 1 shows a typical IoT structure diagram [9].

3.1.2. IoT Architecture. The Internet of Things technology includes computer and Internet technology. It identifies and manages physical objects through modern information technology and uses wireless communication technology to achieve information exchange [10]. The Internet of Things has obvious advantages, the most notable feature of which is that it greatly reduces production costs while improving economic benefits. The Internet of Things is usually divided into five parts, namely, readers, electronic tags, Internet of Things name resolution servers, Internet of Things middleware, and Internet of Things information publishing services.

At present, the Internet of Things is at the forefront of technology, the technology is strict and complex, and the technology is not mature enough [11]. From the analysis of the current application requirements of the Internet of Things, the academic community generally divides the Internet of Things into three levels (1. perception layer; 2. network layer; and 3. application layer) as shown in Figure 2.

Perceptual recognition technology is the core technology of the Internet of Things [12]. The perception layer is mainly composed of various sensors and their gateways, which are mainly used to collect data. Its specific data indicators include various types of digital data, video data, audio, and identification [13]. The key technologies of IoT data collection include sensor technology, RFID technology, multimedia information collection technology, two-dimensional code technology, and real-time positioning technology. Taking people as an example, the nerve endings of human sensory eyes, ears, throat, nose, and skin are equivalent to the perception layer mentioned above. In the Internet of Things, identifying objects and collecting information sources is the core function of the perception layer [14].

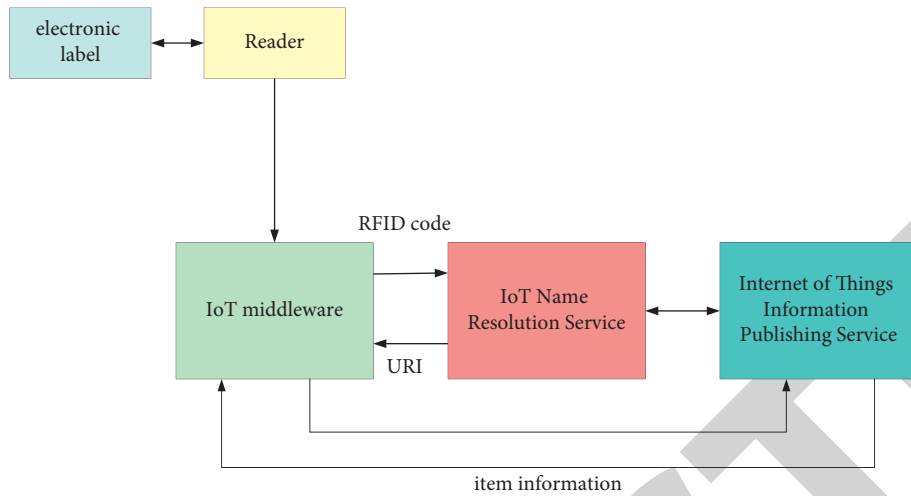
The three compartments in the Internet of Things are independent of each other, but there is a close connection between the three compartments. In the introduction to the network layer, people are also taken as an example. The network layer can be compared to the human nerve center, which is responsible for transmitting and processing the digital information taken by the perception layer. The technical functions on each compartment complement each other and play different roles according to different


FIGURE 1: The structure of the Internet of Things.
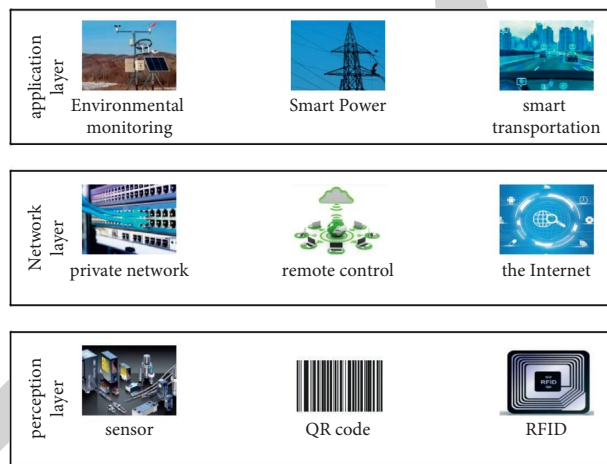

FIGURE 2: Internet of Things technology system framework.

environments to adapt to different application environments, thus forming a complete coping strategy for the compartment technology [15]. The security technology, identification and analysis, service quality management, and network management in the public technology are related to the above three layers of the IoT architecture to a certain extent, but they do not belong to a specific layer in the IoT technology.

3.1.3. Perception Layer Functions and Technologies. In view of the large amount of information obtained through perception functions, there is a large demand for geographic and spatial scope. The devices in the perception layer also need to form a self-organizing multinode network in a cooperative manner, and transmit data through the self-organizing network technology [16]. To realize the sensing function, the sensor network firstly touches and senses the sensed object in all directions through different sensors, and then comprehensively identifies and analyzes the acquired sensing data.

3.1.4. Key Technologies of the Perception Layer. RFID tags contain electronically stored information, so they can be identified within a few meters. Some tags do not need energy themselves and obtain energy from electromagnetic fields during identification; some tags themselves have power or energy, which can actively generate radio waves, the so-called electromagnetic fields tuned to radio frequencies. RFID technology has been used in most industries today [17]. Car manufacturers can know the progress of the car on the production line based on the label on the car, and the warehouse can also know the information of the goods in real time. In addition, radio frequency tags can also be applied to animals to facilitate the positive identification of animals. The radio frequency transponder installed on the car can be used to collect parking fees and also can be used to collect road tolls. Of course, this technology has the possibility of obtaining personal information without the consent of the individual, and this technology will infringe on the privacy of others to a certain extent [18].

The RFID application system is mainly used to control, detect, and track objects. The principle of RFID is not

complicated, its application system principle is actually very simple, the composition is also simple, and it is composed of two basic devices. The system consists of an interrogator, the so-called reader, and many transponders [19]. Its basic composition is shown in Figure 3.

Signal receivers also exist in RFID systems, which are often referred to as readers. The sophistication of readers varies widely based on the types of tags supported and the capabilities they perform. Its main function is to provide a data transmission method.

Receiving the radio frequency signal sent by the reader, the tag relies on the energy obtained by the induced current to send out the product information stored in the chip, or the tag can actively send a signal of a specific frequency. After reading and decoding the information, the reader sends the data and information to the central information system for further processing [20].

The signal transmitter exists in the RFID system, and its existing forms are also different according to the requirements of the application, and the label is its typical form. The tags include antennas, coils, memory, and low-power integrated circuits for control systems. The role of the label is like a barcode, and its role is to store information [21]. However, compared with barcodes, it has the characteristics of actively transmitting information [22]. The salient feature of RFID tags different from barcodes is that they do not need to be placed in the line of sight of the identifier, and RFID tags can also be embedded in the tracked object.

3.2. Power Transmission of the RFID Real-Time Positioning System.
In order to analyze the link characteristics and system indicators of the system, it is necessary to quantitatively analyze the power transmission mechanism of the RFID real-time positioning system. This includes the analysis of the path loss characteristics of the channel and the reflection characteristics of the tags. It first analyzes the path loss characteristics of the system.

The RFID system is a short-range wireless communication system, and the path loss of the system can be analyzed using the free space propagation model [23]. Assuming that the transmitting power of the reader is, it is transmitted outward through the antenna with a gain of. It can be seen from the formula that the relationship between path loss and distance is as follows:

$$P_{\text{channel}}|_{dB} = 20 \, \log\left(\frac{\lambda}{4\pi d}\right). \tag{1}$$

It can be known from the above formula that the maximum linear dimension D of the cross section of the transmitting antenna is related to the wavelength. Fraunhofer distance is defined as

$$d_f = \frac{2D^2}{\lambda}. \tag{2}$$

Let h_1 be the height of the reader, h_2 the height of the tag, and d the horizontal distance between the reader and the tag.

E_{tag} is the electric field strength received by the tag, and its expression is as follows:

$$\left|E_{tag}\right| = 2 \cdot \frac{\sqrt{30 \cdot \text{EIRP}}}{d} \cdot \, \sin\left(\frac{2\pi h_1 h_2}{\lambda d}\right). \tag{3}$$

Assuming that the EIRP is 4 W, the height of the reader and the tag are both 1 m, and the signal power received by the tag can be expressed as

$$P_{tag} = \frac{\left|E_{tag}\right|^2 \lambda^2}{480\pi^2},$$

$$P_{tag} = \sin^2\left(\frac{2\pi}{\lambda d}\right) \cdot \left(\frac{\lambda}{d\pi}\right)^2. \tag{4}$$

When the effective transmit power of the reader is 4 W, the received signal power obtained according to the free space attenuation model is as follows:

$$P'_{\text{tag}} = 4 \cdot \left(\frac{\lambda}{4\pi d}\right)^2,$$

$$P'_{\text{tag}} = \frac{1}{4}\left(\frac{\lambda}{\pi d}\right)^2. \tag{5}$$

As shown in Figure 4, the relationship between the received signal power of the tag and the distance obtained under the two models is given.

According to the working principle of the UHF RFID system, the energy received by the tag is roughly divided into two parts. One part is received by the tag antenna, enters the tag chip, and is rectified for the tag to work, and the other part is backscattered by the tag antenna [24]. To quantify the energy distribution between received and reflected, the tag antenna and tag chip can be modeled as shown in Figure 5.

v_s and I_s in the figure represent the peak voltage and peak current that can be induced by the tag antenna when it is not loaded; z_A represents the impedance of the tag antenna, z_L represents the impedance of the tag chip, and there are as follows:

$$Z_A = R_A + jX_A,$$
$$Z_L = R_L + jX_L. \tag{6}$$

Then, the reflection coefficient of the label is defined as

$$\Gamma = \frac{Z_L - Z_A^*}{Z_L + Z_A}. \tag{7}$$

Then, the power that can be obtained by the tag is as follows:

$$R_{\text{RF,in}} = \frac{1}{2}\text{Re}\left(V_S^* \cdot I_S\right). \tag{8}$$

Available power is as follows:

$$R_{\text{RF,in}} = P_{\text{avail}}\left(1 - |\Gamma|^2\right), \tag{9}$$

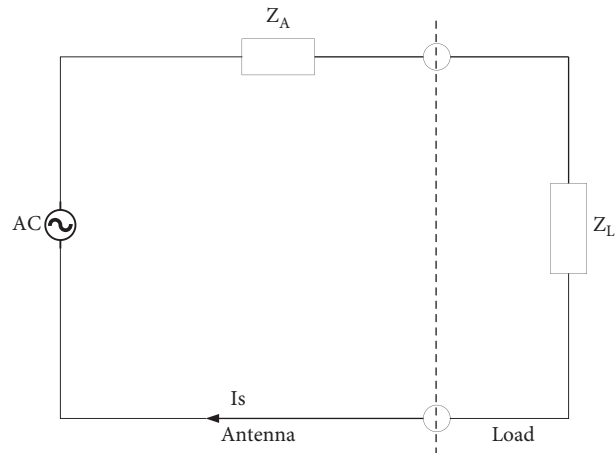
where
FIGURE 3: Basic composition of RFID.
FIGURE 4: Relationship between received signal power and distance under the two models.


FIGURE 5: Label equivalent circuit.

$$P_{\text{avail}} = \frac{V_S^2}{8R_A}. \tag{10}$$

The load impedance of the tag during normal operation switches between two impedances is as follows:

$$
\begin{aligned}
Z_1 &= R_1 + jX_1, \\
Z_2 &= R_2 + jX_2.
\end{aligned}
\tag{11}
$$

The reflection coefficient and the power received by the tag also vary between the two states with

$$R_{\text{RF,in},1,2} = P_{\text{avail}}\left(1 - |\Gamma_{1,2}|^2\right). \tag{12}$$

Assuming that the probabilities of the two states appearing are $P1$ and $P2$, respectively, the average available power received by the tag is as follows:

$$P_{\text{RF,in,ave}} = p_1 P_{\text{RF,in},1} + p_2 P_{\text{RF,in},2}. \tag{13}$$

In order to calculate the power reflected back by the tag antenna, the resistance of the antenna can be divided into two parts: radiation resistance R_{rad} and lossy resistance R_{loss}, namely,

$$
\begin{aligned}
Z_A &= R_A + jX_A, \\
Z_A &= R_{\text{loss}} + R_{\text{rad}} + jX_A.
\end{aligned}
\tag{14}
$$

The current flowing through the antenna as the tag changes between the two states is as follows:

$$i_{1,2} = \frac{V_S}{Z_A + Z_{1,2}}. \tag{15}$$

Suppose the two states are equally likely to occur, both are as follows:

$$p_1 = p_2 = 0.5. \tag{16}$$

Then, the signal power reflected by the tag is as follows:

$$P_{bs} = \frac{P_{\text{avail}}}{4L_A}|\Gamma_1 - \Gamma_2|^2. \tag{17}$$

3.3. International Trade and International Logistics.

With the development of international trade, international logistics has been continuously improved. As a bridge of economic exchanges between countries, international logistics and international trade together constitute two indispensable aspects of international economic development [25].

Generally speaking, international logistics mainly face three barriers (Market and Competition, Financial Barriers, and Distribution Channels), as shown in Figure 6. The development of international logistics must balance the relationship between the actual cost of overcoming these barriers and the potential benefits of international trade, in order to obtain actual benefits through successful international operations.

Market and competitive barriers: market and competition barriers in international logistics mainly refer to market entry restrictions, information symmetry, pricing, and competitive environment [26].

First, market entry restrictions often create market entry barriers for imported goods through legislation or judicial practice.

Second, information symmetry is another barrier to international logistics. In addition to information asymmetry about market size, population, and competition conditions, the information used to clarify import operations and related documents is often not coordinated [27].

4. RFID Experiment Based on IoT

4.1. Distribution and Transportation Experiment.

In the international trade logistics, the logistics distribution center plays a linking role. Its upstream is international processing enterprises, and its downstream is major users. The international processing enterprise sends the processed products to the warehouse of the distribution center, and the distribution center completes the distribution of the processed products through transportation vehicles according to the requirements of customers. Because of the particularity of international trade logistics, enterprises are required to maintain a reasonable placement of finished products in a series of processes (warehousing and warehousing, loading and unloading, and distribution and transportation). The data collected during the distribution and transportation process and the corresponding equipment are shown in Table 1:

4.2. Example Application Experiment.

The calculation of genetic algorithm can be performed by the computer to verify its effectiveness in the optimization of cold chain logistics distribution path. With the help of Matlab 2011a, by writing the corresponding computer program of the model, the genetic algorithm is used to calculate the model, and the optimal solution of the problem is obtained. Taking city A as an example, the location coordinates of the distribution center and 10 customers, and the product demand of each customer are shown in Table 2.

At the same time, obtain the relevant receipt time window, unloading time, and stopover time in the international trade logistics center for statistics, as shown in Table 3.

Assuming the parameters corresponding to the traffic conditions in city A, the transport vehicles equipped in the distribution center are changed to Dongfeng Duolika transport vehicles (with a load capacity of 7 tons). Statistics are made on the number of transport vehicles required by these 10 distribution points. And taking into account the location coordinates of 10 customers, the demand for chilled meat, and the 7t load of refrigerated transport vehicles, the 10 customers are divided into the following 3 routes, as shown in Table 4.

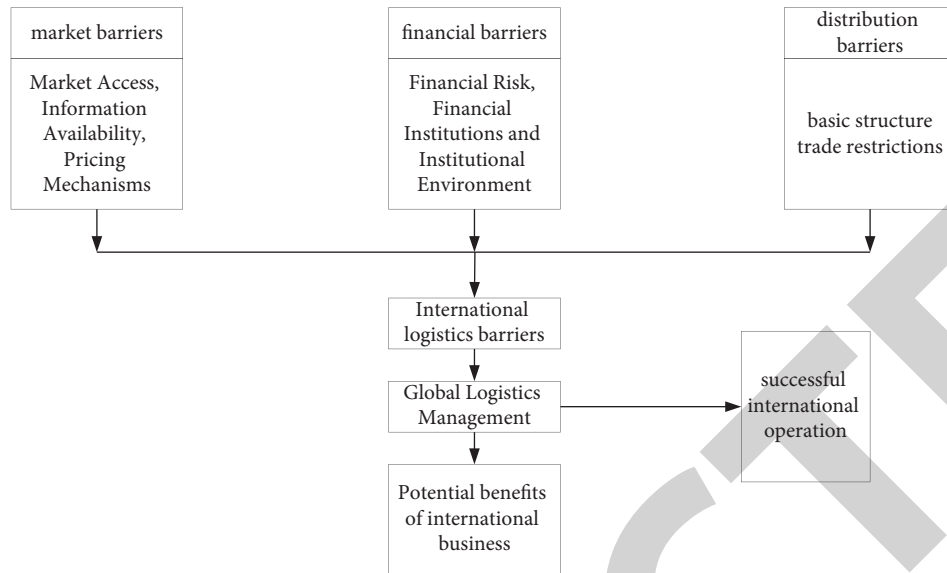
Using Matlab 2011a calculation, decode the calculated solution space to get the optimal distribution route scheme. The results are shown in Table 5.


FIGURE 6: International logistics barriers.

TABLE 1: Collected data and equipment used.

Numbering	Link	Collected data	Equipment
1	Discharge	Distribution vehicle situation, cargo situation, distribution center information	RFID reader, measuring instrument information
2	Sales and processing	Workshop information, operating hours, operators, packaging information	RFID reader, video capture
3	Sales	Product information	RFID reader, barcode

TABLE 2: Statistical table of customer coordinates and product demand.

Serial number	X coordinate	Y coordinate	Demand
0	13426.14	2893.12	0
1	13462.11	2894.16	1
2	13428.16	2897.36	1.2
3	13422.62	2894.19	2
4	13429.18	2894.43	2
5	13481.64	2896.36	3.5
6	13492.11	2891.18	2
7	13466.23	2899.48	1
8	13428.36	2894.18	0.5
9	13492.16	2895.77	2.5
10	13411.12	2894.61	1.5

TABLE 3: Receipt time window, unloading time, and dwell time statistics.

Serial number	Earliest pickup time	Latest pickup time	Dwell time
0	6:00	17:30	0
1	7:15	14:30	0.5
2	6:00	15:30	0.75
3	7:00	16:00	0.25
4	7:00	10:30	0.25
5	6:30	8:00	0.75
6	6:45	13:00	0.5
7	6:45	10:30	0.5
8	6:30	17:15	0.33
9	6:00	12:00	0.5
10	6:00	15:00	0.25

TABLE 4: Route division table.

Vehicle serial number	Customer point	Number of customers	Vehicle capacity
1	1, 2, 4, 7, 8	5	6
2	5, 9	2	6
3	3, 6, 10	3	5.5

TABLE 5: Optimal route delivery table.

Vehicle serial number	Shipping order	Number of customers	Delivery mileage	Waiting time	Delay time
1	0-7-2-8-4-1-0	5	13.47	0	0
2	0-5-9-0	2	21.09	0	0
3	0-9-30-26-23-0	3	17.82	0	0

From the improved optimal route distribution table, we can see that after the improvement, the delay time in the logistics distribution process is basically 0, which can save time in the transportation process.

5. RFID Tags and Optimization Analysis

5.1. Modulation Mode Simulation. Different modulation methods can be achieved by changing the load impedance to change the current flowing through the antenna and the reflection coefficient of the antenna: ASK modulation can be achieved by changing the amplitude of the current, and PSK modulation can be achieved by changing the phase of the current. Under different modulation modes, the reflection coefficient of the tag is different, and the power entering the tag and the power reflected by the tag are different. Figure 7 shows the Smith chart of reflection coefficients under different modulation modes.

Comparing the above four modulation methods, we can see the following:

(1) Under ASK1 modulation, the available power entering the tag and the power reflected by the tag remain unchanged, which are 50% and 25%, respectively; under the other three modulation modes, the available power entering the tag decreases with the increase of the reflection coefficient.

(2) PSK and ASK2 have the same tag useable power (83%) and reflected power (17%), but under ASK2 modulation, part of the tag useable power is consumed by extra resistors and cannot be used effectively.

(3) ASK and PSK use nonlossy components to change the state of impedance, similar to PSK modulation. In the ideal case, the sum of the tag's available power and the tag's reflected power is a constant value. The tags of UHF RFID systems usually use load capacitance modulation to achieve ASK and PSK modulation from the tag to the reader. At this time, the power reflected by the tag is related to the modulation index and antenna loss, generally accounting for 10% to 20% of the total received power.

5.2. Tag Antenna Performance. By understanding the design of the tag antenna, we can see that the reduction or increase of the resonant frequency of the tag antenna can be achieved by adding capacitive or inductive loads. A capacitive load (low frequency) and an inductive load (high frequency) work together so that the tag antenna has two resonance modes, high and low. And the bandwidth of the S-parameter curve of the tag antenna can be changed by adjusting the length of the T-shaped microstrip structure and adjusting the depth of the U-shaped hollow structure. RFID tag antennas for metal backgrounds were designed and simulated using HFSS as shown in Figure 8.

It can be seen from the simulation results of the tag antenna that the two lowest points of the S-parameter curve of this tag antenna are 870 MHz and 915 MHz, respectively, and these two frequencies are also the resonant frequencies of the tag antenna.

The comparison between the measurement results of the tag antenna and the simulated junction impedance curve is shown in Figure 9. At 915 MHz, the antenna impedance obtained by simulation is (13.5~120j) ohm, and the antenna impedance is (15.3~123j) ohm obtained from the test, and the tag antenna and the tag chip are well matched.

5.3. Optimization Results. In order to have a general understanding of the optimization results of international trade logistics based on the Internet of Things technology proposed in this paper, this paper makes a rough simulation of the trade logistics of city A and analyzes it. It analyzes and compares the improvement effect of this paper with the effect before improvement and makes statistics on five different logistics distribution centers. It counts the amount of goods carried in the same time period to reflect the optimization effect of trade logistics. The specific situation is shown in Figure 10.

Through the above comparative analysis, we can see that after the improvement, the logistics has a relatively obvious increase in the carrying capacity. Before the improvement, the carrying capacity of site 1 was 15,000 tons, accounting for 12.93%; the carrying capacity of site 2 was 19,000 tons, accounting for 16.38%; the carrying capacity of site 3 was 26,000 tons, accounting for 22.41%;
FIGURE 7: Reflection coefficients of labels under four different modulation modes.
FIGURE 8: The frequency correspondence between the T-shape and U-shape of the S-parameter curve of the tag antenna.

the carrying capacity of site 4 is 31,000 tons, accounting for 26.72%; and the carrying capacity of site 5 is 25,000 tons, accounting for 21.55%. On the other hand, for the improved carrying capacity, the carrying capacity of site 1 is 25,000 tons, accounting for 15.82%; the carrying capacity of site 2 is 29,000 tons, accounting for 18.35%; the carrying capacity of site 3 is 34,000 tons, accounting for

21.52%; the carrying capacity of site 4 is 38,000 tons, accounting for 24.05%; and the carrying capacity of site 5 is 32,000 tons, accounting for 20.25%.

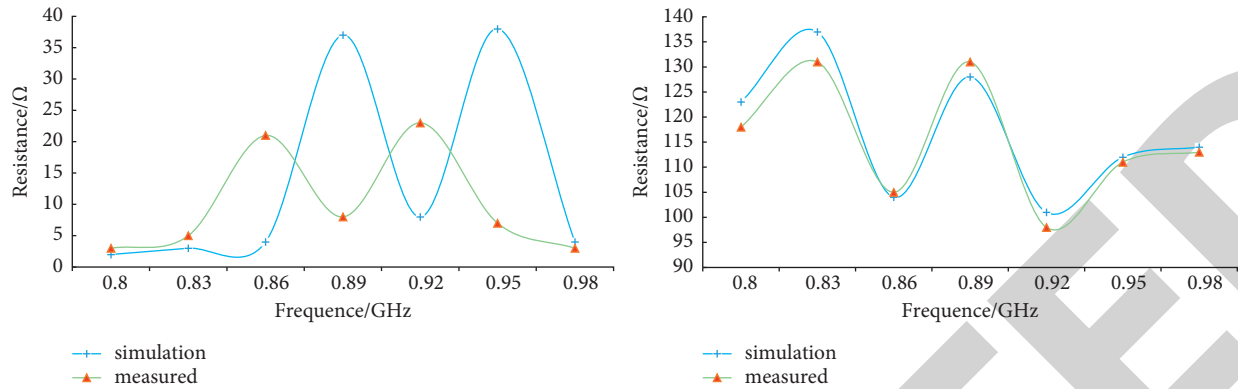
Based on the above analysis, we can conclude that the improved international trade logistics has increased the carrying capacity by 34.2% and shortened the carrying time by 28.6%, which has been significantly improved.


FIGURE 9: Comparison of measurement results of tag antenna resistance and reactance with simulation results.
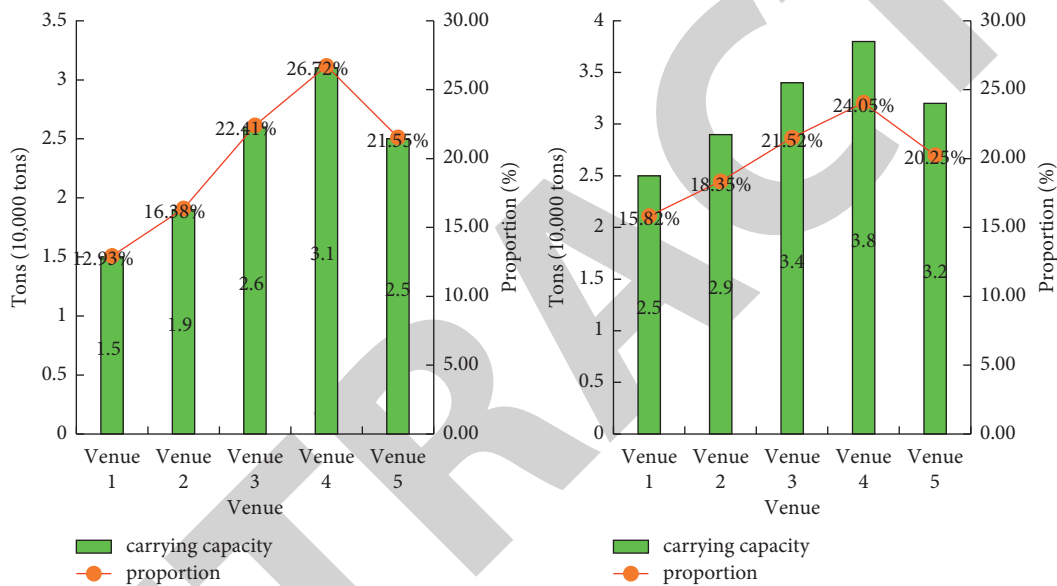

FIGURE 10: Comparison of logistics carrying capacity before and after optimization.

6. Conclusions

This paper mainly studies the optimization design of international trade logistics based on the Internet of Things technology, through the optimization and improvement of RFID technology, and the key technology of the Internet of Things. Through its tracking and identification of a path in the process of trade logistics transportation, and optimizing it, the optimal transportation path can be achieved in the actual transportation process. This also fully guarantees the international trade carrying capacity, carrying capacity, and carrying efficiency. And in the experimental part, a simulation experiment is carried out on the optimization of its logistics, the results also show that the scheme is feasible. And in the analysis part, the relative RFID technology is compared and analyzed to explore the actual effect of its optimization.

As possible diseases develop on plant leaves, classification is constantly hampered by obstacles such as overfitting and low accuracy. To distinguish healthy products from defective ones, the agricultural industry requires precise and error-free analysis. Deep convolutional neural networks are an efficient model of autonomous feature extraction that has been shown to be fairly effective for detection and classification tasks. However, deep convolutional neural networks often require a large amount of training data, cannot be translated, and need a number of parameters to be specified and tweaked. This paper proposes a highly effective structure that can be applied to classifying multiple leaf diseases of plants and fruits during the feature extraction step. It uses a deep transfer learning model that has been modified to serve this purpose. In summary, we use model engineering (ME) to extract features. Multiple support vector machine (SVM) models are employed to enhance feature discrimination and processing speed. The kernel parameters of the radial basis function (RBF) are determined based on the selected model in the training step. PlantVillage and UCI datasets were used to analyze six leaf image sets containing healthy and diseased leaves of apple, corn, cotton, grape, pepper, and rice. The classification process resulted in approximately 90,000 images. During the experimental implementation phase, the results show the potential of a powerful model in classification operations, which will be beneficial for a variety of future leaf disease diagnostic applications for the agricultural industry.

1. Introduction

Before they reach maturity, the diseases in the leaves of fruits, citrus, wheat, and rice can have a significant impact on their yields [1]. This necessitates rapid and precise diagnosis of leaf diseases in fruits, citrus, wheat, and rice as well as early delivery of tailored cure [2]. Human investigation-based recognition of leaf diseases is severely hampered due to the huge area, and a model capable of tackling this issue is urgently required. The plant itself typically has its own recognition model when a leaf disease of a certain sort is recognized. A problem with storage capacity will occur if each disease of fruits, citrus, wheat, and rice has its own recognition model. Multitask learning allows features to be shared and aided by one another. This allows the leaf disease recognition models to meet current needs while reducing

storage space and increasing recognition accuracy. For this reason, a model that can detect and identify leaf diseases in fruits, citrus, wheat, and rice must be developed.

For image classification, the adoption of deep learning (DL) has been driven by recent advancements in computer vision and artificial intelligence [3–5]. Convolutional neural networks (CNNs) are an efficient model of DL structure. Self-learning, adaptability, and generalization are the hallmarks of CNN. The leaf diseases in fruits, citrus, wheat, and rice have been classified by machine vision approaches in numerous studies. Azadbakht et al. [6] achieved 82 percent correct classification of the normal and diseased rice leaves. Azadbakht et al. [6] employed machine learning (ML) approaches to analyze the wheat leaf hyperspectral data. Plant leaves are usually the first place where plant diseases are classified, and signs of most diseases may arise on the leaves

[7, 8]. CNN requires no manual feature extraction as in classic machine vision (MV) procedures, which rely on manual classification. Instead, CNN only requires visual input. In recent years, deep learning approaches, specifically CNNs, have become the preferred method to overcome learning challenges [9, 10].

The network's ability to self-learn allows it to complete the image classification process successfully [11]. It has become increasingly common in recent years to use DL image classification strategy in agriculture for detecting plant diseases [12–15].

Three typical rice leaf diseases were categorized using a DL network that was trained using DenseNet and Inception models with ImageNet pretrained. The accuracy percentage was found to be 94.07 percent [16].

Support vector machines (SVM) and DL were utilized by Jiang et al. [17] to identify four distinct rice leaf diseases. Using SVM and CNN, they were able to extract the features from various leaf images and recognize the extracted features, with an accuracy of 96%. Transfer learning-based powdery mildew disease detection was proposed by Shin et al. [18]. Using six different models, they compared their categorization findings. In this case, they found that ResNet-50 had satisfactory accuracy in identifying objects, while AlexNet had the quickest recognition time. In order to diagnose grapevine leafroll disease, Gao et al. [19] employed ML techniques to analyze hyperspectral images of grape leaves. The disease in grapevine leafroll can be diagnosed in its asymptomatic stage using this model, which achieved an accuracy of 89.93 percent [19]. DL networks were utilized by Long et al. [20] to recognize four different forms of camellia diseases based on image processing analysis. They employed ImageNet to train AlexNet and then built a novel fully linked layer with an accuracy of 91.25%. The pretrained model can greatly enhance accuracy when there are few samples available. Generally, we can utilize the same machine learning model to do many tasks using multitask learning, which is a common practice. For the strawberry Verticillium wilt classification, researchers applied the multitask learning network of the attention system. Additionally, 99.95% of the time, they properly diagnosed strawberry Verticillium wilt [21]. Plant phenotyping was studied by Dobrescu et al. [22] using multitask learning. Genotype classification, leaf counting, and PLA estimation were achieved using the ResNet-50 model trained on ImageNet. Each of the three locations has a significant advantage over the other options.

To simulate realistic situations of leaf disease, Arsenovic et al. [23] used images taken in a range of weather conditions, at various angles and at different times of day, all with varying backdrops. In their study, the authors propose a novel two-stage neural network (NN) approach for classifying plant diseases in the context of a real environment. Their model's accuracy was 93.67%.

Karthik et al. [24] presented a design based on residual learning to classify significant aspects for detecting infection in tomato leaves. Their proposed approach makes use of the PlantVillage dataset, which contains three diseases, and

CNN-learned features. They achieved 98 percent accuracy on the validation sets after fivefold cross-validation.

Sharma et al. [25] developed an approach for CNN model training. When tested on unlabeled data, the S-CNN model trained employing segmented images outperformed the F-CNN model by more than doubling its performance to 98.6% accuracy.

Sambasivam and Opiyo [26] suggested an approach for detecting cassava leaf disease in their study. They achieved an accuracy score of over 93% by using deep CNN built from scratch, class weight, and the Synthetic Minority Oversampling Technique.

Ma et al. [27] claimed that they used VGG to identify and classify four diseases in cucumber leaf leaves which resulted in crop loss. The classification was done on a vast volume of plant leaf images with the goal of classifying the presence or causes of disease in the leaves.

Too et al. [28] used four transfer learning (TL) models to classify the absence and presence of disease in plant leafs. These components included the VGG16, early V4, ResNet, and DenseNet structures. DenseNet, when compared to the other forms, generates more relevant responses with less processing time.

He also evaluated 12 different species of plants in another study [29], which were used to classify the presence or absence of disease in plants.

Kaya et al. [30] investigated datasets such as Flavia, Swedish, and UCI Leaf using TL for deep NNs in plant classification procedures. Similarly, Singh et al. [31] investigated the leaves of the corn plant using a deep NN model and suggested an automatic classification approach.

The study by Dhivyaa et al. [32] selected the appropriate features based on bidirectional long short-term memory (Bi-LSTM) to detect plant diseases by utilizing an expanded complexity network and other dense blocks. Data from cassava disease and PlantVillage dataset have demonstrated the validity of their proposed model. According to their findings, the proposed model for the diagnosis of cassava leaf disease achieved a maximum F1 score of 95.49%.

In a study by Bhujel et al. [33], the performance of the models was improved by using a lightweight convolution neural network with several attention modules. They were able to train their models with data about tomato leaf diseases. They evaluated the models' performance (F1 score, accuracy, and recall) according to standard classification accuracy metrics. With an average accuracy of 99.69%, the convolution block focus module was the most accurate.

By using R-CNN Mask, Storey et al. [34] segmented samples to diagnose leaf and rust disease in apple orchards. For object detection, segmentation, and sickness detection, three R-CNN Mask backbones were trained and evaluated. Using the R-CNN Mask model and the ResNet-50 backbone, they were able to detect extremely small rust-covered objects.

Prabu and Chelliah [35] have developed a new method of detecting mango leaf diseases. Over 388 images of healthy and ill subjects (mango anthracnose, soot mold, and bac-

terial black spot) were selected. MobileNetV2 is used during the learning phase, and the SVM is used to classify diseases at the end.

Singh et al. [36] used the AlexNet model to identify leaf disease in maize quickly and accurately. The results were verified with PlantVillage data. *Cercospora* and Gray are two common rust-based infections covered with 99.16% accuracy in the data collection.

A lightweight convolutional neural network, RegNet, was presented by Li et al. [37] for the detection of apple leaf disease. They were able to identify five different apple leaf diseases from 2141 images of healthy and diseased apple leaves. It achieved an overall accuracy of 99.23% in the test set and 99.8% in the validation set, with a learning rate of 0.0001.

Shahoveisi et al. [38] used ML techniques to model the risk of *Sclerotinia sclerotiorum*-induced disease development in canola and dry beans. Using a broad genome correlation study [39], they previously examined the genomic regions associated with *Leptosphaeria maculans* resistance in rapeseed.

Plant leaf diseases may be consistently diagnosed using deep learning. However, TL may be used to overcome the difficulty of small datasets in plant leaf disease recognition and significantly increase the approach's accuracy. A single structure can be utilized to perform multiple tasks through ensemble learning. To solve the challenge of recognizing leaf illnesses on two different plants, the study provides research on deep transfer learning and alternate learning. Improvements were made to the residual neural network (ResNet) model, while keeping the ResNet model's convolutional layer structure. As a result, these two components of the ResNet model's classification layer can be shared across different datasets. A new fully connected layer is built to address the various classification challenges that arise while working with several data sources. The loss function and optimizer for each classifier are unique. The convolutional layer of the ResNet is fixed during formal training, allowing the TL architecture to be used for transfer learning. Formal instruction utilizes only the newly developed categories and layers that are completely interconnected. Digital cameras may be used to take on-the-spot images utilizing fruits, citrus, and rice leaves and models to diagnose leaf diseases, allowing crops to be saved before irreparable harm occurs. Although several approaches exist for diagnosing fruit leaf disease, key questions remain unresolved.

(1) Identifying and collecting critical information from fruit leaves is fairly difficult, as is distinguishing the features of particular diseases utilizing conventional image processing methods.

(2) Due to the huge variability in the features of different diseases, the attributes of disease patterns must be thoroughly studied using a diverse set of images in a smart fashion.

(3) The efficiency of ML techniques is entirely determined on the type of the hand-crafted features. As a result, feature extraction must be performed automatically in order to pick and learn the optimal collection of features for recognition.

(4) Certain deep learning models make advantage of well-established architectures such as TL structures. As a result, it employs millions of images for classification procedure. To enable immediate implementation of such models, a trade-off between computing load and accuracy must be determined.

(5) Additionally, the DL network should be trained with a large number of images to guarantee that the features are more generalized.

By employing a modified deep model and ensemble of learning based on the pool of SVM method with RBF kernel for disease detection in fruit leaves, the proposed study solved the identified research gaps. The following are some of the project's most significant contributions.

(1) A novel and distinct DL architecture has been presented in this field of research. The first goal was to use color space to improve feature classification. The second stage uses TL to learn and enhance performance by learning distinct feature maps.

(2) This is the first time a hybrid model based on the modified deep TL network and ensemble of learning has been used to diagnose disease in a significant number of fruit leaves, as far as we know.

(3) Samples from a variety of approaches were used to train the design. We trained the architecture with 90000 and validated it with 10-fold cross-validation of images.

Section 2 focuses on fruits, citrus, and rice leaf diseases, along with related datasets and processing methods. Identifying fruits, citrus, and rice leaf diseases is the subject of Section 3, which examines several concepts and methodologies. Section 4 tests the model described in this article and compares it to other models. There is a brief summary of the article in the Section 4.

2. Proposed Method

The suggested technique is depicted in Figure 1, which begins with feature extraction using a deep convolutional neural network model and ends with classification using an optimum support vector machine as the final decision layer.

2.1. Preprocessing. To accurately reproduce the appearance of colors in natural light on the image processing step, an HSV (color, saturation, and quantity) display must be used. Since the strongest color of HSV can be compared to white light, the terms "HSV" and "white light" are often used interchangeably (i.e., bright white light shining on a red object). In low light, a red object seems darker and brighter, while it appears redder and brighter in high light. We are in dire need of ensuring that no light is lost in the process; a single point source must be achieved in the light of leave images. A preprocessed RGB image is fed into the HSV converter to keep the brightness constant. The process of transforming an RGB image to an HSV image is shown visually in Figure 2.
FIGURE 1: The general procedure for the suggested implementation approach is illustrated in this figure.
FIGURE 2: Graphic schematic from stages of RGB image to HSV image transform [40].

2.2. Convolutional Neural Network (CNN).

We use nonlinearity and a series of convolutional filters to solve equation (1). There is a level of hierarchy in a CNN. The following layers (x_j) are derived from the input signal x [41]:

$$x_j = \rho W_j x_j - 1. \tag{1}$$

However, even though W_j is a linear operator, this situation exhibits nonlinear behavior. Additionally, W_j is frequently employed in convolutions in CNNs, with ρ being either a rectifier $\max(x; 0)$ or an exponential sigmoid $[1 + \exp(-x)]^{-1}$. Convolutional filter stack W_j is assumed. As a result, the convolutions in each layer are defined as the total of the convolutions in the layer before it [41, 42].

$$x_j(u, k_j) = \rho \left(\sum_k \left(W_{j, k_j}(., k) * x_{j-1}(., k) \right)(u) \right). \tag{2}$$

In addition, a discrete convolution process known as $*$ is employed [41]:

$$(g * f)(x) = \sum_{u=-\infty}^{\infty} g(u) f(x - u). \tag{3}$$

CNN architecture optimization is a nonconvex issue. Weights W_j are frequently trained using stochastic gradient descent, with their gradients commonly determined using backpropagation. The reliance on data is a critical concern in deep learning. Deep learning models are largely reliant on massive volumes of data to be trained. In comparison to more standard machine learning algorithms, this is a significant improvement. The issue is that, in order to train the underlying data patterns, a large amount of data is required. TL can be used to address the issue of training data being distributed uniformly independent of the distribution of the test data (i.e., which motivates us to employ TL to address the problem of insufficient training data). VGG, DenseNet, and ResNet are three well-known deep learning networks that train their models using CNNs procedure.

2.3. Dilated ResNet.

ResNet's 3×3 Visual Geometry Group (VGG) full-layer design is the best on the market for transfer learning. The 3×3 output channels for each of the remaining convolutional layers are shown in Figure 3(a). After the data has been modified, it is submitted to ReLU layers. ReLU is activated following two convolutions. ResNet is based on the GoogLeNet structure as a starting point. Following the 7×7 layers are two strides and a convolution layer with up to 64, 3×3 input channels. It is feasible to connect the convolutional layer's outputs to a single input. Increasing the number of channels is one possibility. Furthermore, additional 1×1 convolution layers are also necessary. ResNet
FIGURE 3: We use the ResNet residual block in the modified ResNet architecture: (a) direct mapping based on the training; (b) computation difference between the output and input.

nodes are depicted in block form in Figure 3(b). ReLU takes nonlinear input into account. This layer has no effect on the channels preceding it. Due to the small volume of diseased spots in leaf images, the dilated ResNet structure aids in the detection of images with a small volume of disease. Due to the higher-quality leaf images in the ResNet architecture, a broader range of dilated structure-based features will be available. By employing samples and preceding layers, it is feasible to preserve fine-grained features. Thus, the lightweight structure of ResNet-18 was developed by experimentation with various convolution scales and dilation rates. Concatenation hence minimizes the computational cost while increasing the quantity of fine-grained attributes. Accordingly, samples must be collected in order to combine lower-level components into higher-level maps. The bottom and top layers should be merged to improve the identification of small volumes of illness in leafs.

Each of the 64 filters illustrated in Figure 4 has the 7×7 dimension, for a total of 64. To put it simply, $Conv1$ features a significantly larger 7×7 dimension, 64 filters, and a two-step stride. The stride length of the MaxPool 2×2 is two. Following feature extraction by deep structure, we further select the feature with the lowest computational complexity. The weights of features in a neighborhood can be computed using distance measures. It is feasible to minimize the size of the required feature vectors by employing the neighborhood component analysis (NCA) [43] technique, which stands for "supervised and nonparametric." This approach allows for the enhancement and modification of the k-nearest neighbor (k-NN) structure. We choose this method to decrease the amount of feature vectors obtained from leaf images. This is because it assigns a positive weight to each feature and the feature rank can be computed using NCA.

When a desired feature reduction strategy is applied, the NCA is used to estimate the feature weights. A feature set is subdivided into overlapping blocks. As a result, it is evident that k is a collection of smaller vectors.

2.4. Ensemble Learning. The classifying leaf images with the SVM model are a significant step toward generating the ideal hyperplane as a decision surface with the highest margin for interclasses of leaf diseases. As a result of the inherent separation issues, we present the radial basis function (RBF) kernel function and its associated decision components for SVM classification. A nonlinear kernel improves the overall performance of the SVM.

$$K(x, x_i) = \exp\left(-\frac{\gamma \|x - x_i\|^2}{2\sigma^2} \right).$$ (4)

The determined RBF kernel in equation (4) contains fewer variables (C and γ), is mathematically simpler, and has fewer hyperparameters than other kernels. This is why it has gained widespread acceptance. The classification step utilizes training data to implement the SVM with RBF-based learning pool as the ensemble learning procedure. The extended ensemble learning structure is depicted in Figure 5 as a general schematic.

3. Experimental Results

This section describes the dataset and leaf image that were analyzed, as well as the model's results.

3.1. Procedure Setting. On Windows 10 PCs, the proposed solution was implemented using MATLAB R2021b. The

$$\text{Conv2} = \begin{pmatrix} 1 \times 1, 64 \\ 3 \times 3, 643 \\ 1 \times 1, 64 \end{pmatrix} \quad \text{Conv3} = \begin{pmatrix} 1 \times 1, 128 \\ 3 \times 3, 128 \\ 1 \times 1, 64 \end{pmatrix} \quad \text{Conv4} = \begin{pmatrix} 1 \times 1, 256 \\ 3 \times 3, 256 \\ 1 \times 1, 1024 \end{pmatrix} \quad \text{Conv5} = \begin{pmatrix} 1 \times 1, 512 \\ 3 \times 3, 512 \\ 1 \times 1, 2048 \end{pmatrix}$$

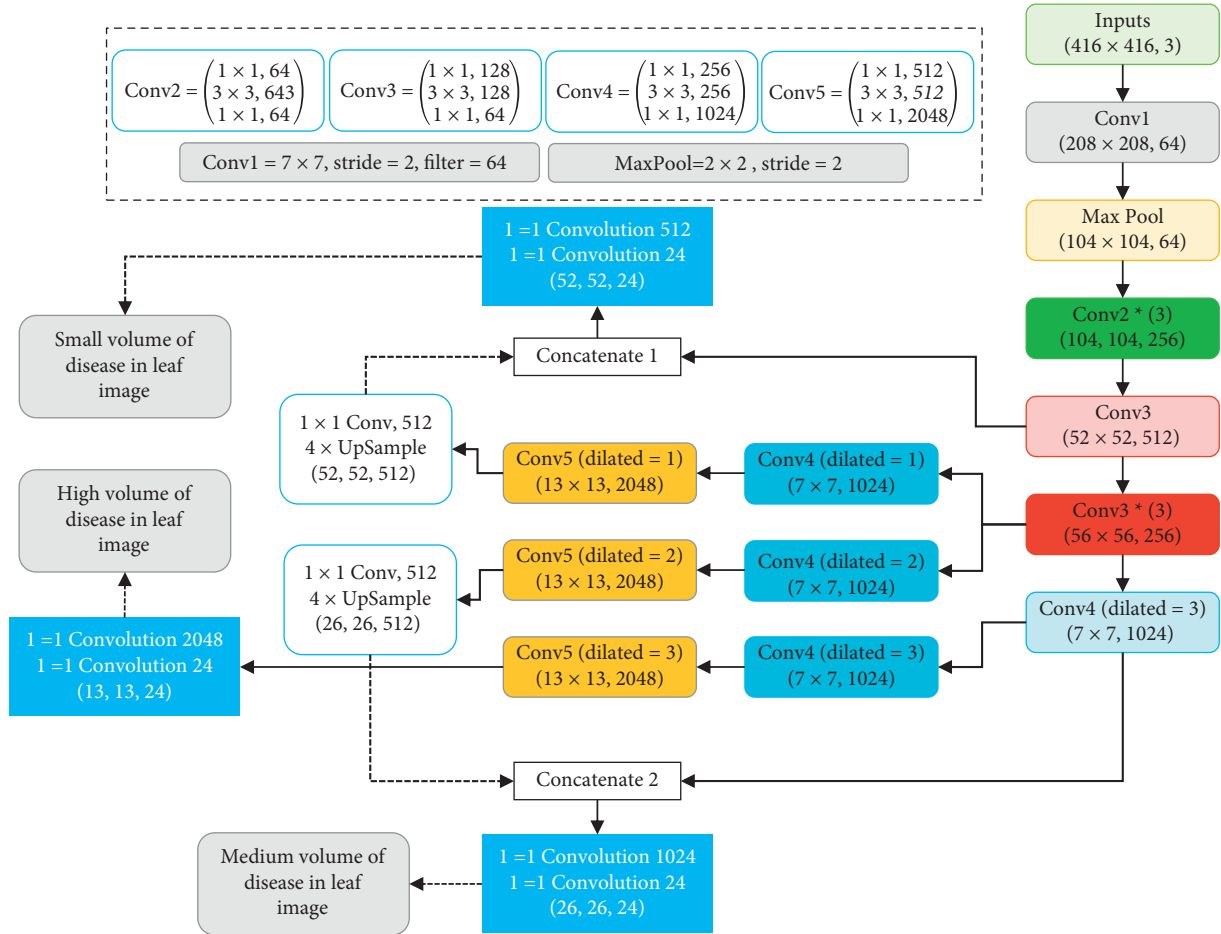
Conv1 = 7 × 7, stride = 2, filter = 64   MaxPool = 2 × 2 , stride = 2


FIGURE 4: The overall architecture of modified transfer learning structure by using dilated and concatenation design.
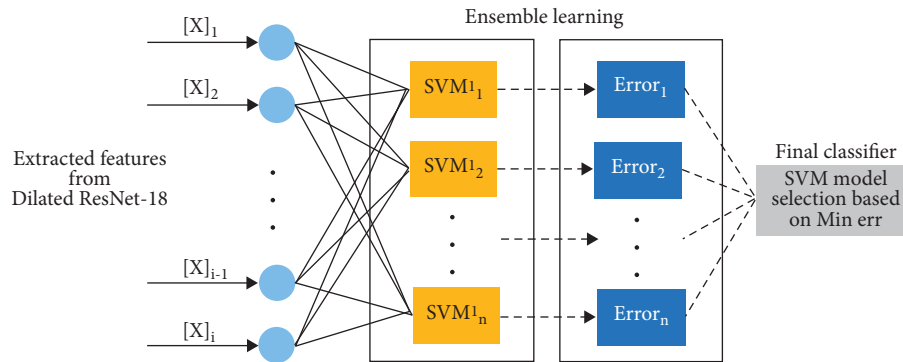

FIGURE 5: The procedure of decision-making part based on the ensemble of learning in pool of SVMs models with RBF kernel.

simulation was conducted utilizing an Intel® Core™ i5-8500 processor (single CPU), 16 GB of RAM, and 16 GB of SSD RAM on a test computer. Additionally, we used additional applications, such as SPSS. The optimal parameters of the RBF kernel are then chosen for initialization. The initial ResNet-18 model had a primary learning rate (μ) of 0.002 and an epoch range of 100–1000. To avoid overfitting, the proposed ensemble learning system determined the ideal

training iteration size by a mix of parameter tuning and early stopping.

3.2. Dataset. The images of plant leaves were created by analyzing six different types of plant leaves: apple fruit leaves, maize leaves, cotton plant leaves, grape fruit leaves, pepper leaves, and rice leaves. Figures 6 and 7 illustrate
FIGURE 6: A collection of images of plant leaves, including the first row of apple fruit leaves, the second row of maize leaves, the third row of pepper leaves, and the fourth row of grape leaves, all of which have leaves with various pests. Additionally, some leaves are healthy.
FIGURE 7: Rice leaves are divided into three different classes of bacteria, stains, and plants.

sample images, while Table 1 summarizes the number of images and other pertinent information.

3.3. Evaluations. Our early findings analyze how machine learning techniques based on ResNet structure families can be applied to improve leaf disease categorization. The feature extraction stage was carried out using an improved ResNet-18 (dResNet-18) version in ResNet structures with multiple classes and two classes, as indicated in Table 2. Additionally,

a number of previously unknown leaf diseases were identified as a result of the multiclass classification based on region of interest (ROI) part and non-ROI segment (see Table 1).

While the remainder parts of the proposed method stay unchanged, the ResNet deep transfer learning family has been in its place. Numerous parallels exist between the qualities associated with deep learning. To conduct the classification, the best SVM model is selected using an ensemble learning technique. However, the technique used

TABLE 1: This table shows the details of the leaves of the various fruits analyzed in the study.

Leaf type	Number of classes	Disease type	Dataset size	Sample		
Apple	4	Scab	3150			
		Black rot	3726			
		Cedar apple rust	1650			
		Healthy	4284			
Corn	3	Common rust	7152			
		Healthy	6972

		Black measles	8304			
		Leaf blight	6456			
Pepper	2	Bacterial spot	5982			
		Healthy	8868			
Rice	3	Bacterial leaf blight	40			
		Brown spot	40			
		Leaf smut	40			

to extract features by ResNet-101 and ResNet-164 is nearly identical.

While the proposed strategy for deep learning feature extraction outperformed other methods within the ResNet structure families in some circumstances, it is obvious that these methods occasionally produced a very small classification error.

Six different sets of gathered leaf photos are shown in Figure 8, each with its own RMSE convergence and loss function denoted by a curve and the lowest achievable value. The model's complexity is reduced by increasing the layer-wise reduction factor. As the model becomes simpler, the RMSE tends to rise. If the algorithm is trained to employ efficient features, it is feasible to improve discrimination outcomes. As a result, increasing the quantity of characteristics obtained by dilated deep transfer can help with learning. It is possible to create

useful feature maps from a leaf image with only a few iterations and a short period of time. Because of the processing time involved, we may want to avoid deeper structures for real-time or near-real-time applications (particularly during training). The confusion matrices for the integrated model's categorization across all six datasets are shown in Figure 9.

While the classification accuracy of the grape and cotton leaf datasets is lower than that of other datasets, adding the proposed extracted features significantly improves classification accuracy. In addition, 10-fold cross-validation is used to demonstrate the ability of the system to classify leaf disease. For images of healthy or sick leaves, this approach asserts a 99.1% accuracy.

Using the approach explained here, numerous low and high intensities leaf diseases can be detected in a wide variety of fruits. It is reasonable to anticipate the proper classification rate

TABLE 2: Comparison of the findings of ResNet family's error in leaf disease classification using normal and ROI images for a multiclass problem.

because it consistently obtains a 99.1% accuracy rate in trials involving two classes in a range of situations. Our model achieves a precision score of 100% on each rice and apple leaves image. The proposed deep model and effective learning approaches for feature extraction may have resulted in appropriate sensitivity. The results show that the proposed method for diagnosing and classifying leaf diseases tends to be reliable. When a leaf image is complicated, as seen in Figure 9, various techniques' accuracy and precision rates often decrease (e.g., especially when the images are noisy or non-RoI image is selected as based for processing). The approach for analyzing leaf images, on the other hand, is consistent and reliable, making it a cost-effective method.

4. Discussion

This study employed a technique known as model engineering (ME) learning. There are various approaches to train a model for plant disease recognition; however, our model was trained using the dilated ResNet-18 framework for deep transfer learning.

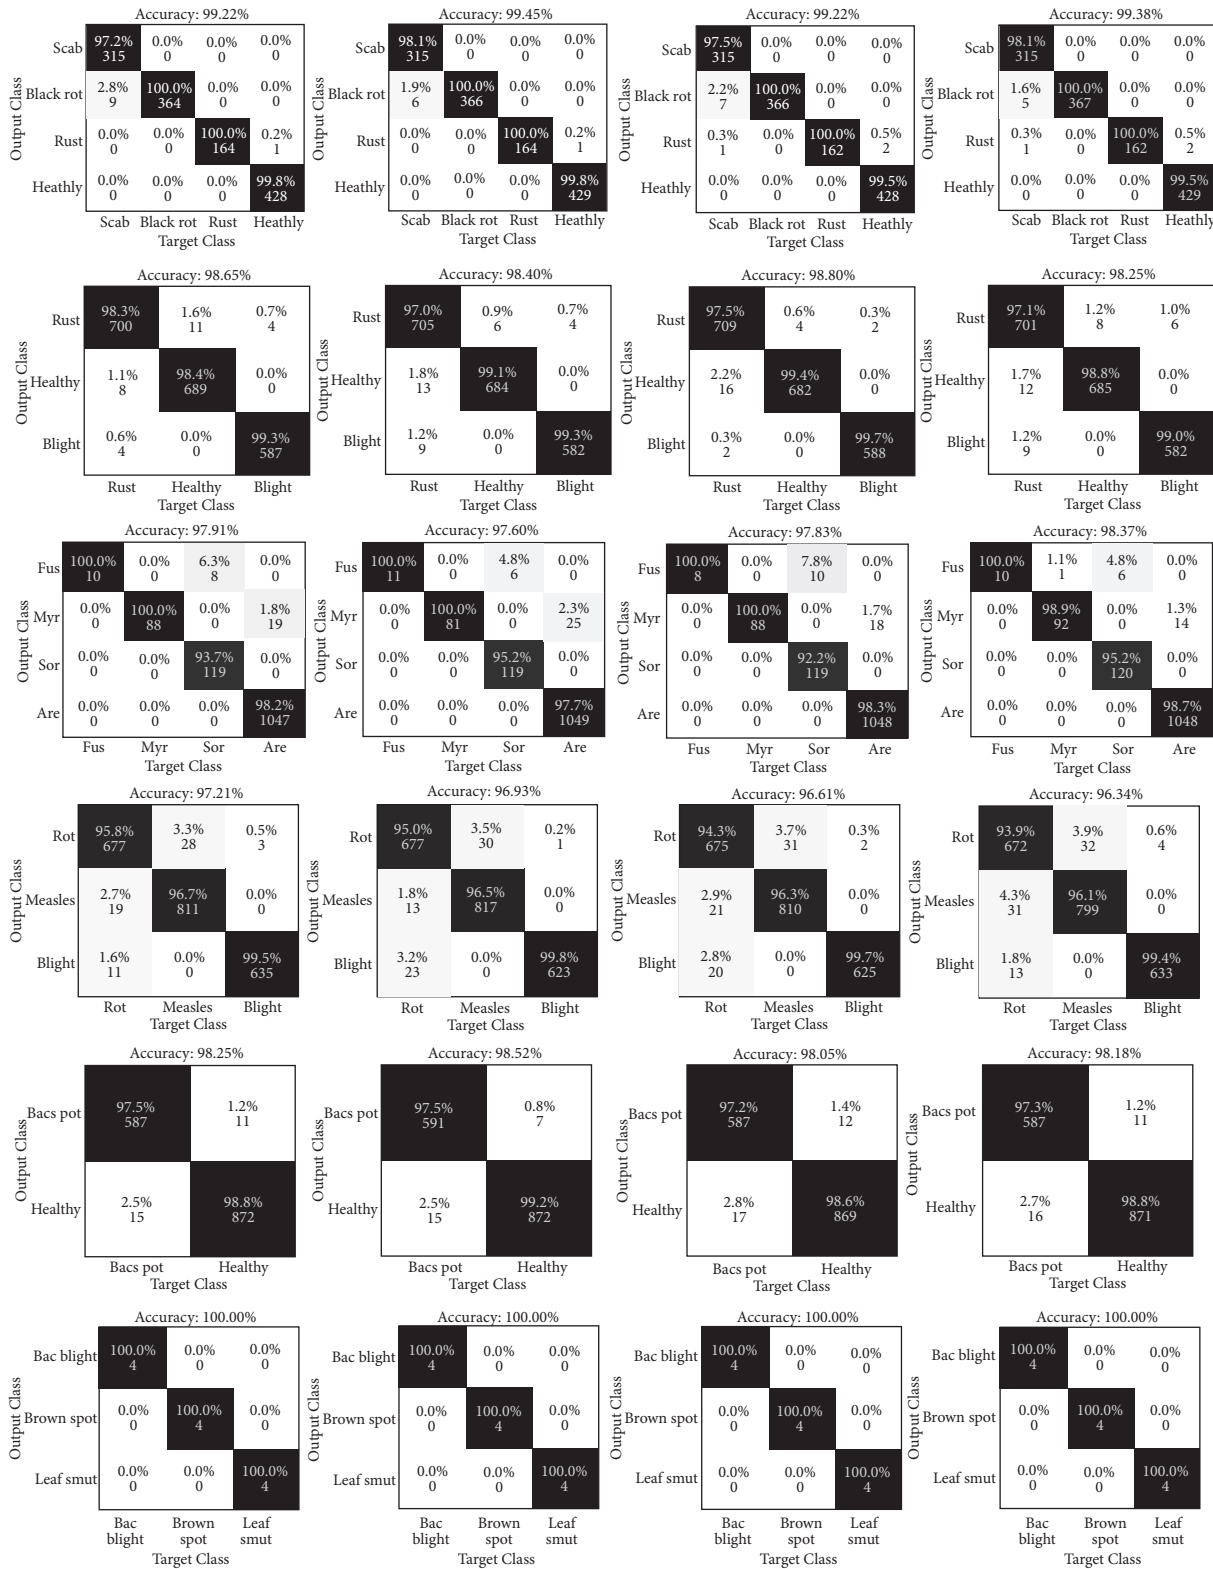
Our learning algorithms were all constructed using identical data and loss functions. The ME model described in this article was applied to a range of fruit leaf images. The RMSE and loss error change curves for each model's training set are displayed in Figure 8. Figure 10 illustrates the accuracy change for various TL model


FIGURE 9: Confusion matrix: the suggested approach is used to diagnose leaf disease in a variety of hitherto unexplored datasets. The method's output is displayed four times at random. The first row represents apples, the second row represents corn, the third row represents flax, the fourth row represents grapes, the fifth row represents peppers, and the sixth row represents rice, accordingly.
FIGURE 10: This figure illustrates the accuracy change for various TL model verification sets based on the low and high levels of complexity.

verification sets based on the low and high levels of complexity.

The accuracy rates for the different decision-making part based on various test sets are shown in Table 3 based on k-nearest neighbor (k-NN), decision tree (DT), feedforward neural network (NN), SVM with linear kernel (SVM-L), SVM with RBF kernel (SVM-RBF), and Ensemble SVM-RBF (E-SVM-RBF).

The dilated learning model outperforms the typical ResNet-18 design in terms of stability. This model has an average accuracy of 98.5% on the test set for leaf disease recognition models. A test set accuracy of 97.93% is less than the suggested structure's accuracy of 97.93% in recognizing Grape or Cotton leaf diseases. For instance, our new deep learning model outperforms existing deep learning models by an average of 1 to 2 percentages. The addition of acceptable noise while learning a task aids in the improvement of models, which is analogous to removing unnecessary steps from the process. In contrast to conventional learning, interaction can assist in preventing the overfitting of different leaf image conditions from collapsing. As a result, the proposed ME learning technique can aid in the achievement of numerous, relatively related objectives. For all leaf disease recognition, the proper epochs were used to optimize the training time in the procedure. This resulted in a more rapid and constant drop in the recognition model's accuracy. Our

TABLE 3: The comparison of the different decision-making part based on various test sets.

Leaf image type	k-NN (%)	DT (%)	NN (%)	SVM-L (%)	SVM-RBF (%)	E-SVM-RBF (%)
Apple	97.56	97.31	96.11	95.48	98.13	99.47
Corn	97.08	96.83	95.78	94.11	97.29	98.69
Cotton	95.71	96.10	95.39	96.73	97.76	98.91
Grape	96.18	96.51	96.26	95.31	97.07	98.74
Pepper	97.09	96.65	95.62	96.13	97.87	99.12
Rice	98.31	98.87	97.91	96.44	98.76	100

ME model surpasses existing feature extraction-based deep TL models.

There are multiple distinct methods for incorporating pretrained structures into TL models. Minor changes are made using the TL approach. This was no longer essential as a result of the ensemble classification approach. Model reuse is distinguished by the fact that it uses the model's structure but not its pretrained parameters. We processed images of leaves on a variety of fruits using the approach indicated above. According to the results in Table 4, when using the DL structure with a limited number of epochs in the training stage for creating proper features with the appropriate metrics computation, the hybrid model is capable of recognizing leaf disease with a maximum accuracy of 99.1%.

TABLE 4: Comparison of proposed method with other deep and classical learning structures.

Reference	Type of leaf	Model	Accuracy (%)	Computational complexity
Chen et al. [10]	Rice	VGGNet	92.00	High
Sharma et al. [25]	Tomato	S-CNN and F-CNN	98.30	High
Atila et al. [44]	Plant leaf	EfficientNet	96.18	High
Kaur et al. [45]	Grape	Hy-CNN	98.70	Medium
Ji et al. [46]	Grape	United model	98.20	High
Gadekallu et al. [47]	Plant leaf	Whale and DL	95.10	Medium
Azimi et al. [48]	Crop	FCNN and SCNN	92.01	High
Joshi et al. [49]	Coffee	Deep CNN	98.00	High
Paymode and Malode [50]	Grape and tomato	VGG	98.40 and 95.71	High
Jiang et al. [51]	Rice and wheat	VGG16, DenseNet-121, and ResNet-50	97.22 and 98.75	High
Nandhini and Ashokkumar [52]	Plant leaf	DenseNet-121 and optimization algorithm	98.70	High
Our model	Plant leaf	Dilated TL and ensemble learning	99.10	Medium

Our model, which was taught to recognize leaves in a variety of fruits, demonstrated a reliable effect that might be used as actual smart technology in agriculture. Other studies looked into whether DL-based models are unique in their ability to distinguish between diseases from different time periods. The table below compares the dResNet-18 and other decision-making structures to a variety of feature extraction and ensemble learning models. To detect, recognize, and describe leaf disease in plants, many deep learning models are used. Various CNN models, such as S-CNN and F-CNN [17], EfficientNet [43], Hy-CNN [45], and the united deep learning model [46], have been applied to various plant leaf images by a number of authors. On plant leaves, a hybrid analytic model [47] obtains 95.1 percent precision, while other models achieve 92.01% precision [48]. The classification of images of coffee leaves is improved by texture image analysis [49]. In addition, our approach is a fast method that has less computational complexity than other similar methods in leaf disease classification.

As a result of its many advantages, deep learning in data science can lead to more efficient processing models [53]. A decision-making approach proposed in this study could be of significant help in classifying leaf diseases. By using deep learning, accuracy can be continuously increased and knowledge can be continuously gained without supervision. Additionally, data analysts will benefit from more accurate and concise results as a result of this initiative.

5. Conclusion

This article analyzes and provides a dataset of six different types of crop disease leaves. The deep CNN-based dilated ResNet-18 model is trained and evaluated using data processing, preprocessing of the dataset, training, and experimental procedure. The proposed model is constructed and tested to determine whether it can improve on the outcomes obtained thus far. Various datasets indicate that the metrics parameters are stronger and higher than those of other techniques. As a result, our proposed research work increased the accuracy of various leaf images of various fruits by 99.1 percent, including Apple, Corn, Cotton, Grape, Pepper, and Rice. We were able to achieve the highest level of performance possible with our model when it came to on-

field crops, leaf images, and disease classification and analysis. Agriculture and food production are the core objectives of university and government-funded research. It is intended that real datasets comprising a variety of leaf crops would be collected and processed for usage in deep learning models in the future. Crop images will significantly benefit from the future usage of hybrid models based on improved TL architecture and traditional models. Farmers gain from our efforts because we encourage and stimulate agriculture, which boosts agricultural revenue and contributes to the development of strong countries. Additionally, in the future, the authors of this study will attempt to reduce the algorithm's computational complexity and execution time.

Correspondence should be addressed to Peizhi Zhao; pz1u20@soton.ac.uk

Globally, the energy supply in the market is tight and the oil price fluctuates sharply. With the increasing degree of environmental pollution, both developed and developing countries pay special attention to the development of new energy, and energy conservation and emission reduction have been put on the agenda. As new energy vehicles have the advantages of energy conservation and environmental protection, they are strongly supported by governments. Many countries regard new energy vehicles as substitutes for traditional vehicles, and their development has ushered in a good opportunity. Under the background that the government and enterprises pay more attention to the development of new energy vehicles, it is of positive significance to study the intelligent manufacturing enterprises of new energy vehicles in a province. This paper studies the manufacturing of new energy vehicles through soft computing. Next, this paper also analyzes the financial market. Enterprise risk is closely related to investor income and social healthy development, which is a hot issue concerned by the public and the government. However, in recent years, there have been a series of cases in which enterprises have suffered huge losses using "hedging" to avoid operational risks, which has aroused public concern about the motivation of enterprises to use derivative financial products. Based on the leverage characteristics of derivative financial instruments, scholars believe that the high leverage profit in the capital market is the main incentive for enterprises to use hedging for hedging speculation. Existing studies pay more attention to the consequences of enterprise hedging, and they analyze the impact of enterprise hedging, focus on the result level after enterprise hedging, and seek the significance of enterprise hedging. Through the research on soft computing, this paper will apply it to the intelligent manufacturing of new energy vehicles and promote the development of hedging in China's financial market

1. Introduction

After decades of development, the traditional automobile industry has become more technologically mature and has made great contributions to facilitating people's travel. However, with the development of the economy and the popularization of automobiles, the following two problems have also appeared: on the one hand, oil is the "blood" of the development of traditional automobiles, and it is a nonrenewable resource [1, 2]. If oil is used as the power source of automobiles for a long time, the development of cars becomes unsustainable, and the problem of fuel shortage is highly valued by governments of various countries [3]. On the other hand, traditional cars produce a lot of waste during use, causing serious damage to the environment, and car

exhaust pollution has also been criticized by people [4, 5]. Environmentalists all over the world are calling for environmental protection and green and low-carbon travel [6]. Therefore, countries all over the world are paying more attention to energy conservation and emission reduction [7]. Combining the above two factors, to solve the problem of environmental pollution, new energy vehicles based on soft computing will be an important way to solve this problem, and it has also become an important direction for the green development and sustainable development of new energy vehicle intelligent manufacturing [8]. Next, this article analyzes the financial market. In the context of the integrated development of the global financial system, financial liberalization and economic globalization are becoming more important. China's financial market and the international

financial instrument market are becoming closer [9]. Therefore, for Chinese companies, it is difficult to avoid risks caused by the price fluctuations of raw materials, products, and the financial environment [10, 11]. Companies are affected by the large fluctuations in the prices of bulk goods and upstream raw materials, and the company's profits have become more uncertain, causing huge losses to the company, and even endangering the company's operations [12]. Affected by the financial crisis and economic globalization, the price fluctuations in the bulk commodity market are not a short-term phenomenon [13]. How to deal with the impact of price fluctuations is the key to a company's sustainable operation [14]. For stable operations, companies should constantly adjust their business models to ensure that the importance of accurately identifying, grasping, and effectively avoiding risks brought by price fluctuations, and making effective use of the futures market for companies risks are hedged [15]. However, the huge losses caused by the use of hedging by enterprises are caused by the use of derivative financial instruments [16]. Based on the important management foundation of the enterprise, the perspectives of senior management and internal governance and the important external management foundation of the company are discussed from the macroperspective of the use of hedging [17]. Motivation issues help companies make decisions on derivative financial products, such as hedging, and avoid corporate risks [18].

2. Related Work

The literature shows the importance of studying the financial performance evaluation of new energy vehicles in a certain province and strives to provide suggestions for the development of the new energy vehicle industry in a province. Part of the research puts forward the improvement suggestions of the quality management team; the visual interface and system functions of the complete SPC software are designed. At the same time, it provides a software basis for the realization of the previously designed quality control system, also determines the thermal resistance of key parameters according to customer feedback and production performance, and determines the key process of heat sink dispensing process and DBC (ceramic copper sheet) cutting and mounting process. Through the 5M1E fishbone diagram analysis method, the cause of the defect was deeply analyzed, and the improvement plan, the adverse reaction plan, and the three-stage plan of SPC real-time monitoring were established. The SPC monitoring of thermal resistance parameters, glue quantity and DBC (ceramic copper sheet) placement pressure parameters, and other parameters were gradually realized, and the SPC control chart of thermal resistance parameters was drawn. There are also some literatures that propose the construction of a financial performance indicator system, which lays the foundation for the following AHP. The literature proposes to build a financial performance indicator system, which lays the foundation for the following level analysis. The literature proposes the construction of a financial performance indicator system, which lays the foundation for the analysis of the hierarchy below. At the same time, it pays attention to the benefits and problems of the company's

hedging scheme, as well as the matters that should be paid attention to in hedging. And the Shanghai copper option is introduced, by designing two optimization schemes for hedging; one is using the Shanghai copper option alone and the other by combining the Shanghai copper future and the Shanghai copper option, and forecasting the scheme. After analyzing the advantages and existing problems of the G enterprise hedging scheme, it puts forward some matters that G enterprise should pay attention to in the future hedging. The literature proposes a method of matching car styling features according to user needs and builds a multilevel labeling car styling library. The literature shows case studies on user demand feature extraction, car styling feature matching, and car styling intelligent generation.

3. Soft Computing and Intelligent Manufacturing Technology of New Energy Vehicles

3.1. Soft Computing.
Soft computing is a technique that increases actual uncertainty on the basis of hard computing to obtain an approximate solution or optimal solution to a practical problem to achieve the best solution. Soft computing technology can be applied to the research of product image design, and it can convert physical phenomena in a certain process or level of complex problems into mathematical models. At present, domestic and foreign scholars' research on soft computing methods mainly focuses on artificial intelligence and predictive models. In terms of product design, especially product images, there are few pieces of research on soft computing. The research on product image design based on computing methods in this article has certain theoretical and practical value.

As shown in Figure 1, soft computing is a set of methods used to infer and learn human thoughts, process fitting models, and provide solutions to complex problems. It allows uncertainty and incomplete actual values to exist, and this method can better solve the uncertainty problem that is common in reality.

3.2. Intelligent Manufacturing of New Energy Vehicles

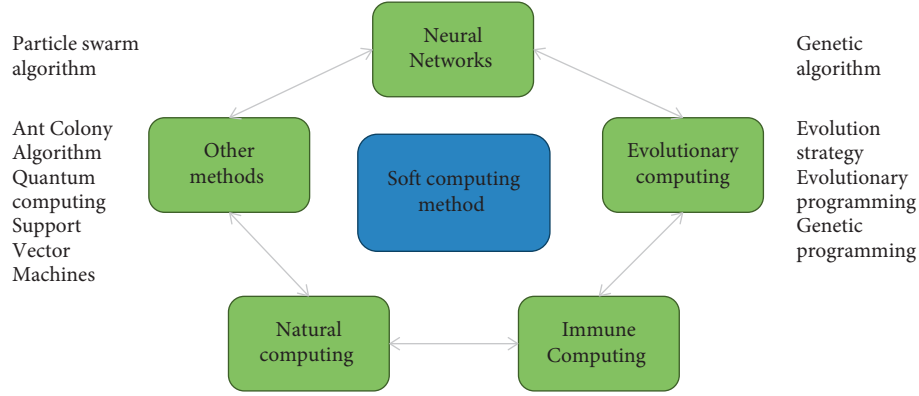
3.2.1. Algorithm Model.
The TFIDF algorithm is one of the classic algorithms of keyword extraction technology. The central idea is to extract keywords in the text according to the statistical information of word frequency and calculate the weight of the corresponding keywords. The high word frequency information of a certain keyword in the text and the low word frequency information of other texts reflect the keyword's ability to distinguish other texts. Therefore, keywords can be used as keywords in the text. The specific definition of TFIDF is in equations (1) and (2).


FIGURE 1: Soft computing method.

$$\begin{cases} \text{TF}_{ij} = \dfrac{n_{ij}}{\sum_k n_{kj}}, \\[4mm] \text{IDF}_i = \log \dfrac{|D|}{|D_i| + 1}, \end{cases} \tag{1}$$

$$\begin{cases} w_{ij} = \text{TF}_{ij} \times \text{IDF}_{ij}, \\[4mm] w_{ij} = \dfrac{w_{ij}}{\sqrt{\sum_k w_{kj}}}. \end{cases} \tag{2}$$

The principle of the cosine similarity calculation method is to use the cosine value of the angle between the two vectors in the vector space as the difference between individual objects. The specific definition is given in equations (3) and (4).

$$\begin{cases} A = \{a_1, a_2, a_3, \ldots, a_n\}, \\ B = \{b_1, b_2, b_3, \ldots, b_m\}. \end{cases} \tag{3}$$

From equation (3), we can see that A and B represent two independent objects, and each object contains N-dimensional features.

$$\text{sim}(A, B) = \cos\theta \frac{\vec{a} \cdot \vec{b}}{\|a| \cdot |b\|}. \tag{4}$$

It can be seen from formula (4) that the method of calculating cosine similarity is to regard the object as a coordinate point in the N-dimensional coordinate system.

To continuously optimize the generated result image, a total loss function is defined, which is used to perform gradient descent to obtain a result image that matches the original image features. The formula of the total loss function is as follows:

$$L_{\text{total}}(\vec{p}, \vec{a}, \vec{x}) = \alpha L_{\text{content}}(\vec{p}, \vec{x}) + \beta L_{\text{style}}(\vec{a}, \vec{x}). \tag{5}$$

Among them, L_{content} is the content loss function, and L_{style} is the style loss function. The specific definitions are given in equations (6) and (7).

$$L_{\text{content}}(\vec{p}, \vec{x}, l) = \frac{1}{2}\sum\left(F_{ij}^l - P_{ij}^l\right)^2. \tag{6}$$

Use the original image to calculate the convolution feature P_{ij}^l and the convolution of the l layer.

$$L_{\text{style}}(\vec{p}, \vec{x}, l) = \frac{1}{4N_l^2 M_l^2}\sum\left(A_{ij}^l - G_{ij}^l\right)^2. \tag{7}$$

3.2.2. Data Processing. Word frequency information is a measure of the frequency of words appearing in a document, and the specific definition is as follows:

$$p(s) = p(w_1, w_2, \ldots, w_n) = \prod_{i=1}^{n} p(w_i|w_1, w_2, \ldots, w_{i-1}). \tag{8}$$

Mutual information statistics originally originated from the information theory, reflecting the connection between words. In the field of natural language processing, mutual information usually represents the internal cohesion between words, reflecting whether words can form new words. It is used to identify unregistered words and eliminate ambiguous words, and the specific definition of mutual information is as follows:

$$M(A, B) = \log_2 \frac{P(A, B)}{P(A)P(B)}. \tag{9}$$

However, upon considering the cohesion of the words alone, it is easy to split the words. The "keywords" in the "keywords" have a high mutual information value in the document, however, they are not unregistered words. Therefore, we need to introduce the concept of boundary freedom. The core idea of boundary freedom is to judge whether words can be used freely in each part of a sentence. Here, the minimum value of the number of words appearing on the left side of the phrase and the number of words appearing on the right side of the phrase is set as value of the boundary degrees of freedom. Equation (10) is defined as follows:

$$F(L, R) = F_{\text{minlen}}\left(L(w_1, w_2 \ldots w_n), R(w_1, w_2 \ldots w_m)\right). \tag{10}$$

The word span reflects the description range of the descriptive vocabulary. The more the span, the more important the word and the stronger the whole. The calculation method is as follows:

$$W_{\text{span}} = \frac{|l_i|}{|L|}. \tag{11}$$

Following the above-mentioned vocabulary and emotional feature factors, this article gives a definition of the TFIDF algorithm that integrates multiple features.

$$W_{ij} = \left(tf_{ij} \times idf_{ij} + W_{\text{span}_j} \right) \times W_{10c_{ij}} \times W_{\text{speech}_{ij}} \times M_{ij}. \tag{12}$$

The effect of user demand extraction is composed of three evaluation indicators. The experiment uses fit, recall, and $F1$ value ($F1$-measures) to evaluate the effectiveness of keyword extraction. The calculation method is shown in formulas (13)–(15).

$$P = \frac{C_{\text{correct}}}{C_{\text{extract}}}, \tag{13}$$

$$R = \frac{C_{\text{correct}}}{C_{\text{standard}}}, \tag{14}$$

$$F_1 - \text{Measure} = \frac{2pr}{p + r}. \tag{15}$$

To verify the effectiveness of the fusion multifunctional TFIDF method proposed in this paper and the method of retrieving unregistered vocabulary, the PUBLIC-PRAISE dataset is used to test the experimental results of various vocabulary function combinations, and the specific experimental results are obtained using the experimental evaluation indicators, as shown in the Table 1 shown.

The visualization result is shown in Figure 2.

To improve the performance of the keyword extraction effect of the method in this paper, the number of extraction of different keywords is set to $K = 5, 10, 15, 20, 25, 30$ for exploration, and the experimental results are shown in Figure 3.

The definition of bilinear upsampling is given in equations (16)–(18).

$$\begin{cases} f(R_1) = \dfrac{x_2 - x}{x_2 - x_1} f(Q_{11}) + \dfrac{x - x_1}{x_2 - x_1} f(Q_{21}), \\[2ex] f(R_2) = \dfrac{x_2 - x}{x_2 - x_1} f(Q_{12}) + \dfrac{x - x_1}{x_2 - x_1} f(Q_{22}), \end{cases} \tag{16}$$

$$f(P) = \frac{y_2 - y}{y_2 - y_1} f(R_1) + \frac{y - y_1}{y_2 - y_1} f(R_2), \tag{17}$$

$$\begin{aligned} f(x, y) = {} & \frac{f(Q_{11})}{(x_2 - x_1)(y_2 - y_1)} (x_2 - x)(y_2 - y) + \frac{f(Q_{21})}{(x_2 - x_1)(y_2 - y_1)} (x - x_1)(y_2 - y) \\ & + \frac{f(Q_{12})}{(x_2 - x_1)(y_2 - y_1)} (x_2 - x)(y - y_1) + \frac{f(Q_{22})}{(x_2 - x_1)(y_2 - y_1)} (x - x_1)(y - y_1). \end{aligned} \tag{18}$$

The optimized image I_c^* is initialized to $I_c^* = I_c$ to facilitate subsequent optimization work and avoid local minima. To calculate the loss value of I_c^*, I_s, and I_c, the definition of the loss function is shown as follows:

$$L_{\text{loss}} = \text{argmin} E_s\left(\phi(I_c^*), \phi(I_s)\right) + \alpha_1 E_c\left(\phi(I_c^*), \phi(I_c)\right) + \alpha_2 \gamma(I_c^*). \tag{19}$$

E_s is the square of the Euclidean distance ($L2$ normal distance) between the optimized image layer and the corresponding feature layer of I_c, i.e., the Markovian loss function defined as follows:

$$E_s\left(\phi(I_c^*), \phi(I_s)\right) = \sum_{i=1}^{m} \psi_i\left(\phi(I_c^*)\right) - \psi_{N(i)}\left(\phi(I_s)\right)^2. \tag{20}$$

The calculation method of the optimal feature block is as follows:

$$N(i) = \text{argmin} \frac{\psi_i\left(\phi(I_c^*)\right) \cdot \psi_j\left(\phi(I_s)\right)}{\left|\psi_i\left(\phi(I_c^*)\right)\right| \cdot \left|\psi_j\left(\phi(I_s)\right)\right|}. \tag{21}$$

To match the semantic label obtained by the semantic segmentation network with the result image of style transfer, the process uses the Hadamard image matrix to calculate the pixels between the semantic label and the result image. The calculation method is as follows:

$$R = Y \cdot Z. \tag{22}$$

The background pixel retention rate is as follows:

$$I = \frac{N}{M} \times 100\%. \tag{23}$$

The structure is similar.

TABLE 1: Comparison of TFIDF effects of different feature combinations.

Method	Precision	Recall	Fl-measure
TFIDF	0.353	0.400	0.376
TFIDF + unregistered vocabulary	0.378	0.426	0.400

\end{cases}
\tag{24}
$$

4. Financial Market Hedging Strategy and Optimization Research

4.1. Concept and Process. There are many types of hedging strategies, the most basic of which are long hedging and short hedging. The so-called long hedging is to buy derivative contracts at the moment when the spot price is expected to rise. The basis is that the derivatives and spot prices change in the same direction. When the spot price rises in the future, profits in the derivatives market are used to offset the spot market. Through this process, the purpose of hedging is achieved; the price forecast of short hedging is opposite to long hedging. At present, we mainly sell derivative contracts, however, the principle is the same as that of long hedging. They all use price fluctuations in the same direction. The principle is to achieve the purpose of using the derivatives market to avoid the price risk of the spot market.

In addition, there are initial assumptions in the initial selection and operation of the hedging strategy. If the hedger wants to hedge, he must conduct it in the spot risk exposure, and he can find a suitable time and amount of equivalent derivative products for his subject matter.

However, in the relationship between the actual spot market and the derivatives market, it is difficult to find derivatives that accurately correspond to the spot risk exposure, or there is a problem that there are no hedging instruments available in the derivatives market. In other words, the hedger needs to consider a cross-hedging strategy and should use another financial derivative that has a price correlation with the corresponding financial derivative.

The current real hedging in the derivatives market has also extended some more complex strategies based on long hedging and short hedging strategies. There are "rolling hedging" and "stripe hedging" in the short-term interest rate futures market. However, the core of these strategies is, in fact, still long and short strategies, which are only special forms extended under special circumstances. These expansion strategies have high requirements for use occasions. Hence, they can only solve the problems that exist in some special environments.

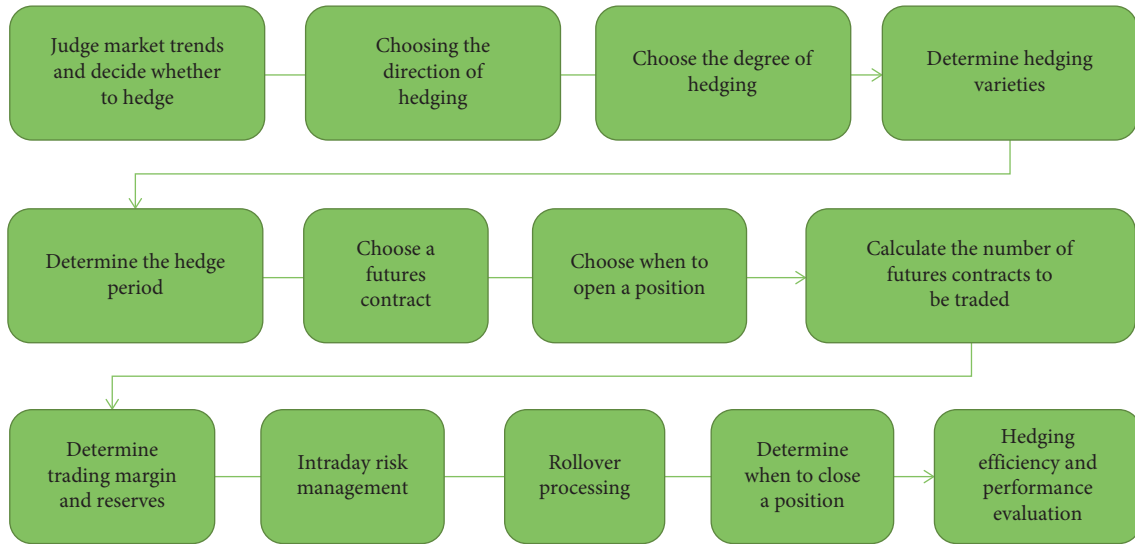
In the process of designing the actual hedging strategy, in addition to the principles of the derivatives market, it is also necessary to analyze the basic situation of the company itself. A more important aspect is the scope of hedging and the total amount of hedging. The scope of hedging refers to the company's outsourcing of raw materials, raw material production, raw material inventory, and spot products involved in product sales for hedging business operations through the corresponding futures varieties of the futures exchange.


Figure 4: Hedging process.

The total amount of hedging includes the following parts: (1) the total amount of various specific types of hedging is limited to the company's total production of raw materials, total purchases of raw materials, and total product sales. (2) The total amount of various hedging operations shall not exceed the total amount limited by this plan; (3) When the hedging working group develops a hedging plan for specific project types, it will quantify step-by-step and implement step-by-step according to the actual situation and establish an optimized operating plan to allow the company's hedging. The period of preservation reaches the best state, as shown in Figure 4.

4.2. Strategy Classification and Evaluation. It is possible to conduct risk exposure analysis on the company's future raw material production, raw material procurement, product sales, and other business links to avoid the risks that market price fluctuations bring to the company's business.

The so-called unilaterally exposed enterprises are those with closed upstream and open downstream. On the contrary, the upstream and downstream enterprises are closed.

For companies with one-sided exposure, the focus of value preservation is the absolute price, and the price is unilaterally closed. Whether it is upstream or downstream, what the company has to do is to buy at the lowest possible price or sell at the highest possible price.

For this type of company, the basic method of hedging is relatively simple, either buying or selling, because one side of the price is fixed.

For companies with one-sided exposure, the uncertainty they face lies in the choice of projects, the choice of futures, the choice of the number of positions, and the choice of derivatives.

Therefore, the steps for a unilaterally exposed company to use the derivatives market for hedging can be mainly divided into three steps, which are as follows:

Firstly, determine the company's hedging target, then carry out price analysis and forecasting, and finally determine the hedging mode.

Different from unilateral exposure, bilateral exposure means that both the input price (cost) and output price change according to the price of the hedged object. This type of company usually comes from the middle reaches of the industrial chain, and the company's main business is trade or processing direction.

If the spot market price of the input and output products is the same, the company's core profit point is the difference between the processing fee and processing costs. In reality, the actual profit risk of the company lies in the price difference between the output product and the spot price of the input.

Since the actual spot target price usually fluctuates greatly, the value goal of the bilateral exposure company is to avoid the risk of the difference in the spot price of the sales item. In the actual hedging business, these companies are interested in the relative price of the spot rather than the absolute price of the spot target. The main purpose of the hedging plan is the hedging of the relative price.

According to the definition of hedging, an effective hedging operation must ensure that the combined benefits of the spot interest and the derivative market interest are positive, at least to ensure that the operation of the derivatives market allows the spot market to reduce losses.

In the current market, many companies do not know how to use hedging tools, especially after some state-owned enterprises have been involved in the "hedging" whirlpool of foreign futures markets. There are many doubts and negative comments in the market, which has led to the dismissal of companies that conduct hedging operations through the derivatives market.

In the actual operation of hedging companies, the evaluation of hedging effectiveness can be misleading. They may focus on the book profits and losses to evaluate the overall hedging effect. Obviously, this method is one-sided.

In addition, based on the correct hedging concept, the company can flexibly manage hedging based on actual risk exposure and cash flow in actual operations. It is not limited to copying and imitating the relatively successful models of other companies. Each company has its own special parts in terms of business conditions and financing methods, which need to be analyzed based on specific conditions, and different hedging models can be designed for different companies to better manage risk.

No matter how mature the company is, there is no guarantee that the actual hedging business will be perfect. There are uncertain factors, such as fundamental differences, cross hedging, and hedging costs. In addition to the company's natural profit-seeking nature, hedging operations are also the product of the game between controllable risk and excess profit, the product of the game between controllable risk and the maximum avoidance, and the reduction of basic differences and spread losses.

Therefore, when evaluating a company's hedging performance, firstly, determine the company's hedging target based on its own circumstances. In other words, to avoid spot market risks, the evaluation of the hedging effect should be based on whether to reduce risks and losses and how to operate the futures market. Loss can be reduced. Even if the risk exposure is not fully covered, hedging should be considered effective.

4.3. Effect Analysis. Table 2 shows the specific hedging strategies.

In early March 2020, according to the average price of nonferrous copper, the spot price of nonferrous copper was 45,390 yuan/ton. By May 2020, the spot price of nonferrous copper has fallen to 42,930 yuan/ton. Without hedging, a company's net asset loss would be RMB 12.3 million.

The specific calculation is as follows: a company's spot market profit and loss = (May-March copper market price) × company copper stock = (42930 yuan/ton − 45390 yuan/ton) × 5000 tons = 12.3 million yuan.

According to the aforementioned Shanghai copper futures hedging strategy, a company sold a total of 401 CU2005 and CU2006 contracts in early March. According to the set opening price, the average selling price in May was 44,601 yuan/ton, and the buying price was 42,861 yuan/ton and 42,721 yuan/ton.

According to calculations, the profit and loss of using the CU2005 contract is (44601 − 42861) × 2001 = 3.482 million yuan, the profit and loss when using the CU2006 contract is (44601 − 42721) × 2001 = 3.762 million yuan, the cumulative profit and loss is 7.244 million yuan, and the overall profit and loss situation is as shown in Table 3.

Taking the company's cash and cash equivalents as an indicator of the daily available cash flow, whether it is using Shanghai copper futures or Shanghai copper options for hedging, the funds occupied are covered by the company's daily operating cash flow, as shown in Figure 5. Cash flow pressure is relatively low.

According to the previous calculations, the hedging results, in this case, can be visually displayed, as shown in Table 4.

TABLE 2: Hedging content of enterprises using Shanghai copper futures.

Item	Content
Hedging purpose	Hedging the risk of 4,000 tons of standing inventory depreciation
Contract selection	Shanghai copper 2005 and 2006 contracts
Transaction direction	Sell
Length of preservation	March–May
Opening date	March Closing date May
Opening price range	44,000–45,000
Number of contracts	800 hands
Method of opening a position	Set up positions in batches, set up and sell 80 lots of Shanghai copper 2005 and 2006 contracts at 44,200, 44,400, 44,600, 44,800, and 45,000, respectively
Program features	Avoid systemic risks to a certain extent, and retain the possibility of copper prices going up

TABLE 3: The hedging effect of using Shanghai copper futures.

	CU2005	CU2006
Average selling price (yuan/ton)	44,601	44,601
Purchase price (yuan/ton)	42,861	42,721
Total number of contracts (hands)	401	401
Cover the risk part (tons)	2001	2001
Contract profit and loss (ten thousand yuan)	348.2	376.2
Total futures profit and loss (ten thousand yuan)	724.4	
Spot profit and loss (ten thousand yuan)	−1230	
Total profit and loss (ten thousand yuan)	−505.6	
FIGURE 5: Corporate cash flow.

4.4. Optimized Plan Design. Shanghai copper options were listed for trading in September 2020. Like other commodity futures options, the basis of copper options contracts is copper futures contracts. Generally speaking, copper options are actually an option, i.e., traders can choose whether to

TABLE 4: Comparison of the results of no hedging and hedging.

—	No hedging	Shanghai copper futures
Total profit and loss (ten thousand yuan)	−1230	−505.6
Capital occupation (ten thousand yuan)	0	C. 901

withdraw their purchases at any time or the right to sell copper futures.

The general idea of using Shanghai copper options is similar to that of using Shanghai copper futures, both of which hedge the risk of falling copper prices while maintaining the potential for copper prices to rise. Therefore, the strategy of buying put options is adopted, the exercise price is set to 44,000–45,000, and the Shanghai copper options contract with the exercise price of 44,000 is finally selected, namely CU2005P44000.

Because of the low daily trading volume of Shanghai copper options, each order is limited to 100 lots, and the Shanghai copper options also use the bulk subscription method, with a total of 800 put options purchased.

When designing the hedging plan, the use of Shanghai copper options for hedging is another option for the company. It is mainly because Shanghai copper options use a lower option fee to obtain the future and buy and sell according to higher established prices. In the actual hedging process, because of the large trading volume and the difficulty of trading in the Shanghai copper options market, this option was not selected. However, in the following procedures, the benefits of this option can be analyzed through simulation, which can provide reference experience for the following design.

Because of the low daily trading volume of Shanghai copper options, the simulated backtesting process is difficult to meet the needs of one-time trading to cover the risk exposure. Hence, the transaction is carried out in batches, and the order is finally placed through 6 transactions. For the part of the transaction of 100 lots or more, the option premium is the average transaction price of the day.

According to the Shanghai copper option hedging strategy in the previous section, at the beginning of March, a company bought 800 lots of CU2005 P44000 at an exercise price of 44,000 yuan/ton. After the futures exercise, the partial profit and loss = (exercise price-CU2005 settlement on the exercise date) Price) × 4000 tons = (44000 yuan/ton − 41,725 yuan/ton) × 4000 tons = 9.1 million yuan, cumulative profit and loss = futures partial profit and loss-spot partial loss-option price = 9.1 million yuan − 12.31 million yuan − 428,800 yuan = −363.88 million yuan, the intuitive cost, and profit calculation are shown in Table 5.

The hedging optimization ideas in this paper have two main points: one is to use only Shanghai copper options and to introduce options that optimize the combination of Shanghai copper futures and options. The other is to consider whether the company can adopt the possibility of long-term hedging.

Although the optimization solution solved some of the problems in the case, it still exposed some risk points, which may require special attention in future operations.

First of all, in this case and optimization plan, the possibility of adjusting the production plan of the company was not considered. The company is at the downstream and end of the copper industry chain. The theoretical risk exposure should come from the upstream. Because of the adjustment of the production plan, the company's inventory is insufficient. To support daily production, the direction of hedging may be completely reversed. With the continuation of the current hedging direction, companies will also face losses.

In addition, because of the short hedging period of the company, neither the case nor the optimization plan has the expiry date of the derivative market contract, nor does it consider the risk of month-swapping and long-term coverage of the risk exposure. It is the hedging of other companies. Questions that cannot be skipped at the time. By comparing optimization plans and cases, we can understand the importance of derivatives trading volume in facilitating transactions, which also has a significant impact on the final hedging effect. If the trading volume in the options market is insufficient, the optimization plan has not been fully analyzed to support the possible consequences of hedging needs.

Neither the case nor the optimization plan considers other costs of the company's hedging, hedging expenses, other costs that need to be outsourced to specialized agencies, and other risks.

In addition, the company itself does not have a lot of hedging experience. Hence, it needs to seek the guidance of futures companies. There is a risk of leakage of the company's production and management secrets. Even if the company wants to carry out long-term hedging operations, it still needs training or employment and professional derivative personnel to design and manage its own hedging operations.

4.5. Analysis of Hedging Strategies in the Financial Market. In the process of using the derivatives market for risk management, companies establish a correct concept and make it clear that the original intention of the company to use derivatives is to avoid risks and not to profit through speculation. It requires a clear understanding of the risks that the company can bear. In the futures market, the high leverage provided by margin trading allows companies to support larger transactions with less capital. At the same time, it also introduces new risks and has higher requirements on whether companies understand the nature of futures market transactions.

Enterprise experience shows that the direction of the company's hedging may not match the company's position in the industry chain. The company is located in the downstream or terminal position of the copper industry

TABLE 5: Hedging backtest results using Shanghai copper options.

CU2005P44000 transaction situation	
Option fee (yuan/hand)	Volume (hands)
501	201
336	101
550	201
601	201
651	101
Analysis of profit and loss results	
Total option premium (ten thousand yuan)	42.88
Partial profit and loss of futures after exercise (ten thousand yuan)	910
Spot profit and loss (ten thousand yuan)	−1231
Accumulated profit and loss (ten thousand yuan)	−363.88

chain. Traditional hedging thinking requires companies to hedge upstream risk exposures and is more sensitive to copper price increases. However, the company's inventory situation, in fact, is very good. For the company's daily production, it is more urgent to prevent inventory depreciation. In short, the company's actual risk exposure is similar to that of copper material manufacturers. What is worrying is that the price of copper has fallen. Therefore, the direction of hedging is opposite to the experience of hedging in the industry chain.

The derivatives market is the main place for companies to hedge, and it has an irreplaceable effect on companies to avoid market risks. However, it is undeniable that in the process of using the derivatives market, future market price fluctuations, margin risks, and liquidity risk may arise. Failure to correctly understand the existence of these risks will reduce the effectiveness of hedging and increase losses for companies.

As mentioned above, companies need to improve their professional knowledge and correctly understand the risks in the derivatives market. In addition to looking for specialized agencies to guide hedging, companies themselves also need to improve the professional quality of internal risk management institutions, fully understand the futures market, and improve the futures market. The risk identification and management functions enable the company's employees engaged in related businesses to strengthen their understanding of the futures market and strengthen the risk concept of all employees.

In addition, it should be recognized that under the current market environment and accumulated experience, risks in the derivatives market can be controlled by effective means, rather than allowing companies to withdraw.

Whether using futures or hedging options, capital occupation is inseparable. In the futures market, capital occupation is mainly reflected in the margin, while in the options market, capital occupation is mainly reflected in the option premium. Generally speaking, option costs are relatively fixed. Hence, the option use of a hedge fund can be determined at the time of trading. The futures market is traded on margin, and the amount of margin is much lower than the actual transaction amount supported. However, for companies with large positions, margin occupancy should also be considered.

5. Conclusion

The automobile industry is one of the important pillar industries of China's economy and has made great contributions to the vigorous development of China's economy. However, the future development of traditional automobiles has many limitations, and the new energy and green automobile industry are thriving with huge development potential, providing a strong driving force for promoting economic development. As new energy green vehicles are more energy-saving and environmentally friendly, the state and local governments provide fiscal and tax subsidies for the development of new energy vehicles, which brings many opportunities for the development of new energy vehicle intelligent manufacturing. This article starts with the company's actual hedging needs, analyzes the company's risk exposure, determines the hedging target, analyzes the copper spot market fundamentals, and predicts the price trend. In the process of simulating the company's hedging, we mainly evaluate the effect of hedging in terms of operability, current market profit and loss, and capital occupation. After evaluating and analyzing the case, this paper proposes an optimization plan based on the existing problems and conducts an evaluation of the backtest results.

Research Article

Research on Innovation Ecosystem of Dairy Industry Cluster Based on Machine Learning and Improved Neural Network

Yang Hui [iD]**, Yanni Jiao, Can Cui, and Ke Ma**

College of Economics and Management, Northeast Agricultural University, Heilongjiang, Harbin, China

Correspondence should be addressed to Yang Hui; yanghui@neau.edu.cn

With the rapid development of global economy, the industrial cluster has become the new trend of world economic development. So far, the industrial cluster mode with space as the main division has been formed. The cooperation of industrial clusters is dynamic. The industries in the cluster cooperate with each other for mutual benefit and win-win, occupying a place in the fierce market competition. In addition, the industrial cluster is also conducive to strengthen the international economic division of labor and points out the direction of regional industrial transfer. China is now in a critical period of economic development; the industrial cluster plays an important role in China's industrial transformation and economic development. At present, the most common regional development mode in China is industrial cluster. The emergence of industrial cluster accelerates the development of industrial regional economy and the balance of industrial layout. Industrial clusters occupy a key position in China's economic industry chain, and the development and change in industrial clusters will directly affect the development of the entire industrial chain. This study first simulates the evolution path of industrial cluster and then establishes the relevant data model. Finally, through repast simulation, it puts forward conclusions and suggestions according to the verification results. The construction of dynamic model can realize the simulation of industrial cluster theory. According to the simulation results, we can find that the ecosystem in different stages will produce different characteristics; the formation and evolution of industrial clusters are actually the epitome of market development. In this process, the government guidance and market regulation are needed to accelerate the formation of industrial cluster ecosystem and increase the scale of industrial cluster.

1. Introduction

After the reform and opening up, China's industrial clusters have developed rapidly. On the one hand, the economic development after the reform and opening up relies more on the development of regional economy, and the development of industries in the same region is basically the same, which is conducive to the formation of industrial clusters; on the other hand, there is a highly specialized division of labor and close industrial ties between different industries. It has laid a rich foundation for the formation of industrial clusters [1]. At present, China has formed a relatively mature industrial cluster ecosystem. Different industries cooperate with each other and occupy a dominant position in the market. In the development process of China's industrial clusters, each stage has different changes. Industrial clusters should also make corresponding changes according to the characteristics of different stages, follow the trend of market development, and maintain the advantages of industrial clusters. So far, the common idea in academic circles is that China's industrial clusters will develop in the direction of cluster ecosystem, thus forming the advantage of market competition [2]. However, the current academic research on the cluster ecosystem is not deep enough, and the social understanding of the cluster ecosystem only stays on the concept of "ecolgical rent," but there is no accurate understanding of the specific concepts of cluster ecosystem and "ecological rent." This is the focus of our future research; we need to popularize the concept of cluster ecosystem to the whole society.

The theory of multi-industry cluster and social organization is a kind of complex system. Among the organizations and institutions that make up the cluster, microenterprises occupy the most important position. The formation of industrial clusters does not depend on the drive of a single enterprise, but requires the collaborative development of enterprises in the industry [3]. To form a mature and orderly industrial cluster structure, we should constantly innovate and update the cluster system and related decisions to ensure that the industrial cluster can keep up with the pace of the times. It is also very important for industrial clusters to make correct decisions. Good decisions can promote the rapid development of industrial clusters, even change the macrostate of industrial clusters, and promote the sustainable development of industries. Therefore, before carrying out the policy, we should fully consider whether the policy meets the actual requirements and whether the policy is rigorous enough. Only after the rationality of the policy is fully determined, the policy can be issued. In addition, through the establishment of industrial cluster simulation model to test whether the various factors affecting the development of industrial cluster are reasonable.

2. Related Work

The idea of industrial cluster was first put forward by Adam Smith. Literature [4] thinks that division of labor is very important in industrial cluster. Only by determining the role of each part of industrial cluster, we can give full play to the advantages of industrial cluster and form scale economy. The development of industrial clusters should not only pay attention to the cooperation between various departments but also pay attention to the refinement of functions. On the research of industrial clusters, the theory of industrial location proposed by literature [5] and the theory of industrial location proposed by literature [6] have become the important ideas for the development of industrial clusters, and more and more studies have been carried out with these two ideas. However, foreign scholars only focus on the causes of industrial clusters and do not conduct in-depth research on the follow-up development of industrial clusters. Research: in addition, most of the foreign research on industrial cluster is based on the theory of industrial cluster. Literature [7] and others began to study the theory of technology spillover, and literature [8] carried out the research on knowledge management of industrial clusters. In the research, we should first study different cluster organizations separately. Literature [9] classifies the research focus as the knowledge resources of industrial clusters. At present, the research focus of industrial clusters is the research integration between different schools of industrial clusters and the theoretical knowledge in industrial clusters. This change shows that the academic research on industrial clusters has begun to transition from theory to practice, which is a qualitative leap for industrial clusters.

Literature [10] puts forward that in the whole industrial cluster ecosystem, some ecological factors related to the industrial cluster ecosystem jointly promote the development and progress of the cluster industry, promote the formation of the cluster effect within the industry, and promote the cooperation of all parts of the cluster. In reference [11], the industrial cluster ecosystem should not be a simple industrial collection, it is formed in the long-term evolution process, and the regional economic ecosystem is a dynamic system. In the development of industrial clusters, we should pay attention to the establishment of industrial brands to form competitive advantages. Literature [12] believes that the emergence of brand effect is with the development of industrial clusters, and when the industrial clusters develop to a certain extent, it will promote the formation of brands within the industry, thus producing brand effects externally. Literature [13] has proved that for industrial clusters, transformation is the only way, and the key to achieve transformation is to maintain the competitive advantage within the cluster. Literature [14] analyzes the impact of network on industrial clusters from the perspective of network. The analysis results show that the use of network in the cluster can strengthen the relationship among various parts of the cluster and can also improve the competitive advantage of individual enterprises in the cluster. According to the resource-based theory proposed in reference [15], heterogeneous resources of enterprises can be divided into tangible and intangible resources. Although the existence forms of these two resources are different, they are indispensable resources in the process of cluster. These resources are the source of competitiveness and creativity of enterprises and play an irreplaceable role. Literature [16] believes that rich resources can ensure the dominant position of enterprises in the competition. In literature [17] for the enterprises in the cluster, it is very important whether they have their own rooted resources, which is the key element to distinguish enterprises from other enterprises in the cluster, and the core and key in the cluster ecosystem. Literature [18] has proved the importance of heterogeneous resources to enterprises. Heterogeneous resources can catalyze the emergence of competitive advantages of enterprises in clusters. In addition to promoting the development of individual enterprises, they can also promote the common development of industrial clusters and even the entire industrial chain. According to the literature [19], competition and cooperation are the two basic ways of industrial cluster formation. The existence of these two ways ensures the continuous creation of new things within the industrial cluster, with continuous vitality and sustainable development. The industrial cluster ecosystem is similar to the natural ecosystem, but the competition between enterprises cannot be compared with the relationship in the natural ecosystem. The competition between enterprises includes both struggle and cooperation, which is different from the single competition in nature. In fact, competition is the best cooperation. Based on the theory of cooperative competition, literature [20] confirmed that orderly competition in the cluster can promote the common development of enterprises and clusters and make the enterprises in the cluster improve their competitiveness in the market. Literature [21] holds that competition is necessary for cooperation. In fact, cooperation is developed from competition, and cooperation is a consensus reached in the process of competition. According to the niche theory, literature [22] holds that market competition is actually a struggle for innovation

ability, especially for enterprises of the same nature, and if they want to stand out among the same kind, they must have strong innovation ability and seek new profit growth points; in addition, competition is necessary for the development of clusters, and competition can promote cooperation and division of labor among enterprises. At the same time, it will promote the exchange and integration of different enterprises in the same industry chain. In reference [23], the industrial cluster ecosystem is a dynamic system. In the long-term development process, each component of the ecosystem realizes common survival and coevolution, aiming at improving the overall competitiveness and making common progress.

Agent theory was first proposed in the field of artificial intelligence. As mentioned in literature [24], so far, agent theory has not only existed in the field of artificial intelligence, but also applied to various fields of society. For different fields, the meaning of agent theory is different. Different fields will give different meanings to agent theory to meet the needs of this field. Therefore, it is very difficult to determine the unified definition of agent theory. Although different fields have different definitions of agent theory, each domain has some common characteristics, such as autonomy, intelligence, autonomy, and sociality.

3. Technology and Theory of the Dairy Industry Cluster Ecosystem

3.1. Modeling Method of the Multiagent System. Multiagent system comes from the field of artificial intelligence and has been applied to many fields. MAS is a system composed of multiple agents. MAS can achieve the task goal through the cooperation between agent systems. MAS is actually a complex joint system. This system can realize data simulation and solve the actual problems.

Before using multiagent system for research, we should first determine the specific role of each element in the system and clarify the relationship between different elements; secondly, we should extract the key elements of the system, establish the agent model of the system, and set the rule conditions of the agent model; finally, after the establishment of the agent model, the model is run and data statistics and analysis are carried out, and the analysis results with the actual results are compared.

In MAS system, the agent is defined as individual, and the relationship in MSA system can be regarded as the static relationship model between different individuals; in the construction of multiagent class, the interaction and cooperation are carried out through the establishment of each class to form a model for operation and solve each level and task in the system.

3.2. Quantitative Model of Competition Cooperation Interaction Game of Industrial Cluster

3.2.1. Basic Assumptions of the Model

(i) Suppose that there are only two enterprises (1, 2), and the two enterprises are substitutes. The total supply and demand function in the market is as follows:

$$Q = q_1 + q_2,$$
$$p(Q) = p(q_1 + q_2). \tag{1}$$

(i) P is the price, and Q(p) is the original demand function. The two companies here have the same unit cost c and total output Q. Suppose

$$p(Q) = A - Q,$$
$$C_i(Q) = q_i c. \tag{2}$$

(i) Profit R is paid by the enterprise itself, and it is a function of output Q.

3.2.2. Game Model Analysis. We can get the model we want by comparing the companies in a single time. According to the model obtained, the profit of the two companies is calculated as follows:

$$R_1 = R_2 = Q * P = \frac{A-c}{4} \times (P-c) \frac{(A-c)^2}{8}. \tag{3}$$

The profit of a single enterprise is increased, and the scale is expanded. The profit obtained is as follows:

$$R_1 = q_1(p-c) = q_1(A - Q - c) = q_1[A - (q_1 + q_2) - c]. \tag{4}$$

The optimized first-order condition is as follows:

$$\frac{\partial R_1}{\partial R_2} = A - (2q_1 + q_2) - c = 0. \tag{5}$$

The relationship between the profit and output of the company can be obtained. In the case of other companies also cooperating,

$$q_2 = \frac{A-c}{4},$$
$$q_1 = \frac{3(A-c)}{8}. \tag{6}$$

Thus,

$$R_1 = q_1(p-c) = q_1[A - (q_1 + q_2) - c] = \frac{9(A-c)^2}{64},$$
$$R_2 = q_2(p-c) = q_2[A - (q_1 + q_2) - c] = \frac{3(A-c)^2}{32}. \tag{7}$$

When another company chooses not to cooperate due to its own choice, it still follows the principle of profit maximization:

$$R_2 = q_2(p-c) = q_2[A - (q_1 + q_2) - c]. \tag{8}$$

The first-order optimal conditions are as follows:

$$\frac{\partial R_1}{\partial R_2} = A - (q_1 + 2q_2) - c = 0. \tag{9}$$

Comprehensively, the above two formulas are solved:

$$q_1 = q_2 = \frac{A - c}{3},$$

$$R_1 = R_2 = \frac{(A - c)^2}{9}. \tag{10}$$

Regarding the use of game analysis, if both parties choose to cooperate at this time, they will get the effect of cooperation.

$$K = \frac{(A - c)^2}{8}. \tag{11}$$

At the same time, for the intention of cooperation, if one party is willing to cooperate and the other party is unwilling to cooperate, for the party who does not want to cooperate:

$$L = \frac{9(A - c)^2}{64}. \tag{12}$$

Partners get

$$M = \frac{3(A - c)^2}{32}. \tag{13}$$

If both parties are unwilling to cooperate, then the result is as follows:

$$N = \frac{(A - c)^2}{9}. \tag{14}$$

It can be concluded that the order of benefits after cooperation between them is as follows: $L > K > N > M$.

If companies conduct multiple comparisons and evaluate the results from multiple aspects, this formula can be derived as follows:

$$K = R + \delta^2 R + \delta^3 R + \cdots + \delta^n R = \frac{R(1 - \delta^n)}{1 - \delta} = \frac{(A - c)^2}{8(1 - \delta)}. \tag{15}$$

The profits gained by the refusal of cooperation between enterprises are as follows:

$$N = \frac{(A - c)^2}{9(1 - \delta)}. \tag{16}$$

Therefore, only cooperation is the guarantee of long-term development. For this reason, competition and cooperation within industrial clusters are inevitable. The relationship between the various industries in the process of cooperation is shown in Figure 1.

As shown in Figure 1, the division of labor between different industries in the company is very clear. They let their employees do some major production and development work. The core technology and scientific research work are responsible for the development department. It will be completed by some other companies.

3.3. Mathematical Model of Industrial Cluster Learning

3.3.1. Model Establishment. There are two main aspects that have an impact on the industrial production function, namely the total amount of participation and the effective yield. According to the relationship between them, we can build the following functions:

$$Y = E(,) * F_p. \tag{17}$$

Different mathematical symbols in the function have different meanings. E and Y_p represent the effective yield and participation amount, respectively. k1 and k2, respectively, represent the private knowledge and learning knowledge in the production process, and k represents all the knowledge output, where Y and B represent the functional changes in the learning knowledge and private knowledge in the process, and their scope is γ, $\theta \in (0.1)$. Based on this relationship, we can build the following function:

$$E(,) = E(K_c, k_1; \gamma, \theta) = aK_c^{\gamma} k_1^{\theta}. \tag{18}$$

The sample size of the research object is set as x, and the total amount of learning knowledge, learning rate, and total enterprise knowledge from these samples are extracted as follows:

$$K_c = \int_0^k k_2 dt = xk_2,$$

$$\pi = k_2/k, \tag{19}$$

$$k = k_1 + k_2.$$

FR and σ are used to represent the mathematical characteristics of enterprise knowledge under different elements:

$$K_c = xk_2 = x\pi k = K_c^{\sigma} F^R,$$

$$K_c = \left(x\pi F^R\right)^1 / (1 - \sigma), \tag{20}$$

$$K_c^{\gamma} = \left(x\pi F_R\right)^{\gamma/1 - \sigma}.$$

Because

$$k_1 = k - k_2,$$

$$k_1^{\theta} = (k - k_2)^{\theta} = (1 - \pi k)^{\theta} k^{\theta},$$

$$k^{\theta} = \left(K_c^{\sigma} F_R\right)^{\sigma} = \left(x\pi F_R\right)^{\partial \sigma/1 - \sigma}, \tag{21}$$

$$k_1^{\theta} = (1 - \pi)^{\theta} k^{\theta} = (1 - \pi)^{\theta} \left(x\pi F_R\right)^{\partial \sigma/1 - \sigma}.$$

Combining equations (19)–(21), these three formulas can be solved:

$$E(,) = aK_c^{\gamma} k_1^{\theta} = a(1 - \pi)^{\theta} \left(x\pi F_R\right)^{\lambda},$$

$$\lambda = \frac{\lambda + \theta\sigma}{1 - \sigma}. \tag{22}$$

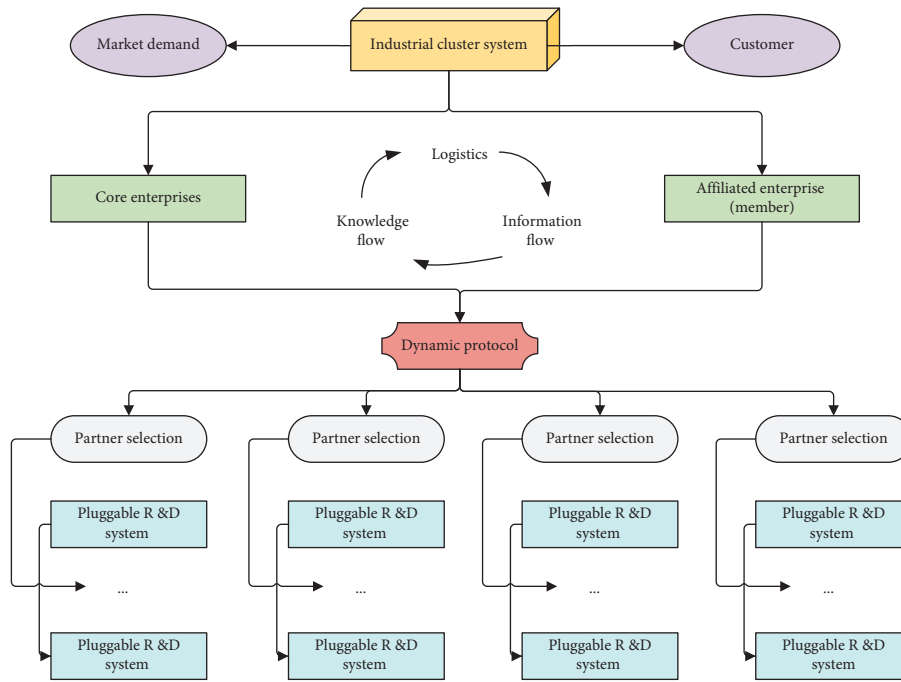
3.3.2. Model Analysis. Because the sample size is fixed, we can establish the following relationships according to the different uses of the input elements:


FIGURE 1: Mechanism of interfirm cooperation in the industrial cluster system.
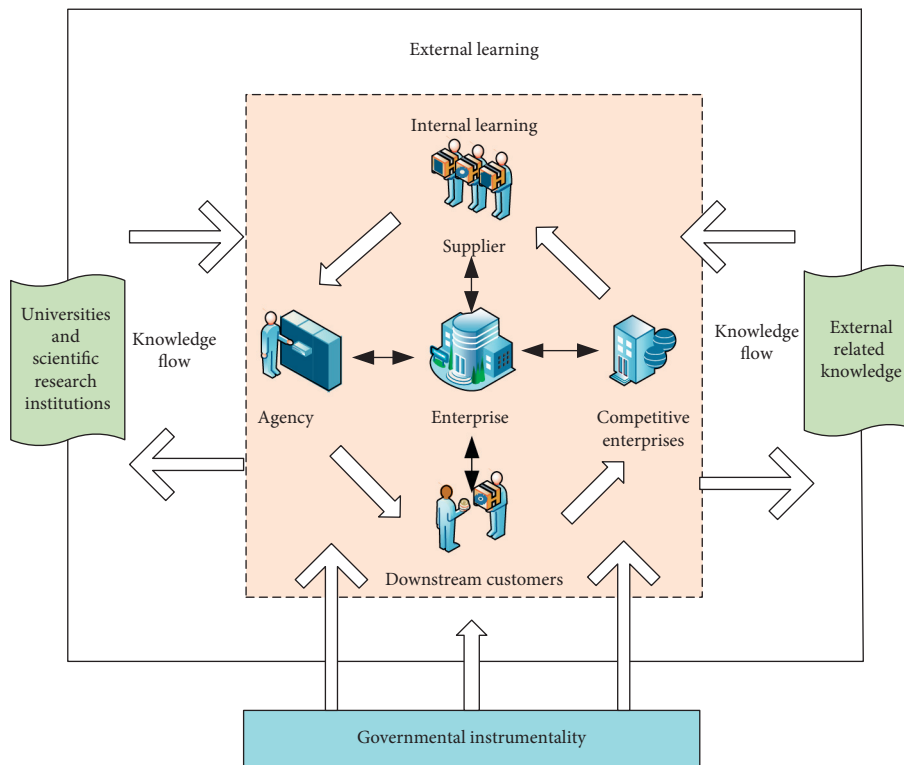

FIGURE 2: Schematic diagram of the industrial cluster learning system.

$$F = F_P + F_R,$$
$$y = a(1-\pi)^\theta (x\pi F_R)^\lambda F_R. \tag{23}$$

After establishing the Lagrangian function and solving,

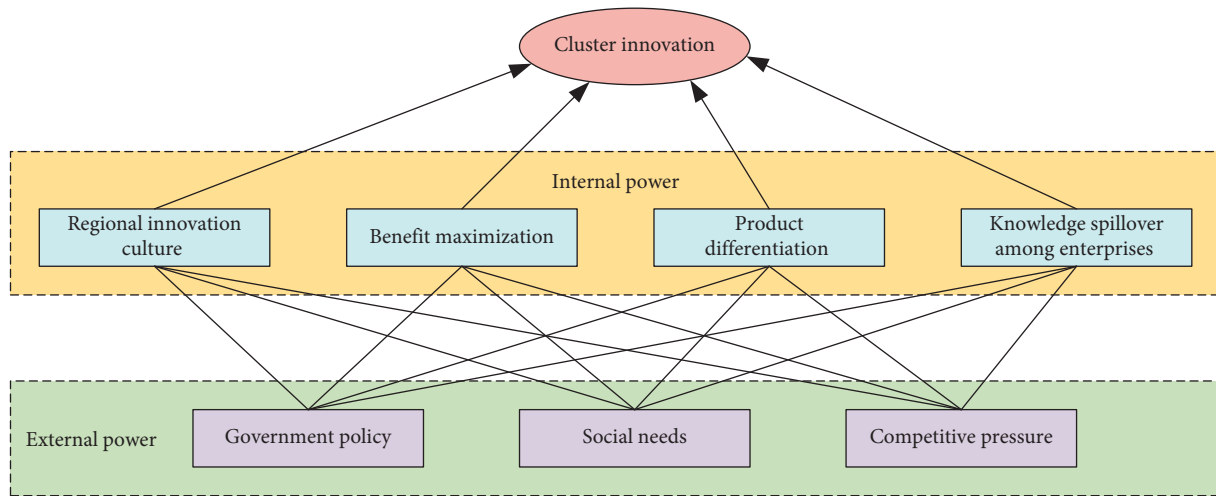
$$L = y - \lambda[(F_P + F_R) - F],$$
$$\lambda F_P = F_R, F_R = F/(1+\lambda),$$
$$F_P = \lambda F/(1+\lambda). \tag{24}$$


FIGURE 3: Composition diagram of the main body of industrial cluster innovation.

Low-income households	71.58	79.46	101.41	19.3
Middle-lower	96.53	111.50	132.20	17.0
Middle-income households	115.13	120.81	136.41	8.9
Upper-middle class	139.23	144.66	155.05	5.5
High-income households	158.82	182.38	162.30	1.9
Highest income households	207.32	197.61	211.58	12

After substituting formula (23),

$$y = A(1-\pi)^{\theta}\lambda x^{\lambda}\pi^{\lambda}F_R^{1+\lambda},$$
$$A = a\lambda^{\lambda}(1+\lambda)^{-(1+\lambda)},$$
$$\text{if } F = F_P + F_R = 1, \quad (25)$$
$$y = f(\pi, x) = A\phi(\pi)\varphi(x),$$
$$\phi(\pi) = (1-\pi)^{\theta}\pi^{\lambda}, \varphi(x) = x^{\lambda}.$$

By analyzing the formula, we can draw the conclusion that there is a positive mathematical relationship between the output of the cooperative group and the knowledge learning rate and the number of enterprises, and the geographical location of the enterprise is also more positive than the output of the cooperative group. The output of the cooperative group mainly depends on the company's technology and knowledge characteristics.

3.4. Analysis of Innovation Motivation Mechanism of Industrial Clusters

3.4.1. Path Analysis of Industrial Cluster Learning. The learning system in the industrial cluster is shown in Figure 2.

3.4.2. Industrial Cluster Innovation and Power System. Innovation can bring development and competition for industrial clusters, and competitors can continuously improve the strength of the enterprise, so innovation is very important between enterprises. Many components can promote the innovation and development of an enterprise. We can roughly divide them into internal and external components. The internal and external components interact and influence each other to form a new driving force to promote the innovation of the cluster, as shown in Figure 3.

4. Dairy Industry Cluster Ecosystem Simulation Research Design

4.1. Analysis of Dairy Industry Development and Cluster Status

4.1.1. Overview of Price Competition among Dairy Companies. In recent years, the competition among the dairy industries in Western country is mainly reflected in prices. Many companies will reduce prices to increase their competitiveness. Some companies will choose to hold some promotional activities or give away some gifts to improve their

competitiveness. In the years of competition, the market value of different dairy industries and the prices of ordinary dairy products will also fluctuate greatly. See Table 1 for specific data.

See Table 2 for analysis of price changes in dairy products in different regions and different brands.

The data image corresponding to Table 2 is shown in Figure 4.

4.1.2. Questionnaire Survey-Specific Plan. Many people in China only tasted milk after the founding of New China.

Therefore, after the founding of New China, the Chinese country's dairy industry has developed rapidly. Among them, the per capita consumption of dairy products by urban residents in all provinces, cities, and towns across the country in 2013 and 2017 expenses is shown in Table 3.

The data in the table show that the consumption of dairy products in our country is at a relatively low level, not only much lower than some developed countries in Europe and North America, but also much lower than many Asian countries. The per capita consumption of liquid milk in major countries in the world is shown in Table 4.
FIGURE 6: Model mean error analysis bubble chart.

4.1.3. Group Structure of Dairy Product Consumption.
During the research process, the staff sampled the consumption of dairy products by urban and rural residents in a certain province from 2015 to 2017 and studied the differences and mathematical relationships between the consumption of dairy products by residents of different incomes. The specific results are shown in Tables 5 and 6.

4.2. The Overall Structure of the Evolution Model of the Industrial Cluster Ecosystem

4.2.1. Ricardo's Rent Subsystem Feedback Loop.
Instead, the enterprise's resource stock, specialization degree of engineering, resource allocation efficiency, etc., are taken. As the research objects, a circular relationship diagram is established, the relationship between them is analyzed, and the analysis results are shown in Figure 5.

The efficiency of resource allocation of enterprises is mainly affected by the specialization of labor and internal exchanges. Staff draw the cause tree to explore the influencing factors of the formation of industrial clusters. Through the observation table, we can intuitively get the

relationship between different influencing factors and influencing factors.

4.3. The Main Variables and Properties of the Evolution Model of the Industrial Cluster Ecosystem.

The rent system of this model and its cluster ecological rent system, the main variables, and types involved are shown in Table 7.

The staff will apply the parameter selection method in the mathematical research to the model to optimize the model, and the specific parameters will be determined after continuous experiments. During the experiment, the staff will make a correction based on the preliminary parameter values obtained. The model is adjusted to a certain extent. If the function of the model does not change significantly before and after the adjustment, then this parameter is the final parameter, as shown in Table 8.

5. Simulation Results and Analysis of the Dairy Industry Cluster Innovation Ecosystem

5.1. Fitting Test of the Dairy Industry Cluster Ecosystem Evolution Model.

The staff will adopt different testing methods to test whether the model is valid and whether the fit of the parameters meets the requirements:

$$R^2 = 1 - \frac{\sum_{i=1}^{n} (y_i - \widehat{y}_l)^2}{\sum_{i=1}^{n} (y_i - \overline{y}_l)^2}. \tag{26}$$

Different mathematical symbols in the formula represent different meanings.

In this study, industries in a certain area were randomly selected as objects to test the fit. The test process is shown in Table 9.

Table 10 shows that the selected model has practical meaning and is very accurate.

The values in Figure 6 represent the errors generated by the model, and these errors are within the tolerable range, so the model is credible and relatively accurate.

5.2. Model Data Extraction and Analysis.

Table 11 reflects the changes in the average technical efficiency of my country's dairy industry from 2016 to 2019. Through the table, it is not difficult to see that the per capita efficiency levels of different companies have changed significantly.

TABLE 17: Evolution stage characteristics of the industrial cluster ecosystem based on simulation.

Cluster development history	Segmentation basis	Characteristics of each course
The initial phase	None of the rents appeared	With Ricardo's rent as the mainstay, the advantages of clusters begin to manifest
Progression stage	A small amount of rent	The rents are evenly matched
Perfect stage	The relationship between rents begins to change	Ricardo's rent status has been replaced by the other three rents; the overall level of the cluster is the highest
Metamorphosis stage	Changes in different rent levels	Cluster level decline

Table 12 shows us the distribution of technical efficiency of various dairy companies in my country in 2018.

The staff summarized the approximate level of technical efficiency of my country's dairy companies in 2019, as shown in Table 13.

Based on the above data, the staff has integrated the distribution of the scale of my country's dairy companies in 2019. For detailed data, see Table 14.

The staff collected relevant data on the scale and marketing profit of each dairy industry in 2019 and integrated them into a table (Table 15).

Table 16 shows the calculation status and efficiency of the super-SBM model in each province across the country from 2014 to 2018.

It can be drawn from Table 16 the ranking of super-SBM in various provinces and municipalities across the country from 2014 to 2018.

5.3. Simulation Results and Analysis of the Dairy Industry Cluster Ecosystem Evolution Model. The characteristics of the evolution stage of the industrial cluster innovation ecosystem based on simulation are summarized in Table 17.

6. Conclusion

With the development of Internet technology, the Internet has played an increasingly important role in industrial clusters, not only affecting the development path of industrial clusters but also changing the development mode of industrial clusters. It can be said that the Internet has a historical role in industrial clusters. In the development process of industrial clusters, there are not only golden opportunities but also severe challenges. We should seize the opportunities without being afraid of the challenges. For industrial clusters, the development of network technology can promote changes in the industrial environment, thereby promoting the development of industrial clusters. In the development process of industrial clusters, the most important thing is practice. Industrial clusters can continuously improve and find and solve problems in practice. Through practice, the development of industrial clusters can be more mature, so that they can adapt to the new environment and welcome new ones. Challenge: the important role of industrial clusters in industrial development has also attracted the attention of many scholars. In recent years, more and more scholars have begun to take industrial clusters as their research direction.

This study mainly analyzes and studies the system and marketing profit level of my country's dairy industry in the form of a combination of research and theory and uses this as a sample to analyze the factors that will have a significant impact on industrial clusters in the process of entrepreneurial cooperation.

The preliminary conclusion drawn from the research is that factors such as government policies, industrial creativity, and industrial scale will all have a greater impact. To promote the long-term development of enterprise clusters, it is necessary to increase innovation and government support.

With the explosive growth of the number of sports videos, the traditional sports video analysis method based on manual annotation has been difficult to meet the growing demand because of its high cost and many limitations. The traditional model is usually based on the target detection algorithm of manual features, and the detection of human posture features is not accurate. Compared with global image features such as line features, texture features and structure features, local image features have the characteristics of rich quantity in the image, low correlation between features, and will not affect the detection and matching of other features due to the disappearance of some features in the case of occlusion. Referring to the practice of Deep-ID network considering both local and global features, this paper adjusts the traditional neural network, and combines the improved neural network with the human joint model to form a human pose detection method based on graph neural network, and then applies the algorithm to multiperson human pose estimation. The results of several groups of comparative experiments show that the algorithm can better estimate the human posture in sports competition video, and has a good performance in solving multiperson pose estimation in sports game video.

1. Introduction

With the development of society, more and more sports videos have entered people's daily life. Analyzing these sports videos can not only bring more wonderful content to the audience but also find out the shortcomings of athletes for improvement. Accurate athlete detection and pose estimation are important links in sports video analysis. The existing human target detection and pose estimation algorithms have achieved good performance in general human detection tasks, but they will detect athletes and spectators at the same time in sports video, so they cannot further distinguish athletes' targets, which will interfere with the subsequent video analysis. At the same time, the sports video data with human body annotation is scarce, and the cost of obtaining a model suitable for the field of sports video is high. Athletes are a special case of general human body detection task. If the general human body detection model can be used to detect and estimate athletes in sports video, it can undoubtedly save a lot of cost. The analysis and

understanding of sports video have a huge market demand [1], and can provide standard teaching cases for sports lovers. In addition, the statistics of various data of athletes in the video can not only help athletes improve their technical level, but also adjust the tactical deployment for the whole team, and help coaches and athletes improve the strength of the team to a certain extent. The demand for sports video analysis and understanding is increasing.

The existing target detection and human pose estimation technologies have achieved good performance in the general scene detection task based on pictures, but there are few algorithms and data for target detection in sports video scenes. The usual approach is to label these data, and then train the target detection algorithm with new data to obtain the detection model [2]. Although this method can achieve results, it needs to retrain the model every time, which requires a lot of labeling cost and training cost. There are many kinds of sports videos, and a video contains a large number of pictures [3], so it is undoubtedly expensive to label the video. When analyzing sports video, the focus is on

athletes. The target detector trained based on general target detection task itself has the ability to recognize people. Similarly, human posture estimation for sports video is also one of many human posture estimation scenes. The human posture detector based on general scene training also has the ability to recognize human posture in sports video. Ifmmc1 the trained general detector can be directly used for the detection of athletes, it can undoubtedly greatly reduce the cost [4]. However, in sports video, people are crowded, occlusion often occurs between people, motion blur is serious, and the general target detector does not have the ability to distinguish ordinary spectators and athletes [5], which brings challenges to the use of general detector in sports video scenes.

This paper mainly studies the athlete detection and human posture estimation in sports video. Based on graph neural network algorithm and human posture estimation algorithm, combined with the characteristics of sports video, the target detection and human posture estimation model based on general data set training is transferred to the field of sports video, The purpose is to reduce the training and labeling cost of athlete detection and pose estimation for sports video, and improve the performance of athlete detection and human pose estimation in sports video. In this paper, the task of athlete detection and human posture estimation for sports video mainly focuses on the problem of multiperson motion in video. The LSP data set with 14 labeled joint points is adopted to meet the characteristics of multiperson motion and recognizable posture. The performance of this algorithm is compared with four mainstream methods of human pose estimation in multiple databases to verify the effectiveness of this algorithm in the field of multiperson pose estimation.

2. Related Work

Target detection is a basic task in the field of computer vision, and has always been a hot research topic. Before the introduction of depth neural network, the target detection algorithm is mainly realized by extracting the manual features of the image for feature matching [6]. Many image manual features such as sift and surf have achieved good results. A lot of work has tried to design different manual features for target detection according to the characteristics of detection targets, such as V-J detection, hog detection [7], and DPM [8] algorithm. The target detection algorithm based on manual features mainly uses the information of target color, texture and edge structure to recognize objects. It can achieve good results in a relatively simple background. However, in practice, the background changes in different fields are complex, and the image is often affected by illumination and resolution, resulting in target deformation and blur, so it is difficult to cover all the cases by manual features. The generalization ability of target detection algorithm based on manual features is weak. Therefore, the performance in complex scenes is not very good.

With the development of deep learning, human pose estimation algorithm based on deep learning has become the mainstream. The human posture estimation algorithm based on deep learning regards human posture detection as a key point regression problem, trains through a large number of data with joint point category and position annotation, and finally obtains a model that can predict the position and category of human joint points [9]. In the early days, people mainly studied single person pose estimation, that is, there is only one human body in the detected picture. The single person Newell et al. [10] designed an hourglass like network structure for attitude detection, and added a supervision signal in the middle of the network. The single person pose task only detects one human pose, which has simple picture background and less interference. The existing single person pose estimation algorithms have achieved good performance and achieved an accuracy of more than 93% on the single person pose estimation data set MPII. However, in practice, most pictures have multiple human bodies, so the single person pose estimation algorithm is no longer applicable. Compared with single person pictures, multiperson pictures have complex background and serious interference between people. The attitude estimation algorithm for multiperson faces more problems [11]. The existing multiperson attitude estimation algorithms are mainly divided into two categories: top-down multiperson attitude estimation algorithm and bottom-up multiperson attitude estimation algorithm. The top-down multiperson attitude estimation algorithm first detects the human body in the figure through target detection, then cuts out a single human body according to the detection frame and sends it to the single person attitude detector to obtain the human body attitude, and finally puts the single person's attitude back to the corresponding position in the original figure to obtain the human body attitude of all people [12]. Alphapose [13] algorithm introduces the spatial transformer network module to optimize the positioning accuracy of the detection frame and achieve a more accurate multiperson attitude estimation effect. Chen et al. [14] designed a cascaded pyramid network to complete multiperson attitude estimation through multiple regression and adjustment. The top-down multiperson attitude estimation algorithm decomposes the multiperson attitude detection problem into multiple single person attitude detection problems, which is realized by target detection and single person attitude detection. This method is simple and effective, but its performance will be affected by the target detection results. Because of the limitations of the target detection frame, when there are multiple people gathering and occlusion, there will be multiple human bodies in the target detection frame. At this time, the effect of the top-down multiperson pose estimation algorithm will be affected.

To sum up, the existing target detection algorithms are mainly based on convolutional neural network [15], and have achieved good performance on the general target detection data set. At the same time, the algorithm needs a lot of data-driven, and the cost of training a new model is high [16]. When target detection is carried out in some specific fields, the existing methods usually design and retrain the target detection model based on the data in this field. Although it can achieve good performance, it costs a lot. However, in practice, the specific target to be detected is

often a specific example of a certain class in the general target detection task, such as van detection and athlete detection, which are special cases of vehicle detection and human body detection in the general target detection task. At this time, if the trained general target detection model can be used to detect these specific targets, it can not only reduce the training cost, but also improve the application scope of the general detection model. The existing algorithms pay more attention to how to improve the detection performance in specific fields, and there is less research on how to migrate the general target detection model to specific fields to achieve specific targets.

3. Multiperson Pose Estimation Algorithm Based on Graph Neural Network

3.1. Graph Neural Network Algorithm.
The structure of neural network mainly includes convolution layer and pooling layer. The function of convolution layer is to extract abstract features by convolution kernel and reduce the number of parameters by local perception and weight sharing. The function of the pool layer is to aggregate and count the feature map extracted from the convolution layer, and further reduce the number of neurons by down sampling [17]. When using convolution check sample image block to extract abstract features, different regions of the sample image are treated equally, but in fact, the joint is only located in the central region of the positive sample image, so the central region plays a greater role in identifying the joint than other regions. Therefore, when extracting features, we should pay more attention to the central region and weaken the edge region. Therefore, this paper improves the convolution operation of neural network, and assigns different weights to the convolution operation in different regions of the image. Due to the similarity of the same species, although the appearance features of the same joint image block of different human bodies will be different due to different body shapes and postures, the difference is not very large, especially in the central area of the image, so they have similar local features. Since the same joint image blocks of different human bodies have similar local features, their global features will also have great similarity. The global features can also play a certain role in identifying joints. Therefore, in identifying joints, we should consider not only the local features of the image, but also the global features. Therefore, this paper improves the structure of the traditional neural network by referring to the deep id network in the face recognition algorithm, which considers both local and global features, and the global and local features of the image were extracted and combined as image features. The image features include 32-dimensional local features and 1-dimensional global features, which are mainly determined by local features, as shown in Figure 1.

Firstly, the local response of the color image is normalized to improve the generalization ability of the neural network. According to the size of the input vector and the global features of the output one-dimensional image, the neural network structure set in this paper is shown in Table 1, including 3 convolution layers, 4 pooling layers, 1 lead-

in layer and 3 full connection layers. Some of the parameters are shown in Table 1.

The improved graph neural network contains three convolution layers. The meaning of the parameters of each convolution layer in Table 1 is similar. For example, the output parameter of convolution layer 3 is $9 \times 9 \times 32$, where 32 is the number of convolution kernels. A convolution kernel corresponds to a feature extraction method. After convolution, a feature map is obtained, 9×9 represents the size of the characteristic image obtained after convolution, and the convolution step of all convolution layers is 1×1. The convolution layer activation function adopts the modified linear unit (ReLU) with strong anti-overfitting ability. ReLU will make the output of some neurons 0, which leads to the sparsity of the network, reduces the interdependence of parameters and alleviates the over fitting problem.

The learning algorithm of the improved CNN adopts the random gradient descent algorithm, and the objective function is set as

$$O(W) = \sum_{i=1}^{N} \left(f^i(W) - d^i \right), \tag{1}$$

where N is the number of samples, $f^i(W)$ is CNN output, d^i is the sample classification label, and positive and negative samples are 1 and 0 respectively. The improved graph neural network contains three full connection layers, and the neurons in the layer are connected with all the neurons in the upper layer. In front of the full connection layer is the introduction layer, but the convolution layer 3 and the pooling layer 4 are introduced into the full connection layer. The activation function of the first two fully connected layers adopts the modified linear unit (ReLU), and the fully connected layer 3 adopts the logistic regression function, and the output is the joint label.

3.2. Human Pose Estimation of Single Frame Image.
In this section, the video is divided into a series of single frame images. For each frame image, the position of each joint point of the upper body of the human body is obtained, and the posterior edge probability distribution of the wrist is calculated. Maximum likelihood estimation can be understood as a map estimator when the prior probability is uniformly distributed, and obtains the point estimation of the difficult to observe quantity according to the empirical data. The maximum a posteriori estimation is integrated into the prior distribution of the quantity to be estimated, which can be regarded as the regularized maximum likelihood estimation. In order to realize the human body pose estimation of a single frame image, the most commonly used graph structure model is used to represent the basic human body architecture, and the reasoning algorithm is used to obtain the exact joint position by transmitting messages between the parent node and the child joint point.

Figure 2 shows a schematic diagram of a structural model. The structure of human body is described by undirected graph G(E, V), where the vertex $v_i \in V$ represents a
Figure 1: Improved graph neural network structure.

Table 1: Figure structural parameters of neural network.

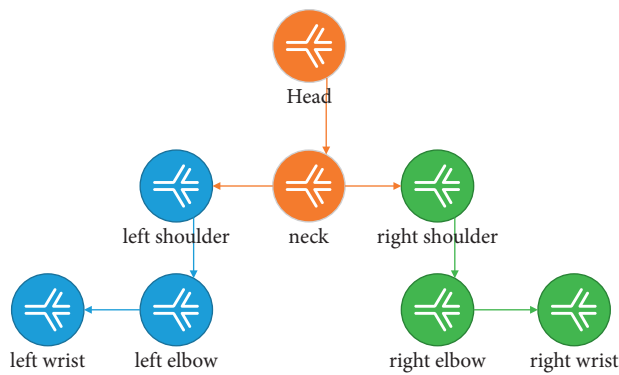
Layer	Conv1	Pool1	Conv2	Pool2	Conv3
Input	$64 * 64 * 3$	$60 * 60 * 32$	$30 * 30 * 32$	$24 * 24 * 32$	$12 * 12 * 32$
Output	$60 * 60 * 32$	$30 * 30 * 32$	$24 * 24 * 32$	$12 * 12 * 32$	$9 * 9 * 32$
Size	$5 * 5 * 3$	$2 * 2 * 1$	$5 * 5 * 32$	$2 * 2 * 1$	$5 * 5 * 32$
Layer	Pool3	Pool4	FC1	FC2	FC3
Input	$9 * 9 * 32$	$5 * 5 * 32$	$1 * 1 * 2400$	$1 * 1 * 2400$	$1 * 1 * 500$
Output	$5 * 5 * 32$	$1 * 1 * 32$	$1 * 1 * 2400$	$1 * 1 * 500$	$1 * 1 * 100$
Size	$2 * 2 * 1$	$5 * 5 * 1$	—	—	—


Figure 2: Structural model of human upper body diagram.

human body part, and the edge line e represents the adjacent joint point vi and vj For example, in the human body structure, there is a physical connection between the left wrist and the left elbow. Use the human body configuration $P = \{p^1, p^2, \ldots p^i, p^{n-1}, p^n\}$ to describe the posture of the human body, where $p^i = (x^i, y^i, \theta^i)$ is used to describe the human body part vi. (xi, yi) represents the coordinates of the center point of the rectangular box of part v^i, θ^i Indicates component v_i The direction of the rectangle. Given a frame of image I, the human body configuration P is defined as

$$P = k \cdot e^{\sum \varphi(p^i, p^j) + \sum \phi(p^i, I)}, \quad (i, j) \in E, i \in V, \quad (2)$$

where $\varphi(\cdot)$ and $\Phi(\cdot)$ are potential energy functions. Paired term potential energy function $\varphi(p^i, p^j)$ model the geometric constraint relationship between two adjacent joint points by encoding the human body a priori model. $\Phi(p^i, I)$ indicates the feasibility that the component v_i is located at the p^i position in the image I.

The best posture of human body in a single frame image is obtained by formula (1). Generally, the graph structure model has a tree structure, so two different reasoning algorithms can be used in reasoning. When reasoning with the maximum a posteriori (map), select the maximum product method to obtain the globally optimal maximum a posteriori estimation and the sum product method to obtain the edge distribution of the wrist, and take the edge distribution of the wrist as the a posteriori distribution probability of the tracking algorithm in the next stage.

In order to process video sequences more effectively, each frame needs to be read. Processing video frames mainly applies some processing functions to each video frame. As shown in Figure 3, the data processing module first divides the input sports video into frames, and unifies the size of the video frame to 1000×600 pixels, then detect people in each frame of the video based on the general target detector, then input the detection results obtained by the general target detector into the trained example feature metric classifier to obtain the athlete's detection results, and then fuse the multi frame detection results based on the video time domain context to obtain the optimized athlete's detection results.

3.3. Graph Neural Network Structure Model for Multiperson Attitude Estimation.

In order to ensure the recall rate of athletes, this paper takes all the detection frames of the general target detector as candidate frames when the threshold is 0. Extracting the features of the detection frame is to extract the features of the image content contained in the detection frame. The CNN network in the detection model has extracted the features of the whole image. According to the position of the detection frame, the ROIAlign method is used to extract the features of the detection frame.

Firstly, the feature map is resized to the size of the original map by bilinear interpolation, and then crop is performed on the feature map according to the position of the detection frame. Then, the detection frame feature map max pool to a unified size. Finally, the detection frame feature map is linearly expanded to obtain one-dimensional detection frame features. The size of the feature map of the detection frame after Max pooling will change according to different convolution neural networks, so that the feature length of the one-dimensional detection frame is between 1024 and 2048. In particular, a two-stage target detection network with RPN structure, such as fast RCNN, will extract features from each detection frame for classification and frame regression, that is, each detection frame obtained by fast RCNN target detection algorithm has a unique depth feature corresponding to it. RPN network compares the predicted results with the real results, reflects the gap between the predicted and the real value through the user-defined "distance," and optimizes the "distance" through the optimization algorithm, so the prediction is closer to the real value. In this paper, these features are directly used to identify the candidate frame as the feature of the candidate frame, The frame feature dimension extracted by the fast RCNN model used in this paper is 2048 dimensions.

The multilevel feature diagram is shown in Figure 4. To identify athletes, that is to distinguish athletes and nonathletes, the essence is to classify them according to the characteristics of candidate boxes. A feature vector q is defined to represent athletes, so that the candidate frame features of athletes are close to Q and the candidate frame features of nonathletes are far from Q. in this way, a threshold can be set to distinguish athletes from nonathletes.

From the candidate frame selection and feature extraction module, the 2048 dimensional depth feature corresponding to each detection frame can be obtained. This feature can be used to distinguish different detection frames, but cannot distinguish athletes from nonmobilization. Therefore, it is necessary to carry out a linear transformation on these features. This linear transformation module transforms the 2048 dimensional candidate frame feature into a 512 dimensional new feature. Initialize a 512 dimensional feature vector Q to represent the athlete. By continuously optimizing the parameters of this linear transformation module, the similarity between the new features of the athlete candidate box and Q becomes larger, and the similarity between the new features of the nonathlete candidate box and Q becomes smaller. The calculation formula of the linear transformation module is: $R = \tanh(W f)$.

where f represents the original 2048 dimensional feature of the candidate box, R represents the 512 dimensional new feature after linear transformation, tanh is one of hyperbolic functions, and tanh () is hyperbolic tangent. In mathematics, the hyperbolic tangent "tanh" is derived from the hyperbolic sine and hyperbolic cosine of the basic hyperbolic function, and W is the weight parameter of the linear transformation module.

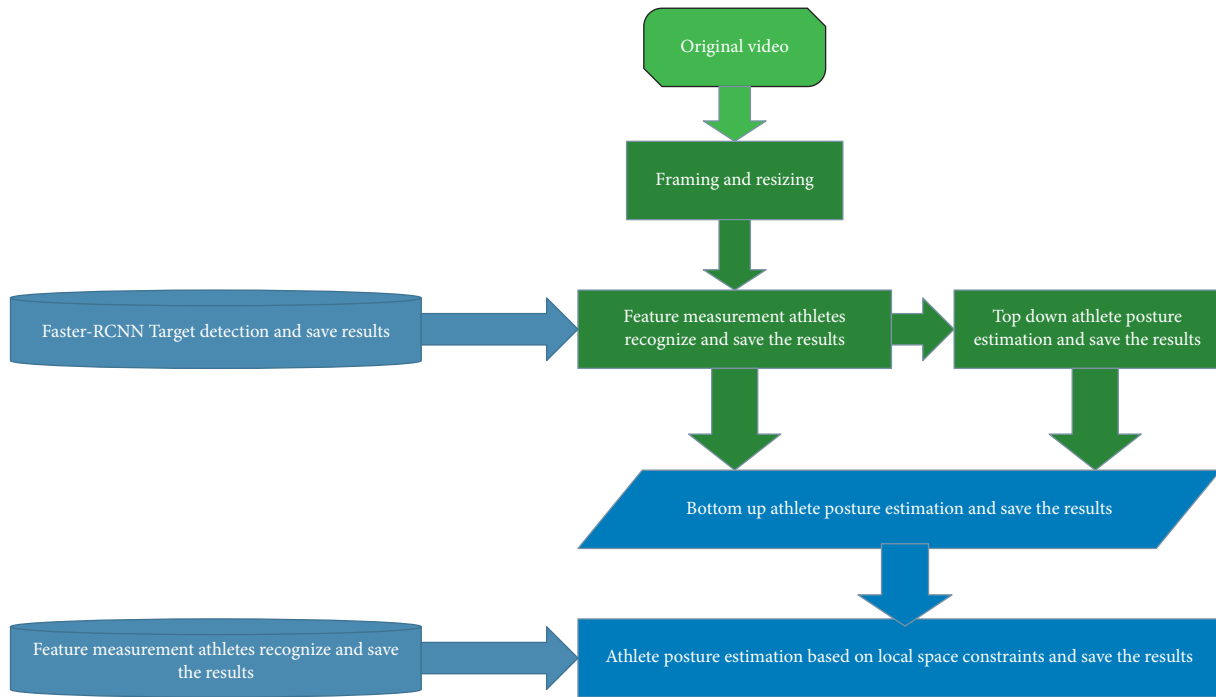
Firstly, initialize a 512 dimensional feature vector Q to represent the athlete, then select the candidate box and extract the features of the picture to obtain n 2048 dimensional candidate Box feature vectors F, and then linearly transform the candidate box features to have the same dimension as the athlete features to obtain n 512 dimensional candidate box features R. Then calculate the cosine similarity between each candidate frame feature R and athlete feature Q to obtain AI, where I represents the number of candidate frames, and the values are 1 to n. All the detection frames in a picture are regarded as a package, and the maximum cosine similarity between the candidate frame feature and the athlete feature is taken as the similarity S between the package and the athlete feature. Suppose Q represents an athlete, R represents a picture containing an athlete, then the positive packet similarity can be expressed as $s(Q, R)$, P represents a picture without an athlete, and the negative packet similarity can be expressed as $s(Q, P)$. Theoretically, the similarity between a picture containing an athlete and an athlete category is greater than a picture without an athlete, that is, $s(Q, R) > s(Q, P)$.


FIGURE 3: Data processing module.
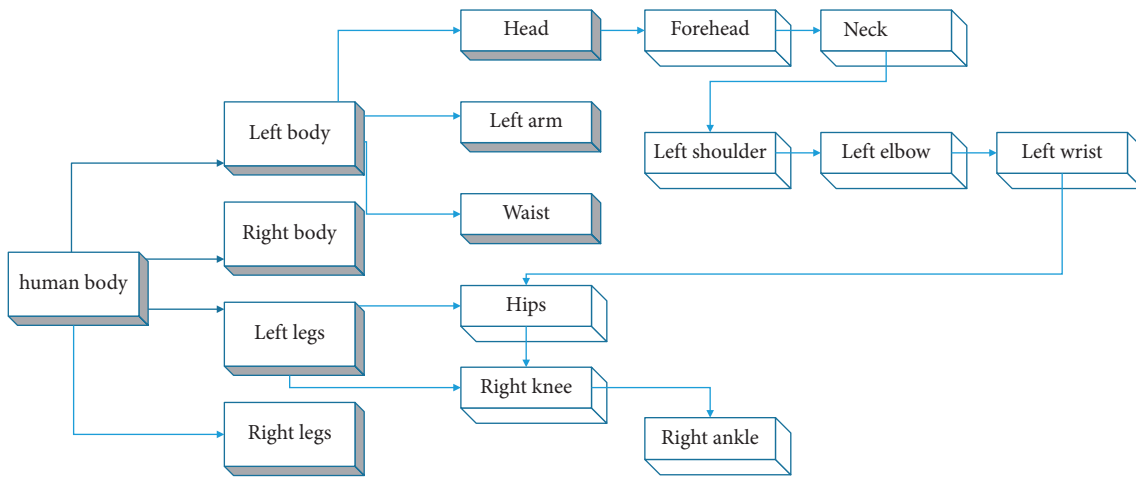

FIGURE 4: Multilevel characteristic diagram of athletes in sports competition.

The graph neural network is mainly composed of feature extraction layer, region recommendation layer, region of interest pooling layer and classification layer. Feature extraction layer and region recommendation layer have an important impact on the realization of network functions. Figure 5 is the network structure diagram of the neural network, which integrates the functions of feature extraction, candidate box selection, location refinement and classification into the same network. The designed structure corresponds to the feature extraction layer, region recommendation layer, region of interest pooling layer and classification layer respectively.

Given a natural image containing human posture, its size $P * Q$ needs to be reduced to a fixed size $M * N$ and then input into the graph neural network. $M * N$ images first pass through the feature extraction layer in the network, use this layer to extract the feature map describing human posture, and share the feature map describing human posture image in the subsequent region suggestion layer and region of interest pooling layer. The part of the graph neural network that is only directly connected with the feature extraction layer is called the region recommendation layer, which can be used to generate candidate frames of human parts. The region suggestion layer first generates rectangular boxes of different sizes through the convolution layer, then uses the classification function to judge whether the image block contained in the generated rectangular box is a human body part or a background pixel, and simultaneously calculates
Figure 5: Neural network structure diagram of human posture in sports video.

the offset of the generated rectangular box to fine tune the position of the generated rectangular box. So far, the graph neural network has completed the positioning function of human parts. Considering that the region suggestion layer generates a rectangular box with non-fixed size, which cannot be directly used as the input of the classification layer, the region of interest pooling layer is introduced into the graph neural network. The region of interest pooling layer takes the original feature map and the generated rectangular box as the input at the same time, and extracts the feature vector of the image block in the generated rectangular box by blocking in the original human posture feature map, so as to ensure the output of the feature vector of fixed size. Finally, the fixed size feature vector is input to the classification layer, and the specific human body part type of the image block contained in the generated rectangular box is output.

Supervised learning is a machine learning task to infer a function from the marked training data. The training data includes a set of training examples. In supervised learning, Each instance consists of an input object (usually a vector) and a desired output value (also known as supervised signal) composition. Supervised learning algorithm is the function of analyzing the training data and generating an inference, which can be used to map new instances. An optimal scheme will allow the algorithm to correctly determine the class labels of those invisible instances. This requires that the learning algorithm is in a "reasonable." The way is formed from a training data to an invisible situation. Before training the network, the position of each part of the human body is marked in a rectangular box to realize the supervised learning of network parameters. When testing the network, the static image containing human body is directly input. After the graph neural network, the image with a series of rectangular detection boxes and the fractional probability vector corresponding to the rectangular detection box are output.

3.4. Evaluating Indicator. The athlete detection and evaluation is the same as the evaluation standard of general target detection. This paper evaluates by calculating the joint sum intersection ratio IoU (interaction over union) between the detection result frame and the marked frame. When IoU >0.5, it is considered that the athlete is correctly detected.

For the estimation and evaluation of athletes' posture, there are two evaluation methods of human joint points: PCK [18] (percentage of correct keypoints) and OKS [19]

(object keypoint similarity). This paper selects the commonly used OKS method, which will calculate the similarity between the two postures and give a score between 0 and 1. In this paper, the OKS scores of predicted posture and real posture are calculated. The OKs score is calculated as follows:

$$\text{OKS}_p = \frac{\sum_i \exp - d_{pi}^2 / 2S_p^2 \sigma_i^2 \delta(v_{pi} = 1)}{\sum_i \delta(v_{pi} = 1)}. \tag{3}$$

p represents the ID of the person in the growth truth, and i represents the ID of the keypoint. D_{pi} represents the Euclidean distance between each person in the growth truth and the predicted key point of each person. S_p represents the scale factor of the current person, which is equal to the square root of the area occupied by the person in the ground truth. σ_i represents the normalization factor of the i-th bone point. Therefore, this is obtained by calculating the standard deviation of all ground truths in the data set, reflecting the standard deviation when labeling the current bone point. v_{pi} represents whether the i-th key point of the p-th person is visible. δ function for selecting visible points for calculation. When OKS >0.5, it is considered that the athlete's posture is correctly detected. Athlete detection and posture estimation are both kinds of detection tasks. According to the evaluation method of detection tasks, this paper selects three common evaluation indexes, namely maximum recall rate, AP value and P-R curve, which are defined as follows. For the test results, there may be four situations between the predicted value and the actual value: TP, FP, FN, TN. TP and FP respectively indicate that the predicted positive sample and negative sample are true, FN and TN respectively indicate that the predicted positive sample and negative sample are false. Where P in the P-R curve represents precision and R represents recall. The formula are as follows:

$$P = TP(TP + FP)^{-1},$$
$$R = TP(TP + FN)^{-1}. \tag{4}$$

By setting different detection confidence thresholds, different detection results will be generated. The accuracy and recall rate of the detection results of each threshold can be calculated. The recall rate obtained by setting the confidence threshold to the minimum is the maximum recall rate. Calculate the accuracy and recall for each confidence threshold, and then take the recall as the abscissa and the

accuracy as the ordinate to draw the P-R curve, which can well reflect the performance change of the detector. The AP value of target detection can be obtained by calculating the integral of the curve in the interval [0, 1]. The AP value is an important index to measure the performance of target detection. The larger the AP value, the better the performance of the detector.

This article selects two objective evaluation criteria to objectively evaluate the experimental results of this algorithm, one is the percentage of detected joints (PDJ) and the other is the percentage of correct parts (PCP). The specific meaning of PDJ evaluation standard is that for each joint point, when the distance between the predicted position and the real position (calculated by Euclidean distance here) is less than the given threshold, the joint point is correctly located. The PDJ value of each joint point changes with the change of threshold value. The resulting curve depicts the change trend of joint point positioning accuracy, which is called PDJ curve. The specific meaning of PCP evaluation standard is that when the two joint points corresponding to both ends of a human part are correctly positioned, the part is correctly positioned.

4. Experiment and Analysis

4.1. Experimental Setup and Data Set. Based on the video time domain context, the effective fusion of the detection results of different video frames can effectively improve the recall rate of athlete detection, and solve the problem of missing detection caused by motion blur to a certain extent,

but it may also bring the risk of false detection. The optimization strategy of detection results based on time-domain context involves multiple super parameters. In order to ensure the optimization effect, these super parameters need to be set reasonably. The super parameters and value ranges involved are as follows: the value range of adjacent frame interval n is [0, 30], the value range of interframe similarity threshold s is [0, 64], the value range of local similarity threshold D is [0, 64], and the value range of supplementary detection frame confidence threshold T is [−1, 1]. In this paper, the grid parameter search method is used to experiment on NBA basketball video data set to determine the best parameter combination. In order to improve the efficiency of grid parameter search, the computational cost of parameter search can be reduced by removing some obviously unreasonable parameter ranges. According to experience, the search interval and search step of each super parameter are as follows: the search range of adjacent frame interval n is [0, 10], the search step is 1, the search range of interframe similarity threshold s is [0, 10], the search step is 1, the search range of local similarity threshold D is [0, 10], the search step is 1, the search range of supplementary detection frame confidence threshold T is [0, 1], and the search step is 0.1. After continuous parameter search, when the super parameters $N = 3$, $s = 5$, $d = 2$, $t = 0.3$, the sports competition video data set constructed in this paper can achieve good results. Parameter W represents the weight vector in the multilevel graph structure model. The process is as follows:

$$\min_{w}\langle\omega_{ij}, w_{ij}\rangle + \sum C \max\left[0, 1 - y_n\langle w, \Phi(I^n, l^n, t^n)\rangle\right], \quad y_n \in \{0, 1\}. \tag{5}$$

In the above formula, $\Phi(n)$ is the sparse feature of the n-th training image.

In this paper, the grid parameter search method is used to experiment on the data set to determine the best parameter combination. Grid search method is an exhaustive search method to specify parameter values. The optimal learning algorithm is obtained by optimizing the parameters of the estimation function through cross validation. That is, the possible values of various parameters are arranged and combined, and all possible combination results are listed to generate a "grid." Then each combination is used for SVM training, and the performance is evaluated by cross validation. After the fitting function tries all the parameter combinations, it returns an appropriate classifier and automatically adjusts to the best parameter combination. In order to improve the efficiency of grid parameter search, the computational cost of parameter search can be reduced by removing some obviously unreasonable parameter ranges. According to experience, the search interval and search step of each super parameter are as follows: the search range of adjacent frame interval n is [0, 10], the search step is 1, the search range of inter frame similarity threshold s is [0, 10], the search step is 1, the search range of local similarity

threshold D is [0, 10], the search step is 1, the search range of supplementary detection frame confidence threshold T is [0, 1], and the search step is 0.1.

At present, the mainstream human posture data sets used in the research include 2D and 3D. The 2D human posture data sets are shown in Table 2, BBG, and common data sets include MSCOCO, MPII, LSP, FLIC, posetrack and AI challenger.

Leeds sports pose is a sports pose data set, which is divided into sports, badminton, baseball, gymnastics, parkour, football, volleyball and tennis. It contains about 2000 pose notes, and the images are from the athletes of Flickr. Each image is a 3-channel color image, and each image is marked with 14 joint positions, and the left and right joints are always marked with human center. The LSP data set is collected from different motion scenes. Its extended version includes 11000 training samples and 1000 test samples. There are 14 labeled joint point types in the LSP data set, and the LSP data set does not need to be cropped, because the author of the data set provides preprocessed images. In the experiment, only the provided images need to be scaled to a fixed size. Therefore, the human posture estimation data set LSP is selected in this experiment, and other data sets such as

TABLE 2: Human pose estimate datasets.

Dataset	Feature
LSP	The data comes from sports category labels, image zoom, only annotated in each picture-one person, 14 key points
FLIC	Data comes from hollywood movies, 10 key points
MPII human pose	The data comes from YouTube videos, which covers 410 human activities, each image has an activity tag, and 16 key points
MSCOCO	The data comes from the internet, it contains various activities, 17 key points
Al challenge	The data is captured from the internet. It is currently the largest human pose image data set, and 14 key point
PoseTrack	The data comes from the MPII human pose data set and 15 key points
Buffy	The data comes from a TV show. Line segments are provided to indicate the location, and the size and direction of the body parts are also provided

FLIC, MSCOCO and Buffy pose are also used for comparison.

4.2. Evaluation of Multiperson Attitude Estimation Model. Figure 6 shows the loss curve during the training of the three-dimensional attitude estimation network. The training process is 300 rounds in total. It can be seen that the loss function (loss) value shows a decreasing trend with the increase of the number of training rounds, and tends to be stable after 250 rounds, indicating that the model training is gradually convergent.

We use a graph neural network algorithm for multiperson human pose estimation. The human posture estimation process is divided into two stages: detection component and positioning component [20]. In the first stage, the specific deep learning network is used as the human part detector to realize the detection function of human parts; In the second stage, a new spatial constraint relationship of human parts is designed to uniquely determine the position of each part from the candidate box of human parts, realize the positioning function of joint points, and finally complete the estimation process of human posture. In order to objectively verify the role of the component detection model based on graph neural network and the designed human component spatial constraint model in the whole algorithm, experiments on controlling a single variable are carried out on FLIC and Buffy databases, which can represent the overall performance of the traditional attitude estimation method. Green curve is the average PDJ curve obtained by hiding the spatial constraint model of human parts and directly taking the rectangular box position corresponding to the highest score probability vector output by fast R-CNN as the positioning result of human parts; The red curve is the average PDJ curve obtained by the algorithm. Comparing the green curve and purple curve longitudinally, it can be concluded that compared with the traditional methods, only using deep learning network to solve the problem of human posture estimation from the perspective of target detection has great advantages in positioning accuracy. In addition, as can be seen from Figure 7, both the component detection model based on fast R-CNN and the proposed human component spatial constraint model contribute to the final realization of accurate human pose estimation results.
FIGURE 6: Loss curve of human posture estimation network.
FIGURE 7: Running time comparison of human pose estimate.

In order to test the running time of this algorithm in the process of 3D human body pose estimation, this algorithm is compared with literature [20] and literature [21] under the same software and hardware conditions. The results are shown in Figure 7. The average time per frame of algorithm [20] is 32.801 s, because the model mainly matches the SMPL model with two-dimensional joint points based on parameter optimization, and the optimization process takes a lot of time; SMPL needs to consider not only the basic
Figure 8: PDJ curve comparing this algorithm with other algorithms on VIPS-VideoPose database.

Table 3: Comparison of PCP value results between this algorithm and other algorithms on vipsvediopose.

Methods	Algorithm (%) [20]	Algorithm (%) [21]	Algorithm (%) [22]	Algorithm (%) [23]	Ours (%)
Neck	78.1	62.8	78.2	57.8	87.1
Elbow	80.9	69.3	79.4	54.7	88.2
Shoulder	91.7	83.3	90.5	34.2	95.1
Wrist	65.4	84.2	93.2	78.5	92.7
Waist	63.8	83.0	92.5	81.0	95.9

human body configuration, but also whether the joint density can control the movement of points. Therefore, when there are no obvious joints in the chest, several joints are added, while the number of joints on the hand is less. For better manikin expression, SMPL adds more points to finer parts, such as fingers. According to the area of normal people, there should be fewer points, but this is unfavorable to SMPL model. The average time per frame of algorithm [21] is 6.281 s. The model combines a large number of 3D attitude prior constraints and 2D data sets, so its attitude estimation has high efficiency; The average running time of each frame of the algorithm in this paper is 1.115 s, in which the process of two-dimensional human posture estimation takes an average of 0.015 s, and the process of three-dimensional SMPL model parameter estimation and three-dimensional joint point calculation takes an average of 1.10 s. The fully connected network structure design proposed in this paper saves a lot of model calculation time, improves the accuracy and maintains high efficiency.

4.3. Results of Comparative Experiments. In order to further illustrate the effectiveness of the algorithm in the field of human posture tracking, the performance of the algorithm is compared with four methods in videopose2.0 and VIPs Videopose databases. The four mainstream methods selected include: (1) the improved method of

graph model in document [21], (2) the model proposed in document [22], (3) the extensible model proposed by document [23], and (4) the hybrid component model proposed in document [24]. In order to ensure the comparability of the experimental results, the training or test of the above four methods are exactly the same as that of the algorithm.

Generally speaking, the PDJ and PCP values of each algorithm when detecting the head are basically close to the real values, so the positioning results of these two joint points are not recorded in this experiment. This experiment only counts the positioning accuracy of 6 joint points and 4 parts (upper and lower arms) on videopose 2.0 and VIPs videopose databases. Figure 8 shows the PDJ curve of this algorithm and the above four methods on VIPs Videopose database. As can be seen from Figure 8, the algorithm adopted in this paper is higher than the conventional algorithm in the positioning accuracy of each joint point, and can obtain better human posture tracking effect. In particular, for the wrist joint points most concerned in the process of human posture estimation, the positioning accuracy of this algorithm is significantly higher than that of the other four methods. For example, taking 30 pixels as the threshold, the wrist PDJ value of this algorithm is 98.3%, which far exceeds the PDJ value of reference [20] 82.1%, reference [21] 84.1%, reference [22] 78.2% and reference [23] 80.1%.

Table 3 shows the comparison results of PCP values of this algorithm and the above four methods (with 30 pixels as the threshold) on VIPs Videopose database. The PCP value of the waist of this algorithm is 95.9%, which far exceeds the PCP value of 63.8% in reference [20], 83.0% in reference [21], 92.5% in reference [22] and 81.0% in reference [23]. It is confirmed that the algorithm still maintains good positioning accuracy on VIPs videopose.

5. Conclusion

In this study, the structure of traditional neural network is improved. In order to study the posture estimation of multiple people in sports competition video, a human posture estimation algorithm based on graph neural network is adopted by using Multi level characteristic diagram. After statistics of 6 joint points and 4 parts on VIPs videopose database show that the graph neural network algorithm can complete the positioning function of human parts, so as to achieve accurate human body tracking effect. Comparing the PDJ curves and PCP values of varIoUs algorithms, it can be seen that the algorithm based on graph neural network greatly improves the positioning accuracy of varIoUs parts of the human body compared with other algorithms. Therefore, when applied to athlete posture tracking in sports competition video, this method can effectively estimate the posture of multiple people.

In order to walk in a physical environment, the biped will encounter various external disturbances, and walking under persistent conditions is still challenging. This paper tries to improve the push recovery performance based on capture point (CP) and model predictive control. The trajectory of zero moment point (ZMP) and center of mass are solved and predicted in a limited time horizon. Online footprint generator is combined with MPC walking pattern generation, which can keep biped stable in the next few steps, and projection of ZMP is used to calculate the next footprint and reach the target CP in an incremental way. Verification of the proposed stable biped walking method is conducted by simulation and experiments.

1. Introduction

tBiped robot is one kind of mobile robot and belongs to the field of leg robot. In the world of robotics, biped walking is one of the fields with the most interesting research [1]. Robots need to interact and collide intermittently with the environment to complete specific actions and tasks [2]. Compared with other forms of robots, biped robot has more advantages: the biped with a humanoid structure can adapt to various environments, and it can replace humans in many dangerous jobs and offer services for humans, such as artificial limb and medical rehabilitation [3].

The biped robot model is nonlinear dynamic with multiple degrees of freedom and constraints, and it is important to interpret and predict the long-term behavioral trends of the dynamic system for various control tasks. A simplified biped walking linear inverted pendulum model (LIPM) is the baseline of humanoid walking pattern controller [4, 5], and passive walking and under-actuated robots have certain advantages in energy-saving walking. But passive walking has poor terrain adaptability and can only

walk downhill or on flat ground; while under-actuated walking robots require special structural design and rely on complex walking control strategies [6]. Zhang et al. [7] proposed a walking pattern generator for omnidirectional walking on a slope and uneven plane and realized the oblique walk and heading for any direction, but the performance of push recovery under external persistent force is not analyzed. Oliver et al. proposed an improved model named the flexible linear inverted pendulum model (FLIPM) which integrate damped spring and second center of mass to LIP [8], which realized a stable walk on a servo-driven biped robot. However, the performance is only improved in the z direction, which is not included by FLIPM and causes a rotation of the root alongside the x-axis towards the ankle joint lifting up from the plane. Biped robot has dozens of degrees of freedom and no fixed base, which leads to its dynamic system is very complex. Juang et al. proposed the fully connected recurrent neural network optimized by continuous multiobjective ant colony optimization to form CpG to solve the multiobjective gait generation problem of Nao robot. An open-source multiple DOF servo-driven

robot Robotis op [9] is used to test their method performance, but the coupled oscillator model is not able to keep stability under an unpredictable perturbation.

In the process of walking, the biped robot will inevitably be affected by various uncertain factors, such as the uncertainty of mathematical model based on different assumptions [10], the uncertainty of robot system parameters caused by the structural size, material properties, manufacturing and assembly errors, and the random uncertainty of driving torque caused by actuator noise and joint friction, and the external environment disturbance and plane condition uncertainty in the process of robot walking [11]. Pratt et al. [12] introduced the concepts of capture point and capture area by LIPM and flywheel model, and CP is the key metric for push recovery of the biped which shows the target direction to maintaining body stability by keeping center of pressure (CoP) inside the foot support area. But how the capture region adapts with other biped models is not discussed. Majid et al. generate walking patterns for the biped by two stages: computes the best step location and duration and adapts these values using divergent component of motion (DCM) measurement. Englsberger [13] designed CP following and CP step-end controller and has proved the antipush stability of CP control principle, but real-time footprint position adjustment is not included to enhance the robustness of the walking pattern against external perturbations. Since the large number of joints, it is very complex to use CPG model to describe the joint angle for the 3D humanoid robot. Q-learning-based CPG model [14, 15] can keep the body recover from horizon perturbation, but it need different expertise to redesign the controller. In addition, the motion obtained by this gait control method is generally not optimal, and the anti-interference in vertical direction ability is poor.

Humanoid walking pattern generation can be solved by model predictive control (MPC) with efficient constraint handling [16]. The optimization-based method is utilized so as to generate, at each iteration, the optimal gait trajectory of the system satisfying the given constraints. However, it is well known that the action of a bounded persistent disturbance can destabilize a predictive controller which has been designed to be stabilizing for the nominal case [17]. These controllers can be used with a cost function that at the specific problem of generating trajectory by quadratic programming in linear system control, a fast optimization algorithm is proposed. However, several papers like [18–20] used restrictions on model state at the end of the prediction horizon. Since the state of the system is completely dependent on the beginning and the end of the horizon, motions lack the flexibility to perform secondary control objectives. Amos et al. [21] proposed the strategy architecture designed for end-to-end training, the robot learned to combine high-level planning strategy with low-level motion controller to realize autonomous navigation on a curved path, which is less computationally and memory intensive compared to traditional optimization solutions, but the model used in that article is still linear which is hard to extend to complex systems like the biped walking. Scianca et al. [22] introduced an IS-MPC framework for gait generation which extend LIPM with ZMP trajectory input, and recursive feasibility of internal stability is realized for biped dynamics, but the cost of control and response speed of method are not analyzed for position control based humanoid robot [23].

The gait trajectory planning method based on LIP does not consider the external interference force, so it cannot walk in a contact-rich environment. The gait pattern generator can only calculate the trajectory position at the next time according to the state transition equation but cannot predict the trajectory in the future. This paper proposes footprint planning and MPC method for stable biped walking considering the capture point principle. The framework of the method is summarized in Figure 1. LIPM is used to linearize the dynamic model of biped walking, and MPC is used as a gait pattern generator to generate a smooth trajectory of CoM. Online footstep generator based on capture point feedback is combined with the MPC controller, and the biped can take one or more steps to reach the stable state and realize omnidirectional walking on the horizon plane. And a projection function maps the target ZMP into support polygon which makes inverse kinematics is solvable.

2. Materials and Methods

2.1. Approximation of Walking Model. Approximation acts effective method to deal with complex systems. Most humanoid robots use the model-based walking planning method to get the gait pattern and abstract the biped dynamics equation from the model by approximating the center of mass (CoM). The classical inverted pendulum model is widely used for humanoid walking pattern generation. Some conditions are mentioned first as follows:

(1) Whole-body mass of the robot is concentrated on the CoM.

(2) CoM height h_{CoM} in 3-dimensional space is invariant.

(3) Biped legs are massless and contact with the ground through a pivot that can be rotated.

Under the joint action of the supporting moment and the force along the stretching direction of the rod, the dynamic equation of LIPM is established, and the trajectory of the CoM is obtained by solving the dynamic equation. Using the LIPM, let p denote the position of the center of pressure (CoP) on the plane, and the horizontal dynamics differential equation of CoM is

$$\ddot{x} = \omega_0^2 (x - p), \tag{1}$$

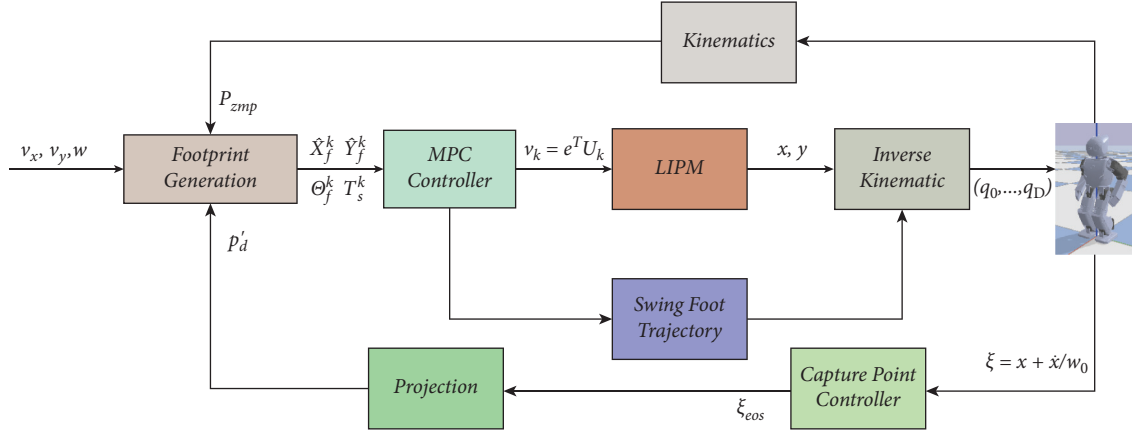
where $w_0 = \sqrt{g/h_{CoM}}$ and g is gravity force, and h_{CoM} is the constant height of CoM along z-axis. x denotes the position of CoM along x-axis, and $\ddot{x}$ denotes body acceleration. This approximation (1) decouples the sagittal and coronal motions of the biped robot, so we will focus on the x-axis motion throughout this paper, and y direction motion is totally identical.


FIGURE 1: Block scheme of the proposed CP- and MPC-based framework for walking gait.

Considering the discretization at a minimum interval time T, CoM, and CoP are discretized. Let input control signal $u(t) = \dddot{x}$ which is the jerk of CoM position in state-space equation, then the system state transition at time $t = kT, k = 1, 2, \ldots$ with notation

$$\widehat{x}_k = \begin{bmatrix} x(kT) \\ \dot{x}(kT) \\ \ddot{x}(kT) \end{bmatrix}, u_k = \dddot{x}(kT), p_k = p(kT). \tag{2}$$

From (2), we can get the ZMP position

$$p_k = \begin{bmatrix} 1 & 0 & 1/w_0^2 \end{bmatrix} \widehat{x}_k. \tag{3}$$

For the system state $\widehat{x}_k$, the discretized system of LIPM is

$$\begin{aligned} \widehat{x}_{k+1} &= \begin{bmatrix} 1 & T & T^2/2 \\ 0 & 1 & T \\ 0 & 0 & 1 \end{bmatrix} \widehat{x}_k + \begin{bmatrix} T^3/6 \\ T^2/2 \\ T \end{bmatrix} u_k \\ &= A\widehat{x}_k + Bu_k. \end{aligned} \tag{4}$$

In the process of bipedal walking, the position of ZMP p_k always falls into the support polygon of the foot, so the range of ZMP can be limited within

$$p_k^{\min} < p_k < p_k^{\max}. \tag{5}$$

The range of ZMP $[p_k^{\min}, p_k^{\max}]$ depends on foot contact condition with the horizontal plane at time kT. According to the state transition (2), the next state at time $k + 1$ is decided by the current state x_k and input control u_k. The core idea of MPC makes the actual ZMP p_k most likely close to reference ZMP trajectory p_k^{ref} at the minimum control cost at time kT. Then, the optimal control sequence $u_k, u_{k+1,\ldots}$ can be get by solving the quadratic problem (QP).

$$\min_{u_k, u_{k+1}, \ldots} \sum_{i=k}^{\infty} \frac{1}{2} \alpha \left(p_{i+1} - p_{i+1}^{ref} \right)^2 + \frac{1}{2} \beta u_i^2, \tag{6}$$

where $\alpha/\beta \, (\alpha > 0, \beta > 0)$ are factors to balance the system response ratio and control cost. If α/β rises, the tacking speed of system and control costs increase. And if α/β is lower, the tracking speed of the system and control costs decrease.

2.2. Capture Point Controller.
For push resistance of the bipedal, instantaneous capture point (ICP) was utilized. During the motion of a LIP model, there exists a metric point on a walking plane, where placing the center of the landing foot can stabilize the motion of the model. This point can be calculated as

$$\xi = x + \frac{\dot{x}}{w_0}, \tag{7}$$

where ξ is the x or y component of ICP position on plane. Due to the limitation of robot dynamics, when the capture point is not captured, the CP will be away from CoP in a straight line until it falls down that is noted by Figure 2.

The features of the capture point can be described as follows:

(1) Due to the regular dynamics of the robot, if the point is not captured, with time, the ICP moves in a straight line joining the CoP and the CP in a direction away from the foot, as shown in Figure 2.

(2) Zero-step capturability: If the ICP falls inside the support polygon, then the robot can balance itself with the application of a good control like MPC; however, if the ICP falls outside the support polygon, the robot will have to take at least one step to protect itself from falling down.

(3) One-step capturability: The model can come to stability within a step if the ICP falls within the reachable range. The reachable region is bounded by the maximum step length.

According to equation (1) and equation (7), the dynamic relationship between CP and ZMP is

$$\dot{\xi}_x = w_0 \left(\xi_x - p_x \right). \tag{8}$$

Since the pole of transition function is w_0, equation (7) is an unstable system without external additional input. The idea of CP control is to generate the ZMP trajectory so that the current CP reaches the target CP within a given time interval, and then, the CoM follows the planning CP curve. The solution of equation (7) in the time domain is
FIGURE 2: Top view of the LIPM with point foot for a given initial state.

$$\xi_x(t) = e^{\omega_0 t}\left(\xi_{x,0} - p_x\right) + p_x, \tag{9}$$

where $\xi_{x,0}$ is the initial position of CP. It can be seen that when ZMP p_x is constant, CP will change exponentially. Let $\xi_{x,d}, \xi_x$ represent the target CP and current CP, respectively, and time from $\xi_{x,d}$ to ξ_x is dT, and then, (9) can be discretized as

$$p_x = \frac{\xi_{x,d} - e^{w_0 dT}\xi_x}{1 - e^{w_0 dT}} = \frac{1}{1 - e^{w_0 dT}}\xi_{x,d} - \frac{e^{w_0 dT}}{1 - e^{w_0 dT}}\xi_x. \tag{10}$$

The goal of end-of-step CP controller: ZMP trajectory is generated by $\xi_{x,d}$ and variable time span dT. Let $\xi_{x,eos}$ represent the end of step at the ending of each foothold, and $\xi_{x,d} = \xi_{x,eos}$. Suppose the center of the support foot is approximately regarded as the ZMP point p_i at step i, and the initial CP is

$$\xi_{init,i} = p_i + \left(\xi_{eos,i} - p_i\right)/e^{w_0 t_{step}}, \tag{11}$$

where t_{step} is the duration of each step. Iterative relation of CP state is $\xi_{eos,i-1} = \xi_{init,i}$. When the robot is subjected to external thrust, CP changes suddenly, and the biped needs to replan the landing footprint so that the CoM is adjusted to ξ_{eos}. According to the iterative relationship (11), the CP position in each support leg cycle can be calculated. Then, the system reaches a stable state following the new reference ZMP sequence generated by the CP controller.

ZMP reference trajectory is a continuous curve and constrained by robot dynamics of support polygon. When the system is disturbed by a large external force, CP varies fast out of feet support polygon on the plane. If p_x is calculated by (11), $\hat{p}_d$ might locate out of support polygon. And the incremental progressive method can be adopted for ZMP, and CoM is controlled to move along the target CP direction within the current support polygon. Formula (9) is differentiated as follows:

$$d\xi_{eos} = \frac{\partial \xi_{eos}}{\partial p_d} = \left(1 - e^{w_0 dT}\right)dp_d,$$

$$\Delta\xi_{eos} = \int d\xi_{eos}dt. \tag{12}$$

A method to implement the incremental integration (12) is the ZMP projection as shown in Figure 3. If the projection is not applied, p_d from (11) could beyond the support
FIGURE 3: Projection of p_d in support polygon.

polygon, and the CoM trajectory generated by p_d will cause falling on the ground.

As Figure 3 shows, we found a new projection ZMP p_d' in support polygon to make CoM follow the target direction of CP. The projection rules can be summarized as follows:

   (i) If p_d is located in support polygon, the target ZMP p_d is in the reachable region of the biped, then projection ZMP $p_d' = p_d$.

   (ii) If p_d is located outside the support polygon, p_d' is the closest point on the inner boundary of the support polygon to $(\xi_d - \xi)$.

In practical application, the number of reverse iterative footprint calculation F is limited. Based on the current foothold p_i and initial CP $\xi_{init,i}$, the position of ZMP can be solved on a limited horizon F. CoM mapping is used to make the CoM approach the target position. But as 3 shows, there is a discontinuity between current p and $p_d' = p_d$ which leads to discontinuous input to the walking pattern generator. To compensate for this problem, the MPC controller is introduced in the next section to track the CP trajectory on the one hand and export smooth CoM trajectory, so that the biped will not lose stability due to the sudden change of dynamic parameters in the process of walking.

2.3. Footprint Generator with Variable Velocity.
The footprint generator module and MPC controller module are implemented synchronously. The input of the footprint generator is reference velocity v_x, v_y and angular velocity w around the z-axis. The output of this generator is the next

footprint position, direction, and time. With the change of input reference velocity, the cycle and step length of biped walking will be affected, and the footprint generator calculates the next foothold position by solving the quadratic optimization problem. The time and orientation of the foothold of the output of the footprint generator will be used as the reference input of the MPC controller in the next step.

As shown in Figure 1, the input of the footprint generator is v_x, v_y, w from time t_k to $t_{k+P} = t_k + T_p$, where T_p is the duration of the footstep. The output of the footprint generator is the sequence $(\widehat{X}_f^k, \widehat{Y}_f^k, \Theta_f^k)$ on time sequence $\mathcal{T}_s^k$, and

$$
\begin{aligned}
\widehat{\mathbf{X}}_f^k &= \left(x_f^1 ... x_f^F \right)^T, \\
\widehat{\mathbf{Y}}_f^k &= \left(y_f^1 ... y_f^F \right)^T, \\
\Theta_f^k &= \left(\theta_f^1 ... \theta_f^F \right)^T, \\
\mathcal{T}_s^k &= \left\{ T_s^1, ..., T_s^F \right\},
\end{aligned}
\tag{13}
$$

where F is the number of next footprints, and $(x_f^j, y_f^j, \theta_f^j)$ is the position and orientation of j-th footprint. T_s^j is the duration from $j-1$-th to j-th footprint. Since the input velocity is variable, the prediction horizon of time T_s is constant, and $\sum_{j=1}^{F} T_s^j = T_p$, and then, distribution of $(x_f^j, y_f^j, \theta_f^j)$ is nonequidistant during T_p.

Assume that the biped is within the j-th support phase switching duration T_s^j, $\overline{v}$ is average velocity, $\overline{T}_s$ is step period duration, and $\overline{L}_s$ is stride length, so $\overline{v} = \overline{L}_s / \overline{T}_s$. Walking velocity is limited by the biped dynamics such as CoM height, degree of freedom, and leg length. $\overline{v}$ is determined by both T_s^j and $\overline{L}_s$. Δv is velocity small variation in Δt, and then,

$$
v = \overline{v} + \Delta v = \frac{\overline{L}_s + \Delta L_s}{\overline{T}_s - \Delta T_s},
\tag{14}
$$

where $\Delta L_s = \gamma \Delta T_s$, and (14) can be expressed as

$$
T_s = \overline{T}_s \frac{\gamma + \overline{v}}{\gamma + v}.
\tag{15}
$$

Let $\overline{v} = 0.01 m/s$, $\overline{T}_s = 0.8 s$, and the relationship between velocity and duration can be shown in Figure 4.

During a small time interval δt, velocity can be approximately regarded as a linear variation. Therefore, the orientation angle of the robot can be approximately constant, and angular velocity is ignored in (14).

Considering time sequence $t_1^j, t_2^2, ..., t_s^F$ iterative relation, the time iterative equation within $[t_k, t_k + T_p]$ is

$$
t_s^j = t_s^{j-1} + \overline{T}_s \frac{\gamma + \overline{v}}{\gamma + v \left(t_s^{j-1} \right)},
\tag{16}
$$

where t_s^0 is the end time of the last support leg duration, and the iteration is over when $j > k + P$. Then, a time sequence $\mathcal{T}_s^k = \left\{ T_s^1, ..., T_s^F \right\}$ is outputted with $T_s^j = t_s^{j+1} - t_s^j$.

According to the omnidirectional motion model of a mobile robot, the bipedal moves to the target point at any angle and direction in the horizontal plane with v_x, v_y, w.
FIGURE 4: Rules for step duration T_s and velocity $\overline{v}$, and comparison of different γ.

$$
\begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{\theta} \end{pmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} v_x \\ v_y \\ \omega \end{pmatrix}.
\tag{17}
$$

The idea of the footprint generator is to allocate the future foothold under the condition of considering the constraints of kinematics and dynamics parameters of the biped in time $\mathcal{T}_s^k = \{T_s^1, ..., T_s^F\}$. When the body root is subjected to push forces, according to (7), $\dot{x}$ will change suddenly, which will affect the planned trajectory of x. The velocity and acceleration change suddenly, which affect the planning trajectory of CoM. The position of the foothold need be adjusted to make the CoM as close as possible near new CP so that the CoM can keep a gradually stable state.

The footprint planning can be transformed into two QP optimization problems as follows:

$$
\left\{ \min_{\Theta_f^k} \sum_{j=1}^{F} \left(\theta_f^j - \theta_f^{j-1} - \int_{t_s^{j-1}}^{t_s^j} \omega(\tau) d\tau \right)^2 st. \left| \theta_f^j - \theta_f^{j-1} \right| \leq \theta_{\max},
\right.
\tag{18}
$$

where $\theta_{\max}$ is the maximum steering angle allowed for two consecutive footprints according to the physics dynamics of the biped. And the second QP problem is

$$
\min_{\widetilde{x}_f^k, \widetilde{r}_f^k} \sum_{j=1}^{F} \left(\widehat{x}_f^j - \widehat{x}_f^{j-1} - \Delta x^j \right)^2 + \left(\widehat{y}_f^j - \widehat{y}_f^{j-1} - \Delta y^j \right)^2.
\tag{19}
$$

where the supporting foot position is $(\widehat{x}_f^0, \widehat{y}_f^0)$ at the starting time t_k. The output of the footprint generator $(X_f^k, Y_f^k, \Theta_f^k)$ is the input of the MPC controller, and the final ZMP and CoM trajectory is calculated by MPC. Figure 5 shows an example of footprint generation where the orientation of the robot coincides with the tangent of the motion path. The swing foot trajectory planning is simple, and in order to avoid sudden changes in the velocity of end point, we use Bezier curves to generate swing foot trajectory and then solve the joints rotation by inverse kinematics.
FIGURE 5: Candidate footsteps generated by the footprint generator in half circle demonstrate the omnidirectional feature.

2.4. MPC Controller. Predictive control approximates the robot to a three-dimensional linear inverted pendulum, introduces the state space method, optimizes the performance index by the linear quadratic regulator, and limits the movement of the CoM in the horizontal plane with constant height. The state feedback gain and predictive gain of the predictive controller are generated by solving discrete algebraic Riccati equations. Due to the consideration of state feedback, error feedback, and future target information, a stable walking mode can be generated with less computation.

The system only performs prediction of MPC controller at kT, then measures the actual state $x, \dot{x}$ of the system as feedback by LIPM, and calculates the optimal control by solving QP. N represents the prediction horizon of the MPC controller, and equation (6) can be rewritten within $[kT, (k + N)T]$.

$$\min_{u_k,\ldots,l_{k+N}} \sum_{i=k}^{k+N-1} \frac{1}{2}\alpha\left(p_{i+1} - p_{i+1}^{ref}\right)^2 + \frac{1}{2}\beta u_i^2. \tag{20}$$

The above equation (20) is solved by solving complex algebraic Riccati equation in [5], but this method has low computational efficiency. Within MPC prediction horizon, equation (4) can be transformed to matrix operation. The state transition equation is rewritten with length N as

$$\begin{bmatrix} p_{k+1} \\ \vdots \\ p_{k+N} \end{bmatrix} = \begin{bmatrix} 1 & T & T^2/2 - 1/w_0^2 \\ \vdots & \vdots & \vdots \\ 1 & NT & N^2T^2/2 - 1/w_0^2 \end{bmatrix} \hat{x}_k$$

$$+ \begin{bmatrix} T^3/6 - T/w_0^2 & 0 & 0 \\ \vdots & \ddots & 0 \\ \left(1 + 3N + 3N^2\right)T^3/6 - T/w_0^2 & \cdots & T^3/6 - T/w_0^2 \end{bmatrix}$$

$$\times \begin{bmatrix} u_k \\ \vdots \\ u_{k+N-1} \end{bmatrix}, \tag{21}$$

And (21) can be abbreviated as

$$P_{k+1} = Q_x \hat{x}_k + R_u U_k. \tag{22}$$

According to (20), the QP equation can be represented as

$$\min_{x_k} \frac{1}{2}\alpha\left(P_{k+1} - P_{k+1}^{ref}\right)^2 + \frac{1}{2}\beta U_k^2, \tag{23}$$

And a standard QP form can be generated by substituting (22) into (23)

$$\min_{U_k}\left[\frac{1}{2}\left(\alpha R_u^2 + \beta\right)U_k^2 + \alpha\left(Q_x\hat{x}_k R_u - P_{k+1}^{ref}R_u\right)U_k\right]. \quad (24)$$

According to the definition of MPC, u_k at the current moment is the first prediction of MPC prediction trajectory; that is,

$$u_k = e^T U_k, \quad (25)$$

where $e^T = [1, 0, ..., 0]^T$, and according to the state formula of LIPM (4), the trajectory of x and output position of ZMP at the next moment are calculated as

$$\hat{x}_{k+1} = A\hat{x}_k + Bu_k = A\hat{x}_k + Be^T U_k. \quad (26)$$

Within the predictive horizon NT, a balance between response speed and control cost of system can be found by adjusting $\alpha/\beta\,(\alpha > 0, \beta > 0)$, and in this article, $\alpha/\beta = 10^{-5}$. When the system and environment models are well known, NT can approach infinity. But LIPM model itself is a linear approximation to the walking dynamics of biped robot with systematic model errors, and environment cannot be accurately modeled. So prediction horizon could not be infinite. In fact, when N increases, the gain of the system is close to 0, which means that the influence of the predicted future value on the stability of the current system is reduced, but it will significantly decrease the computational efficiency of QP calculation. Therefore, this paper sets the MPC control horizon to $NT = 1s$.

3. Results

The performance of the proposed dynamic balance control framework in Figure 1 is proved by simulation experiment, we present simulation results using the LIPM and MPC simulation in bullet environment, the input velocity is constant, the single leg support phase time is constant $t_{sup} = 0.5s$, supporting leg switching time $t_{sw} = 0.33s$, MPC horizon $N = 30$, and the minimum control frequency is 100 Hz. The external push force $f_{ext} = 0$, and the robot is not subject to external interference, so that walks along a straight line with $N_{step} = 6$, and according to the foothold generator, the robot's foothold position is shown in Figure 6.

Since the LIPM is decoupled from each other in X and Y directions, body CoM and ZMP are solved separately by the MPC controller, as is shown in Figure 7. Although there is slight noise jitter in the output ZMP trajectory, the CoM maintains smooth transition, and there is no big speed mutation when the support legs are exchanged. Therefore, the MPC method has good tracking performance.

For the omnidirectional walking, Figure 5 shows velocity direction of walking can be changed in real time by the footprint generator, and $\theta_{max} = \pi/4$. The robot walks around the center of the circle along with a radius of 2m. The system receives high-level control input v_x, v_y, w, and the optimization problems (18)and (19) is solved at each step. By
FIGURE 6: The CoM and ZMP trajectory when walking in a straight line $N_{step} = 6$.
FIGURE 7: When walking in a straight line, the CoM in the X direction (up) and Y direction (down) and ZMP trajectory.

solving the inverse kinematics, the next step foothold rotation is realized by the hip joint rotation; thus, the omnidirectional walking on the horizon plane of the biped is implemented.

The performance of the proposed method is measured in case of external disturbance in x-y plane, as shown in Figures 8–11. An instantaneous external thrust $f_{ext} = 10N$ is added to the CoM of the robot between 4s and 5s, that duration is 0.01 s. It can be seen that the system can adjust the foothold position in 1 step in both directions and be stabilized.

Since the interference of external thrust, the biped will deviate from the predetermined trajectory, but the velocity and direction of biped walking can be changed in real time, and the system has the ability to adjust the input parameters to make the biped walking towards the target position.

4. Conclusions

At the first, a simplified LIPM is used to linearize the dynamic model of biped walking, MPC is used as a gait pattern generator to keep dynamics and kinematics feasibility, and CoM and ZMP trajectory of the biped is solved and predicted in a limited horizon. Since the bipedal system is an unstable system, it is easy to be disturbed by external thrust, resulting in system instability and falling down. Therefore, this paper designs a bipedal balance control method considering capture point with MPC controller, which realizes the footprints planning with variable speed, so that the robot can walk in omnidirectional directions on the plane. At the same time, the capture point parameters of the system are introduced as feedback. When the system is disturbed by external thrust, the acquisition point will change suddenly. By controlling the ZMP point trajectory, the centroid can track the direction of the capture point, and the system will walk to keep it stable. However, CP may fall outside the support polygon. We use a projection method to make the next landing footprint always fall in the range of the biped reachable area and reach the target CP in an incremental manner. For solving the problem of ZMP input point discontinuity caused by projection, the system uses the MPC method to predict the smooth trajectory curve of centroid in the future according to the new foothold position. The position of joint of the full body is calculated by inverse kinematics and drives the biped realized stable walking.

We only focus on the dynamic walking of bipedal on the horizontal plane. It is necessary to analyze the dynamic walking of bipedal on the nonstationary ground and extend the planning of foothold in a two-dimensional plane to three-dimensional space. On the other hand, the gait pattern generator is mainly a linear inverted pendulum model, which is an approximation of bipedal walking and can not plan complex action behavior. And there will be some improvements in the system approximation model, and a more accurate dynamic and environmental model will be used to predict and analyze the robot's future actions and behaviors.

Atmospheric turbulence is an intrinsic factor that causes uncertainty of wind speed and its power generation by wind turbine. The research of atmospheric turbulence characteristics of wind farms can be used to reduce this uncertainty. In this paper, enough measurement data getting from actual wind farms is used for information processing to quantitatively analyze the daily variation of wind speed and its power output characteristics. Furthermore, the concept of spatiotemporal diurnal modulation characteristics of atmospheric turbulence is proposed with a global scope, which is an intrinsic property of wind. Besides the daily variation characteristics, the average hourly wind speed has a short-term modulation effect on its turbulence and provides a modulation characteristic on wind speed uncertainty. Moreover, the long-term modulation process is affected by seasonal and regional factors, indicating that it has spatiotemporal characteristics. This atmospheric turbulence characteristic has similar effects on characteristic description parameters. However, the characteristics description parameters of wind speed and wind power variation fail to reflect such intrinsic characteristics that are not affected by the spatiotemporal diurnal modulation characteristics of atmospheric turbulence. This indicates that they do not have diurnal characteristics. Finally, a time-varying model combined with the spatiotemporal diurnal modulation characteristics of wind speed and its power generation is discussed by applying on the evaluation of frequency control in power systems. It is shown that the results obtained by measured data processing could improve the power generation quality of large-scale wind power effectively.

1. Introduction

As one of the renewable resources, wind energy is being used worldwide. Researchers from various countries have carried out lots of work on the current status and future of wind power in their countries [1–6]. Development of wind power from the viewpoints of political, social, and technical issues was analyzed in [7]. In China, wind power is the leading energy development sector under the low-carbon development policy, while a series of wind power development plans were drawn up by the government [8–10].

However, the uncertainty in wind speed poses challenges for the utilization of wind power [11–13]. In addition to randomness and volatility, intermittency is another problem that plagues the large-scale application of wind energy [14]. A series of strategies and paths covering the source sides, grid sides, and load sides have been studied and explored to use large-scale wind power safely and efficiently [2, 5, 15]. In [16], China's feed-in tariff mechanism for large-scale wind power is shown. Moreover, the characteristics of Chinese energy structure determine the developmental path of rapid and deep peak regulation of thermal power [17, 18]. Several novel methods were proposed for wind power to smooth the output power of wind energy [19, 20].

Considering the uncertainty of wind energy on grid connection, research work focuses on wind power

prediction and how to do global dispatch planning and design by prediction results [6, 21, 22], including data model, physical model, and hybrid model [23–25]. The continuous development of artificial intelligence algorithms has further expanded the scope of its application to new areas [26, 27]. Using data obtained from data-rich farm, high-dimensional data features are obtained through a series of data extraction methods and applied to newly built farm. This transfer learning research is attracting further attention [28].

However, prediction error cannot be avoided due to wind speed uncertainty [29]. Further, quantitative characterization of the wind speed and generated power's persistence and variation is also urgently needed [30]. In view of the physical nature of the random fluctuation of wind speed and the characteristic of wind power, several studies have been carried out on their uncertainty, including instantaneous characteristics (power spectrum), short-period characteristics (daily variation), and long-period statistical characteristics.

In terms of the nature relationships of range to standard deviation of wind fluctuations, the fluctuation variance caused by turbulence is dependent on the mean wind speed per hour [31]. Literature [32] tries to predict the turbulence standard deviation of wind speed. Because of the importance of long-period characteristics, the spatiotemporal complementarity between solar and wind power in the Iberian Peninsula has been researched as the key problem [33, 34]. Additionally, wind speed variance is also an important parameter to characterize wind and turbulence intensity. Turbulence intensity can be used in fan safety design [35–37], life analysis [38–41], and wind farm layout design [42, 43] and, hence, has long been the focus of many researchers.

Although characterization of the wind resource is important [44], the most significant one is the intermittency caused by the inherent instability of atmospheric turbulence. In [45, 46], the measurement and analysis of intermittency for power generation and wind speed were performed based on historical data of wind speed and wind power. Although the intermittent characterization index of wind speed and power has the characteristics of daily cycle, neither the practical application of daily cycle nor the global perspective on the summarized daily modulation has been discussed.

In fact, due to the existence of the diurnal modulation of atmospheric turbulence, the diurnal periodic characteristics are reflected in the average wind speed and temperature [47, 48]. Many factors, such as atmospheric stability [49], time scale [48], near-surface temperature, and turbulence intensity [50], will all influence the wind characteristics. Therefore, modeling and research on diurnal cycle characteristics are also being carried out [51, 52].

In summary, the average wind speed followed by a certain law has been deeply studied presently. Scholars have studied several systematic algorithms on wind speed and its generated power prediction. However, only few studies study on turbulent wind speed due to the uncertainty caused by turbulence, and only a few researchers have conducted studies on turbulence intensity from the application aspects of wind turbines' life analysis and design of wind farm

layout. Although several researches have pointed that the average wind speed, turbulence intensity, and temperature show diurnal characteristics, there is no study that has proposed the intrinsic characteristics of spatiotemporal diurnal modulation of atmospheric turbulence from a global perspective. Furthermore, there is also absence of a systematic analysis of the influences of diurnal modulation on wind speed and wind turbine randomness, volatility, and intermittency based on the essential characterization parameters of its output power.

In this paper, the spatiotemporal diurnal modulation characteristics of atmospheric turbulence and their influence on the indeterminacy of wind speed and power generation are discussed. The rest of this paper is organized as follows: in Section 2, the spatiotemporal diurnal modulation characteristics of atmospheric turbulence are proposed from a global perspective based on the analysis of its physical mechanism. In Section 3, the influence of spatiotemporal diurnal modulation of atmospheric turbulence on wind speed and its power production's random fluctuation range is analyzed based on their corresponding characterization index called the variance. In Section 4, the law of the influence of spatiotemporal diurnal modulation of atmospheric turbulence on the random fluctuation rate of speed is analyzed by variation index. Furthermore, this method is extended to analyze wind power fluctuation rate. In Section 5, the influence of wind speed and wind power intermittency on turbulent spatiotemporal daily modulation is analyzed based on the ramp duty ratio index. Moreover, another wind power intermittency characterization parameter without daily modulation is analyzed by the start/stop frequency of the wind turbines. In Section 6, considering the fluctuation range of wind speed and wind power as examples, the quantitative characterization modeling of the uncertainty and its introduction strategy in the evaluation of real-time frequency modulation capability of power grid are used to explore the feasibility of such spatiotemporal daily modulation characteristics. The seventh section is the conclusion and prospection of the paper.

2. Intrinsic Properties of Spatiotemporal Diurnal Modulation in Atmospheric Turbulence

2.1. Diurnal Modulation and Spatiotemporal Characteristics of Atmospheric Turbulence. Atmospheric turbulence is an intrinsic factor of uncertainty in wind speed and the power output of wind turbine. This uncertainty performance in atmospheric motion is attributed to the random fluctuation of various sizes superimposed by its average wind speed and wind direction. Similarly, it also applies to the power output of wind turbines.

Turbulence is a different kind of motion that takes place in the atmospheric boundary layer (ABL). The factors affecting its formation differ during day and night with apparent diurnal periodic characteristics. Generally, the turbine hub height is in the ABL. The diurnal variation of the sun rising in the east and setting in the west highly

influences the convective motion of the ABL in a flat terrain where surface roughness is uniform. Therefore, diurnal variation can reflect the change in an underlying flat surface in the boundary layer. However, the turbulence intensity in the underlying surface layer of a complex mountainous area is affected by the vortex flow around the local landform, leading to the formation of intense turbulence as well, which is stronger than that caused by sunlight, where diurnal period characteristics are submerged. This influence, especially, is greater when the altitude closer to the ground, leading to a greater turbulence than that at a higher altitude. The diurnal periods of flat areas, such as plains or plateaus, have common features. For example, the time of maximum turbulence intensity is similar. Therefore, the diurnal period has spatiotemporal characteristics, which are derived from the intrinsic characteristics of the turbulence in ABL.

The process of controlling one parameter of a signal with another signal is defined as modulation in communication systems. Based on the influence of the diurnal period on turbulence and wind speed, this diurnal period can be considered as the modulation of wind speed. In other words, the diurnal period is a diurnal modulation process of wind speed caused by a longer weather process, and a diurnal modulation process of the atmosphere is the physical mechanism for the existence of diurnal period phenomenon in the turbulent part of wind speed and wind power. Therefore, several characterization indexes of wind speed uncertainty are affected by spatiotemporal diurnal modulation of atmospheric turbulence, such as the average wind speed of wind farm, the output power of the wind turbines, the random fluctuation part and internal intermittency, and the average temperature (heat flux) of the wind field. However, the descriptive parameters that cannot reflect the inherent characteristics of wind speed are not affected.

2.2. Other Recommendations. The scheduling, control, and planning arrangements in a power system have different time scales. The day-ahead prescheduling planning takes one day as a computation period, while the real-time scheduling and optimization control takes hours as the time scale. These correspond to the 0~24 h day-ahead forecast and 0~4 h ultra-short-term forecast of wind power, respectively. Therefore, if the parameters related to wind power prediction, such as the mean time value of wind speed and wind power, wind power uncertainty, and intermittency, especially for the hourly scale statistic rules, have diurnal modulation characteristics, it will have a guiding significance for the day-ahead prescheduling planning and real-time scheduling of primary and secondary frequency modulation in the new energy power system after large-scale wind power grid connection.

Autocorrelation analysis is a mathematical tool used to find repeated patterns and analyze value functions or sequences of signal processing, such as a periodic signal masked by noise. As for periodic sequences, the autocorrelation sequence shows periodic change [43].

3. Influence Law of Turbulence Diurnal Modulation on Wind Power Random Fluctuation Range

3.1. Quantitative Characterization of Wind Power Fluctuation Range. Generally, the actual wind speed can be divided into hourly average wind speed and turbulent wind speed based on Reynolds averaging. Research results show that the turbulent part of the wind speed depends on the average time strongly. A turbulence intensity model in international IEC standard realizes the wind speed fluctuation range (intensity). Subsequently, a universal model of turbulence intensity was proposed [43], as given by the following equation:

$$TI = \frac{\sigma}{\overline{v}} = \alpha \cdot \overline{v}^{-\beta} + c, \tag{1}$$

where σ is variance of wind speed turbulence; $\overline{v}$ is the mean wind speed per hour; α, β, and c are constants. Similarly, the model of single power and relative variance for wind turbine or wind farm can be established. I_p, the wind power fluctuation intensity, is the characteristic parameter of power fluctuation range [40]. The relative variance is the unit value of the residual fluctuation components after subtracting the mean value from the actual wind power. Based on the wavelet algorithm, the multiscale fluctuation intensity suitable for frequency modulation capability evaluation can be obtained as the minute-scale wind power fluctuation intensity I_{pm} and secondary wind power fluctuation intensity I_{ps}, shown in equations (2) and (3), respectively.

$$I_{pm} = \frac{\sigma_m}{\overline{P}} = \alpha_m \times \overline{P}^{-\beta_m} + c_m, \tag{2}$$

$$I_{ps} = \frac{\sigma_s}{\overline{P}} = \alpha_s \times \overline{P}^{-\beta_s} + c_s, \tag{3}$$

where σ_m is the instantaneous standard deviation of wind power in minute-scale; σ_s is the instantaneous standard deviation of secondary wind power; $\overline{P}$ is the mean wind speed per hour; α_m, β_m and c_m are the fitting constants of minute-scale wind power fluctuation intensity; α_s, β_s, and c_s are the fitting constants of secondary wind power fluctuation intensity.

3.2. The Influence Law on Wind Speed Fluctuation Range. There are many factors that affect the actual wind speed fluctuation uncertainty, and the three-parameter power law model also has a fitting error under certain conditions. The fitting error is defined as follows:

$$e = \sigma - \left(\alpha \cdot \overline{v}^{-\beta} + c\right)\overline{v}, \tag{4}$$

where σ is the residual fluctuation standard deviation of the actual wind speed after eliminating average.

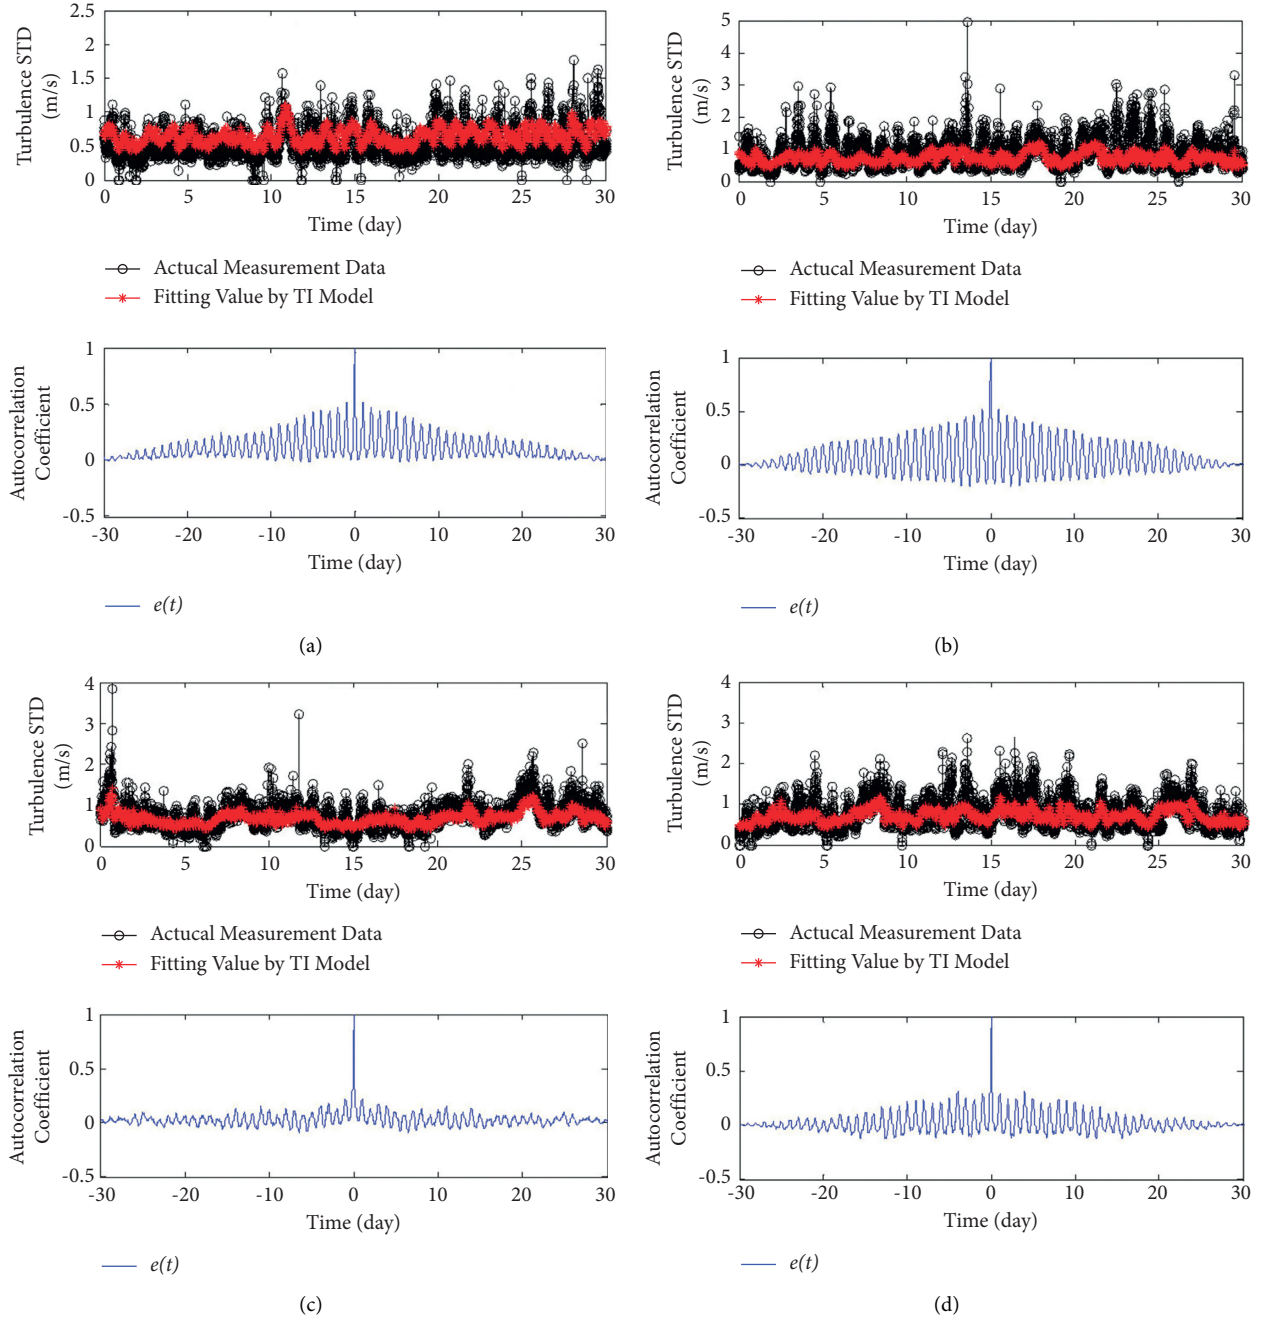
Figure 1 shows the autocorrelation analysis of the fitting error. It can be seen that the fitting error has strong diurnal period characteristics, and the diurnal period change pattern is different for the four seasons.


FIGURE 1: The fitting error of the model and its diurnal period pattern. (a) Wind data in spring. (b) Wind data in summer. (c) Wind data in autumn. (d) Wind data in winter.

There is an obvious diurnal periodic change pattern of turbulence intensity combining the above analysis. Figure 2 shows the variation law of the model parameters within 24 h obtained by fitting the data in Figure 1. It indicates that the model parameters are variable throughout the daily cycle, and the differences are relatively large, which cannot be ignored.

Viewing from the perspective of wind turbine scheduling and controlling, the average turbulence intensity is defined by the effective section in the middle of the cut-in/cut-out speed of the universal fan. As shown in

Figure 3, the average turbulence intensity in the wind speed section, ranging from 3 m/s to 25 m/s, corresponds to the hub height of the fan. The calculation used is shown in the following equation:

$$\bar{I} = \frac{1}{n} \sum_{i=1}^{n} I_i, \tag{5}$$

where I_i is the turbulence intensity corresponding to the average speed range from 3 m/s to 25 m/s; n is the number of samples within the average speed range from 3 m/s to 25 m/s.
FIGURE 2: Model parameter variation within 24 h.
FIGURE 3: The hub height's average turbulence intensity.

Figure 4 shows the diurnal period variation pattern of different wind speed turbulence intensities obtained by the fitting model. Figure 5 shows the diurnal period patterns of different wind speed turbulence intensities obtained from the measured data. All of them prove the existence of the diurnal period change pattern of turbulence intensity.

Figures 6(a)–6(c) show seasonal and monthly variation patterns of turbulence intensity in diurnal period, including diurnal variation patterns of turbulence intensity in four seasons and twelve months. It can be seen that the diurnal period pattern of turbulence intensity in this region is affected by the season and month. Generally, the average turbulence intensity is the highest in spring and the lowest in winter. The maximum value of average turbulence intensity in a single month occurs in May and September. In terms of the 24 h variation in a day, the maximum value occurs around 14 : 00~15 : 00, and the minimum value occurs around 20 : 00 of the same day~08 : 00 of the next day. The maximum value occurs earlier in winter compared to other seasons.

All the investigated wind farms were located in typical areas of northern China, but the diurnal cycle patterns of the actual offshore wind farms were different. Land turbulence intensity whose driving energy is predominantly from the sun has a diurnal cycle variation pattern, and the difference is mainly due to the difference in light intensity and illumination time during different seasons and months. It means that the diurnal modulation of atmospheric turbulence has spatiotemporal characteristics.

To further illustrate the issue, the one-year data from three wind farms in different regions are analyzed based on effective average turbulence intensity parameters. Figure 6(d) shows the diurnal characteristics of average turbulence intensity in different regions. The diurnal cycle patterns of three wind farms differ with the time and location. The main reason for this is the wind farms located in the different latitudes and longitudes. It means that the time of sunrise and sunset is different, resulting in a time deviation of the maximum value.

As shown in Figure 7, the influence of the sunshine on the diurnal variation is weakened by complex topography and varied surface roughness. Figure 8 shows the maximum value of the average turbulence intensity corresponding to the fan at the lowest altitude is nearly twice that of its maximum value corresponding to the fan at the highest altitude. Therefore, complex topography has a great influence on the average turbulence intensity. The lower the altitude, the greater it is affected by topography and roughness. However, literature [43] does not elaborate on these aspects.

3.3. The Influence Law of Turbulence Diurnal Modulation on Wind Power Fluctuation Range. The diurnal cycle characteristics of wind power fluctuation intensity are not mentioned in the existing literature. Figure 9 shows the diurnal cycle characteristics of wind power fluctuation intensity of the different fans in the same wind field. Due to the variance of wind speed has diurnal cycle characteristics, the variance of wind power also has diurnal cycle characteristics. Moreover, the wind power fluctuation intensity corresponding to different power values also has diurnal cycle characteristics. However, after the conversion of wind speed into energy by means of the fan, the regularity of the diurnal cycle change of wind power fluctuation intensity is not as apparent as that of the diurnal cycle change of wind speed turbulence intensity.

4. Influence Law of Turbulence Diurnal Modulation on Wind Power Random Fluctuation Rate

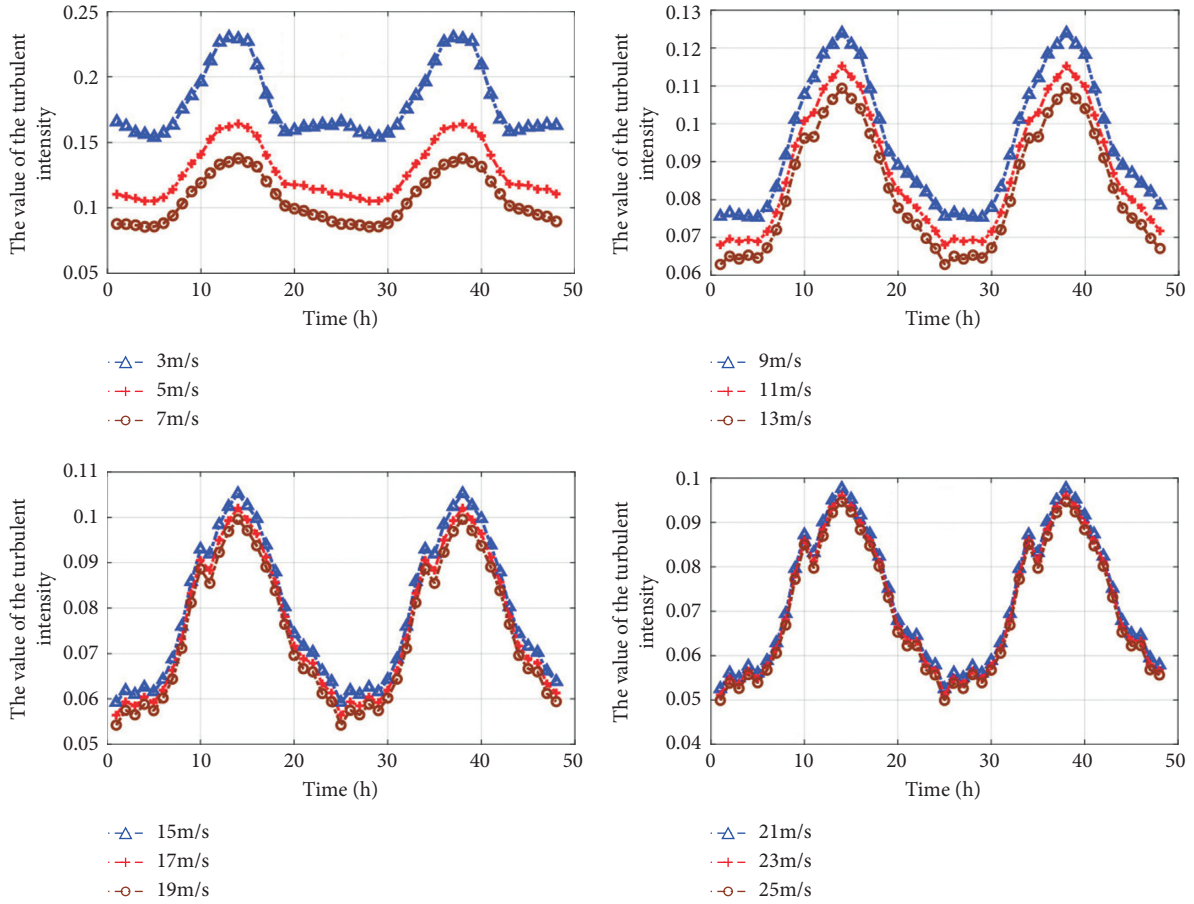
4.1. Quantitative Characterization of Wind Power Fluctuation Rate. Variational analysis is introduced in [41] to establish a computing model of instantaneous wind speed variation based on wavelet algorithm. In addition, the quantitative characterization of wind speed fluctuation rate is realized based on the dependence of wind speed variation on hourly average wind speed, similar to turbulence intensity. The


FIGURE 4: The variation of turbulence intensities for different wind speeds within 24 h using fitting model.
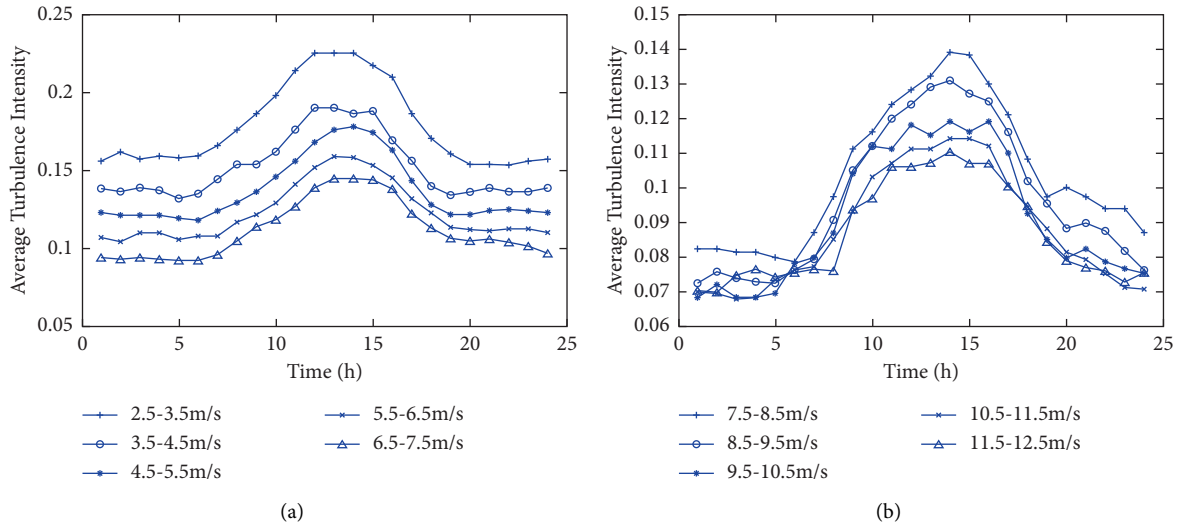

FIGURE 5: The variation of the mean turbulence intensities value within 24 h time interval (actual data). (a) Wind speed range from 2.5 m/s to 7.5 m/s. (b) Wind speed range from 7.5 m/s to 12.5 m/s.

variation of wind power also has the same characteristics. We further defined the variable intensity of wind power χ_p as the derived parameter to describe wind power variation quantitatively, as given by the following equation:

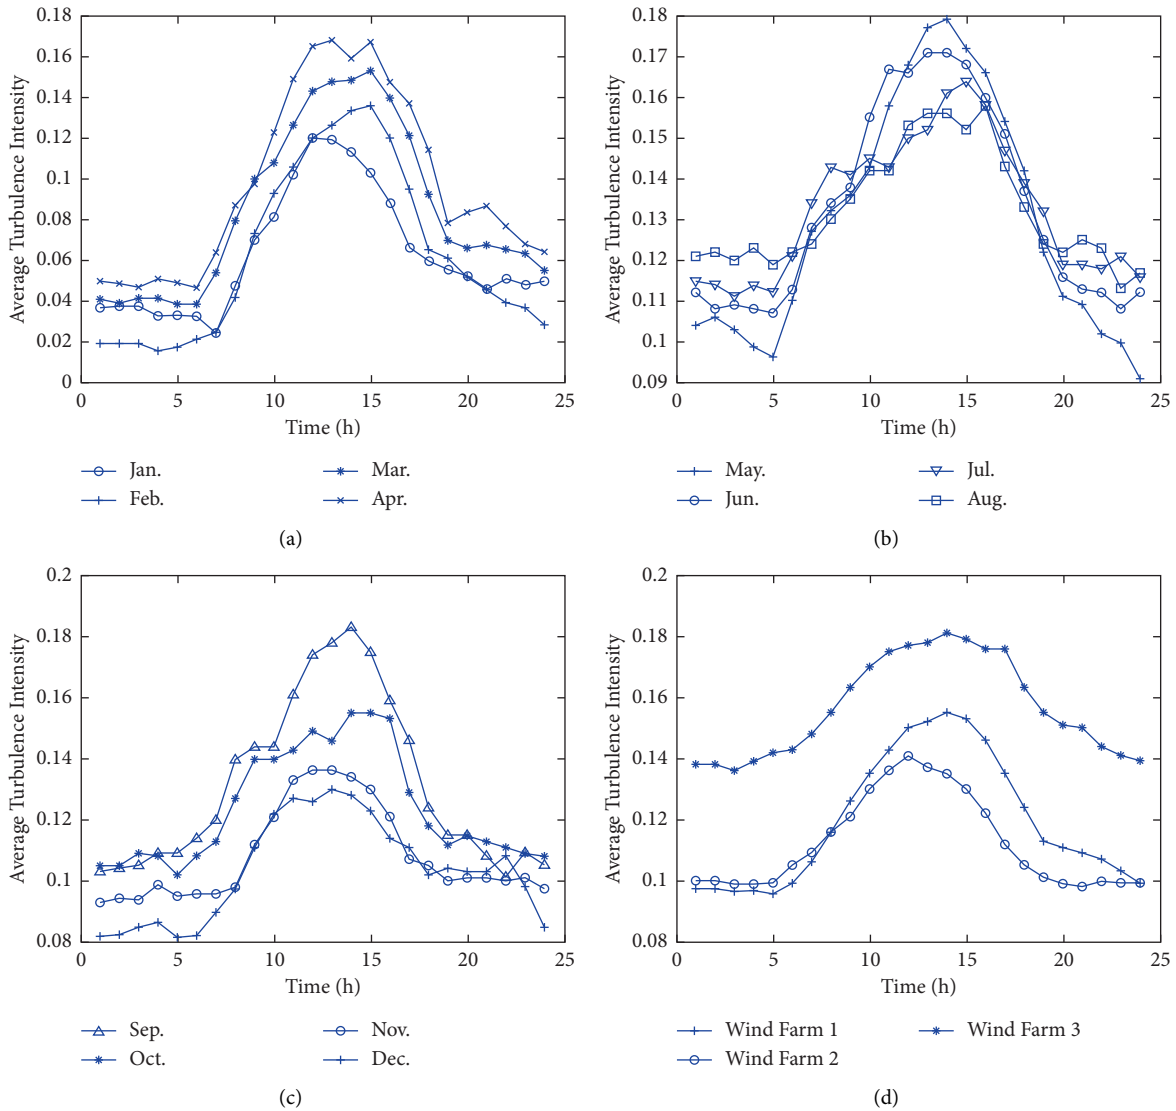
$$\chi_p = \frac{\left[\gamma_p^*(\Delta t) \right]^{1/2}}{\overline{p}^*} = \alpha \cdot \left(\overline{p}^* \right)^{-\beta} + c, \tag{6}$$


FIGURE 6: The diurnal cycle variation of TI during different seasons and months of a year. (a) The diurnal cycle from January to April. (b) The diurnal cycle during May and August. (c) The diurnal cycle from September to December. (d) The diurnal cycle variation of mean TI in three different farms.
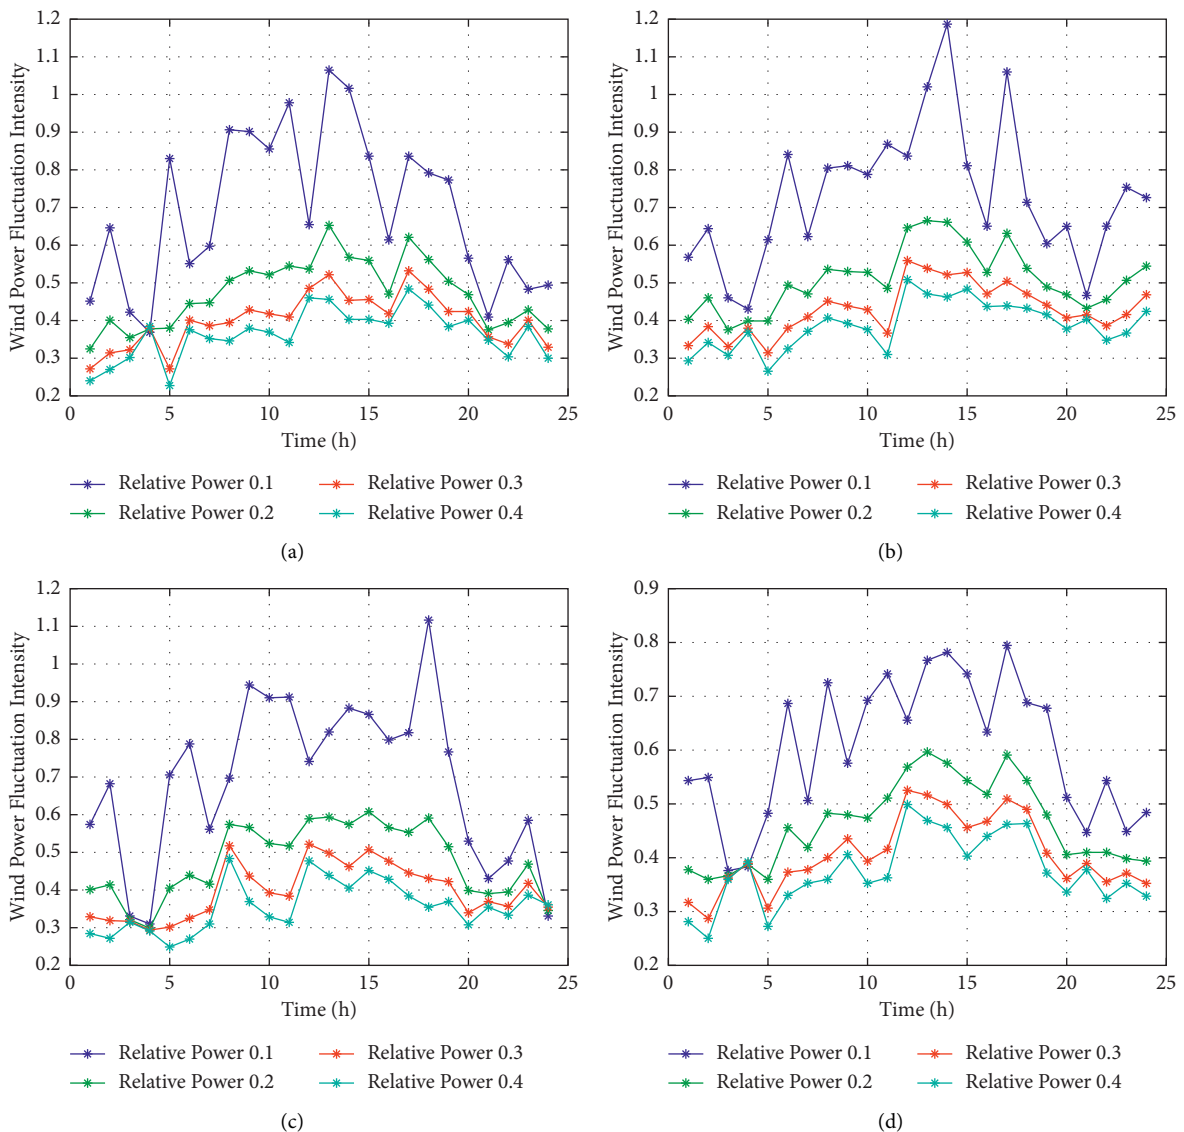
FIGURE 7: The diurnal cycle variation of TI in land farm with complex terrain.
FIGURE 8: The diurnal cycle variation of TI in land farm with complex terrain.


FIGURE 9: The diurnal cycle of wind power variance in same wind field. (a) #19 turbine. (b) #39 turbine. (c) #69 turbine. (d) #119 turbine.

where $\gamma_p^*(\Delta t)$ is the relative variation of wind power; $\overline{p}^*$ is the unit value of the average hourly power; α, β, and c are fitting constants.

4.2. Influence Law of Turbulence Diurnal Modulation on Wind Speed Fluctuation Rate. In [41], one-month time series data was used for autocorrelation analysis, which adopted multitime interval variation calculation. The results show that the time lag of the variation function is a periodic component in the time series, and the variation period is 1 day. The regularity of diurnal cycle change pattern remains constant with an increase in time interval. The diurnal cycle regularity becomes weaker only when the time interval reaches a certain level. The variation function of wind speed has the same diurnal cycle pattern as the variance. The time series $\gamma(\Delta t)$, as in [41], has different time lags, and the diurnal pattern of wind speed variation function is analyzed in detail. $\gamma(\Delta t)$ is large from 8 a.m. to 6 p.m., especially at its peak between 12 a.m and 4 p.m, and relatively small during other times of the day. On the basis of [41], further analysis reveals that diurnal cycle characteristics are not related to the speed, and speeds at different sizes have similar daily cycle characteristics shown in Figure 10.

4.3. The Diurnal Period Characteristics of Wind Power Variogram. Based on [41], the universality of the diurnal period characteristics of wind power variogram is further analyzed. As shown in Figure 11, the measured wind power data of multiple Wind generators are selected. It shows that wind power variogram is modulated by the diurnal process and has an obvious diurnal period characteristics. However, none of the present literature mentions the diurnal cycle characteristics of wind power variogram. Therefore, we extend the results of our research from characteristics of wind speed to its producing wind power. In power grid dispatching, the wind speed during noon has strong fluctuations at a fast rate. Therefore, when the disturbance caused by the power stroke of the grid is suppressed, it is necessary to reasonably configure fans with different suppression capacities to ensure safe and stable operation of the grid.

5. Influence Law of Turbulence Diurnal Modulation on Wind Power Intermittency

In [45], a quantitative description method of intermittency is proposed based on the duty ratio of abrupt change in wind speed, which considers the atmospheric turbulence physical essence. Furthermore, in [46], this kind of quantitative description method is extended to the definition of wind power intermittency, which is of great significance to the power system.

In [45, 46], similar autocorrelation has been adopted to analyze the measurement parameters of wind speed and its generating power intermittently in detail. It was found that the abrupt duty cycle parameters of wind power had obvious diurnal cycle characteristics. Similar to the diurnal cycle of wind power variance and variogram parameters, the steep

duty ratio between 8 a.m. and 8 p.m. is larger than other times. It reaches its daily peak between 12 a.m and 4 p.m. With similar statistical analyze methods, the results calculated on sufficient data from this farm but other months and other wind farms are identical. A study on the daily-cycle characteristic of the abrupt duty cycle of wind speed at different time intervals showed that the diurnal cycle phenomenon of the abrupt duty cycle of wind speed still exists. This proves the universality of the diurnal cycle phenomenon. The abrupt change in the diurnal cycle phenomenon of wind speed in duty cycle indicates that the wind power intermittency is stronger during the day than during night. Wind power intermittency reaches its daily peak between 12 a.m and 4 p.m. Therefore, the intermittent characterization index reflects the intrinsic characteristics of wind power uncertainty.

Although several parameters are used to characterize wind power intermittency, these parameters that cannot describe the nature of the intermittent wind speed and atmospheric turbulence also have no modulation effect.

6. Applications

6.1. Improved Wind Power Uncertainty Model Considering the Diurnal Modulation Characteristics of Atmospheric Turbulence. The study of the diurnal modulation characteristics of atmospheric turbulence on wind power uncertainty has the following practical significances for the utilization of wind power:

(1) The diurnal period characteristics indicate that some factors of turbulence will affect the parameters of wind power variance and variogram model. Therefore, the region, topography, seasons, and weather patterns (such as sunny and rainy weather) will influence atmospheric turbulence.

(2) The diurnal period of wind speed variance is a reflection of the random fluctuation of wind speed. Therefore, wind speed fluctuation range should be larger when turbulence intensity is higher, instead of a fluctuation range of equal widths.

(3) According to the diurnal period of the wind speed variogram, the wind power change rate is unstable at different times during a day, which means that system operators must change their strategies in different states. More specifically, complementary power and control strategies that respond faster must be provided to ensure the safe and efficient operation of the new energy power system when the light intensity is stronger.

(4) In addition, the diurnal cycle characteristics of wind speed variance and variogram also have reference value of the electricity price bidding for wind farm. The diurnal cycle characteristics of intermittency indexes have a similar significance for the operation of wind farms [53].

The diurnal cycle characteristics of wind power have a great impact on the precision of qualitative model fitting.

(a)

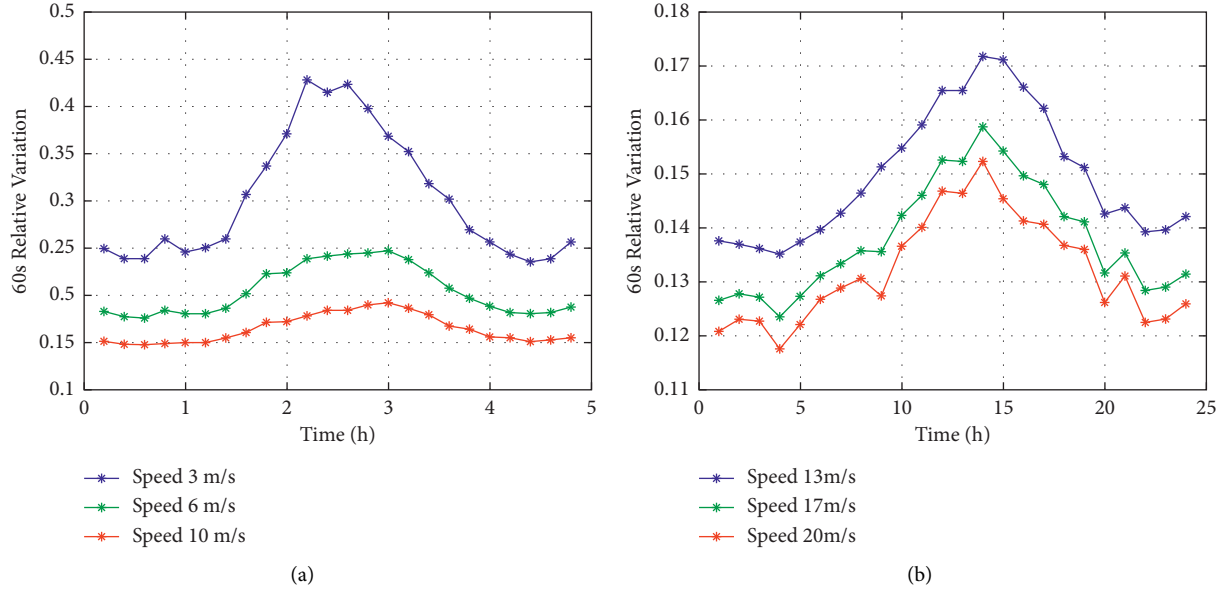
(b)


FIGURE 10: The diurnal cycle of different wind speed variation. (a) Wind speed: 3 m/s, 6 m/s, 10 m/s. (b) Wind speed: 13 m/s, 17 m/s, 20 m/s.

According to the fitting effect of time-sharing model in [43], we can further optimize the variation and intermittency models. Taking the variance model as an example, the model considering time-varying parameters has the higher fitting accuracy [54]. The time-varying parameter model is shown in the following equation:

$$\frac{\sigma(t)}{\overline{v}(t)} = \alpha(t) \cdot \overline{v}(t)^{-\beta(t)} + c(t), \tag{7}$$

where $\sigma(t)$ is the variance of actual measurement wind speed; $\overline{v}(t)$ is the mean actual wind speed per hour; $\alpha(t)$, $\beta(t)$, and $c(t)$ are a group of constants obtained by data fitting and time-sharing modeling.

As shown in Figure 12, the fitting error of this model considers the characteristics of diurnal cycle. Compared with Figure 1, the results show that this model has a great fitting accuracy rather than the original one (equation (1)).

The following four indicators of quantitative fitting effect are statistically analyzed.

$$\text{MNRE} = \frac{1}{n} \sum_{i=1}^{n} \left| \frac{(y_{ri} - y_{fi})}{y_{ri}} \right|,$$

$$\text{MNSE} = \frac{1}{n} \sum_{i=1}^{n} \left| \frac{(y_{ri} - y_{fi})^2}{y_{ri}^2} \right|,$$

$$\text{HASL} = k_{(\rho_k > 0.6)}, \tag{8}$$

$$\text{MAC} = \frac{1}{n} \sum_{k=1}^{n} |\rho_k - \min(\rho_k)|,$$

where MNRE and MNSE are mean normalized relative error and mean normalized square error, respectively. y_{ri} and y_{fi} are the actual variance values calculated by using wind speed

data and obtained by using model fitting, respectively. HASL and MAC are the mean of the highly autocorrelated step size and autocorrelation coefficient, respectively. ρ_k is the autocorrelation coefficient. $k_{(\rho_k > 0.6)}$ is the step size corresponding to $\rho_k > 0.6$.

Table 1 shows a comparison of the results. It can be seen that the fitting-effect of the time-varying parameter model is better than that of the original model.

6.2. Example Analysis of Frequency Modulation Capability Estimation Considering the Diurnal Characteristic of Wind Power Fluctuation Intensity.

According to [40], the fluctuation range measurement of wind power can be analyzed combined with the primary frequency modulation (PFM) and secondary frequency modulation (SFM) characteristics of thermal power units. The units for frequency modulation can be rationally configured to meet the analysis requirements of frequency modulation. The fluctuation intensity of minute and second wind power in a wind farm during a day was fitted, and the corresponding fluctuation time series were calculated as follows:

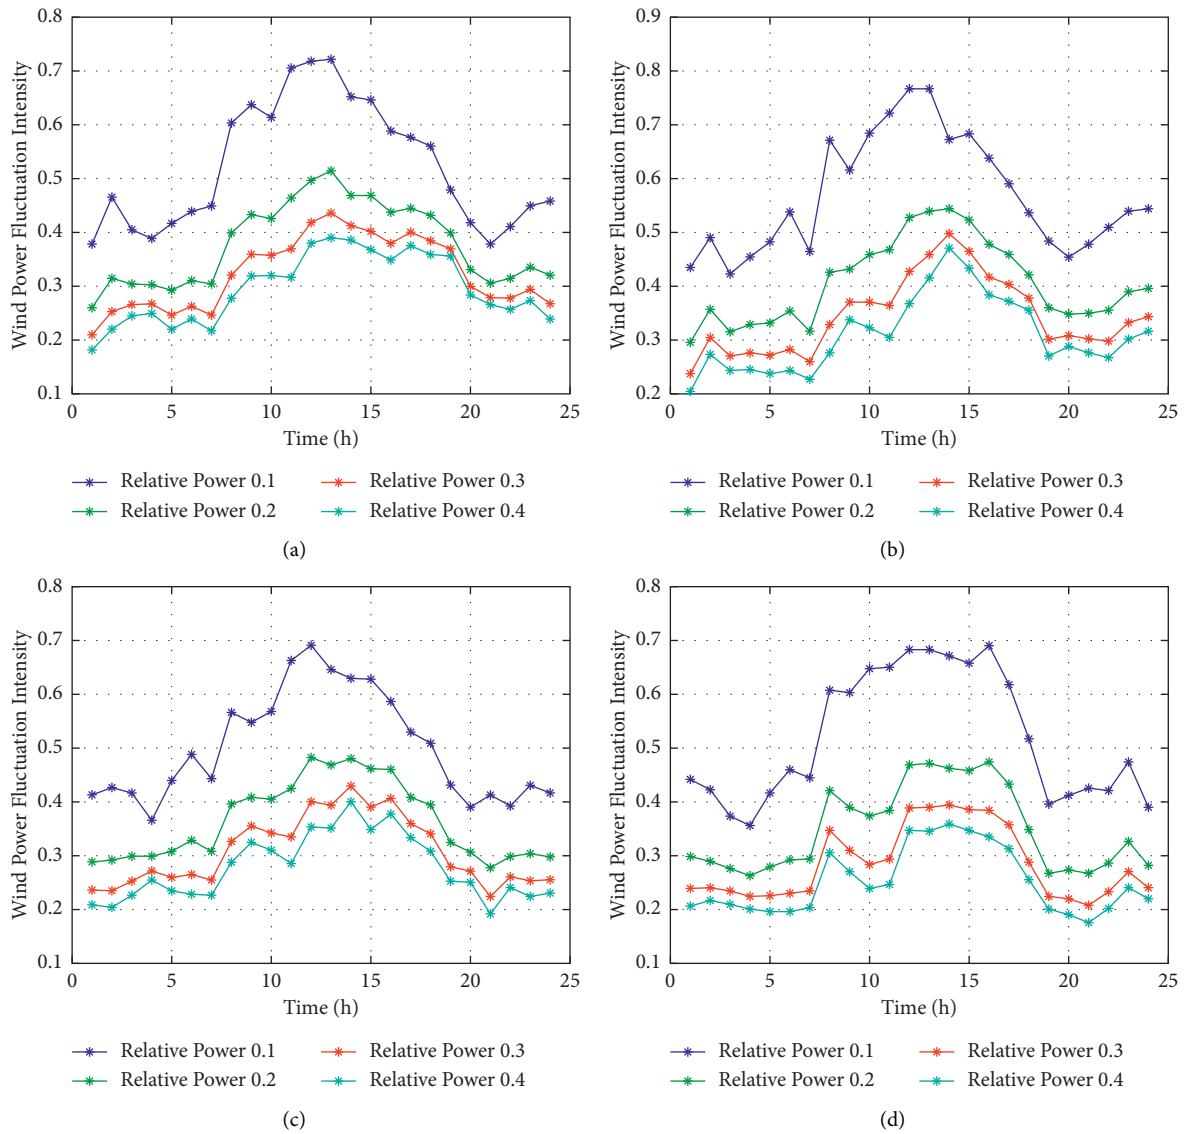
(1) When curve fitting is carried out at all time periods, the corresponding single-fitting parameter in equation (2) can be obtained. Based on the fitting model, wind power fluctuations in different time scales are estimated. The allocation scheme 1 is as follows: the proportion of primary FM unit is 80%. The inequality of turbine generator unit $\delta iA = 0.05$. The proportion of secondary FM unit is 40%, and the integral gain KA of secondary FM channel is 0.25. At this time, formula 20 in reference [40] (DFPRA) of the primary frequency modulation capability of the system increases from 7.9523 to 15.9045, and formula 21 in reference [40] (DSPR) of the secondary frequency modulation capability increases from 11.9636 to 23.9273.


Figure 11: The diurnal cycle of different wind turbine power variogram in wind field. (a) #19 turbine. (b) #39 turbine. (c) #69 turbine. (d) #119 turbine.
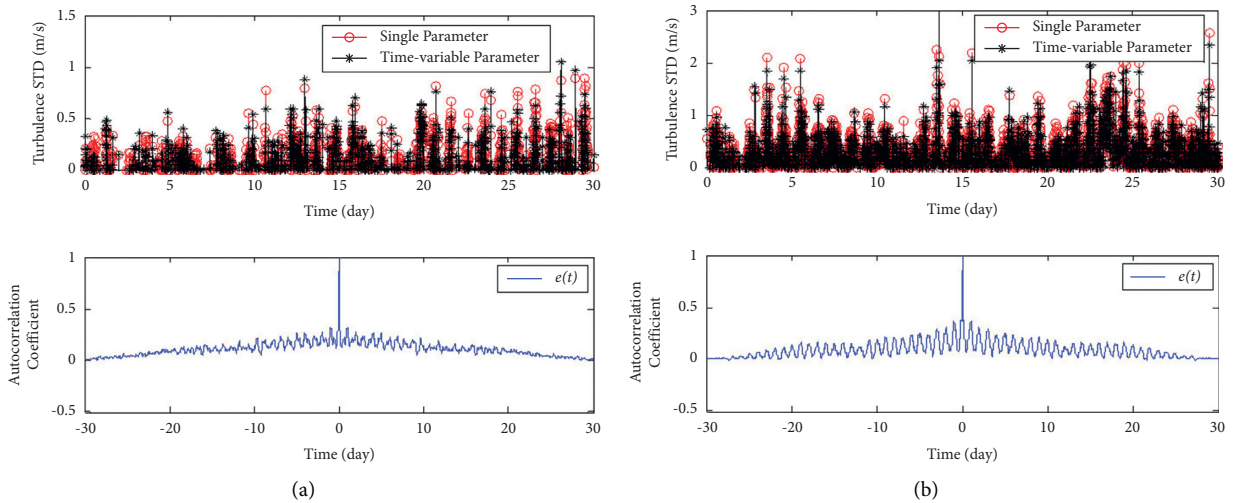

Figure 12: Continued.
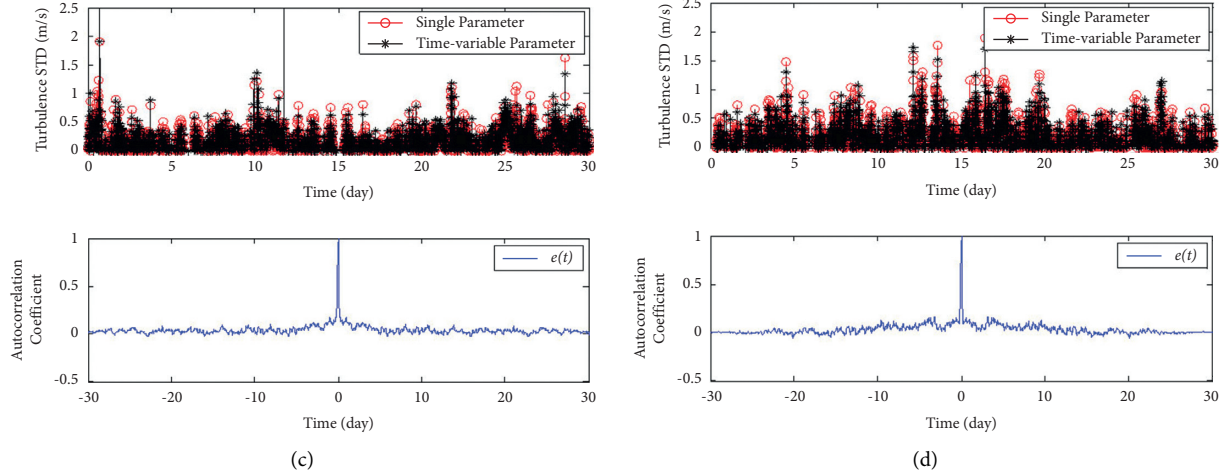

FIGURE 12: The fitting error of time variant model considering daily cycle model. (a) Wind data in spring. (b) Wind data in summer. (c) Wind data in autumn. (d) Wind data in winter.

TABLE 1: Statistical analysis of the fitting error.

Dataset	Original model				Time-varied model			
	MNRE(%)	MNSE(%)	HASL	MAC	MNRE(%)	MNSE(%)	HASL	MAC
1	47.53	13.90	8	0.1222	38.78	9.56	3	0.1091
2	36.12	15.21	8	0.2661	28.40	10.44	2	0.0943
3	27.73	7.68	2	0.1181	25.11	6.73	1	0.0658
4	33.41	10.87	5	0.1493	27.71	7.88	2	0.0853
FIGURE 13: Comparison of simulation results of two different schemes.

(2) According to the diurnal modulation characteristics, the data are fitted during a day. The corresponding power law model of wind power fluctuation in this period is obtained subsequently. Based on the law model of time-sharing wind power fluctuation, the wind power fluctuation during this period can be estimated accurately. So, scheme 2 is as follows: the primary FM unit of share A is increased from 40% to 50%. The range of turbo-generator set rate δiA is reduced from 0.05 to 0.025. The secondary FM unit share is increased from 20% to 40%. The integrator gain KA is increased from 0.25 to 0.5. Such a system

has the primary frequency capacity DFPRA increasing from 7.9523 to 19.9004, and secondary frequency modulation capacity DSPRA increased from 11.9636 to 60.0533. The system's frequency deviation after adopting the two schemes is shown in Figure 13. It can be seen that the standard deviation of the frequency fluctuation of the system $\sigma = 0.00003416$ when scheme 1 is used in region A being reduced to $\sigma = 0.00002698$ when scheme 2 is used. Therefore, the time-sharing modeling method, considering the daily modulation characteristics, can achieve accurate estimation of wind power fluctuations, realize the optimal allocation of FM units, and provide a reference for the power grid dispatchers to rationally allocate FM units.

7. Conclusion

Considering the physical nature of atmospheric motion, the wind power uncertainty is studied in the present research. The influence of the diurnal cycle characteristic of atmospheric turbulence on the fluctuation of wind speed and wind power is studied in this paper. The results show that this characteristic itself is affected by season, latitude, longitude, and topography. However, its influence on wind power fluctuation is weakened after the energy conversion process. Then, we analyze the influence of the diurnal cycle characteristic on the random fluctuation rate of wind power, and wind power intermittency. The results show that this parameter has no influence on the wind speed and the proportion of wind speed steepness but affects the duty ratio of abrupt change in wind speed.

Based on this research, we propose a time-varying model considering the diurnal cycle characteristic, and the fitting error of wind speed and its power generation fluctuation models are all smaller compared with the original models. At the same time, the wind power fluctuation is estimated based on the law model of time-sharing wind power fluctuation. In the two simulation schemes, the standard deviation of the system frequency fluctuation is reduced to 0.00003416 and 0.00002698, respectively, which verifies the validity of the model.

This paper presented the spatiotemporal diurnal modulation characteristics of atmospheric turbulence from the perspective of real-time scheduling and optimal control of power systems. This is of practical significance for power grid dispatchers to adjust the frequency modulation resources in real time and ensure the safety and reliability of system frequency.

Science and technology innovation (STI) policy is a strategic principle to guide the whole cause of STI. The study on STI policy and its effect is particularly important. Most of the existing studies on the effect of STI policy focus on the effect of a single policy, and the studies on the effect of policy combination and its differences need to be further enriched and improved. This study proposes a method combining system simulation experiment and analysis of variance (ANOVA) to study the differences of combination effects of STI policies. The results show that there are significant effect differences in the combination of STI policies as a whole, but when it comes to different combinations of STI policies, not all policy combinations have significant differences. This study not only points out whether there are significant differences in a certain effect among which combinations of STI policies but also points out whether there are significant differences in all effects among which combinations of STI policies at the same time. This study has theoretical and practical significance for realizing scientific policy-making and sustainable development.

1. Introduction

STI is the inexhaustible driving force for the development of modern countries and the fundamental driving force for realizing sustainable economic development. At present, the improvement of STI ability and the high-quality development of STI have become the theme of the times. Nowadays, countries all over the world attach great importance to their own STI. Effective innovation and high-level patented technology have become important indicators to measure the level of national economic development and comprehensive national strength. In order to accelerate the pace of STI, countries all over the world have formulated STI policies to promote the development of innovation activities and the transformation of achievements. STI policy is the basic action criterion stipulated by a country to realize the STI task in a certain historical period. It is the strategic principle to determine the development direction of STI and guide the whole STI [1]. STI policy can ensure the effective implementation of various innovation activities and the rational allocation of innovation resources. Its reasonable formulation will help to improve innovation performance, so as to promote the construction of national innovation system. As a key factor to strengthen the national scientific and technological strategic force and drive the development of STI, STI policy has attracted extensive attention in the academic circles and has become an important research topic [2].

After studying the existing literature, it is found that the research on policy effects (including STI policy effects) related to this research is mainly reflected in the following two aspects:

(1) What methods are used to study policy effects? The existing research methods on policy effects (including STI policy effects) are divided into two categories: qualitative research methods and quantitative research methods. Most of them analyze the impact of policies from a qualitative perspective. For

example, Surianto et al. studied why policy efforts to reduce disaster risk often fail to improve future disaster relief [3]; Krivosheev et al. studied the effectiveness of EU policy in Walloon, Belgium, and the economic development of the region compared with Flanders, another Belgian region [4]. Based on the current situation of industrial transfer in Guangdong Province, Shi et al. discussed the role of policies in promoting industrial transfer and existing problems, and put forward suggestions on the innovation of regional policies in Guangdong Province [5]; Yu [6] and Lan et al. [7] studied the impact of policies on regional economic development and believed that the government should formulate regional economic policies in line with its own regional economic development direction according to the economic development of each region, so as to scientifically and reasonably allocate the resources of each region; Lin studied the impact of EU policies on Portugal's national STI capacity [8]. In addition, a few of them analyze the impact of policies from a quantitative perspective by establishing models. Wang et al. used system dynamics to build a mechanism model of the impact of STI policies on regional innovation capability and studied the impact mechanism of different policies on regional innovation capability [9]; Avdiushchenko and Zając proposed a set of possible indicators to evaluate the progress of EU countries in realizing circular economy at the regional level [10]; O'Brien and Burrows used vertical and mixed methods to analyze the effectiveness of regional policies for large-scale layoffs [11]; Gülal and Ayaita took the introduction of minimum wage in Germany as the standard experiment and used the double difference model to analyze the impact of minimum wage on well-being [12].

(2) Research on the effect of single policy: most of the existing research on the effect of STI policy is to study the effect of a single STI policy. Cheng et al. found that government research and development (R&D) investment and human investment have a positive effect on STI, while enterprise financing policy has a significant negative effect on STI [13]; Deng and Long [14] and Yu [15] pointed out that R&D investment has a positive impact on STI; Fan [16] and Wang and Deng [17] believed that intellectual property protection helps promote STI; Zhuang et al. emphasized that the environmental policy of STI has a significant impact on STI [18]; Álvarez-Ayuso et al. studied the impact of tax credit on R&D [19]; Raffaello and Paolo studied the innovation effect of R&D subsidy policy in northern Italy [20]; Mukherjee et al. studied the relationship between taxation and innovation and pointed out that taxation hinders innovation [21]; Cappelen et al. believed that tax incentives have little effect on the marketization of new products

and patented products, but they are conducive to the innovation of product production process and the formation of new products [22]; Guerzoni and Raiteri took enterprises in EU Member States as samples, and considered that government procurement not only stimulates enterprises' R&D investment, but also stimulates innovation output [23]; Aschhoff and Sofka empirically tested the effect of government procurement on innovation output by using the survey data of German enterprises and the results show that government procurement can promote enterprise innovation [24]; Song and Zhang studied the relationship between government procurement policies and implementation rules to promote independent innovation, combed the practices in typical countries, and pointed out that government procurement is an important policy tool to support the innovation [25]; Hu et al. used provincial panel data to conduct an empirical test on whether China's government procurement has produced the expected technological innovation effect and the results show that China's government procurement not only does not promote innovation, but hinders innovation [26]. At present, there are also a few studies on the combination effect of STI policies. Kalcheva et al. used the triple difference method to study the impact of the combination of supply policy and demand policy on innovation [27]; Dou et al. found that the combination of STI policies has a significant impact on enterprise technological innovation [28]; Guo et al. believed that the combination effect of various STI policies is better than a single type of policies. When the policies are issued, we should pay attention to the complementarity and systematicness of the policies and avoid focusing too much on a certain link [29].

To sum up, the existing research on the effect of STI policy is mainly the effect of a single policy, and the research on the combination effect of STI policy needs to be further enriched and improved. In fact, the effect of STI policy is often the result of the joint force of multiple policies. At the same time, the existing research on the combination effect of STI policy needs to pay more attention to the research on the difference of policy combination effect. The detailed analysis of the difference of policy combination effect is helpful for researchers and policy makers to have a deeper understanding of the effect of policy combination, and it is also helpful for scientific policy implementation. In view of this, this study will use the ANOVA method to study the differences of the combination effects of STI policies.

The above is the first part of this study, that is, the introduction. This study will be carried out according to the following structure: firstly, the research methods used are introduced, that is, the one-way ANOVA method and multiple comparison method are introduced; secondly, the differences of policy portfolio effects are analyzed in detail by

using one-way ANOVA and multiple comparison method; the last part is the summary of this study.

2. Relevant Theoretical Basis

Because STI has the characteristics of externality and risk of public goods, it will hinder the enthusiasm of the main body of STI, and lead to the fact that the supply quantity in the market is often difficult to reach the social optimal level. This provides a theoretical basis for the government to stimulate the innovation power of STI subjects through policies [30]. Market failure theory holds that in the case of market failure, it is difficult to achieve Pareto optimal state only by market domination. At this time, it is necessary to combine the market with the government. R&D and innovation activities have the characteristics of externality and risk of public goods to a certain extent, which will lead to the failure of STI market, and provide a theoretical basis for the government to intervene in the R&D activities of STI subjects. Endogenous growth theory is based on Schumpeter's innovation theory, takes technological progress as an endogenous variable, and believes that human capital and knowledge accumulation bring the increasing marginal rate of return, so as to ensure economic growth and social progress. These endogenous factors that bring about the economic growth will be affected by government policies and are sensitive to policies. Romer [31] pointed out that we should vigorously promote various policies to promote innovation, such as giving direct subsidies to knowledge output, paying attention to education, strengthening intellectual property protection, etc. Through these policy orientations, we should send signals to STI subjects and stimulate their R&D enthusiasm.

3. Research Method: One-Way ANOVA and Multiple Comparison

ANOVA is used to test the significance of the difference between the mean of two or more samples. Its basic idea is as follows: by analyzing and decomposing the fluctuation of experimental data, and then comparing the possible systematic fluctuation and random fluctuation between each group of experimental data under a certain influencing factor, it is inferred whether there is a significant difference between the overall mean values. If there is a significant difference, it indicates that the influence of this factor is significant; otherwise, it is not significant [32, 33]. When the influence of only one factor on the experimental results is considered, it is called one-way ANOVA; when two factors affect the experimental results, it is called two-way ANOVA; by analogy, when more than two factors affect the experimental results, it is called multiway ANOVA.

The multiple comparison method in the parameter method is to test which overall mean values are equal and which overall mean values are different through pairwise comparison between the overall mean values. There are many methods for multiple comparison. In this study, the least significant difference (LSD) method proposed by Fisher is used. It is a simple deformation of t-test. It makes full use of sample information in the calculation of standard error and uniformly estimates a more robust standard error for the mean of all groups [34].

3.1. Related Concepts and Basic Assumptions of One-Way ANOVA. The one-way ANOVA method involves three terms: factor, level, and observation. Their meanings are as follows:

(1) Factor, also known as condition, refers to the object to be tested in the ANOVA

(2) Level, also known as treatment, refers to different values corresponding to factors

(3) Observation, refers to the experimental data obtained at each level of the factor

The one-way ANOVA method has the following basic assumptions:

(1) The assumption of normality is that each population obeys the normal distribution. For each level of factors, the observed values are simple random samples from the normal population.

(2) The homogeneity of variance is assumed, that is, the variance of each population should be equal. For each group of observation data, they are extracted from the normal distribution of the same variance.

(3) Independence assumption, that is, the observations are independent of each other.

3.2. Basic Process of One-Way ANOVA. When the one-way ANOVA method is used for research analysis, the basic process shown in Figure 1 can be adopted.

Firstly, the null hypothesis and alternative hypothesis are put forward. If the factor to be tested has k levels, and the corresponding mean value of each level is u_i, where $i = 1, 2, \ldots, k$, then the null hypothesis and alternative hypothesis are as follows:

H_0: $u_1 = u_2 = \ldots = u_k$ (independent variables have no significant impact on dependent variables);

H_1: $u_1, u_2, \ldots, u_k$ are not all equal (independent variables have a significant impact on dependent variables).

The null hypothesis (H_0) means that the factor to be tested has no impact on the experimental results, while the alternative hypothesis (H_1) means that the factor to be tested has an impact on the experimental results.

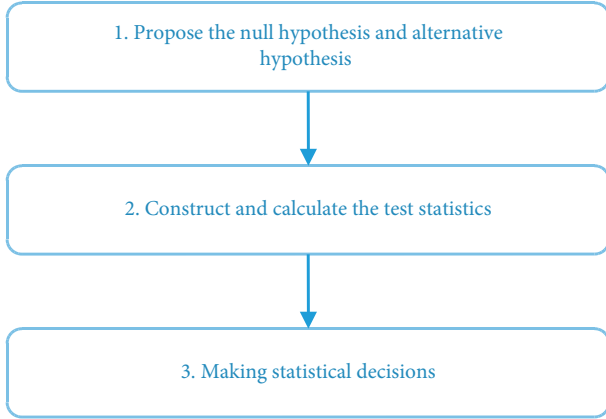
Secondly, the test statistics are constructed and calculated. In order to test whether the null hypothesis (H_0) is true, it is necessary to construct appropriate test statistics first. Specifically, it is necessary to construct three sums of squares of error, which are sum of squares of total error (SST), sum of squares of factor error (SSA) and sum of


FIGURE 1: Basic process of one-way ANOVA.

squares of random error (SSE). Let x_{ij} represent the j-th observation value of the i-th level, then the calculation formulas of these three sums of squares of error are

$$SST = \sum_{i=1}^{k} \sum_{j=1}^{n_i} \left(x_{ij} - \bar{\bar{x}} \right)^2,$$

$$SSA = \sum_{i=1}^{k} \sum_{j=1}^{n_i} \left(\bar{x}_i - \bar{\bar{x}} \right)^2 = \sum_{i=1}^{k} n_i \left(\bar{x}_i - \bar{\bar{x}} \right)^2,$$

$$SSE = \sum_{i=1}^{k} \sum_{j=1}^{n_i} \left(x_{ij} - \bar{x}_i \right)^2, \tag{1}$$

$$\bar{x}_i = \frac{\sum_{j=1}^{n_i} x_{ij}}{n_i},$$

$$\bar{\bar{x}} = \frac{\sum_{i=1}^{k} \sum_{j=1}^{n_i} x_{ij}}{n} = \frac{\sum_{i=1}^{k} n_i \bar{x}_i}{n},$$

where $\bar{x}_i$ represents the mean value of the factor at Level i and n_i is the number of the i-th overall experimental data, $i = 1, 2, \ldots, k$; $\bar{x}$ represents the mean value of all observations, $n = n_1 + n_2 + \cdots + n_k$.

These three sums of squares of error satisfy the following identity relationship.

$$SST = SSA + SSE. \tag{2}$$

The sum of squares of error divided by their corresponding degrees of freedom is called mean square error. The degree of freedom of SST is $n - 1$, where n is the number of all observed values. The degree of freedom of SSA is $k - 1$, and its corresponding mean square error is usually recorded as MSA, where k is the number of factor levels. The degree of freedom of SSE is $n - k$, and its corresponding mean square error is usually recorded as MSE. Thus, the value of $F = MSA/MSE$ can be obtained, and it obeys the F $(k - 1, n - k)$ distribution.

Finally, make statistical decisions. According to the given significance level α, check the F distribution table to determine F_α $(k - 1, n - k)$. If $F > F_\alpha$ (or $P < \alpha$), then reject the

null hypothesis, indicating that the factor has a significant impact on the experimental results. Otherwise, accept the null hypothesis and consider that the factor has no significant impact on the experimental results.

3.3. Basic Flow of LSD Method. When the one-way ANOVA method is used for research analysis, the basic process shown in Figure 1 can be adopted.

After one-way ANOVA, if you want to know which population means are equal and which population means are different, you need to make multiple comparisons. In this study, LSD method is used for multiple comparison, and its basic steps are similar to one-way ANOVA, as follows:

Firstly, the null hypothesis and alternative hypothesis are put forward.

H_0: $u_i = u_j$;

H_1: u_i, u_j are not equal where $1 \le i < j \le k$.

Secondly, the test statistics are constructed and calculated. The test statistic of LSD method is t statistic, and its calculation formula is

$$t = \frac{\left(\bar{x}_i - \bar{x}_j \right) - \left(u_i - u_j \right)}{\sqrt{MSE \left(1/n_i + 1/n_j \right)}}. \tag{3}$$

t statistic obeys the t distribution with $n - k$ degrees of freedom.

Finally, make statistical decisions. According to the given significance level α, check the t distribution table to determine $t_{\alpha/2}$ $(n - k)$. If $|t| > t_{\alpha/2}(n - k)$ (or $P < \alpha$), then reject the null hypothesis, indicating that there is a difference between the two population mean values. Otherwise, accept the null hypothesis and consider that there is no difference between the two population mean values.

3.4. Welch's ANOVA and Games–Howell Test. It is worth noting that in this study, when the variances are unequal, we will use Welch's ANOVA method to replace the aforementioned one-way ANOVA method for corresponding analysis, because Welch statistic is better than F statistic when the variance is unequal [35]. At the same time, we will use the Games–Howell test method to replace the above LSD method for corresponding analysis. For a detailed introduction to the Games–Howell test method, please refer to reference [36].

4. Analysis on the Differences of Combination Effects

This study is based on our previous research achievement "Analysis on the combination effect of science and technology innovation policy: from the perspective of system simulation" (hereinafter referred to as Achievement A), which proposes a system simulation method to analyze the combination effect of STI policy. This study uses the system simulation model in Achievement A to carry out simulation experiments and obtain simulation experimental data, so as to analyze the differences of policy combination effects. The

following is a brief introduction to the system simulation model in Achievement A.

Rothwell and Zegveld [37] believe that the policy effect originates from different levels. Therefore, the STI policy can be divided into three categories, one is supply policy, and the other two are demand policy and environmental policy. In this study, our goal is to analyze the impact of different level STI policies. Therefore, this classification method will be adopted. Considering the quantification of policies and the availability of data, the STI supply policy in Achievement A only considers the capital investment policy and talent training policy, the STI demand policy only considers the intellectual property policy and STI service policy, and the STI environment policy only considers the enterprise financing policy and enterprise tax policy. The Achievement A establishes the conceptual model as shown in Figure 2, that is, the causality diagram. The system simulation model corresponding to the conceptual model, that is, the stock flow diagram, is shown in Figure 3.

The above is a brief introduction to the system simulation model in Achievement A. For the detailed introduction of Achievement A, please refer to my previous research Achievement A.

It is worth noting that Achievement A has conducted an empirical study using the relevant data of STI in Guangdong Province from 2010 to 2019. Its system simulation model does not consider the uncertain factors, but this study will take the uncertain factors into account. Specifically, this study will add random distribution to the expression of relevant variables in Achievement A, as shown in Table 1. For example, for the annual GDP, the expression in this study is: annual GDP = the expression of annual GDP in Achievement A + RANDOM NORMAL (−5460.12, 5291.63, 0, 3622.37). Among them, RANDOM NORMAL(min, max, mean, stdev) is the normal distribution form in the system dynamics simulation software VENSIM, which needs to input four parameters.

It can be seen from Table 1 that all the random distributions in the expressions of Variable 1 to 9 are a normal distribution, because the expressions corresponding to these variables in Achievement A are obtained by linear regression analysis method, which requires that the error term obey a normal distribution and the mean value is 0. In Achievement A, the expressions of Variable 10 to 13 are obtained by weighted regression analysis. This study assumes that the error terms of variables 10 to 13 obey a normal distribution. The parameters of the random distribution shown in Table 1 are obtained by analyzing the error term.

This study will make a difference analysis on the combination effects of the above three types of policies in SPSS statistical analysis software. The effects here mainly refer to the economic effect and STI effect. The per capita GDP and patent application acceptance are used as the effect indicators respectively. In this study, each type of policy takes three levels. Specifically, the three levels of supply policy are benchmark level, relative benchmark increase of 5% and relative benchmark decrease of 5%. The three levels of demand policy are similar to those of supply policy. The three levels of environmental policy are the benchmark level, the

relative benchmark increase of 1% and the relative benchmark decrease of 1%. The benchmark levels for each policy are detailed in Achievement A. Since there are three types of policies, and each type of policy has three levels, this study will design $3^3 = 27$ simulation experiments, as shown in Table 2.

4.1. Descriptive Statistics.
After the preliminary analysis of the data (that is, the model output data with the simulation time of 2025) obtained from the above simulation experiments, some descriptive statistical analysis results are obtained as shown in Table 3. It is not difficult to find from Table 3 that the number of experiments in each experiment is the same, 50 times. From Table 3, we can also see the mean value and standard deviation of per capita GDP (PCGDP) and annual patent application acceptance (APAA) of each simulation experiment.

4.2. Test of Normality and Test of Homogeneity of Variance.
Because the one-way ANOVA method requires that the population should meet the normality and homogeneity of variance, it is necessary to test the normality and homogeneity of variance before analyzing the differences of policy combination effects. It can be seen from Table 1 that the normality requirements are met. From Table 4, it can be seen that the significance (P value) of per capita GDP is greater than 0.05. Thus, the homogeneity of variance is met at this time. For the annual patent application acceptance, the significance (P value) is less than 0.05. Hence, the homogeneity of variance is not met at this time.

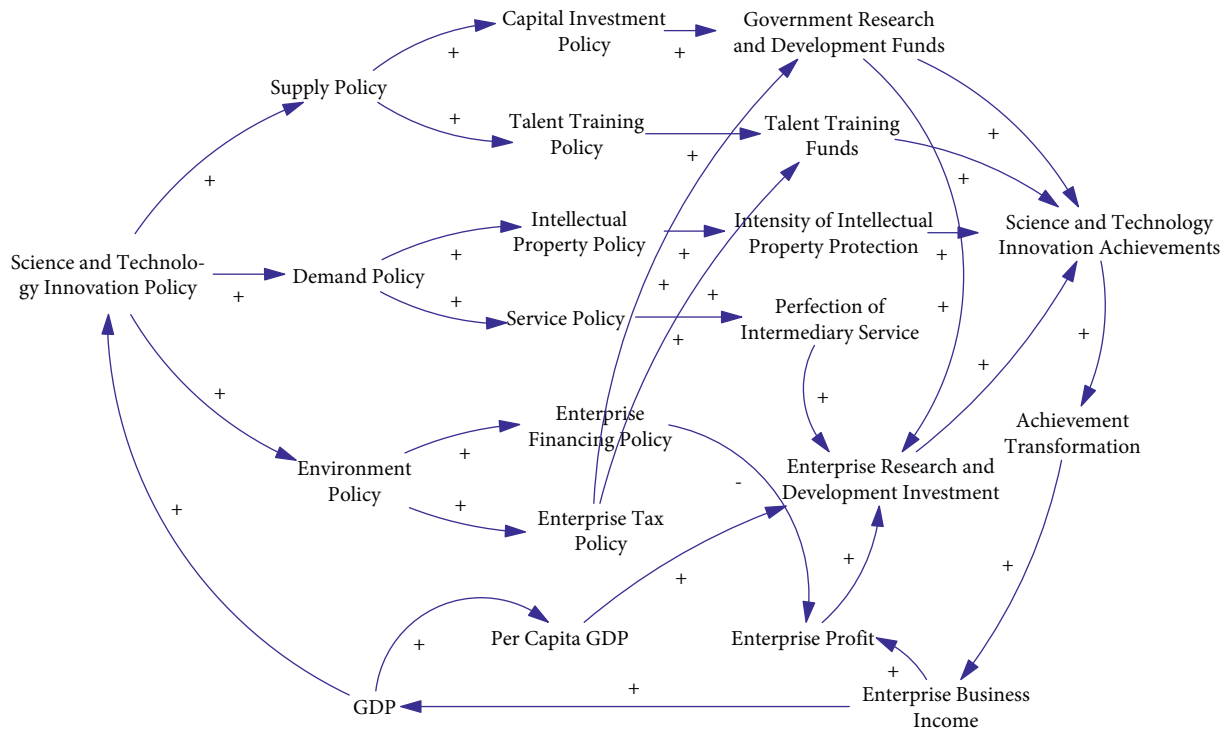
4.3. Difference Analysis of Economic Effect.
For the per capita GDP, since each population meets the requirements of normality and homogeneity of variance, we use the abovementioned one-way ANOVA method for analysis. As can be seen from Table 5, the significance (P value) is less than 0.05, which indicates that there are significant differences in the economic effect (i.e., per capita GDP) of various combinations of STI policies. It is worth noting that this significant difference refers to the significant difference of the whole. At this time, we do not know which combinations have significant differences, and which combinations have no significant differences. In order to answer this question, it is necessary to make multiple comparisons so that we can clearly understand which combinations have significant differences. It can be seen from Table 6 that when 0.05 is taken as the significance level, there is a significant difference between the economic effect of the policy combination corresponding to Experiment 1 and the economic effect of other policy combinations, except that it is not significantly different from the economic effect of the policy combination corresponding to Experiment 7, 10, 13, 19, and 25. In addition to the policy combination corresponding to Experiment 1, similar difference analysis can also be carried out for other policy combinations in combination with Table 6, which will not be repeated here.


FIGURE 2: Conceptual model.
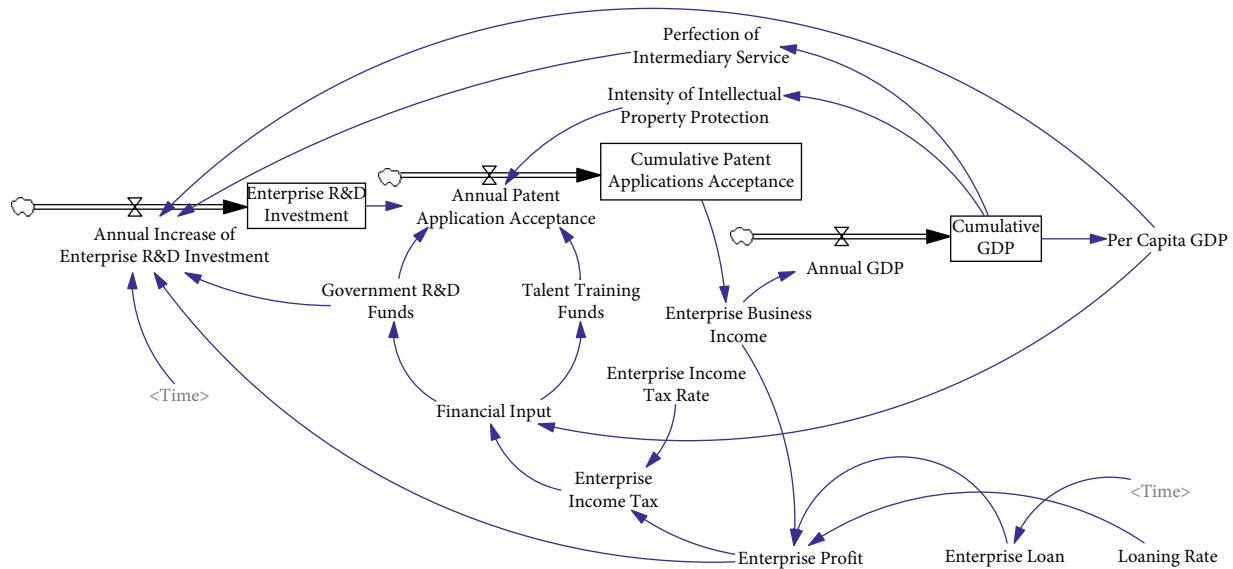

FIGURE 3: Simulation model.

4.4. Difference Analysis of STI Effect. For the annual patent application acceptance, although each population meets the requirements of normality, they do not meet the requirements of homogeneity of variance. Therefore, the abovementioned one-way ANOVA method is not applicable here. At this time, we can use the abovementioned Welch's ANOVA method for analysis. As can be seen from Table 7, the significance (*P* value) is less than 0.05, which shows that the STI effect (i.e., annual patent application acceptance) of various combinations of STI policies are significantly

different as a whole. In order to further understand which population mean values are equal and which population mean values are different, it is necessary to make multiple comparisons using the aforementioned Games–Howell test method. It is not difficult to find from Table 8 that, at the significance level of 0.05, there is no significant difference between the STI effect of the policy combination corresponding to Experiment 1 and the STI effect of the policy combination corresponding to Experiment 4, 7, 10, 13, 16, 19, 22, and 25. However, there are significant differences

TABLE 1: Random distribution in variable expressions.

Number	Variable name	Random distribution to be added
Variable 1	Annual GDP	RANDOM NORMAL (−5460.12, 5291.63, 0, 3622.37)
Variable 2	Enterprise loan	RANDOM NORMAL (−6092.92, 8022.4, 0, 5002.37)
Variable 3	Enterprise income tax	RANDOM NORMAL (−107.338, 67.0867, 0, 52.0629)
Variable 4	Perfection of intermediary service	RANDOM NORMAL (−1.2481, 0.755273, 0, 0.789901)
Variable 5	Enterprise business income	RANDOM NORMAL (−12078.2, 13275.6, 0, 8515.95)
Variable 6	Talent training funds	RANDOM NORMAL (−213.521, 161.98, 0, 126.222)
Variable 7	Government R&D funds	RANDOM NORMAL (−118.463, 103.843, 0, 76.0717)
Variable 8	Intensity of intellectual property protection	RANDOM NORMAL (−0.184447, 0.11458, 0, 0.117456)
Variable 9	Per capita GDP	RANDOM NORMAL (−1081.07, 1585.02, 0, 838.532)
Variable 10	Annual increase of enterprise R&D investment	RANDOM NORMAL (−71.0683, 19.1128, −8.75484, 25.325)
Variable 11	Annual patent application acceptance	RANDOM NORMAL (−129351, 50584.4, −6503, 46332)
Variable 12	Enterprise profit	RANDOM NORMAL (−362.065, 1172.9, 77.7868, 427.839)
Variable 13	Financial input	RANDOM NORMAL (−661.539, 1540.54, 66.5193, 658.025)

TABLE 2: Simulation experiment.

Experiment	Supply policy	Demand policy	Environmental policy

Experiment 27	Decrease of 5%	Decrease of 5%	Decrease of 1%

with other policy combinations in the effect of STI. In addition to the policy combination corresponding to Experiment 1, similar difference analysis can also be carried out for other policy combinations in combination with Table 8, which will not be repeated here.

4.5. Comprehensive Analysis of Differences. The above analyzes the differences of the economic effect and STI effect of each combination of STI policies. Next, we take policy Combination 1 as an example and analyze these two effects of each combination of STI policies at the same time. By sorting out Tables 6 and 8, we can get Table 9. It can be seen from Table 9 that the economic effect and STI effect of policy Combination 1 are significantly different from those of policy Combination 2, 3, 5, 6, 8, 9, 11, 12, 14, 15, 17, 18, 20, 21, 23, 24, 26 and 27, but not from those of policy Combination 7, 10, 13, 19 and 25. In addition, there are significant differences in economic effect between policy Combination 1 and policy Combination 4, 16 and 22, but there is no significant difference in STI effect.

TABLE 3: Descriptive statistical analysis of effect indicators.

TABLE 9: Differences.

| | Policy combination | | | | | | | | | | | | | | | | | | | | | | | | | |
	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27
Dif1	✓	✓	✓	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	✓	✓	✓	×	✓	✓	✓	✓	✓	×	✓	✓
Dif2	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓
Dif3	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓	×	✓	✓

Note. Dif1 refers to whether there is a significant difference in the economic effect with policy combination 1, Dif2 refers to whether there is a significant difference in the STI effect with policy Combination 1, and Dif3 refers to whether there is a significant difference in the economic effect and STI effect with policy Combination 1 at the same time.

5. Conclusions

5.1. Research Summary. STI has become an important driving force for national and regional economic and social development. As a tool for the government to guide and promote the promotion of scientific and technological competitiveness, STI policy has a significant impact on STI. Most of the existing studies focus on the effect of a single policy, and the studies on the effect of policy combination and its differences need to be further enriched and improved. Under this background, this study proposes a method combining system simulation experiment and ANOVA to study the differences of the combination effects of STI policies. The research is summarized as follows:

(1) On the whole, there are significant differences in both the economic effect of STI policy combination and the STI effect of STI policy combination.

(2) Specific to different combinations of STI policies, not all combinations of STI policies have significant differences in policy effects.

(3) There are significant differences in the economic effect of some STI policy combinations, but the differences in the STI effect are not significant. There are significant differences in STI effect among some STI policy combinations, but the differences in economic effect are not significant.

(4) This study not only points out whether there are significant differences in economic effect or STI effect among STI policy combinations, but also points out whether there are significant differences in economic effect and STI effect among STI policy combinations at the same time.

5.2. Policy Implications. This study gives us the following enlightenment:

Firstly, the empirical results show that there are significant differences in policy effects among some STI policy combinations, while there are no significant differences in policy effects among some STI policy combinations. Therefore, policymakers should fully consider the differences in policy effects among policy combinations when formulating policies, so as to avoid making useless efforts in formulating policies. In other words, policymakers should avoid formulating policies that have no significant difference in policy effects from the original policies.

Secondly, the empirical results show that the economic effect and STI effect of STI policy combinations are not always synchronous, that is, sometimes there are significant differences in one effect but not in the other. Therefore, when making policies, policy makers sometimes have to make a trade-off among a variety of policy effects.

5.3. Contribution and Prospect. The contributions of this study are as follows:

(1) The existing research mainly focuses on the effect of a single policy, and the research on the combination

effect of STI policy, especially the research on the difference of policy combination effect, needs to be further enriched and improved. This research enriches and expands the relevant literature research, makes up for the shortcomings of previous research, and provides an effective supplement for the existing research on STI policy.

(2) This study proposes a method combining system simulation experiment and ANOVA to study the differences of the combination effects of STI policies. This method based on the combination of system simulation and data analysis and mining enhances the modeling and solving ability of practical problems, provides a reference framework for similar research, and reflects the characteristics of this study in research methods.

This study provides enlightenment for policy makers to fully understand the effect of STI policy and make appropriate adjustment. At the same time, it enriches and expands the relevant literature research, which has certain theoretical and practical significance. However, this study also has some limitations. For example, only six kinds of STI policies are considered, and other STI policies are not deeply studied. In future research, more STI policies can be included in the research.

Data Availability

The data used to support the findings of this study are included within the article.

Conflicts of Interest

The authors declare that there is no conflicts of interest regarding the publication of this paper.

To address the issues of low efficiency in manual terrain feature map annotating and poor realism in terrain elevation map generation, this paper proposes a terrain elevation map generation method based on self-attention mechanism and multifeature sketch. Firstly, the proposed method extracts features from a terrain elevation map using an adaptive feature enhancement method. Afterwards, our method adds a self-attention mechanism to the generator and discriminator of conditional generative adversarial network to capture the global spatial features and generates a realistic terrain elevation map. Finally, a level of detail method is used to visualize the three-dimensional terrain, and an interactive terrain editing tool for roaming interaction is implemented. Experimental data show that the proposed method performs well in subjective visual performance and objective criteria and has obvious advantages over other current typical methods.

1. Introduction

Terrain is one of the most common elements in nature. Realistic 3D terrains have been widely used in 3D video games, military simulations, film industry, and other fields. For instance, developers in 3D video games can create a game world that brings immersive user experience to players; realistic battlefields can be simulated for virtual military training in military simulations; visual effect artists can create scenes with realistic terrains that bring amazing visual experience to the audience in the film industry. Hence, digital terrains with realistic features can play an important role in enhancing the realism of virtual scenes and improving user immersion.

Interactive terrain editing tools aim at generating realistic terrains efficiently based on the sketch input from users. These editing tools should provide rich functionalities that can support users with a little technical background. In terms of realism, generated terrains should have natural features of the terrain in the real world, where no traces of manual editing can be found. Since interactive terrain editing tools can be widely used in various applications, it is important to investigate how to efficiently generate terrain elevation maps with realistic natural features.

In recent years, many researchers have investigated terrain editing. Existing terrain editing methods can be classified into three categories: terrain editing based on fractal noises, terrain editing based on physical erosion simulations, and terrain editing based on real samples. Specifically, for terrain editing methods based on fractal noises, a terrain is simulated by generating fractal noises based on user input parameters. The process is hardly controllable, which is difficult for users to get results that meet their demands. As for the methods based on physical erosion simulations, users need to edit a terrain with the knowledge of physical erosion theory, which is difficult for nonprofessional users. Finally, for the methods based on real samples, despite the fact that generated terrains can retain some natural features of real terrain, there is still much room for optimization in terms of realism and interaction experience. In order to enable users to perform interactive editing flexibly and generate realistic terrain, this paper draws on the methods based on real samples, which not only ensures that the generated results have the features of real samples but also enhances the realism of the generated results further. At the same time, the proposed method can improve computing efficiency, meet real-time interaction requirements,

and enhance the user's interactive experience by visualizing the three-dimensional terrain. Therefore, it is necessary to investigate interactive terrain editing techniques based on multifeature sketches.

The contributions are summarized as follows:

(1) We propose a terrain feature extraction method based on adaptive feature enhancement to solve the problem of low efficiency of manual annotation.

(2) We propose a terrain elevation map generation method based on self-attention mechanism. The conditional generative adversarial network is used to generate a realistic terrain elevation map.

(3) We propose a three-dimensional terrain visualization method based on Levels of Detail, which improves the fluency of user interaction.

(4) We realize an interactive terrain editing tool based on multifeature sketches. The tool runs stably and has a good user interaction experience.

2. Related Work

Interactive terrain editing tools can generate terrain elevation maps based on various terrain features from user input. Relevant scholars proposed a method for interactive generation and display of 3D terrain [1]. The method can automatically generate terrain that meets the user's needs, but the feedback of the interactive operation is yet to be studied. The researchers gradually generated the terrain by expanding the details of the user sketch [2]. The algorithm is computationally efficient and highly interactive. Related scholars used terrain elevation entropy, extracted features from Digital Elevation Model (DEM) data to generate terrain frames, and accelerated mapping using GPU to improve the efficiency of terrain generation during the editing of terrain [3]. Given the high efficiency of the GPU, a terrain editing algorithm based on CUDA architecture was proposed [4], which is applicable to large-scale terrain scene creation. With the development of deep learning, the researchers applied this to the terrain editing problem and proposed a real-time interactive terrain editing method [5]. The results obtained by this method conform to the feature distribution of real terrain samples with high fidelity. Related scholars implemented interactive terrain editing by providing the user with functions related to plate tectonics as well as erosion simulation [6]. The results of terrain editing obtained by this method are in accordance with the theories related to geosciences and are visually closer to the real terrain. Researchers have proved that the approach with machine learning could enhance the realism of procedurally generated terrain [7]. The method used Deep Convolutional Generative Adversarial Network (DCGAN) to generate height maps, and the generated results outperformed the noise-generated elevation map results, achieving a more realistic terrain elevation map editing. The authors proposed a generation method based on implicit feature representation of terrain [8]. This method can create large-scale terrain with less memory consumption and can implement special

terrain. To solve the problem of less efficient manual editing, a semiautomatic procedural terrain generation method for terrain editing tasks has been proven to work [9].

Specifically, terrain feature extraction method, terrain elevation map generation method, and terrain visualization method will be introduced as follows.

For terrain feature extractions, the primary goal is to extract ridge lines and valley lines efficiently and accurately. A Profile recognition and Polygon breaking Algorithm (PPA) was firstly proposed in [10]. This method can efficiently extract terrain ridge lines and valley lines that were consistent with the actual observation. The researchers proposed the necessity of effectively selecting terrain elevation profiles based on DEM data, which can improve the accuracy of traditional elevation profile extraction methods [11]. Based on the research [10], relevant scholars proved that morphological correlation algorithm could be used to complete the region refinement after polygon construction [12]. Related researchers proposed a terrain feature extraction algorithm to control feature significance, which can obtain extraction results of terrain feature lines that were in line with human eye observations [13]. Inspired by PPA, we optimize the process of removing redundant branches and leaves in a feature-connected graph when extracting ridge lines and valley lines. We propose a terrain feature extraction method based on adaptive feature enhancement, which can extract ridge lines, valley lines, and peak points in large-scale data set production tasks.

For terrain elevation map generations, deep learning algorithms become mainstream in the field of image generation. Generative Adversarial Network was proposed [14], which can create a model for generating high-definition images. Subsequently, the researchers proposed Conditional Generative Adversarial Network that added constraints to the Generative Adversarial Network, which can use category labels as a condition to get generation results [15]. The scholars proposed Deep Convolutional Generative Adversarial Network (DCGAN) [16], which introduced convolutional operations into the structure of Generative Adversarial Network for the first time. This method can capture the features of input data well and realize supervised learning. Based on the research in [15], related scholars proposed a method where an input image can be mapped to an output image using a Conditional Generative Adversarial Network, which can effectively convert picture labels to pictures [17]. The researchers added a self-attention mechanism to the network's construction, which can capture structural global features more easily [18]. Inspired by the work [17, 18], we apply a Conditional Generative Adversarial Network in terrain elevation map generation tasks. In addition, a self-attention mechanism is used to capture the global structure of terrain feature map, which can improve the performance of generator and discriminator to generate realistic terrains.

For terrain visualizations, terrain mesh generation and texture mapping are two key issues. For terrain mesh generation, it is mainly based on Levels of Detail (LOD) techniques. Related scholars proposed the concept of LOD for the first time and proposed a method for reducing the

complexity of model mesh in a recursive way [19]. The researchers introduced elevation variation coefficient to describe a terrain, which can improve the rendering efficiency of LOD algorithm when constructing a terrain mesh [20]. Relevant researchers proposed the layer-based Discrete Cosine Transform (DCT) method to simplify the terrain data in the terrain grid construction process, improving the efficiency of terrain grid construction [21]. For texture mapping, the researchers proposed a texture mapping method with multifeature control, which considered both terrain elevation value and terrain slope [22]. Researchers proposed a multiresolution texture seamless mapping method based on error control, which can realize seamless mapping by reducing projection errors based on the distance between texture block and viewpoint and the current LOD level [23]. Related scholars proved that a beach scene simulation method based on Poisson fusion, which can not only ensure realism but also effectively improve the rendering efficiency [24]. In order to build terrain mesh efficiently and improve the efficiency of terrain rendering, this paper adopts the terrain visualization method based on Levels of Detail.

3. Terrain Elevation Map Generation Based on Self-Attention Mechanism and Multifeature Sketches

To generate terrain elevation maps with rich natural features that can improve user immersion, our method first extracts terrain features based on adaptive feature enhancement to obtain terrain feature maps, then generates realistic terrain elevation maps based on self-attention mechanism, and finally realizes 3D terrain visualization based on Levels of Detail.

3.1. Terrain Feature Extraction Based on Adaptive Feature Enhancement. When generating terrain elevation maps, a large number of terrain samples and feature maps are needed as data sets. However, methods based on manual marking terrain feature maps are inefficient and cannot meet the practical application requirements. To extract terrain features efficiently and generate terrain feature maps automatically, it is necessary to study terrain feature extraction algorithms based on adaptive feature enhancement. In our method, an adaptive feature enhancement algorithm is used to preprocess the input data first. Afterwards, ridge lines, valley lines, and peak points are extracted by a profile recognition method. Finally, these terrain features can be extracted quickly and accurately as a terrain feature map.

3.1.1. Self-Adaptive Feature Enhancement. When performing adaptive feature enhancement, data need to be preprocessed first, followed by grayscale expansion. In the data preprocessing stage, when a terrain elevation map is input, the gray histogram is constructed.

As the larger the range of image grayscale, the difference between images will be more obvious, and more features can be distinguished. Hence, it is necessary to expand the

grayscale. The detailed steps of image grayscale expansion are as follows:

Step 1. Pixel number calculation: our method traverses the horizontal axis of a gray histogram in sequential order and then in reverse order to accumulate the number of pixels.

Step 2. Grayscale expansion: our method calculates the percentage of accumulated pixels to total pixels and sets a threshold K_{gray}. When this percentage reaches K_{gray}, the method records the minimum and maximum grayscale values as I_{min} and I_{max}, respectively. Pixel values that are less than I_{min} are mapped to 0 and pixel values that are greater than I_{max} are mapped to 255, as shown in (1):

$$O(i, j) = \begin{cases} 0, & I(i, j) < I_{min}, \\ 255, & I(i, j) > I_{max} \end{cases} \tag{1}$$

where $I(i, j)$ is the pixel value for row i, column j of the input image; $O(i, j)$ is the pixel value for row i, column j of the output image.

Step 3. Histogram equalization: the method performs histogram equalization for those pixels that have a grayscale value between I_{min} and I_{max} using (2), so that the pixels of each grayscale can be evenly distributed.

$$O(i, j) = 255 * \frac{I(i, j) - I_{min}}{I_{max} - I_{min}}. \tag{2}$$

The effect of grayscale expansion is shown in Figure 1, where the input image is shown in Figure 1(a), and the output image is shown in Figure 1(b). By comparison, it can be clearly seen that the terrain features of the output image are much clearer and more obvious.

3.1.2. Ridge Line Extraction. When extracting ridge lines from a terrain elevation map, we can judge whether a sampling point is a terrain feature point by comprehensively considering multiple profiles after adaptive feature enhancement. The specific process can be divided into five steps, namely, sampling map generation, feature point determination, feature-connected graph construction, ridge line prototype generation, and ridge line smoothing.

Step 1. Sampling map generation: since a terrain elevation map contains many pixels, the input data is sampled with a fixed step size to improve the efficiency of ridge line extraction. Using a method that traverses rows first and then columns, the sampling points are selected in order, and a sampling graph is generated.

Step 2. Feature point determination: in the sampling graph, the candidate points are determined by traversing the sampling points from left to right and from top to bottom. Our method traverses four profiles with the sampling point as the center and calculates the height difference between the central sampling point and other sampling points on each profile, as shown in

(a)   (b)
FIGURE 1: Comparisons of the effects before and after adaptive feature enhancement calculation. (a) Input image. (b) Output image.

Figure 2. For instance, in the "upper right-lower left" profile, if the elevation value of the central sampling point is higher than other sampling points on this profile, the central sampling point becomes a candidate point for the ridge line.

However, only depending on height differences to determine feature points is problematic since many ridge line feature points in valleys or with a low altitude will also be included. Hence, it is necessary to set a threshold for further screening. The threshold value is calculated based on the global maximum elevation value I_{max} and the minimum elevation value I_{min} in a terrain elevation map and uses weights to get ridge line feature points. The specific screening process is shown in (3):

$$P'_{(x,y)} \in \left\{ P_{(x,y)} | H_{(x,y)} > = w \left(I_{max} - I_{min} \right) \right\}, \qquad (3)$$

where $P_{(x,y)}$ is the previous sampling point before screening; $P_{(x,y)}$ is the sampled points after screening; $H_{(x,y)}$ is the elevation value of the sampling point; w is the weight.

Step 3. Feature-connected graph construction: based on the extracted ridge line feature points, a feature-connected graph can be constructed, which can be divided into two steps. Firstly, our method traverses the feature points from left to right and from top to bottom. Afterwards, from the current feature point, our method judges whether there are other feature points on every profile that uses the current feature point as the center. To avoid repeated calculation, only half of the profiles are traversed clockwise, and all feature points on the profile are connected, as shown in Figure 3. After traversing all the feature points, a feature-connected graph can be obtained.

Step 4. Ridge line prototype generation: based on the generated feature-connected graph, a ridge line prototype can be generated, which can be divided into three steps. Firstly, a feature edge queue is constructed. In the feature-connected graph, the edge connecting two adjacent feature points is a feature edge, and its weight is the sum of the elevation values of the adjacent feature points. Our method traverses all the feature edges of the feature-connected graph and sorts them
FIGURE 2: Four profiles with the current sampling point as the center.
FIGURE 3: Our method traverses half of the profiles clockwise from the top right direction.

based on their weights in descending order to get a feature edge queue. Afterwards, a minimum spanning tree is generated based on the Kruskal algorithm. Finally, our method removes redundant edges by traversing the feature edges in the minimum spanning tree

and judging the number of feature edges connected by the two endpoints of the current feature edge. If the number of feature edges connected by an endpoint is less than 2, the current feature edge is redundant and can be removed. After multiple iterative removals, a ridge line prototype is generated.

Step 5. Ridge line smoothing: when smoothing ridge lines, our method takes the current feature point as the center and traverses its adjacent feature points. The method accumulates the elevation values and coordinates of all feature points and updates the position of the current feature point according to (4):

$$P'(x_0, y_0) = \frac{\sum_{i=0}^{n} H(x_i, y_i) P(x_i, y_i)}{\sum_{i=0}^{n} H(x_i, y_i)}, \tag{4}$$

where $P'(x_0, y_0)$ is the updated coordinate of a ridge feature point; $P(x_i, y_i)$ is the coordinate value of all adjacent feature points; $H(x_i, y_i)$ is the elevation value for the feature point. This operation can add some disturbance migrations to the current coordinate point, which can make the extracted ridge lines more realistic.

The process of extracting valley lines is similar to the process of extracting ridge lines. In the stage of the sampling map generation, the sampling map is inversed. The rest of the steps above can be performed to obtain the extraction results of valley lines.

3.1.3. Peak Point Extraction.

A peak point is the highest point in a local area of terrain. When dealing with peak points, our method mainly performs the extraction from two perspectives: threshold screening and profile recognition. There are two steps in extracting peak points, namely, threshold calculation and feature point determination.

Step 1. Threshold calculation: to control the number of candidate peak points, it is necessary to perform a preliminary screening of candidate points by calculating the threshold. Firstly, our method constructs a gray histogram by traversing every gray level on the horizontal axis in reverse order and accumulating the number of pixels under each gray level. When the ratio of the accumulated value to the total number of pixels is l, our method stops traversing and takes the grayscale at this moment as the threshold K_{peak}.

Step 2. Feature point determination: our method screens the pixels larger than K_{peak} in the input elevation map to get candidate points. Since the candidate points only meet the global elevation value, further screening is needed to determine the local optimal feature points, which can be divided into two steps. Firstly, our method sets a profile, which is similar to the process in ridge line extraction. Afterwards, the elevation difference on each profile is calculated clockwise.

After traversing all candidate feature points, the final extraction results of peak feature points can be obtained.

Thus, terrain feature extraction based on adaptive feature enhancement is completed. Based on the steps above, extracted ridge lines, valley lines, and peak points features can be distinguished by different colors and are drawn into a terrain feature map to obtain the final result of terrain feature extraction.

3.2. Terrain Elevation Map Generation Based on Self-Attention Mechanism.

Sketch-based terrain editing is to generate a terrain elevation map with realistic natural features based on user-edited terrain feature sketches. To generate realistic terrain elevation maps, our method applies a self-attention mechanism to the Conditional Generative Adversarial Network, realizing a terrain elevation map generation algorithm based on self-attention mechanism.

The input of the algorithm is the terrain feature map obtained in Section 3.1 or a terrain feature sketch drawn by a user. Firstly, our method constructs a generator network based on the UNet network, which is used for generating a terrain elevation map. Afterwards, our method constructs a discriminator network based on the PatchGAN network, which is used for distinguishing real terrain samples from generating results. Then, our method adds a self-attention mechanism to the generator and the discriminator, respectively, for capturing global spatial features, which can improve the performance of the generator and the accuracy of the discriminator. Finally, our method trains the discriminator and generator according to the adversarial rules to get a generator model.

3.2.1. Generator Network Construction.

In this section, we describe how our method constructs a generator based on a UNet network, whose input and output are both two-dimensional matrices so that our method can generate terrain elevation maps based on terrain feature map inputs from users. In particular, the UNet network we used adopts jumping connections, which can avoid the issue of losing input data feature details due to the increase of network depth.

The input of the generator is a terrain feature map, and the output is a terrain elevation map generated based on prediction. The whole network of the generator consists of 10 modules, which are numbered from 1 to 10, respectively. Specifically, the modules numbered from 1 to 5 consist of two convolutional layers and one pooling layer; the modules numbered from 6 to 9 consist of two convolutional layers and an upsampling layer; the module numbered 10 consists of a convolutional layer. The diagram of the network is shown in Figure 4.

The construction process of the generator network can be divided into three steps, namely, encoding unit construction, decoding unit construction, and jumping connection setup.

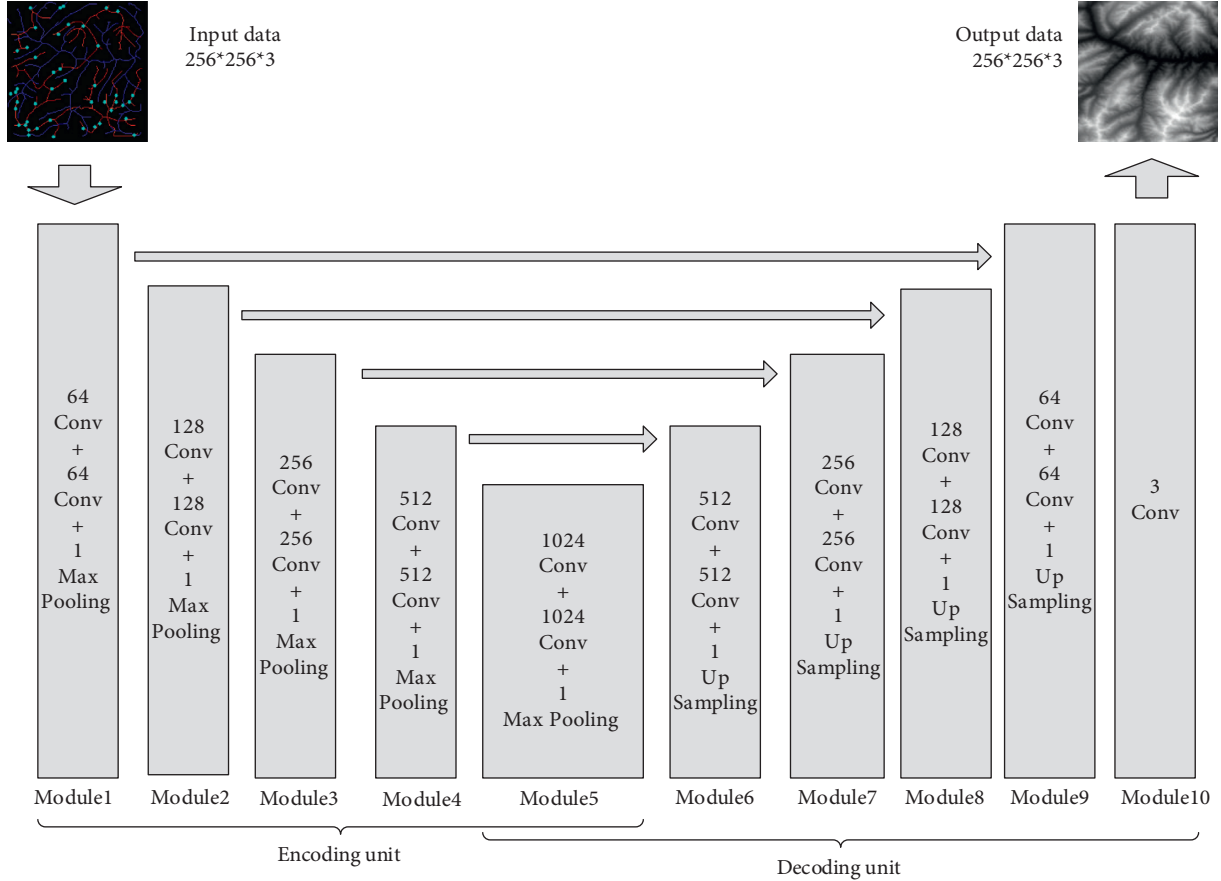
(1) Encoding Unit Construction. The encoding unit is used for encoding the input data to obtain the color, shape, and local spatial features from the input data. The encoding unit includes module 1 to module 5. Each module consists of two


Figure 4: The structure of the generator network.

convolutional layers, one pooling layer, and one activation function. Taking module 1 as an example, the construction process includes three steps: convolutional layer construction, pooling layer construction, and activation function setup.

Step 1. Convolutional layer construction: the convolutional layer is used to encode the input and obtain the implicit features from the input terrain data. The number of convolutional layers is set to 2; the size of the convolutional kernel is set to 3×3; and the number of convolutional kernels is set to 64.

Step 2. Pooling layer construction: the pooling layer is used to compress data and reduce the number of parameters so that the overfitting issue can be mitigated. The number of pooling layers is set to 1. The pooling method adopts the maximum pooling, and the pooling layer window size is set to 2×2.

Step 3. Activation function setup: the activation function is used to activate the input and perform nonlinear output. Leaky ReLU activates the output values that are greater than 0, as shown in equation (5):

$$\text{LeakyReLU}(x) = \begin{cases} x, & x \geq 0 \\ ax, & x < 0 \end{cases} \tag{5}$$

When the input x is negative, neurons can still learn, which will not lead to deviations in the final output results.

The parameter a is generally set to 0.01. Compared with module 1, the number of convolutional kernels of each convolutional layer in modules 2–5 is twice that of the previous module, and other configurations are the same as the previous module.

(2) Decoding Unit Construction. The decoding unit is used for decoding the feature information from input and outputting the predicted result. A decoding unit includes five modules, namely, module 6 to module 10. Module 6 to module 9 adopt the combination of two convolutional layers, one upsampling layer, and one activation function. Taking module 6 as an example, the construction process includes three steps: convolutional layer construction, upsampling layer construction, and activation function setup.

Step 1. Convolutional layer construction: the number of convolutional layers is set to 2; the size of the convolutional kernel is set to 3×3; and the number of convolutional kernels is set to 512.

Step 2. Upsampling layer construction: the upsampling layer and the pooling layer are opposite in terms of functionality; that is, the values of input data are repeatedly filled in the window size area for output. The number of upsampling layers is set to 1, and the window size of the upsampling layer is set to 2×2.

Step 3. Activation function setup: similar to the encoding part, Leaky ReLU is also used for activating output, and the parameter configuration is identical.

Compared with module 6, the number of convolutional kernels of each convolutional layer in module 7 to module 9 is half of that in the previous module, and other configurations are the same as the previous module. Module 10 contains only one convolutional layer; the convolutional kernel size is set to 3×3; and the number is set to 1. The module maps the input into the output result of 3 channels and predicts the terrain elevation map.

(3) Jumping Connection Setup. Jumping connection can solve the problem that the features of shallow output are gradually lost in subsequent network with the increase of network depth. In Figure 4, the jump connection is indicated by arrows between the corresponding modules in encoding units and decoding units. Taking module 1 and module 9 as an example, the output result of module 1 is directly passed to the third dimension of module 9 input data of the decoding unit so that the shallow output features can be retained in the corresponding deep network structure. This can avoid the loss of feature information and improve the performance of the generator.

3.2.2. Discriminator Network Construction. Since Patch-GAN maps the whole input data as a probability matrix, each value in the matrix represents the discriminant result of the local input. This operation can evaluate the locally generated result and improve the performance of the discriminator. Therefore, this section describes how a discriminator based on PatchGAN is constructed, whose structure is shown in Figure 5.

There are two types of input for the discriminator: (1) real terrain features and terrain samples and (2) real terrain features and generated pseudoterrain samples. Through these two sets of data, the ability to discriminate between real results and generated results can be trained.

The construction of a discriminator network is relatively simple. Firstly, our method sets four convolutional layers, and the convolutional kernel size is set to 4×4; the number of convolutional kernels in each convolutional layer is set to 64, 128, 256, and 512, respectively. After each convolutional layer, the output is activated by Leaky ReLU. Then, our method sets a convolutional layer, where the convolutional kernel size is set to 1×1, and the number is set to 1, which is used for combining the number of input channels into 1. Afterwards, the output is activated by a Sigmoid function to obtain a binary prediction result of the local area, where the size of the output probability matrix is set to 16×16, and the number of channels is set to 1. Finally, our method accumulates all the values in the probability matrix and calculates the average value to obtain the final discrimination result.

3.2.3. Self-Attention Mechanism Construction. In the process of terrain generation, the input terrain features include not only color, shape, and local space but also global spatial features. In real terrain elevation map samples, ridge line and valley line feature areas are often continuous areas, which are all global spatial features. This section introduces a self-attention mechanism to capture the global spatial features of the input data.

The process of building a self-attention module is shown in Figure 6. The input data is the feature map output from the previous layer, and the shape of the input data is $[h, w, c]$, where the length of the input feature map is h, the width is w, and the number of channels is c. The output is the fusion result of the self-attention feature and the original feature map, whose shape is consistent with the input data. The construction process includes three steps: input data initialization, local self-attention feature map calculation, and global self-attention feature map calculation.

(1) Input Data Initialization. The input data is initialized by convolution. As shown in equation (6), our method uses convolutional kernels W_f and W_g with a number of c/k and a size of 1×1 to perform convolution operations on the input data to obtain feature maps $f(x)$ and $g(x)$. In addition, our method uses a convolutional kernel W_h with a number of c and a size of 1×1 to perform convolution operation on the input data to obtain feature maps $h(x)$.

$$f(x) = W_f x,$$
$$g(x) = W_g x, \qquad (6)$$
$$h(x) = W_h x,$$

where the shape of $f(x)$ and $g(x)$ is $[h, w, c/k]$ and the shape of $h(x)$ is $[h, w, c]$.

(2) Local Self-Attention Feature Map Calculation. Our method first readjusts the shapes of feature maps $f(x)$, $g(x)$, and $h(x)$ to $[h*w, c/k]$, $[h*w, c/k]$, and $[h*w, c]$, respectively. Afterwards, our method calculates $f(x)g(x)^T$ according to equation (7):

$$a_{j,i} = \frac{\exp(s_{i,j})}{\sum_{i=1}^{N} \exp(s_{i,j})}, s_{i,j} = f(x_i)g(x_j)^T. \qquad (7)$$

Then, the softmax function is used to activate the output of the calculation result and obtain a local self-attention feature map $a_{j,i}$ with a shape of $[h*w, h*w]$, which represents the local attention to the i-th pixel when the j-th pixel is generated.

(3) Global Self-Attention Feature Map Calculation. The global self-attention feature map is obtained by fusing the global spatial information and the local self-attention feature map, as shown in equation (8):

$$o_j = \sum_{i=1}^{h*w} a_{j,i}h(x_i), h(x_i) = W_h x_i, \qquad (8)$$

where $a_{j,i}$ represents the local self-attention feature map; $h(x_i)$ represents the global spatial information; and o_j represents the global self-attention feature map when the j-th region is generated, and the shape is $[h*w, c]$.
FIGURE 5: The structure of discriminator network.
FIGURE 6: The flow of self-attention calculation.

In order to control the influence of the self-attention feature map, it is necessary to set parameters for the self-attention feature map and then fuse it with the initial input as the output. In this case, the network structure can first rely on local spatial features and then rely on remote spatial features during the training process, as shown in equation (9):

$$y_j = \gamma o_j + x_j, \tag{9}$$

where γ is the weight of self-attention with an initial value of 0. γ can be gradually assigned a larger value during the training process. The self-attention module described in this section is added after module 9 of the generator and after the

fourth convolutional layer of the discriminator, and the construction of the entire network is completed.

3.2.4. Network Training. We train the network after the network is built. The training of the network mainly includes three steps, namely, optimization target determination, training process setup, and loss function construction.

(1) Optimization Target Determination. The goal of this step is to generate a real terrain elevation map, and the evaluation standard is to judge whether it is a terrain elevation map

generated by the generator or a real terrain elevation map sample. Since this is a binary classification problem, we adopt a binary classification cross-entropy loss function to optimize the target. The calculation of the binary classification cross-entropy is shown in equation (10):

$$L_n = -\frac{1}{n} \sum_{i=1}^{n} \left[y_i \log(\widehat{y}_i) + (1 - y_i)(1 - \log(1 - \widehat{y})) \right], \quad (10)$$

where n is the number of samples; i is the current i-th sample; y_i is the label of i-th sample; $\widehat{y}_i$ is the probabilistic predicted value of i-th sample.

(2) Training Process Setup. The training process of a Generative Adversarial Network is a confrontation between generator and discriminator. The process of confrontation training is to fix the generator first, where the weights of the discriminator are trained and updated so that the ability of the discriminator to distinguish between true and false images can be maximized. Then the discriminator is fixed, where the network weights of the generator are updated so that the ability of the discriminator to distinguish between true and false images is minimized. As the generator cannot distinguish the true graph from the false graph, the performance of the generator can be improved. These processes are executed alternately until the loss function converges; the performance of the generator will be optimal at this moment, which can be used in practical applications.

(3) Loss Function Construction. According to the optimization goal and training process, the confrontation loss can be obtained, as shown in equation (11):

$$\min_G \max_D L_{G,D} = E_{(x,y)} \left[\log D(G(x \mid y)) \right] \\ + E_{(x,z)\mid y} \left[\log(1 - D(G(z \mid y))) \right], \quad (11)$$

where G is the generator; D is the discriminator; x is the real terrain data; and z is the noise data randomly generated in the generator. In addition, in order to measure the difference between the generated results and the official data at the pixel level and further improve the performance of the generator, this paper also introduces L_1 loss, as shown in equation (12):

$$L_1 = E_{(x,y)} \left[\| G(z \mid y) - G(x \mid y) \|_1 \right]. \quad (12)$$

Finally, the total loss function is obtained by synthesizing the above-mentioned confrontation loss and L_1 loss, as shown in equation (13):

$$L = L_{G,D} + L_1. \quad (13)$$

In this way, the construction of the whole network is completed. According to the training rule, we train the network weights and optimize the performance of the generator so that the trained generator can be used in the task of generating a terrain elevation map.

3.3. 3D Terrain Visualization Based on Levels of Detail. In order to build terrain mesh efficiently and ensure the smoothness of terrain visualization, this section studies the 3D terrain visualization algorithm based on Levels of Detail. Firstly, the nodes are defined by a quadtree structure, and then the terrain mesh is constructed according to the node information. Finally, multiple textures are added to the mesh.

3.3.1. Quadtree Structure Construction. Quadtree structure is a tree structure where each node includes 0 or 4 subnodes. When each node is split, the details can be improved. For a terrain mesh, when the subdivision degree of the mesh is increased, the details of the mesh will be richer. The construction of a quadtree structure can be divided into the following steps: defining nodes, calculating node coordinates, and judging whether a node needs to be divided and stored, and a complete quadtree structure can be obtained finally.

3.3.2. Terrain Mesh Construction. Based on the quadtree structure, a terrain mesh with multiple Levels of Detail can be created. Since a terrain mesh is composed of triangular faces that are surrounded by vertices, there are two steps to construct a terrain mesh, namely, creating vertices and drawing triangular faces. The drawing of triangle faces is based on the quadtree structure, where the nodes are recursively operated from the root node until all elements in the quadtree node array are traversed. Thus, a terrain mesh with Levels of Detail is constructed.

3.3.3. Multiple Texture Addition. Since 3D terrain visualization needs both terrain mesh and texture, it is necessary to add multiple textures to improve the realism of visualization results. It can be divided into three steps, namely, selecting terrain textures, creating mask textures, and fusing output. As shown in Table 1, there are four kinds of terrain textures used for visualization, namely, land, grassland 1, grassland 2, and moss, which correspond to different elevation value intervals in terrain, respectively. When performing texture mapping, the texture pixel value of a mesh vertex is calculated based on the value of mask texture. The four channel values in the mask texture and the corresponding pixel values in the four textures are multiplied and then summed, and the fused texture is the final output.

In this way, the 3D terrain visualization based on Levels of Detail is completed, which can realize the efficient construction of terrain mesh and realistic texture mapping, making interactive terrain editing more interesting.

4. Experimental Analysis

The experiment was designed to verify the feasibility and effectiveness of the multifeature sketch terrain elevation map generation method based on self-attention mechanism. The hardware environment of the verification system includes AMD Ryzen 7 4800H CPU, 16 GB RAM, and NVIDIA GeForce RTX2060 GPU. The software environment includes Windows 10 operating system, PyCharm 2019, Visual Studio

TABLE 1: Textures used in the experiment.

Land	Grassland 1	Grassland 2	Moss

2019, and Unity3D 2019. *Python* and C# are used as the main development languages.

In this study, six experiments are designed, namely, terrain feature extraction experiment, terrain generation comparative experiment, self-attention mechanism comparative experiment, terrain mesh construction comparative experiment, multiple textures addition experiment, and interactive terrain editing software experiment.

4.1. Experiment for Terrain Feature Extraction. To verify the feasibility of terrain feature extraction based on adaptive feature enhancement, a terrain feature extraction experiment was designed.

Firstly, adaptive feature enhancement was performed. Taking the terrain elevation map input in Figure 7(a) as an example, data preprocessing and grayscale expansion were performed. When expanding grayscale, K_{gray} is set to different values in Figures 7(b)–7(d). It can be seen when K_{gray} is set to 1%, the details of terrain features can be well retained while the features can be enhanced. According to the result in Figure 7(c), terrain feature extraction was performed.

The specific steps of ridge line extraction are as follows.

First, we set the sampling distance to 5 pixels to generate a sampling map. We also set the profile for the sampling points, where the length of the profile was set to 7, making preliminary screening based on the profile. Then, according to equation (3), the threshold was set for further screening. Based on our pilot study, we found that 0.03 was an ideal value for the weight w. The final result of feature point extraction is shown in Figure 8. Afterwards, the feature-connected graph was constructed by traversing all feature points, starting from the current feature point and connecting the feature points on the profile. The final construction result is shown in Figure 9. Then, we sorted the feature edges and stored them in the feature edge queue to create a minimum spanning tree according to the feature edge queue, as shown in Figure 10. The number of iterative deletions was set to 3, so the redundant edges in the minimum spanning tree can be removed to obtain a prototype of the ridge feature line, as shown in Figure 11. Then, smoothing was performed on the feature-connected graph to make the feature lines more similar to real terrain features. The smoothing result is shown in Figure 12.

The valley line extraction process is similar to the ridge line extraction process. When generating a valley line sampling map, the sampling map is inversed, and then the steps above are performed to obtain the valley line extraction result, as shown in Figure 13.

Finally, we extracted the peak points. First, we calculated the threshold value. Our pilot study showed that when the accumulated number of pixels accounted for 5% of the total number of pixels, the number of selected peak points was more suitable. Then, we determined the feature points and the peak points through the profile recognition and elevation difference. The extraction result of the peak point is shown in Figure 14.

4.2. Comparative Experiment for Terrain Generation. To verify the feasibility of terrain elevation map generation based on a self-attention mechanism, this experiment was performed from two aspects: (1) using real terrain features to demonstrate generated terrain elevation maps and compare the differences between the generated results and real terrain samples; (2) using hand-painted terrain features to demonstrate generated terrain elevation maps and 3D visualization effects.

(1) Using Real Terrain Features. We input real terrain features in the trained generator model for prediction and compared the differences between the generated terrain elevation maps and real terrain samples.

The experimental results are shown in Table 2, where the features of ridge lines, valley lines, and peak points in the generated terrain elevation maps were consistent with the features in real terrain feature maps. To evaluate the similarity between the generated results and the real terrain results, the SSIM image similarity evaluation algorithm was used. The calculation result of SSIM is between 0 and 1; the closer the result is towards 1, the more similar the two images will be. It can be seen that the SSIM results obtained by our method were all greater than 0.5, which suggested that the similarity with the original image was high. This demonstrated the feasibility of our proposed method, which can meet the needs of interactive terrain editing.

(2) Using Hand-Painted Terrain Features. To further verify the feasibility of our proposed method, this experiment input terrain feature sketches drawn by users into the trained

FIGURE 9: Feature-connected graph build based on feature points.
FIGURE 11: Feature line prototype after redundant edge removal.

generator model for prediction and demonstrated the generated terrain elevation maps and 3D visualization results.

The experimental results are shown in Table 3. It can be seen that terrain feature sketches can be very simple, which only have a few simple strokes. We input these sketches into the trained generator model, which can generate highly realistic terrain elevation maps based on these sketches.

We also used World Machine software to render the terrain elevation maps based on user sketches to further verify the realism of editing results. It can be seen that the rendered terrain results have realistic ridge lines, valley lines, and peak points, which can meet the demands of interactive editing.

4.3. Comparative Experiment for Self-Attention Mechanism. To verify the effectiveness of the self-attention mechanism in terrain elevation map generation, this experiment compared the results with and without the self-attention mechanism.
FIGURE 12: The final result of ridge line feature extraction.
FIGURE 13: The result of valley line feature extraction.
FIGURE 14: The result of peak point feature extraction.

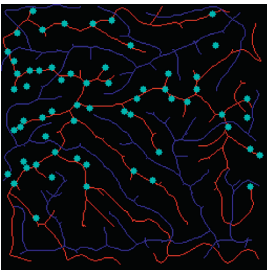
The input was the terrain features of real samples, as shown in Table 4. It can be seen that some ridge line and valley line structures in the generated results are incomplete without a self-attention mechanism, as shown in the places marked by red circles. In contrast, the results with the self-attention mechanism are much better in terms of completeness and detail, and the generator model also has a higher performance.

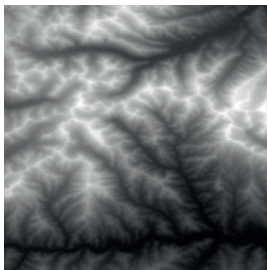
4.4. Comparative Experiment for Terrain Mesh Construction. To verify the feasibility and effectiveness of the terrain mesh construction in our proposed method, a terrain mesh

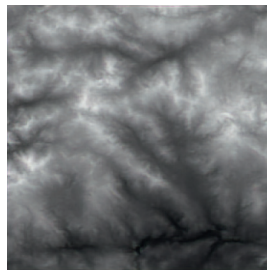
construction experiment based on Levels of Detail was designed.

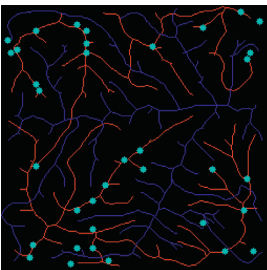
First, we established a quadtree structure. Afterwards, we constructed a terrain mesh and a vertex array. According to whether each node can be divided, a terrain mesh was constructed by drawing triangle faces. In the scene view in Unity3D editor, WireFrame mode was used to display the terrain mesh. The result is shown in Figure 15.

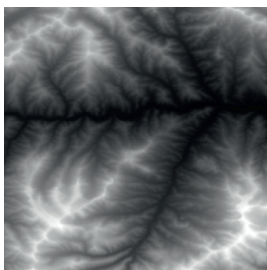
It can be seen that the terrain mesh constructed based on Levels of Detail has lower mesh complexity. While the areas that are far from the viewpoint have lower details, the areas that are close to the viewpoint have greater details. By moving the viewpoint, the changes of details can be clearly seen in local terrain areas. As shown in Table 5, when the camera moved towards the terrain mesh, the terrain details became gradually enriched. Thus, our method realized dynamic control of mesh details, and rendering efficiency was high.

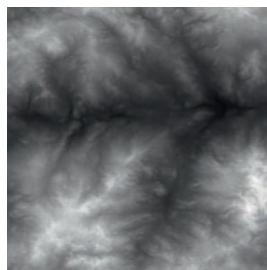
4.5. Experiment for Multiple Texture Mapping. To verify the effectiveness of using multiple textures to enhance the realism of 3D terrain, an experiment of multiple texture mapping was designed.


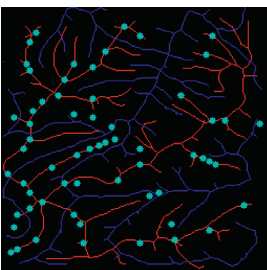


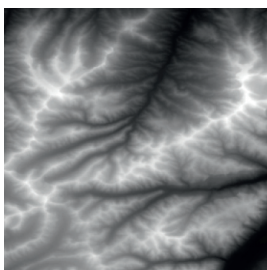


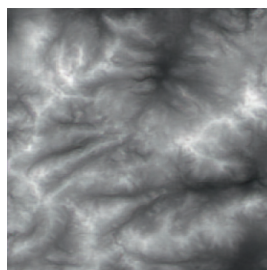












First, a mask texture was created based on a terrain elevation map drawn by a user. Then, the sample texture and mask texture were fused for outputting multiple textures, which adopted different elevation value intervals for different texture mapping. Finally, random translations and mirror operations were performed on the sample texture to reduce texture repetitions during the tiling process.

The experimental results are shown in Figure 16. It can be seen that multiple texture mapping can assign different textures based on the elevation value intervals of the terrain elevation map. From 3D visualizations of terrains, users can have an intuitive and fun experience in interactive terrain editing and terrain elevation map creation.

4.6. Experiment for Interactive Terrain Editing. To provide a good user experience for interactive terrain editing, we designed an interactive terrain editing tool based on the methods for terrain feature extraction, terrain elevation map generation, and 3D terrain visualization that are described earlier in this paper. With the help of this tool, users can freely draw ridge line, valley line, and peak point features on a sketch. The tool can generate terrain elevation maps with realistic features in real time based on the sketch and provide 3D visualization for the terrain that users can interact with.

The interactive terrain editing tool based on a multi-feature sketch can be divided into four modules: terrain feature extraction module, terrain elevation map generation module, terrain visualization module, and human-computer interaction module. Specifically, terrain feature extraction is used for extracting terrain features, creating data sets, and training networks to get the generator model with the best performance. With this generator model, the terrain elevation map generation module can generate a terrain elevation map based on a terrain feature sketch drawn by a user. The terrain visualization module adopts LOD mode to build

TABLE 2: Generated terrain results based on real terrain features.

Terrain features	Real terrain samples	Generated results	SSIM
			0.60
			0.65
			0.63

a terrain mesh and adopts multiple texture mapping to improve the realism of 3D terrain. Finally, the human-computer interaction module provides a user interface for the functionalities above, creating a good user experience for the interactive terrain editing tool.

(1) Terrain Feature Extraction Module. Terrain feature extraction module is the core module for interactive terrain editing. In the terrain editing tool, terrain features are distinguished by using different colors and drawing methods. Specifically, red lines are used for ridge lines; blue lines are used for valley lines; cyan dots are used for peak points.

(2) Terrain Elevation Map Generation Module. Terrain elevation map generation module is the basis for real-time interactive terrain editing. The trained generator model can be loaded by the LoadModel() method in the Keras library. A series of format conversions are performed on the user-created feature sketch to obtain a suitable data format for the model input, and the Predict() method is called to predict and generate a terrain elevation map. Finally, the generated

result is converted to PNG format, where the user can choose different resolutions to save the file.

(3) Terrain Visualization Module. Terrain visualization module allows users to observe the generated results intuitively. The module includes two submodules: mesh construction and texture mapping. Due to the LOD-based mesh construction, it is possible to ensure the user experience on low-performance devices.

(4) Human-Computer Interaction Module. Human-computer interaction module can have a great impact on user experience for the terrain editing tool. The module can be divided into two submodules: interactive user interface module and interactive function module. Specifically, the interactive user interface module includes a main user interface, a feature extraction user interface, and a roaming user interface; interactive function module includes terrain feature extraction function, editing and saving function, and roaming display function.

The initial user interface of our interactive terrain editing tool is shown in Figure 17. The black area on the

left side is the user sketch drawing area, and the white area on the right side is the terrain generation area. The rightmost sidebar has six functions, namely, feature extraction, drawing board emptying, work saving, roaming display, terrain feature selection, and output resolution selection.

Users can click the feature extraction button to start terrain feature extraction, which can perform feature enhancement and feature extraction operations on the local terrain elevation map data sets. The user interface for terrain feature extraction is shown in Figure 18. After successful input, feature enhancement, and extraction, a popup will be

FIGURE 22: The result of snow-style terrain visualization.

displayed to indicate the operation is successful, as shown in Figure 19 and Figure 20.

Users can select different brushes to draw terrain features on a sketch, and the generated results will be displayed in the terrain generation display area. As shown in Figure 21, three types of features, including ridge lines, valley lines, and peak points, are drawn on the sketch. Since the low-level GPU-driven generator is used, the calculation can be done in real time. When a user is drawing terrain features on the sketch, the prediction of terrain elevation map can be completed in real time.

After drawing, the user can click the roaming display button to start interactive roaming to observe the visualization effect of 3D terrain. To increase the fun for user interaction, users can click the number key 1 to display a snow scenery, which can display a terrain under different weather conditions, as shown in Figure 22.

5. Conclusions and Future Work

To address the issues of low efficiency in obtaining terrain feature map by manual annotation and poor realism in generated terrain elevation map, this paper proposes a method of generating terrain elevation map based on self-attention mechanism and multifeature sketch. First, a terrain feature extraction method based on adaptive feature enhancement and profile recognition is proposed to realize the rapid and automatic terrain feature extraction of ridge lines, valley lines, and peak points, which can perform well in large-scale terrain feature map generations. Afterwards, our method adopts terrain elevation map generation based on the self-attention mechanism, where a generator network based on UNet network and a discriminator network based on PatchGAN network are built, and then self-attention mechanism are added to the generator and the discriminator, respectively, to capture the global spatial features for generating a realistic terrain elevation map. Finally, by constructing a terrain mesh and adding multiple textures, a 3D terrain visualization method based on Levels of Detail is proposed, which can provide high rendering efficiency and realistic visualization results. In this paper, an interactive terrain editing tool based on a multifeature sketch is implemented, which allows users to interact with the generated terrain. Experimental data show that the proposed method is effective in terrain feature extraction, terrain elevation map generation, and 3D visualization. In addition, the editing tool can run smoothly, providing intuitive user interactions and a good user experience.

Since the research on interactive terrain editing techniques is conducted under specific conditions, there are certain limitations and spaces for optimization. Here are a few points that can be further studied in theory and practice:

(1) *Network Structure Optimization.* The network adopted in this paper is based on the Conditional Generative Adversarial Network structure. In the future, we can explore the influence of different network structures on the generation results and the efficiency of different training models and further optimize the network structure.

(2) *Texture Mapping Optimization.* Despite the fact that multiple texture mapping is used in this paper, there is a limit on the number of textures. In the future, we can explore new ways to create mask textures, eliminating the limitation on the number of sample textures to achieve more realistic texture mapping.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

The authors declare that there are no conflicts of interest regarding the publication of this paper.

Research Article

Research on the Prediction of Popularity of News Dissemination Public Opinion Based on Data Mining

Jing Tian [iD], Huayin Fan, and Zengwen Hou

Journalism & Communications College, Jilin Normal University, Changchun 130012, Jilin, China

Correspondence should be addressed to Jing Tian; tj80@jlnu.edu.cn

The development of news public opinion presents the characteristics of dynamic changes, and its life cycle is generally relatively short. For news public opinion to be welcomed by everyone, that is, to become hot news, it must be able to spread to a large number of readers in a short time. And, some of its characteristic attributes must satisfy the interests of most users and arouse users' desire to read. Therefore, it is particularly important to extract and study these characteristic attributes that determine the popularity of news public opinion and finally establish a model to describe the relationship between the popularity of news public opinion and these characteristic attributes. Based on data mining, this article mainly studies the popularity of news public opinion from two aspects. First is the sampling and attribute feature extraction of news. Then, considering the nonlinear relationship between the features, an improved principal component analysis method is proposed to analyze the correlation of the features. This can select important features from many irrelevant features and effectively reduce the original high-dimensional features. Second, the application of neural network in the prediction of news public opinion is studied. BP is an efficient data mining method. Considering BP network has some shortcomings. This work uses an improved particle swarm optimization to optimize the initial parameters for BP network, which can compensate for the defects of BP network. After that, the BP network with optimized parameters is used to establish a prediction model for the popularity of news public opinion. The experimental results prove that the neural network model proposed can accurately predict the popularity of news public opinion.

1. Introduction

The term news was first born in the Tang Dynasty and refers to the time that was recently heard or what happened recently in society. The meaning of the word news has not changed much after more than a thousand years of development. However, the dissemination of news has undergone earth-shaking changes after more than a thousand years of historical changes. Traditional news dissemination, from small-scale oral transmission to newspapers, to wireless broadcasting, and to TV broadcasting, blooms in many ways and has various channels. Nowadays, the news is presented on everyone's mobile terminal, and traditional news dissemination methods have gradually withdrawn from the market [1–5].

With the rapid development of the Internet, the Internet has become a part of people's lives. People use mobile phones to receive information and view news anytime and anywhere on the Internet. Compared with traditional news dissemination, the Internet not only brings more traffic but also shortens the generation, creation, and dissemination time of news exponentially. The data shows that more than 2,600,000 news are shared every minute on Facebook, the average number of online videos shared every minute on LINE is 8,333, and the number of news links shared every minute on Twitter is close to 300,000. Interconnection has detonated the information age, and news hotspots have been generated all the time. Traditional news dissemination is restricted by channels, and the audience is limited. Even if it is a hot topic, its influence is also limited. But nowadays, the coverage of breaking news is so wide that it is unimaginable [6–10].

In the Internet age, news and public opinions cover all aspects of our lives. The real-time, uncertain, and rapid

spread of the Internet make the characteristics of online news public opinion show the characteristics of the new era such as randomness, suddenness, and concealment. In such an era, everyone on the Internet can become a publisher and disseminator of information, as well as a creator of news and public opinion. Of course, news and public opinion are not all good, and the domestic Internet environment is not a pure land, which is full of negative, distorted, extreme, inciting violence and division factors. Popular news, especially breaking news, as a powerful means of communication, is not only conducive to the rapid dissemination of information but also conducive to the transfer of value. Under such a background, predictive analysis of the popularity of news and public opinion is beneficial to the healthy development of the Internet and curbs negative information such as rumors and violence, at the same time, producing news or advertisements that can arouse people's general goodwill. It has great value for many Internet publishers, portal websites, and Internet advertising companies. The development of news public opinion presents the characteristics of dynamic changes, and its life cycle is generally relatively short. If a piece of news is to be welcomed by everyone, it becomes hot news. It must be able to spread to a large number of readers in a relatively short period of time, and some of its characteristic attributes must satisfy the interests of most users and arouse users' desire to read. Therefore, it is particularly important to extract and study these characteristic attributes that determine the popularity of online news, analyze their interrelationships, and finally, establish a model to describe the relationship between the popularity of news public opinion and these characteristic attributes [11–15].

The contributions are as follows: (1) This work proposes an improved principal component analysis method to analyze the correlation of features. In this way, important features can be selected from many irrelevant features, effectively reducing the dimensionality of the original high-dimensional features. (2) This work uses an improved particle swarm optimization to optimize the initial parameters for the BP network. It can make up for the shortcomings of BP and use the BP network with optimized parameters to establish a prediction model for the popularity of news and public opinion.

2. Related Work

Compared with traditional news and advertising industries, Internet news, with its low-cost, fast-spreading, and wide-ranging features, had a huge impact on the traditional news industry and had shown initial advantages. Due to the real-time characteristics of news and the guiding characteristics of public opinion, accurately predicting the popularity of a news manuscript for the roles of journalists, content providers, advertisers, etc., had become a new research hotspot. However, predicting the popularity of news articles on the Internet was a challenging task. First of all, the content of these articles was only available online. The structure of the social network that spreads news was different, which would affect the probability that users can see this article. In addition, the coverage of the content of the article was also a

factor that affects the prediction of the results. For example, articles that were closely related to the general public on a global scale are more popular than articles that only targeted a small number of social groups.

For this challenging work, a lot of research had been devoted to it, and a lot of questions had been raised. Literature [16] put forward the problem of tracking the spread of online topics. Literature [17] proposed detecting the public opinion orientation of online communities. The literature [18] put forward the field of prediction of the popularity of social media. There were many different ways of expressing the concept of popularity. For example, our most common classic method was the number of clicks on a piece of news, but this information was of little significance to researchers. Because in fact, due to the existence of web crawlers and search engines, it was difficult for us to estimate the number of times, an article was actually requested by users, which would directly lead to the inaccuracy of the original data. In addition, there were some other methods based on the user's own participation, such as comments, voting, and sharing via email or WeChat. Predicting the popularity of news articles was a difficult task, and a lot of research results had been accumulated over the years. Literature [19] proposed a model to predict the popularity of news published by science and technology information websites. This method believed that the popularity of articles will gradually increase over time. Literature [20] proposed two algorithms for predicting video popularity and news popularity and achieved good prediction results. Literature [21] proposed a linear logarithm method, which can meet the forecasting demand in a specific range. Literature [22] proposed a different way of thinking. He established a new prediction model based on the social influence of news and the characteristics of the publishing platform. The disadvantage of this type of algorithm was that it could only be applied to predictive analysis in a specific field but failed to analyze articles on different topics. Literature [23] proposed a new forecasting idea, which focused on the prediction of the popularity of certain news that would continue to be paid attention to after a certain period of time. Literature [24] proposed a method. Using the number of news sharing as a popular indicator, a clustering algorithm was used to divide different articles into 4 categories according to their popularity. Literature [25] proposed a new idea to predict the popularity of online news and ranked it according to the popularity. The disadvantage of this type of method was that it could not give an accurate prediction value.

Driven by the Internet industry chain, Internet + had become an industrialized concept, and network news was quickly spread through the Internet as a carrier. Data showed that more than 26,000 news were shared per minute on Facebook, the average number of online videos shared per minute on LINE was 8333, and the number of news links shared per minute on Twitter was close to 3,000. Clarifying how popular the public was for a piece of news has become a new branch of research.

At present, many models for tracking and forecasting online news based on time series had been proposed. These models assumed that the evaluation of popularity was time-

sensitive. The number of users of YouTube videos fluctuated continuously within 24 hours, and the number of their shares was also constantly changing. The literature [26] aimed at analyzing the life cycle of online news; this research used a threshold value to compare and calculate the number of news shares in 7 days. At the same time, the feature extraction method was another subtle branch in the field of social news research. It mainly focused on the news itself and removed some possible influence factors, such as time, comment, and emotional color. The reason why time was eliminated was that the number of news sharing gradually increases with the passage of time. But its impact on users would gradually become zero after a certain point in time. In addition, the results of this research field were diversified because of the existence of various media forms, including videos, music records, and plain text information [27].

3. Method

3.1. Improved Principal Component Analysis

3.1.1. Algorithm Background. When predicting the popularity of news public opinion, it is necessary to extract the characteristics of the news. Under normal circumstances, these features are high-dimensional, and processing these features is more complicated. Therefore, it is necessary to reduce the dimensionality of the features before making subsequent predictions. Principal component analysis has become a classic and effective statistical dimensionality reduction method. It has been successfully applied to linearly distributed data for a variety of practical problems and has also achieved remarkable results. At the same time, the algorithm for further expansion of principal component analysis has also been effectively developed.

First of all, through research, we can know that sparse principal component analysis is based on principal component analysis, which mainly transforms the problem of solving the principal component load into a ridge regression problem. A regularization penalty term is added to the essence of such an optimization regression problem to compare the load of each principal component. This promotes a load of some relatively weak variables to approach zero, achieving a sparse effect. At present, there are generally two types of penalty items in sparse principal component analysis: L_1 penalty items and TL_1 penalty items. The L_1 penalty term was originally proposed by the literature [28] when the L_1 penalty term was combined with the ridge regression term in the optimization problem transformed by principal component analysis. It can constitute an elastic net penalty item. The penalty characteristic of the elastic net penalty item is between the L_1 penalty item and the L_2 penalty item. The TL_1 penalty term is based on the literature [29] with a certain transformation in the form of the L_1 penalty term, and new parameters are added to the numerator and denominator to control its characteristics between the L_0 penalty term and the L_1 penalty term. However, the essence of sparse principal component analysis is still aimed at processing linear data, and the processing of nonlinear data has not yet achieved the desired effect.

In view of the situation that nonlinear data cannot be handled well, kernel principal component analysis can solve this problem well. For high-dimensional feature space, this method uses the kernel function to project sample points from the original space with a linear distribution. This method and PCA have been combined naturally. This obtains sample points that are linearly distributed in high-dimensional space and finally uses principal component analysis in this space. Through the addition of the kernel function, the principal component analysis problem of nonlinear data is successfully solved. At the same time, it avoids the difficulty of not being able to obtain an explicit projection function by constructing a kernel matrix. This successfully transformed the way of analyzing the data covariance matrix into the way of analyzing the kernel matrix.

In this section, this article will focus on giving another extension method based on principal component analysis. This method is also an improved method based on the thinking of other expansion methods of principal component analysis in this article. The sparse kernel principal component analysis based on the TL_1 penalty term is based on the thinking of sparse penalty and kernel principal component analysis. After learning sparse principal component analysis and kernel principal component analysis, it is logical to think of merging the two to get a sparse kernel principal component analysis in a high-dimensional space. In this way, the linear transformation of nonlinear data can be realized, and the sparse principal components can also be obtained in the feature space. This highlights the important variables and weakens the influence of some variables on the overall result, which has a simple and robust effect. Therefore, based on the method research on the principal component analysis, this paper proposes a sparse kernel principal component analysis.

3.1.2. Improvement Strategy. The sparse kernel principal component analysis with TL_1 penalty term combines the characteristics of the kernel principal component analysis as well as the sparse penalty, which can be implemented on nonlinearly distributed data. Its idea is similar to the sparse principal component analysis. What is considered in the sparse principal component analysis is to compare and sparse the linearly distributed data subjected to principal component analysis in the original space. When the covariance matrix is used to decompose to obtain the load, it is converted into an optimization problem, and then a penalty term is added to approach the partial load to zero. Therefore, through similar considerations, the original variables are transformed in the nuclear principal component analysis. At the same time, the eigenvalue decomposition of the sample point covariance matrix in the high-dimensional eigenspace is required. However, since the projection function cannot be obtained explicitly, it is finally transformed into the decomposition of the kernel matrix. Therefore, when the kernel matrix is eigen-decomposed, it can be transformed into an optimization problem. Then, we add the TL_1 penalty term to this optimization problem, so that the new coordinates of the sample points in the feature space are sparse.

The characteristic equation for solving the kernel principal component analysis is

$$Kv_i = f_i v_i, \tag{1}$$

where K is the kernel matrix and f_i is the eigenvalue corresponding to the eigenvector v_i.

Then, the above equation can be written as an optimized regression model:

$$\widehat{v}_i = \underset{v_i}{\arg\min} \, K - f_i v_i v_{i2}^{T2}. \tag{2}$$

Assuming $v_i = f_i v_i$ and $\alpha_i = v_i$, then equation (2) can be written as

$$(\widehat{\alpha}_i, \widehat{v}_i) = \arg\min K - v_i \alpha_{i2}^{T2}. \tag{3}$$

So far, this paper has transformed the principal component loading problem in nuclear principal component analysis into a regression optimization model. Therefore, the TL_1 penalty term can be added to the above optimization problem, so that v_i can be sparse. The model based on TL_1 penalty term sparse kernel principal component analysis is obtained as

$$\widehat{v}_i = \underset{v_i}{\arg\min} \, K - v_i \alpha_{i2}^{T2} + \lambda_1 \frac{(b+1)v_{i1}}{b + v_{i1}}, \tag{4}$$

where λ_1 and b are the parameters that need to be customized.

So far, this paper has given a sparse kernel principal component analysis model based on the TL_1 penalty term. It can be seen from this model that its idea is similar to sparse principal component analysis. The biggest difference is that sparse principal component analysis is aimed at the covariance matrix of the data. The sparse kernel principal component analysis based on the TL_1 penalty term is aimed at the mapped kernel matrix. From the perspective of the threshold iteration method, the threshold iteration algorithm for solving the sparse kernel principal component analysis based on the TL_1 penalty term is as follows:

> Step 1: normalize the input matrix to get the output matrix X. Step 2: use the kernel method to process the matrix X to obtain the kernel matrix K in the high-dimensional space. Step 3: use general principal component analysis on the matrix K to get the load matrix V. Step 4: let A' be the first k-dimensional column vector of the load matrix V; that is, $A' = V[, 1: k]$. Step 5: let the initial coefficient of the i-th principal component be x_i, given reasonable parameter values. Step 6: compare the size relationship between the parameters, and then perform the corresponding processing. Step 7: repeat Step 4 and Step 5; stop iterating when the conditions are met.

Therefore, this paper presents the basic model and algorithm of sparse kernel principal component analysis with TL_1 penalty terms. It can be seen from the above steps that the penalty functions used are all TL_1 penalty items. The process is basically similar to the solution of TL_1 penalty

term sparse principal component analysis. However, the most essential difference between the sparse kernel principal component analysis with TL_1 penalty term and the sparse principal component analysis with the TL_1 penalty term in the solution process is whether the original data has undergone a nonlinear transformation, that is to say, whether the data is mapped to the high-dimensional space. If it has undergone nonlinear processing, it is necessary to decompose and iterate the kernel matrix. Without this step, you only need to iteratively decompose the covariance matrix.

In general, an iterative algorithm is a more direct algorithm for solving optimization models. Iterative algorithms do not need to give a specific algebraic solution. Instead, it reaches a local optimal or global optimal solution by going through multiple cycles and iterations in a certain direction until it converges. However, there are many aspects that need attention in iterative algorithms. First, the selection of parameters in the iterative algorithm plays an important role and may even affect the selection of the final optimal solution. Therefore, a suitable method is needed to help the selection of parameters. Secondly, because the iterative algorithm achieves the purpose of solving by means of continuous loop iterations, so it is deeply affected by the number of iterations and accuracy. There may be a relatively large amount of calculation, especially when iterating all the elements in each vector of a matrix. Therefore, it can determine the appropriate threshold and number of iterations.

3.2. Improved BP Network

3.2.1. Improved Particle Swarm Optimization. After using the proposed principal component analysis method to reduce the dimensionality of the features, this paper uses the BP network to model these features to predict the popularity of news public opinion.

Prediction accuracy is low due to random selection of initial threshold and weight parameters and the BP network's tendency to slip into the local minimum state. This results in poor performance. BP neural network model predictions can be enhanced by using an upgraded particle swarm technique to optimize the starting parameters. Model predictions can be made using a more accurate BP model that has been optimized for use in this study.

Particle swarm optimization (PSO) is an algorithm based on swarms that is extremely clever. The algorithm is easy to develop, is precise, and quickly converges to the best solution. It can effectively optimize various functions and is suitable for application in multiobjective constrained optimization problems. And it has better efficiency and practicability in solving various problems. At present, it has achieved good application results in constrained optimization, function optimization, various engineering design problems, and other fields.

Based on population dynamics, particle swarm optimization (PSO) is a population-based approach for solving optimization problems. One of its most fundamental aspects involves the creation of an initial group of particles in space using a randomized search process. Iteration is used to find

the best solution for these particles, which begins with a random solution. There are three ways to express the attributes of a particle in an optimization problem: position, speed, and the fitness value. The fitness function can be used to calculate the particle's fitness value, which can be used to determine the particle's advantages and disadvantages. During each repetition, the particle updates itself by observing two points of departure. The individual extreme value is the one being sought by the particle, whereas the global extreme value is the one being sought by the entire group at the same time. Particles modify their speed and position by following these two extreme values, which each particle follows.

The basic principle of PSO mainly includes the initialization of particle swarm, the calculation for particle fitness, the update of particle speed and position, and the determination of termination conditions. The specific steps are as follows:

> Step 1: initialize the particle swarm. Step 2: calculate the objective function value, namely, fitness. Step 3: calculate fitness after the location update. The fitness is analyzed and compared with its individual extreme value Pbest. If fitness > Pbest, replace Pest with fitness. Step 4: compare fitness with the global extreme value Gbest. If fitness > Gbest, replace Gbest with fitness. Step 5: update the speed and position. Step 6: judgment of termination conditions. If the algorithm progresses until the end condition is met, the iterative calculation process is stopped, and the result is output at this time. Otherwise, the algorithm returns to Step 2.

A particle swarm algorithm can better solve combinatorial optimization problems. But this algorithm also has some shortcomings. Algorithm search accuracy is not very great and it is easy to get caught in the trap of local minimum solutions when using it. A modified particle swarm method using inertia weight has been developed to address these problems; in this way, the algorithm's search performance can be improved and it can avoid getting stuck in a local optimal scenario.

Among the various parameters of PSO, inertia weight w is an important parameter. This parameter affects the local optimal ability as well as the global optimal ability, and its value can reflect the speed of the particle's flight. If, in the algorithm parameter setting, the value for inertia weight w increases, the flying speed will increase, which can enhance the global search capability. On the contrary, if the value of w is reduced, the flying speed of the particles will slow down, which is beneficial to improve the local searchability. Therefore, it is necessary to select an accurate inertia weight w, so that the particles have balanced searchability, and effectively improve the exploration ability of the algorithm.

At present, many scholars have proposed improved methods for inertial weights, such as random weighting algorithms and fuzzy inertial weighting algorithms. One of the more common algorithms uses the method of linearly decreasing weights. Aiming at the characteristic that the PSO algorithm is easy to mature prematurely, literature [30] proposed a linear decreasing weight method. By introducing

a linear transformation weight, the inertia weight decreases linearly from large to small. The formula for change with the number of iterations is as follows:

$$w = \frac{w_{\max} - (w_{\max} - w_{\min})t}{t_{\max}}, \quad (5)$$

where $w_{\max}$ is the maximum inertia weight, $w_{\min}$ is the minimum inertia weight, t represents the current iteration, and $t_{\max}$ is the maximum iteration.

Through analysis, although the introduction of linear inertia weight can make the PSO algorithm adjust the particle's optimization ability, this algorithm has some shortcomings. First of all, in the early stage of operation, due to the large value of the inertial weight w parameter, it is conducive to the global search of particles. If the optimal point is detected in the early stage of the algorithm, it is hoped that the algorithm will quickly converge to its optimal point. However, the linear decreasing characteristic of the inertia weight w slows down the convergence speed of the algorithm. Secondly, in the late running of the algorithm, as w decreases, the global search ability gradually decreases, which is easy to fall into the local optimal situation at this time.

Aiming at the shortcomings, an improved method of nonlinear decrease of inertia weight is proposed on the basis of the algorithm to improve the shortcomings. This algorithm is described as

$$w = w_{\max} - (w_{\max} - w_{\min}) \times \tan\left(\frac{\pi t}{4t_{\max}}\right). \quad (6)$$

In the iterative process of the algorithm, when t is small, the global search capability can be guaranteed. Then, with the increase of t, local search ability can be guaranteed, so the algorithm has strong balanced searchability. Through the above-mentioned improved method, the nonlinear dynamic inertia weights better realize the balance between the global search and the local search. This improves the performance in convergence speed and global optimization.

3.2.2. Improvement Strategy for BP.

BP network is an algorithm based on gradient descent, as shown in Figure 1. As a result, the training effect of the network model will be negatively impacted by its inability to search globally. This cannot provide a more effective training method. Global optimization and simultaneous search are two features of the particle swarm algorithm. This has the potential to enhance global convergence. Neural networks can be improved by using this technique in the neural network algorithm. The particle swarm algorithm's global optimization ability is merged with the neural network's advantages by comparing their properties. It is possible to improve the learning and training speed of the network by establishing a BP neural network model using the particle swarm algorithm and optimizing the initial weights and threshold parameters of the BP network.

PSO may be used to optimize the initial parameters of a BP neural network model by integrating the particle swarm
Figure 1: Structure of the BP network.

4. Experiment and Discussion

method into the model. Iterative particle optimization can be used to find the best parameters for the BP network. When it comes to the PSO algorithm, the BP neural network weights and thresholds are the flying particles of dimension two. In order to find the most optimal particles, you must first select the best initial parameters for the BP network. Additionally, iterative particles constantly adjust their velocity, position, and initial characteristics in space. Searching for the ideal particle is done in accordance with the function's optimization aim so that the particle's optimal parameter can be determined. The fitness value of a particle is the difference between the projected output of the BP model and the expected output, which is the optimization objective function. The fitness function is

$$f = \frac{1}{n} \sum_{i=1}^{n} |y_i - p_i|, \tag{7}$$

where n is the number of samples, y_i is the actual output, and p_i is the predicted output.

Through the continuous update for the position, velocity, weight, and threshold, we determine the parameter value when the particle obtains the optimal fitness, assign the parameter value, and use the parameter optimized model for learning and training.

The principle of using the PSO algorithm to optimize the BP network algorithm mainly includes three parts: determining BP network structure, the PSO algorithm optimizing BP network parameters, and BP network training and prediction. The specific steps are as follows. (1) First, initialize the parameters for the model, including the number of network layers and learning rate of BP network, the number of populations of particle swarm algorithm, inertia weight, and the number of iterations. (2) Calculate and compare the fitness value. The output error of BP network model training is used as the fitness objective function to obtain the fitness value. (3) According to the fitness function, the improved particle swarm algorithm is used to iteratively search the space and update speed and position. (4) Determination of the termination condition of particle population update: when the algorithm reaches the maximum iterations, the loop iterative calculation process is stopped, the optimal fitness value is determined, and the optimal initial parameters are obtained. (5) Assign the optimized parameters to the BP network as initial weight and threshold parameters of the BP model. Combined with the sample data of news and public opinion, the optimized BP model is used to train until the entire model meets the convergence accuracy. (6) Use the trained BP model to predict the popularity of news public opinion.

4. Experiment and Discussion

4.1. Dataset. This article self-made two data sets DS1 and DS2. DS1 comes from online news published by Mashable Publishing House, and a total of 1389 news data are selected. DS2 comes from news published by Facebook, and a total of 1473 news data are selected. The specific distribution of the training set and test set is shown in Table 1. For each piece of news data, a 60-dimensional feature is extracted, and the dimensionality is reduced to a 20-dimensional feature vector through an improved principal component analysis algorithm. Each piece of news is divided into two categories: popular and unpopular. In this work, precision, recall, and *F*1 score are utilized to evaluate the performance of prediction.

4.2. Evaluation of Model Convergence. In the BP network, whether the model converges is an important indicator for evaluating network performance. If the model fails to converge, subsequent predictions are meaningless. Therefore, this article first compares the training loss of the proposed network on two data sets. Experimental results are illustrated in Figure 2.

As the training progresses, the loss of the network gradually decreases. And at the 40th epoch, the loss is basically not decreasing, indicating that the network has reached a state of convergence. Besides the training loss, this work also compares the test performance on two datasets. Experimental results are illustrated in Figure 3.

Similarly, when the training iteration is 40 epochs, the performance of the network on the test set tends to converge, which can obtain 0.91 precision, 0.82 recall, and 0.86 *F*1 on DS1, 0.93 precision, 0.85 recall, and 0.88 *F*1 on DS2. In summary, the designed network can finally converge and make stable and efficient predictions.

4.3. Evaluation on Improved PCA. In this work, an improved PCA is proposed to reduce the dimensionality of features. To prove that this method can effectively improve the performance, the performance when using the improved PCA (IPCA) is compared with that of the improved BP (IBP) network alone. The experimental results are illustrated in Figure 4.

Combining the IPCA method with the BP network can effectively improve the performance. On the DS1 dataset, compared with not using the IPCA method, the performance improvement obtained is 6%, 5%, and 5% on three indexes. On the DS2 dataset, compared with not using the

TABLE 1: The division of training set and test set.

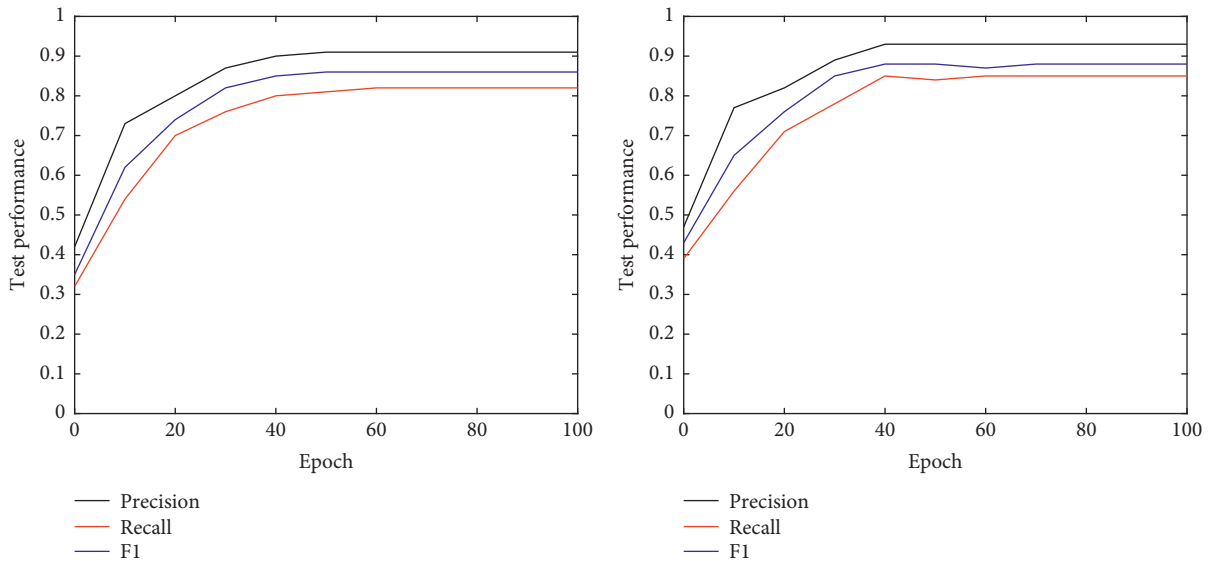
Dataset	Training set	Test set
DS1	1041	348
DS2	1104	369
FIGURE 2: The training loss on DS1 and DS2.


FIGURE 3: The test performance on DS1 and DS2.

IPCA method, the performance improvement obtained is 7%, 6%, and 5% on three indexes. To further illustrate the superiority of the IPCA method, it is compared with the traditional PCA. Experimental results are illustrated in Table 2.

Obviously, compared with the PCA algorithm, the IPCA method can further improve the performance of the BP network. This proves the reliability and effectiveness of the IPCA method.

4.4. Evaluation of Improved PSO.

In this paper, an improved PSO is proposed to optimize the BP network. To prove that this method can effectively improve the performance of the BP network, the performance when using the improved PSO (IPSO) is compared with that of the BP network alone. The experimental results are illustrated in Figure 5.

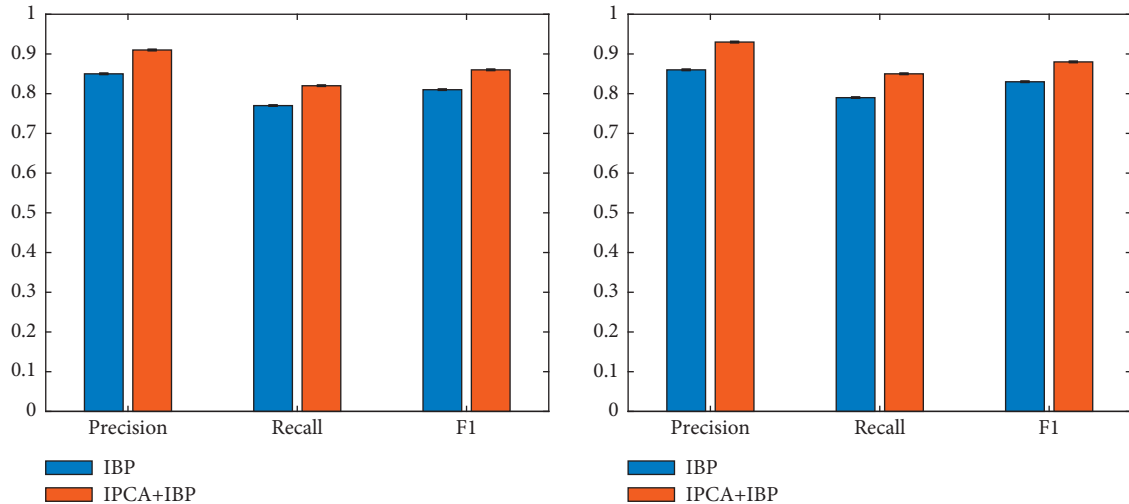
It can be seen that combining the IPSO method with the BP network can improve performance. On the DS1 dataset, compared with not using the BP method, the performance


FIGURE 4: Evaluation of improved PCA.

TABLE 2: Comparison of IPCA and PCA.

Method	DS1			DS2		
	Precision	Recall	$F1$	Precision	Recall	$F1$
PCA + IBP	0.89	0.80	0.83	0.90	0.82	0.84
PCA + IBP	0.91	0.82	0.86	0.93	0.85	0.88
FIGURE 5: Evaluation of improved PSO.

improvement obtained is 4%, 4%, and 4% on three indexes. On the DS2 dataset, compared with not using the IPSO method, the performance improvement obtained is 5%, 2%, and 3% on three indexes. To further illustrate the superiority of the IPSO method, it is compared with the traditional PSO method. Experimental results are illustrated in Table 3.

Obviously, compared with PSO, the IPSO method can further improve the performance of the BP network. This proves the reliability and effectiveness of the IPSO method in this paper.

TABLE 3: Comparison of IPCA and PCA.

Method	DS1			DS2		
	Precision	Recall	$F1$	Precision	Recall	$F1$
PSO + BP	0.88	0.80	0.84	0.91	0.84	0.85
IPSO + BP	0.91	0.82	0.86	0.93	0.85	0.88

4.5. Comparison to Other Methods. To illustrate the effectiveness of our strategy, this article compares our method with other methods. Experimental results are illustrated in Table 4.

TABLE 4: Comparison to other methods.

Method	DS1			DS2		
	Precision	Recall	F1	Precision	Recall	F1
DT	0.75	0.67	0.71	0.79	0.69	0.73
SVM	0.81	0.72	0.75	0.81	0.78	0.75
BP	0.85	0.77	0.79	0.86	0.83	0.82
Ours	0.91	0.82	0.86	0.93	0.85	0.88

Obviously, compared with other methods, our method can obtain the best performance improvement. This demonstrates the correctness of the method in this article.

5. Conclusion

With the development of the Internet, news and public opinion have exploded. It is a very important subject to extract and study the characteristic attributes that determine the popularity of news public opinion and establish a network model to predict the popularity of news public opinion. The main work of this paper has the following two contents. The first is to realize the sampling of news and the extraction of attribute features. Then, considering the nonlinear relationship between features, an improved principal component analysis method is proposed to analyze the correlation of features. In this way, important features can be selected from many irrelevant features, effectively reducing the original high-dimensional features. Second, neural networks are examined for their ability to anticipate public opinion on news stories. By using BP, we can mine data more effectively. The BP neural network, on the other hand, has a number of limitations and uses an improved approach for optimizing the initial parameters of the BP neural network, which successfully compensates for the BP neural network's flaws. Finally, a prediction model for the popularity of news public opinion is built using the BP network with optimal parameters. The new neural network model described in this paper can accurately predict the popularity of news public opinion, as demonstrated by experimental findings.

In the process of urban building design, a new integrated system for monitoring the environment is developed and designed by using embedded development technology and sensor technology. The system uses a wireless sensor network environment monitoring system IoT platform with embedded internal processors. Analyze and design the system as a whole, including the construction of the basic platform of the system, the design of the internal plates and circuits of the system, the monitoring design of the input node, and the monthly design of the output interface calculation. Finally, a physical model is built, and data measurement and analysis are carried out under different conditions, and the evaluation and advantage analysis of the system's operating status are given. The system can carry out all-round, multilevel, and three-dimensional real-time monitoring of the construction site environment, including dust, *PM2.5*, temperature, humidity, wind speed, carbon dioxide, and other indicators in the construction site environment. In addition, the system can upload various monitoring data to the detection system through the internal network. The system has the functions of monitoring, alarming, recording, querying, and counting of the target monitoring station and can also be linked with the environmental control device. The construction site staff can conduct real-time supervision through the mobile terminal and computer terminal management platform. In addition, it can also meet the role of real-time remote monitoring and online guidance and regulation. It has reference value for the safety and management of the actual operation process of the project.

1. Introduction

The construction industry has always been a fast-growing industry. With the emergence of more and more modern high-tech, building environment monitoring system has also become a hot research topic in the field of construction. Before this, people could only passively adapt to the external environment using the materials in the living environment. However, due to the gradual development of science and technology, people have gradually become active in transforming the living environment and have taken active measures to improve the environment of various buildings in terms of building site selection, planning and design, building envelopes, building equipment, and building materials [1]. Most of the office buildings in our country have

serious energy consumption, the unit energy consumption is gradually increasing, and its energy expenditure is also increasing. This requires research on a method to reduce the energy consumption of buildings. Although many scholars have studied building energy consumption monitoring systems, there are many energy consumption monitoring points in buildings and complex wiring. In this way, the monitoring effect is not good, and the energy consumption of the building cannot be effectively reduced. Based on this problem, on the basis of the building site environmental monitoring software we mentioned above, we design and regulate a building comprehensive environmental energy consumption monitoring and management system based on the Internet of Things technology to solve the above problems [2]. In the traditional building environment

monitoring field, the system usually uses a distributed monitoring system composed of an upper computer and a lower computer to monitor the building environment, and the lower computer and various sensors use network communication. This type of monitoring system has the characteristics of flexible structure, easy expansion and upgrading, and low cost [3]. However, with the continuous development of building intelligence, people's requirements for building environment monitoring are also increasing, which usually requires long-distance remote monitoring and big data analysis and decision-making. Therefore, if the traditional environment monitoring system architecture is still adopted, the disadvantages such as heavy wiring workload, troublesome data processing, and unsuitability for long-distance transmission are prominent. With the continuous development of Internet of Things technology and wireless transmission technology, it is possible to design a wireless building environment monitoring system with little or no wiring workload [4].

The role of the Internet of Things has been used in industry, medical care, agriculture, logistics, transportation, power grid, environmental protection, fire protection, furniture, and other aspects, which closely connected with life. With the continuous development and maturity of the technology, the Internet of Things will bring revolutionary changes to life in the future and help human beings to step into the era of wisdom faster and more stably. With the development and improvement of information technology, sensor technology, and Internet of Things technology, it is possible to build an integrated system suitable for long-term monitoring of building environment. In the actual operation state of the building, the performance data such as the energy consumption of the built environment and the indoor environment and the user satisfaction evaluation are collected, and the actual operation effect of the green building is solved through analysis and identification. In this way, it is beneficial to move towards refined green building design and operation optimization. Therefore, it is very necessary to conduct long-term monitoring of the indoor and outdoor environment of the building, fully understand the mechanism, and then analyze the monitoring data and use relevant means to optimize the building environment [5]. IoT technology will reduce site injuries and make building construction more efficient. As the types of monitoring equipment become more and more complex, fieldbus technology can manage different types of monitoring equipment in a unified manner. At present, RS-485 technology is mostly used to monitor the building environment and meteorological conditions, in order to stably and efficiently monitor the environment of the solar greenhouse in the northern cold region. In addition, RS-485 can be used to establish a wired data transmission network for the acquisition node and data transmission between the acquisition node and the sensor group through the Modbus communication protocol and then use the 433 MHz wireless data acquisition device to connect with remote servers and clients [6–9].

In this design system, another latest invention technology is used: wireless sensor network technology. Wireless sensor network technology has the advantages of convenience, flexibility, and wide application. Therefore, in recent years, many scholars have built relatively complete wireless sensor networks for environmental monitoring. With the help of wireless sensor network technology, that is, Arduino devices and VOLTTRON software platform to integrate ZigBee protocol sensors, a low-cost building performance monitoring system toolbox can be established. In addition, with the emergence of ZigBee protocol and Wi-Fi to form wireless sensor network technology, combined with the back-end monitoring information of IoT components, a monitoring system can be formed as an effective service platform [10]. From Figure 1, we can see that the types of building environment monitoring sensors mainly include temperature sensors, humidity sensors, formaldehyde sensors, haze sensors, VOC sensors, noise sensors, etc. Various types of sensors are usually composed of sensing modules, information processing modules, wireless communication modules, and energy supply modules [11]. The building energy consumption and environmental monitoring system based on the Internet of Things technology monitors the five energy systems of electricity, water, gas, heat consumption, and cooling consumption in the building energy consumption and analyzes the energy consumption data in combination with the environmental monitoring system inside the building. In the realization technology, the field bus instrument is used to realize the data acquisition of the 5 types of energy systems. Environmental parameter monitoring is implemented using ubiquitous wireless sensor network-based detectors. The construction industry is bringing real-time information into centuries-old processes. The devices and sensors of Internet of Things (IoT) are gathering workplace data in ways that are more affordable, efficient, and effective than previously thought.

Adopt industrial database and configuration software to realize the summarization and analysis of the collected data [12]. This system is based on computer, communication equipment, measurement, and control unit as basic tools and provides a basic platform for real-time data acquisition, switch status monitoring, and remote management and control of large public buildings. It can form any complex monitoring system with detection and control equipment [13]. The system mainly adopts a layered distributed computer network structure, which is generally divided into three layers: the station control management layer, the network communication layer, and the field device layer [14]. The field device layer is the data acquisition terminal, which is mainly composed of intelligent instruments. From Figure 2, we can see that the distributed I/O controller with high reliability and fieldbus connection is used to form the data acquisition terminal, and the stored building environment monitoring data is uploaded to the data center. Measuring instruments are responsible for the most basic data collection tasks, and the effective data monitored by them must be complete, accurate, and transmitted to the data center in real time.

2. The Composition and Principle of Radio Frequency Identification Technology

The composition of the Radio Frequency Identification (RFID) system includes four aspects:
FIGURE 1: Hoflander's attitude change-persuasion model.
FIGURE 2: Calculation results of three levels of environmental monitoring.

(1) Reader: It sends radio frequency signals to identify the electronic tag. After the identification is successful, it receives the information transmitted by the electronic tag and transmits it to the computer system for data analysis [15].

(2) Electronic tag: It stores the relevant data information of the target to be identified. According to the energy source of the electronic tag, it can be divided into active tags, passive tags, and semiactive tags.

(3) Antenna: including transmitting antenna and receiving antenna, which are used for energy and information transmission between readers and electronic tags and are an important part of RFID system. The quality of antenna performance directly affects the efficiency of energy transmission.

(4) Computer system: data integration, processing, and analysis of the information received by the reader [16].

$$As = A|C|^{-\partial}. \tag{1}$$

In the formula, As is the sensor resistance, A is a constant, and C is the gas concentration.

The RFID system principle is composed of the following requirements. Firstly, a section of inquiry command is encoded, and the signal is modulated, and the radio frequency signal is sent to the electronic tag through the transmitting antenna, and finally the information stored by the tag is received by the receiving antenna [17]. This process enables the transfer of energy while simultaneously decoding, demodulating, and rectifying the received signal. From Figure 3, we can see that passive electronic tags are excited by energy, encode and modulate the information carried by themselves, and resend it to the reader, and the reader receives the information. Finally, the secondary
Figure 3: SVM training set classification accuracy.

information is submitted to the computer system for background processing, so as to complete the automatic identification work, and both modulation and demodulation are completed in the *RF* modem.

The transmission of signals between readers and electronic tags in an *RFID* system takes two types. The first is the inductive coupling model. This model is suitable for *RF* signals in the middle and low frequency bands. Similar to the transformer model, the magnetic induction loop of the electronic tag will be affected by the magnetic field change of the reader coil, which will generate an induced electromotive force and supply energy for the electronic tag, as shown in Figure 3, where the dotted box represents the magnetic field. The second is the electromagnetic backscattering model. This model is suitable for *RF* signals in the high frequency and microwave frequency bands. Compared with the previous model, due to the short wavelength of the radio frequency signal sent by the magic reader, after radiating to the electronic tag, part of it will carry the tag information and be reflected back to the reader. It is interesting that this model works similarly to the detection radar model [18].

$$f(x) = \text{sign}\left(\sum_{t=1}^{m} a y_t k(x_t, x_j) + b\right). \tag{2}$$

In the above formula, since the environmental data is nonlinear, the samples of the original input space should be mapped to the high-dimensional feature space, and then the optimal classification hyperplane should be constructed.

Compared with the traditional automatic identification technology, *RFID* technology has broad development prospects. People's research on sensors pays more attention to technology fusion. For example, by using the fusion of

RFID technology and sensor technology, the sensor and the monitoring terminal can communicate and transmit information through radio frequency signals. From Figure 4, the data on the way accord with the relation of exponential function. From the distribution of fitting curve and actual data points, the mathematical model used in this study can accurately predict the trend of data development. This model can well achieve real-time monitoring and early warning of various indoor and outdoor toxic and harmful gas concentrations. In addition, it can effectively identify the concentration changes of some toxic and harmful gases over a period of time [19]. Based on the principle of this design procedure, the optimal allocation of energy can be effectively realized. In addition, the wireless networking mode and modular structure in the design are simple, the networking is convenient, and the construction and reconstruction are convenient. The visual interface provides a more convenient operation management mode for construction personnel, building management, and users and is easy to promote. This shows that the software can be used as an effective method for building green and energy-saving buildings [20].

3. Design of Automated Supervision Platform

3.1. Key Technologies of Automated Supervision Platform. First, establish the application and demonstration of environmental automation supervision on construction sites covering urban residential areas, and apply Internet of Things technology and cloud computing technology to the data center. From Figure 5, we can see that, after data analysis, statistics, spectrum analysis, storage, recording processing, and meteorological parameters, it is transmitted to the construction site project supervision command center, and various monitoring data are displayed in the real time at the construction site for the supervision of surrounding residents.

Second, establish a supervision cloud platform for environmental protection functional departments. The cloud platform mainly includes data communication supervision system, core management system, and data exchange platform. The core management system is mainly composed of a data display platform, a supervision platform, a public service platform for information release, and a standard data access platform. It is a bridge connecting front-end smart devices and data processing centers. The data processing center is mainly a bridge between the front-end intelligent monitoring sample collection equipment and the data processing center. The data center mainly has the management and control of the front-end intelligent monitoring sample collection equipment. The core management system has the function of virtualized management of all collected monitoring data. The data exchange platform saves the data to the corresponding data processing center according to the requirements of the cloud computing data storage platform.

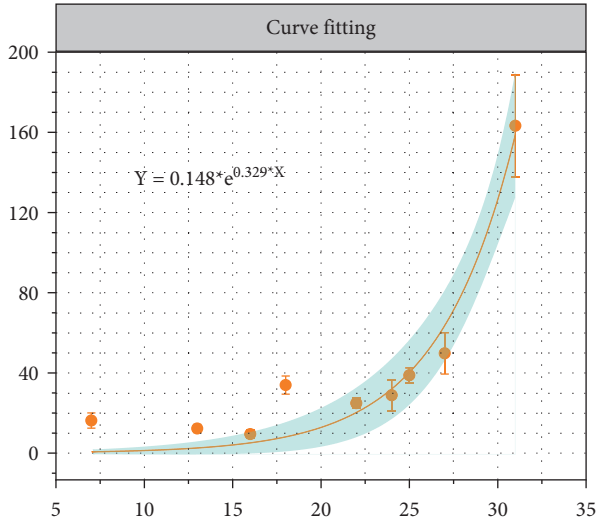
Third, establish a unified data access standard. For example, the environmental information monitoring data and statistical information of construction companies have spatial attributes in addition to time and dynamics. It is suitable for expression using geographic information


FIGURE 4: Simulated data fitting curve.
FIGURE 5: Motion recording of gas molecules in the environment.

system. This system has a powerful data interface. The *GIS* system of the management department command center can integrate the construction site environmental data through the unified platform data access interface and dynamically and intuitively display the data of each environmental monitoring point.

3.2. Environmental Quality Detection and Feedback Circuit Design

3.2.1. Sensor Module Circuit Design.
The sensor used in the environmental quality detection part is composed of *GY-MCU680V1* sensor, *YW-51 GJ* sensor, *MQ-2* sensor, and *MQ-7* sensor. *GY-MCU680V1* indoor environmental quality sensor is a multisensor which is responsible for detecting air index, temperature, humidity, and air pressure. It integrates the BME680 four-in-one environmental sensor and

processes the detected data through its own processor and outputs it through the serial port. *YW-51GJ* dust sensor is the sensor responsible for detecting *PM2.5* parameters. From Figure 6, we can see that the sensor uses the principle of scattering, by detecting the voltage value of the receiving element as a reference for the dust concentration. The sensor is integrated with an *ADC* converter and a processor, and the processor outputs the internal *ADC* conversion result through a serial port. *ZE08-CH2O* formaldehyde sensor is a sensor responsible for detecting formaldehyde concentration parameters. The sensor is responsible for measuring the formaldehyde concentration in the air and outputting it through the voltage value. The *MQ-2* and *MQ-7* sensors are hazardous gas sensors, which change the resistance of their gas-sensing resistors by reacting with the corresponding sensitive gases in the air, thereby producing voltage changes. When the voltage exceeds the limit, it will send out the corresponding high- and low-level signal through the *I/O* port to trigger the alarm.

3.2.2. Display Module Circuit Design.
The display module of the design system uses the 3.5-inch *TFT LCD* screen of Antike Technology which is matched with the core board. At the same time, the matching controller adopts *ILI9488* as the controller and uses the *FPC* cable to connect with the core board.

$$PPD = 100 - 95 \times e^{-0.03353 \times PMV^4 - 02179 \times PMV^2}. \tag{3}$$

This formula expresses the calculation formula of environmental thermal comfort evaluation.

3.2.3. Circuit Design of Alarm Module.
The alarm module is *TELESKY* 3.3~5V low-level drive active buzzer, of which *GND* and *VCC* are connected to the core board power supply circuit (3.3 V) to supply power to the module.

$$APMV = \frac{pmv}{(1 + \lambda \times pmv)}. \tag{4}$$

Among them, λ is the adaptive coefficient, which is -0.3 in the construction site.

3.2.4. Module Circuit Design.
Wi-Fi module uses Shenzhen Zhida *ESP8266* Wi-Fi module, which uses *ESP8266* processor to handle Wi-Fi corresponding operations, and uses serial port to control the processor. The *ZigBee* module uses the Deep Link Innovation *DL-LN33* ZigBee module, which uses the *CC2530* processor to handle the corresponding operations of the *ZigBee*, and uses the serial port to control the processor.

$$y = \frac{2(X_t - X_{\min})}{X_{\max} - X_{\min}} - 1. \tag{5}$$

In the formula, x represents the collected air quality data, and y represents the data after normalization and transformation, which can reduce the deviation between the result and the actual value.
FIGURE 6: Conceptual image of a city IoT network.

$$n = \sqrt{i + o} + m. \qquad (6)$$

In the formula, n, i, and o, respectively, represent the number of monitoring points, the number of calculation units, and the number of display units.

3.3. Overall System Scheme and Basic Software and Hardware Design. From Figure 7, we can see that the building environment monitoring system mainly includes three modules: the collection and control module of environmental parameter information, the information management center module, and the host computer or user terminal module.

(1) The collection and control module of environmental information adopts *ZigBee* technology to form a wireless communication network. The *ZigBee* terminal node is connected to a sensor that collects environmental information and a controller that adjusts and controls the environment. The sensor periodically collects environmental data. The *ZigBee* terminal node sends the collected environmental data to the *ZigBee* coordinator node, which is responsible for collecting the environmental data collected by the terminal node, and then transmits it to the *ARM* home gateway. At the same time, the coordinator node is also responsible for forwarding the control instructions of the home gateway to the terminal node to realize the process of automatic control.

(2) The information management center module uses the *ARM* embedded server as the home gateway, stores the environmental parameters in the database, processes and analyzes the collected environmental information according to the preset environmental

parameters, and automatically sends the control instructions to the corresponding front-end controller. *ARM* embedded low-power and high-performance features make the system more secure, reliable, and energy efficient.

(3) User terminals mainly include communication equipment such as smart phones, tablet computers, and *PCs*. These devices can be directly connected to the gateway through Wi-Fi indoors, view environmental parameters, and send operating instructions, while outdoors they need to be remotely controlled through a *WEB* server.

In order to comprehensively monitor environmental information, the system detects and controls environmental parameters as follows: Temperature and humidity are the most sensitive factors affecting human comfort. The main components of household gas carbon monoxide and formaldehyde gas produced by furniture and decoration are common indoor pollutant gases, which have great harm to people's health. When the set threshold is exceeded, the system maintains air circulation by controlling the ventilation equipment and activates the alarm device (Figure 8). Fire and illegal intrusion are related to the safety of people's lives and properties. When a fire information or illegal intrusion event is detected, the system will immediately activate the fire or security alarm system.

As the core of the whole system, the home gateway and project center process the environmental data and judge the control mode after reading the environmental data. If it is in the manual control mode, it will enter the manual control strategy, and carry out environmental control according to the user's control instructions. If it is an automatic control mode, the judgment of the scene mode is carried out according to the data of the environment, and each scene
FIGURE 7: Harmful gas movement range and release energy.
FIGURE 8: Various parameter values for the two algorithms.

mode will correspond to its corresponding control strategy and store and display the data.

According to the characteristics of the intelligent environmental monitoring system, the principle of modularity should be adopted in the design of the system, so that each module has its independence. In this way, when the system adds new modules or exits old modules, the system will remain stable. At the same time, since each sensor node needs to work for a long time, it is necessary to reduce the power consumption of the node as much as possible. In order to reliably realize the functions of the intelligent environmental monitoring system, it is necessary to design from two aspects of the system's hardware and system's software.

4. System Hardware Design

The system uses *ZigBee* technology to monitor the environmental parameters of the building site. First, use the terminal sensor node to collect environmental data, and then send it to the coordinator terminal node through *ZigBee* two-way wireless communication, upload it to the remote client, and display it in real time through the host computer. The user can monitor the site environment in real time through the host computer, and if an abnormality is found, the alarm can be timely and the intelligent equipment inside the building can be reversely controlled to deal with the dangerous situation. In order to facilitate the early detection

of abnormalities by the personnel in the building, relevant environmental parameters will be directly displayed through the *LCD* liquid crystal display installed on the coordinator node.

$$V_{ij} = X_{ij} + \text{rand}(-1,1)(X_{ij} - X_{kj}). \tag{7}$$

Among them, i and j represent the objective function value of the ith node, and k is a random number.

ZigBee technology is one of the wireless communication technologies. Compared with wired transmission, it has great advantages in construction sites with high security requirements. It has the advantages of low-power consumption, low cost, short distance, low complexity, and fast connection speed. In addition, *ZigBee* communication connection takes only 25 ms, while other wireless communication technologies such as *Bluetooth* require 5 s and Wi-Fi takes 11 s. In the face of frequent environmental data transmission, *ZigBee* is more in line with the project requirements.

$$P_i = \frac{f(X_i)}{\sum_{n=1}^{N_s} f(X_n)}, \tag{8}$$

where $f(x)$ is the software and environment fitness value.

In this design, a single-chip integrated *SoC* solution is mainly used, which is mature, small in size, and convenient and flexible to use. The *ZigBee* hardware platform selects the *CC2530* chip produced by *TI*. Although the sleep voltage of the chip is not the highest, its transmit power and receive sensitivity are the highest, reaching 4.5 dBm and −97 dBm, respectively.

$$Y = Hx + [e_1, e_2, e_3, \ldots, e_n]^T. \tag{9}$$

With the ambient noise and the sensor noise, the actual measured value of the system is x.

This system needs to realize real-time data uploading to the cloud, so the system chooses the *ESP-12F* Wi-Fi module developed by Anxinke Technology. The module is inexpensive and mature in technology, with an operating temperature range of −40 to 125°C. The temperature setting can ensure the stability of the environment in the construction site, with low standby power and fast wake-up speed, which can meet the requirements of real-time data transmission.

$$\hat{X} = (H^T W H)^{-1} H^T W Y, \tag{10}$$

where W is a positive definite diagonal weighting matrix.

Use *DHT11* sensor to collect warehouse temperature and humidity data. *DHT11* collects and combines temperature and humidity data, outputs it in the form of digital signal, and uses special analog signal acquisition, conversion technology, and temperature and humidity sensing technology to ensure that the sensor has good stability and reliability. The average working current of *DHT11* does not exceed 0.5 mA, the power consumption is low, and the working voltage range is 3~5.5 V, which matches the power supply equipped in this design.

5. System Software Design

Sensor-related operations include initializing the sensor, reading sensor values, and writing data to an array in a fixed format. During initialization, it is only necessary to open the clock of the corresponding port and initialize the *GPIO*. The initialization of the environmental quality detection sensor and the *PM2.5* sensor needs to initialize the corresponding *UART*. The former baud rate is 9600; the latter is 2400. From Figure 9, when the initialization is completed, the *UART* needs to be enabled, the Interrupt Enable is turned on, and the first data acquisition after power-on is performed. Finally, the obtained data is filled into the corresponding array according to the node type, and the reading of the environmental quality monitoring sensor refers to the fixed data format.

Wi-Fi mainly includes operations such as initializing the module, sending basic commands, and sending and receiving messages. This system uses *ESP8266* chip for network operation; the chip can set up *TCP/IP* server and monitor automatically through serial port commands. If a remote connection is established with the chip through *Socket* communication, the server will automatically receive this request and automatically assign a source *ID* for communication with the current connection. After the connection is established, if there is still no actual communication content after a certain period of time, the connection will be automatically disconnected to prevent the connection line from being occupied for a long time.

$$E[(x - \hat{x})^2] = E\left\{\sum_{i=1}^{n}\left[\left(\frac{w_i}{\sum_{i=1}^{n} w_i}\right)\right]^2 \varepsilon_i^2\right\}. \tag{11}$$

The above formula represents the sum of the squares of the estimation errors of x.

Select a residential building as an example in the design, import the model into the Unity engine, and add text boxes for displaying data. As Figure 10 shows, a text box for displaying data related to environmental quality is preset on the user form in advance, and the text box on the interface is bound to the corresponding control variable in the main program through the object binding process. When the application is running, a query command is sent to the designated environmental quality monitoring node server, and the text box is filled by parsing the returned data; that is, real-time data embedding is achieved.

UML provides a variety of model diagrams. In software development, these model diagrams can be used to describe the work in each stage of development, which is convenient for work implementation and personnel communication. In real-world applications, *UML* is mainly used in two phases: requirement analysis and system design. In the requirements analysis stage, the use case model diagram is mainly used to describe the system requirements more intuitively and facilitate communication with users. In the design phase of the system, the static model and dynamic model of the system are mainly used.

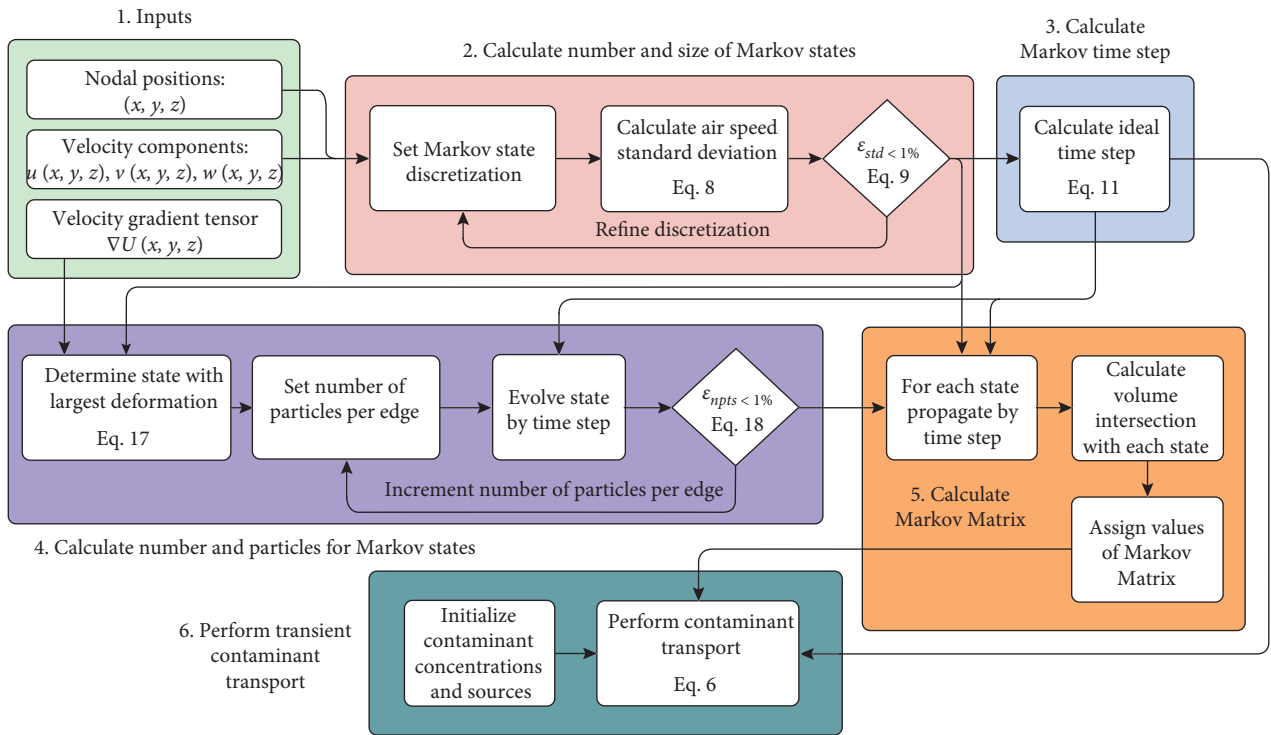
$$\varepsilon_{mi}^2 = E(y_{mi} - \overline{y_m})^2, \tag{12}$$
FIGURE 9: Wireless sensor circuit network node unit diagram.


FIGURE 10: Method from input to accurate matrix of contaminant transport.

where ε is the measurement variance of the mth measurement from the ith sensor.

6. System Testing and Evaluation

In order to test the function of the system, temperature and humidity, harmful gases, and illegal intrusion are used as test samples, so that different environmental areas in the building can be simulated. The ambient temperature and humidity are detected by the *DHT11* temperature and humidity sensor with strong anti-interference ability. Hazardous gas sensors use *MQ-5* semiconductor combustible gas sensors with high sensitivity, and *HC-SR501* human body infrared sensors are used to monitor illegal intrusion events. The biggest advantage of smart site construction project construction is that the site staff can remove faults in time and reduce the occurrence of engineering project safety accidents.

Start each module of the system, the environmental data acquisition system will send the network access request to the gateway through the *ZigBee* wireless sensor network, and the gateway will send the command to assign *ID* after receiving the request instruction. If the light-emitting diode of the environmental data acquisition system flashes three times at this time, it means that the environmental data acquisition system is successfully connected to the network.

In this test, the on/off control of the relay is simulated by the brightness of the *LED* light.

Compared with the traditional environmental monitoring system, this system has the following advantages:

(1) Simple and scalable. There is no need to specially set up independent systems for different objects. In this system, multiple different environmental objects can be monitored, transmitted, and processed in the same network.

(2) The accuracy of the data is high. In the *ZigBee* network, the adopted intelligent optimization algorithm makes comprehensive decision-making, which avoids the error caused by monitoring a single node, and can greatly improve the accuracy of data monitoring.

(3) The node operation is flexible. Users can add environmental information collection nodes or reduce collection nodes according to their own needs, without requiring additional wiring, and the nodes are flexible in operation and can be placed freely.

7. Conclusion

In this paper, through the analysis of the research status of environmental monitoring system design and application scheme, a set of integrated real-time monitoring system based on Internet of Things technology has been successfully constructed, and it is truly stable in the environmental monitoring system, with physical measurement experiments for indoor and outdoor environments of buildings. Based on the scalability and wide application of the system, scholars in the related fields of construction engineering science in the future can expand as needed to meet the comprehensive real-time monitoring of various building types. The platform connects to the Internet through Wi-Fi wireless network for data communication, which can realize office or home networking, and real-time sharing of monitoring data from multiple monitoring points. The access and setting of the equipment can be completed through the computer or mobile *APP*, and the display software is used to realize the three-dimensional visualization of the indoor environmental quality parameter information in the building model. Internet of Things technology has been continuously accumulated and upgraded, and the industrial chain has gradually improved and matured. IoT technology will bring opportunities to upgrade infrastructure construction around the world.

As a pair of closely related technical fields, "Internet of Things" and "big data" are gradually applied to the analysis of online shopping, which is very beneficial to promote the healthy and orderly development of the online shopping industry. This article uses the big data processing technology of the Internet of Things to analyze the influencing factors of online shopping brand sales based on the data collected by online questionnaires. It draws certain rules from it, and provides relevant marketing strategies for online shopping brand sales to assist its market positioning. According to the survey, the five aspects of online evaluation, brand awareness, online shopping community, online public opinion influence of related brands, and other brand information acquisition channels all have an impact on online brand sales. Especially women aged 25–35 will pay attention to online information, and 195 people will not choose to buy from brands with negative news. And during the purchase process, 186 people will check the online reviews of related brand products. Among them, there are 183 men aged 25–35 who will pay attention to online reviews.

1. Introduction

According to CNNIC statistics, as of 2020, the number of search engine users reaches 790 million, and the utilization rate among netizens reaches 82.5%, as shown in Table 1. The popularity of the Internet has not only enabled people to share and obtain information, but also shaped a brand-new business model. Research shows that companies that choose e-commerce platforms for promotion account for the largest proportion, reaching 25.2%. Massive Internet search data records people's hobbies and needs, and provides a data foundation for social and economic development. Online shopping has become the mainstream mode of consumption in today's society. The selection of specific online marketing methods for small and medium-sized enterprises in 2020 is shown in Table 2.

(1) Theoretical significance: through the search of relevant information, most of the research on online shopping uses statistical analysis methods and almost no one cares about the big data processing technology of the Internet of Things. This article discusses the influencing factors of online shopping brand sales through data preparation, Internet of Things big data processing technology, result analysis, discussion and induction. It provides a reference for the research of related online sales and e-commerce industry in the future.

(2) Practical significance: this article collects relevant data through questionnaires, and uses the Internet of Things big data processing technology to analyze, so as to find some rules in online brand shopping. This provides marketing reference for companies engaged in online item sales and operations, and at the same time provides some theoretical foundations for the management of online platforms.

With the rapid development of the Internet of Things technology, many application fields related to the Internet of Things have emerged [1], such as GPS-based Internet of Vehicles systems, Internet of Things logistics systems based on RFID technology, as well as applications in the medical industry, and so on. However, relevant research and analysis on online shopping using the big data processing of the

TABLE 1: Use of search engines by Chinese netizens.

Years	Data	
	Chinese search engine user scale/ten thousand people	Utilization rate among netizens (%)
2017	63956	82.8
2018	68132	82.2
2019	72106	81.8
2020	79461	82.5

TABLE 2: Selection of specific online marketing methods for SMEs in 2020.

Corporate internet marketing	The proportion (%)

Network alliance, joint marketing	2.3
Other online marketing activities	1.1

Internet of Things through the search of relevant information remain scarce. Therefore, this article will analyze the influencing factors of online shopping brand sales through the Internet of Things big data processing technology. It not only promotes the application research of the big data processing technology of the Internet of Things, but also provides certain market analysis value for the e-commerce field.

2. Related Work

With the advent of the Internet age, online shopping has become a mainstream shopping model. With the prosperity of the consumer market and the intensification of commodity competition, the producer-led marketing concept is clearly no longer in line with market rules, and more and more businesses are beginning to pay attention to consumers. Therefore, it is an opportunity to use the big data processing technology of the Internet of Things to analyze the influencing factors of online merchandise sales. Internet of Things (IoT) related applications have become an important area for engineers and researchers. Cai H provides a functional framework for identifying the acquisition, management, processing and mining of big data in the Internet of Things, and defines and describes several related technical modules based on their key characteristics and capabilities. He also analyzes the current research on the application of the Internet of Things and identifies the challenges and opportunities related to the research on the Internet of Things big data [2]. Big data refers to a collection of massive amounts of data that cannot be processed by traditional data processing tools and technologies. A large amount of climate data is collected from IoT weather sensor devices and NCEP. Manogaran G proposes a big data processing framework to integrate climate and health data to find the correlation between climate parameters and the

incidence of dengue fever. The MapReduce framework based on In-Mapper is used to calculate the monthly average of the climate parameters for each latitude and longitude. Experimental results prove that, compared with the existing MapReduce algorithm, the In-Mapper based combiner algorithm has lower response time effectiveness [3]. The Internet of Things generates a lot of big data because it contains billions of devices connected to each other via the Internet. In order to process massive real-time geospatial big data, Limkar and Jha explores a scalable and efficient indexing method. A large number of experimental results show that the generated R-tree and its variants retain similar characteristics to the sequentially generated R-tree and its variants. This has excellent scalability, and reduces a lot of time to build indexes, index updates, and perform spatial range queries [4]. In recent years, e-commerce has been expanding at an alarming rate, and relevant Internet pages called e-services capes now occupy an important position in the business world. Therefore, Wu et al. conducts research on describing the nature of electronic service scenarios, and investigates the relationship between website credibility, website attitude, brand attitude, electronic word-of-mouth intention and purchase intention. A total of 290 responses are collected from Taiwanese consumers through online questionnaires. His research results show that the dimensions of the e-service landscape (aesthetic appeal, customization, usability, and financial security) have a significant impact on consumers' attitudes and trust in websites [5]. Ladhari et al. has also done related research. The goal of his research is to subdivide Gen female online shoppers based on their psychological, demographic and behavioral characteristics. The data comes from consumers of a female fashion retailer, and a total of 538 women shopping on this fashion retailer's website completed the survey. The results reveal four methods of online shopping: trend shopping, fun shopping, price shopping and brand shopping. It also identifies six shopping profiles, each with different goals: price shoppers, discovery shoppers, emotional shoppers, strategic shoppers, fashionistas and shopping fans [6]. In addition, Abbes I and others have studied to determine the stakes of the brand collaborative redistribution platform, and understand the influence of its internal and external characteristics on behavioral intentions. He also conducts a quantitative study on 214 people who had purchased second-hand goods online. The results show that the loyalty intention of the collaborative redistribution platform has an influence on the loyalty intention of the brand. The influence of platform service experience satisfaction on brand loyalty intention is mediated by platform loyalty intention [7]. Swapana and Padmavathy also conducts related research to

study the relationship between the three dimensions of online second-hand shopping, customer satisfaction and repurchase intention. The responses received from 608 Indian online second-hand shoppers indicate that the dimensions of online second-hand shopping, such as price, website quality, nostalgia, and brand image, affect customer satisfaction. In addition, customer satisfaction has a positive impact on repurchase willingness. The research results show that online second-hand marketers enter emerging markets through effective online shopping strategies and provide intuitive guidance [8]. It can be seen that with the rise of online shopping, in the current era of large scale use of IoT big data to achieve efficient data processing, a decided lack of literature on the sales of online shopping brands remains. Therefore, in order to better analyze the influencing factors of online shopping brand sales, this article will use IoT big data processing technology. This has also promoted the further development of the Internet shopping era.

3. Internet of Things Big Data Processing Technology

Apriori algorithm and clustering algorithm are currently the two most widely used data mining algorithms [9, 10]. Its main research fields have a wide range of applications from pattern recognition to data analysis and image processing. Especially for the processing of big data in the Internet of Things, its characteristics are excellent, thus preferred by academic research and widely used in the industry [11, 12].

3.1. Clustering Algorithm. Two Step is a kind of clustering algorithm, which is used to solve the cluster analysis problem of massive data and complex category structure [13]. The difference between this algorithm and the traditional clustering algorithm is that the two types of clustering methods have small memory and fast calculation speed. Two-step clustering is to complete the clustering work through the two steps of preclustering and formal clustering [14, 15]. In the preclustering stage, data points in the dataset need to be inserted into the clustering feature tree (CF tree) one by one to realize the growth of CF tree. When the volume of the CF tree exceeds the set size, the CF tree needs to be thinned. On the contrary, the outliers of the thin CF tree are inserted into the CF tree. After reading all the data points, the potential outliers that cannot be inserted into the CF tree are the true outliers. Finally, the clustering features of the corresponding subclusters of the final CF leaf element are output to the next stage of the algorithm. As shown in from formulas (1) to (9) [16, 17].

$$\vec{\tilde{\Lambda}}_j = \left(\tilde{\Lambda}_{j1}, \ldots, \tilde{\Lambda}_{jD_1} \right)^T = \left(\sum_{n=1}^{N_j} \tilde{x}_{jn1}, \ldots, \sum_{n=1}^{N_j} \tilde{x}_{jnD_1} \right)^T, \quad (1)$$

$$\vec{\tilde{\Sigma}}_j = \left(\tilde{\Sigma}_{j1}, \ldots, \tilde{\Sigma}_{jD_1} \right)^T = \left(\sum_{n=1}^{N_j} \tilde{x}_{jn1}^2, \ldots, \sum_{n=1}^{N_j} \tilde{x}_{jnD_1}^2 \right)^T, \quad (2)$$

where $\vec{\tilde{\Sigma}}_j$ represents the linear summation of the attribute values of the data points in cluster $C_{-}j$.

$$\vec{N}_j = \left(\left(\vec{N}_{j1} \right)^T, \ldots, \left(\vec{N}_{jD_2} \right)^T \right)^T, \quad (3)$$

where $\vec{N}_j$ represents the sum of the squares of the attribute values of the data points in cluster $C_{-}j$.

$$\vec{CF}_{\langle j, j' \rangle} = \langle N_j + N_{j'}, \vec{\tilde{\Lambda}}_j + \vec{\tilde{\Lambda}}_{j'}, \vec{\tilde{\Sigma}}_j + \vec{\tilde{\Sigma}}_{j'}, \vec{N}_j + \vec{N}_{j'} \rangle, \quad (4)$$

where $\vec{CF}_{\langle j, j' \rangle}$ represents clustering characteristics.

$$\zeta_j = -N_j \left(\frac{1}{2} \sum_{s=1}^{D_1} In \left(\hat{\sigma}_{js}^2 + \hat{\sigma}_s^2 \right) + \sum_{t=1}^{D_2} \hat{E}_{jt} \right), \quad (5)$$

where ζ_j represents the definition parameter of cluster $C_{-}j$.

$$\hat{\sigma}_{js}^2 = \frac{1}{N_j} \sum_{n=1}^{N_j} \left(\tilde{x}_{jns} - \tilde{x}_{js} \right)^2, \quad (6)$$

$$\hat{\sigma}_{js}^2 = \frac{\tilde{\Sigma}_{js}}{N_j} - \left(\frac{\tilde{\Lambda}_{js}}{N_j} \right)^2, \quad (7)$$

$$\hat{\Sigma}_{jt} = -\sum_{k=1}^{\epsilon_t} \left(\frac{\ddot{N}_{jtk}}{N_j} In \frac{\ddot{N}_{jtk}}{N_j} \right)$$
$$= -\frac{\vec{\ddot{N}}_{jt}^T}{N_j} \cdot In \frac{\vec{\ddot{N}}_{jt}}{N_j} - \left(1 - \frac{\vec{1}^T \vec{\ddot{N}}_{jt}}{N_j} \right) \cdot In \left(1 - \frac{\vec{1}^T \vec{\ddot{N}}_{jt}}{N_j} \right), \quad (8)$$

$$d\left(C_j, C_{j'} \right) = \zeta_j + \zeta_{j'} - \zeta_{\langle j, j' \rangle}, \quad (9)$$

where $d\left(C_j, C_{j'} \right)$ represents the log-likelihood distance of cluster $C_{-}j$ and cluster $C_{-}\{j'\}$.

The input of the clustering stage is the subclusters of the leaf element items of the final CF tree output by the preclustering stage. Therefore the work of this stage is to perform two-degree clustering on the subclusters according to the input data, and finally achieve the clustering results of the expected number of clusters. As shown in from formulas (10) to (17) [18, 19].

$$BIC(M_i) = -2Inf_i\left(x; \hat{\theta}_i \right) + k_i Inn, \quad (10)$$

$$BIC(C_J) = -2L_{CJ} + KInN, \quad (11)$$

$$L_{CJ} = \sum_{j=1}^{J} L_{Cj} = \sum_{j=1}^{J} \zeta_j, \quad (12)$$

$$K = J \left(2D_1 + \sum_{t=1}^{D_2} \left(\epsilon_t - 1 \right) \right), \quad (13)$$

$$\Delta_{BIC}(J) = BIC(C_J) - BIC(C_{J+1}), \quad J = 1, \ldots, J_0, \quad (14)$$

where $\Delta_{BIC}(J)$ represents the difference between the BIC values of adjacent clusters.

$$r_1(J) = \frac{\Delta_{BIC}(J)}{\Delta_{BIC}(1)}, \tag{15}$$

where $r_1(J)$ represents the rate of change of BIC value;

$$r_2(J) = \frac{d_{\min}(C_J)}{d_{\min}(C_{J+1})}, \quad J = J_I, \dots, 2, \tag{16}$$

where $r_2(J)$ represents the ratio of the closest cluster distance of clusters C_J and $C\_\{J+1\}$.

$$J^* = \left\{ \begin{array}{ll} J_1, \text{if} & \frac{J1}{J} > 1.15 \\ \\ \max\{J_1, J_2\}, & \text{otherwise} \end{array} \right\}, \tag{17}$$

where J^* represents the best number of clusters selected from J_1 and J_2.

3.2. Apriori Algorithm.

Apriori algorithm is a classic data mining algorithm for mining frequent itemsets and association rules [20]. The algorithm can not only discover frequent itemsets, but also mine association rules between items. It uses support and confidence to quantify frequent itemsets and association rules. The algorithm uses the prior properties of frequent itemsets to compress the search space. As shown in the following formula [21, 22].

$$\text{support}(A \Rightarrow B) = P(A \cup B), \tag{18}$$

$$\text{confidence}(A \Rightarrow B) = P(B|A) = \frac{\text{support}(A \cup B)}{\text{support}(A)}, \tag{19}$$

$$\text{confidence}(A \Rightarrow B) = \frac{\text{support\_count}(A \cup B)}{\text{support\_count}(A)}, \tag{20}$$

where

support$(A \Rightarrow B)$: it indicates the degree of support of the association rule

confidence$(A \Rightarrow B)$: it represents the confidence level of the association rule

4. Application of Big Data Processing Technology in the Internet of Things

The actual practice of big data in the Internet of Things shows that reasonable systems and methods play a decisive role in the process [23]. The association rule in the Apriori algorithm refers to the common relationship between items, which is usually used to analyze sales. The Two Step algorithm supports numerical and subtype data. For large amounts of data, the calculation speed is faster and the execution efficiency is high. It provides great convenience in the application [24, 25], so this article will use the Internet of Things big data processing technology to study the influencing factors of online shopping brand sales.

4.1. Data Preparation.

The survey method of this article is online questionnaire survey. It conducted 200 surveys on six groups of junior high school students, high school students, college students, young people aged 25–35, middle-aged people aged 35–50, and over 50 years old, and a total of nearly 200 questionnaire results for each group were recovered. At the same time, some face-to-face questionnaire surveys were conducted offline, and a total of 200 valid questionnaires were collected.

This article uses the Apriori algorithm and the two step algorithm to analyze the impact of online evaluation, brand awareness, online shopping community, related brand network public opinion influence, and other understanding channels on online brand sales, and conducts multiple fields. The results of this questionnaire survey are saved in an excel table, using its filtering function, selecting the T1 field (whether it will view and make relevant product reviews when shopping); selecting the T2 field (whether it will choose to buy products with high brand awareness); selecting the T3 field (whether it will buy through the online shopping community); selecting the T4 field (whether it will pay attention to and care about some negative news about the brand on the Internet) and selecting the T5 field (will it learn about the brand through other channels, such as the third website, offline word-of-mouth, etc.), and then filter out all records with a field value of "Yes". The composition in Figure 1 sorts out five factors that affect online brand sales, including online evaluation and brand awareness, These five aspects are based on the sources that affect online brand sales, and it can be divided into three categories: one category comes from the consumer's online activity itself, that is, online evaluation; one category comes from online brands, including brand awareness of shopping websites, online shopping communities and related network information. Although these three elements will be controlled by the brand, the online activities of customers also play an important role; the last category comes from other channels, including third-party websites and offline word-of-mouth communication. The source of these two elements is not obvious, but they actually exist in the Internet. At the same time, these two elements are also mixed with a large number of online customer activities.

4.2. Data Analysis.

The Internet continues to penetrate into the daily lives of netizens, and the number of online shopping users is increasing year by year. According to CNNIC statistics, as of 2020, the number of online shopping users in China has reached 989 million, and the Internet penetration rate has reached 70.4%. It is shown in Table 3. The development of commercial applications on the Internet is due to the rapid growth of the number of online shopping companies and that of Internet users who have begun to get
FIGURE 1: Based on the five aspects of the impact of online shopping brand sales composition.

TABLE 3: Statistical data table of Chinese internet development status.

| Years | Data | |
	Number of online shopping users	Internet penetration rate (%)
2017	7.72	55.8
2018	8.28	59.6
2019	9.03	64.5
2020	9.89	70.4

TABLE 4: Customer online evaluation questionnaire of major clothing brands in November.

	Praise	Average	Negative ratings
PRADA	425	29	3
ONLY	46	16	0
ZARA	52	18	16
HM	103	12	10

used to this new way of online shopping. Therefore, this article will conduct a quantitative analysis of online shopping brand sales from the following five aspects.

4.2.1. Online Evaluation. Online evaluation is a kind of online information, which mainly refers to the content itself spread by customers online. Every online behavior itself produces a large amount of information content, which will affect the popularity or reputation of online brands. Online information can often be analyzed from two aspects: information direction and information characteristics. Information direction refers to whether the information content itself has a positive or negative view of the online brand. Obviously, the direction of positive information can enhance the reputation of online brands, and vice versa, the direction of negative information will greatly damage the reputation of online brands. Information characteristics usually refer to the characteristics of the information, such as its manifestation, such as the length and type of the information, etc.; it also includes the inherent characteristics of the information, such as the credibility and legibility of the information. On the one hand, information characteristics will affect the information itself, and at the same time affect online brand sales through information.

As shown in Table 4, in November 2020, major apparel brands had a total of 730 online reviews by customers. Through analysis, PRADA pays more attention to online reviews of customers.

In the network context, the role played by the communicator and the receiver becomes difficult to distinguish, and the customer is both the communicator and the receiver. Generally speaking, the identity characteristics of the communicator and the receiver will obviously affect the

credibility of the information they provide, thereby affecting the sales of online brands. The first is the professionalism of the two, which specifically refers to whether the communicator or receiver is an expert in this field. In the network environment, because the identities of the two are difficult to identify, false information is inevitable. But the professionalism can be judged from the content of the information it provides, such as customer reviews. It provides information in the form of reasoning, arranging knowledge, and discussing opinions, which obviously can be convincing. The second is the authority of the two. Compared with professionalism, authority is more difficult to identify. In traditional media, the authority is easy to judge, such as the authenticity and credibility of mainstream media reports. However, in the network environment, it is difficult to determine the authority due to the difficulty of identification. However, as some network applications begin real-name systems, the authority of the communicator or receiver becomes easier to judge. For example, the real-name authentication of Weibo, celebrity Weibo or expert Weibo is more authentic and credible due to its authority. Obviously, if online communicators and receivers are professional or authoritative, the information they provide is more likely to affect online brand sales. Therefore, the survey results based on online evaluation are shown in.

The results of the male and female role survey also showed that, when most people shop, they check reviews and make comments on related product, as shown in Figure 2, the highest enthusiasm for the activity was women aged 25–35, with 186 people. Followed by female college students and 25–35-year-old males, 183 people, and 172 male college students will also have this activity. This shows that most people agree that online reviews have a great influence on their brand choice.

4.2.2. Brand Awareness. This article believes that brand awareness also occupies an important position, and its influence on online brand sales is second only to online customer reviews. Compared with offline shopping, online shopping has its own uniqueness, so many people pay more attention to the brand when buying things. The inability of consumers to directly touch and feel the product increases the difficulty of product quality judgment. It can be seen from this that in the highly competitive e-commerce market, brand awareness is the standard by which buyers' measure stores. The higher the popularity of the store, the natural flow of people will increase, and the sales will also increase. The result of the influence of brand awareness on brand sales is shown in Figure 3.
(a)
(b)

FIGURE 2: Online evaluation survey results. (a) Male survey results on online evaluation. (b) Women's survey results on online reviews.
(a)
(b)

FIGURE 3: Survey results of brand awareness. (a) Men's survey results on brand awareness. (b) Women's survey results on brand awareness.

As mentioned above, brand awareness accounts for a large proportion of online brand sales. 132 male college students and 161 25–35-year-old males will choose well-known brands when shopping, and agree that the brand's products have certain quality assurance. As shown in Figure 3, female college students and women over the age of 25 trust the quality of well-known brands, and their numbers are above 110. This shows that brand awareness has a great influence on sales.

4.2.3. Online Shopping Community. Online shopping community generally refers to a special discussion space

built by merchants in order to activate the atmosphere of online shopping and enhance the initiative and enthusiasm of customers in online activities. Customers share shopping in the community, post orders and post product or service reviews. In the purchase process, users click on the product information of interest according to their own needs, and these evaluations can increase the attention of other customers to the product, thereby prompting customers to click and browse the product information. The results of the face-to-face questionnaire survey in this article show that 30.27%, 22.51%, and 17.25% of users agree that they will click on product information with higher attention, as shown in Figure 4. Not only that, the community homepage has a search function, which can help customers find their ideal products quickly and easily. It can be seen that the huge online activities in the online shopping community will undoubtedly involve all aspects of online brand sales. Therefore, this kind of combined customer online activities dominate online brand sales.

It can be said that the online shopping community is the essence of customer online activities. A variety of customer online activities gather in the online shopping community, such as the communication between the brand and the members, and that between community members. Relying on the contributions of relevant parties, these activities themselves have been continuously optimized. The information provided by community interaction is more comprehensive and specific, which can be said to be the essence of customer online activities. At the same time, the online shopping community itself has a judging function. For example, posts that are popular with customers tend to have a higher click-on rate, more information value, and more active participation among netizens. The refined customer online activities are more credible. Thus both the brand and the customers themselves are making contributions to customer online activities. For example, sellers will show better-selling products through online communities, while buyers will help latecomers through their own shopping experience. Of course, the information will undoubtedly improve the authority and professionalism of customers' online activities. This kind of information content through the discussion can summarize the whole picture of the problem better, thus making the customer's online activities more authentic and credible. Such authentic online activities will undoubtedly affect the sales of online brands. The results of the online shopping community's influence on brand sales are shown in Figure 5.

As shown in Figure 5, many young people are very active in online communities.

Regardless of gender, groups from junior high school students to 25–35 young people believe in product reviews in online communities. The number of them is more than 100, and the highest number is 25–35 year-old women, reaching 153. This shows that the marketing of online shopping communities has a positive role in promoting online brand sales.

4.2.4. Network Message. With the rise of the Internet, there is a huge amount of information on the Internet. In order to get more display opportunities for information, or to allow online brands themselves to gain more public opinion support, brands will inevitably hire network naval forces to spread information, thus creating a false scenario. Network naval forces belong to a relatively special group in the Internet. Generally speaking, the network navy is employed by the brand side, and its behavior is mostly controlled by the online brand side. In addition to the normal way of brand communication, the current online brand communication also has to rely on a large number of network navigators.

First of all, network naval forces generally disseminate information on a large scale, which greatly enriches online information. Although the quality of information varies from good to bad, it often has an absolute advantage in quantity. In terms of the nature of online information provided by the network navy, there are currently two main types: positive online information and negative online information. Positive online information is mostly to promote the enthusiasm of the brand itself or the product, thereby enhancing the popularity and reputation of the online brand. Negative online information is generally done by competitors, who use the network navy to publish information that is unfavorable to the brand itself or the product, and at the same time use malicious posts to attract the public's attention and combat competitors. It is not difficult to see from the above that a large amount of information created by the network navy makes people difficult to distinguish between true and false, and this online information will also affect people's evaluation of the brand.

Secondly, the network navy's all-round online promotion behavior. The promotion behavior of the network navy is often planned and implemented by the public relations company for three-dimensional promotion. There are five common situations in the online promotion of network navy: First, community promotion. It provides dissemination services in communities and forums. Relying on the requirements of the brand or related parties to formulate forum or community communication strategies and specific implementation rules, while targeting target consumers, implement forum precision marketing, and follow up services in accordance with the marketing plan. Second, hot speculation. It uses the focus of attention of the public, media, and netizens to follow up, and creates high-relevant communication topics, and controls and guides them in this process. Third, event marketing. It manufactures hot events related to online brands, carries out all-round packaging and hype, attracts the attention of relevant parties, and at the same time attracts follow-up reports from the media to a certain extent, extends the influence of communication, in order to achieve the goal of online brand marketing. For example, the event marketing of Ganlu has become the target of media hype to a certain extent. Fourth, Weibo and blog marketing. It uses Weibo, blogs, etc. To spread products or brands. There are mainly the following three forms: well-known blog marketing, self-built blog marketing and group-built blog marketing. These three forms are usually implemented in combination. Fifth, deleting negative news. It contacts search engines, uses artificial means or a combination of other illegal means to instantly obtain negative
FIGURE 4: Product information or evaluations with a high degree of attention.
FIGURE 5: Survey results of online shopping communities (a) Male survey results on online shopping communities (b) Women's survey results of online shopping communities.

information related to online brands in the Internet space, and guide or clear it, especially suitable for active defense or prevention of brands negative information. From the above, the online promotion of the network navy has a guiding effect on the network information of related brands, thereby affecting the sales of online brands. Therefore, this article conducted a survey based on the elements of network information, and the survey results are shown in Figure 6.

In the Internet age, people can learn all kinds of information quickly without using traditional media, which brings great convenience to people. Therefore, the brand side will also hire the network navy to create the network focus, attract people's attention, so as to enhance the awareness and reputation of its own brand. As shown in Figure 6, women aged 25–35 will pay attention to online information, but for brands with negative news, they will not choose to buy, and the number of women reaches 195. Similarly, 182 men aged 25–35 also agreed with this view, and 186 female college students also expressed support. This shows that the

orientation of positive online news has a certain boosting effect on brand sales.

4.2.5. Other Channels.
Analysis of elements based on other channels, including third-party platforms, offline word-of-mouth communication.

(1) Third-Party Platform. Third-party platforms refer to customer online activities that appear on other Internet platforms in addition to the brand's own online marketing channels. Third-party websites also gather a large number of customer online activities. Since customer online activities appear on third-party platforms, its authenticity is stronger, and it is easier to get customers' affirmation.

First, the online activities of customers on third-party platforms are displayed. The ways for customers to display their activities online on third-party platforms are mainly self-media such as communities, forums, blogs, Weibo, and

(a)

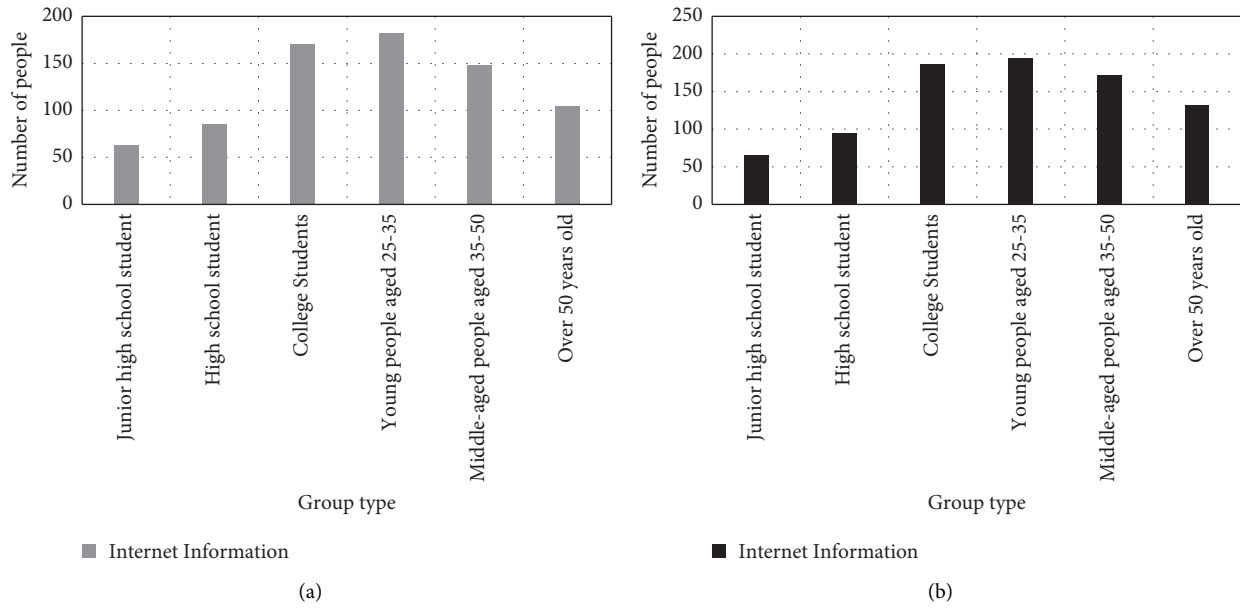
(b)


Figure 6: Survey results of network information (a) Men's survey results on Internet information. (b) Women's survey results on online information.

WeChat. After general customers purchase behaviors, they will evaluate their satisfaction with the products, and the customers will display information about the products in the relevant media or describe their own shopping experience. This kind of display activity that occurs on the self-media is generally consumer spontaneous. Therefore, relatively speaking, it is more authentic and credible. Of course, it is also possible for businesses to hire network naval forces to engage in display activities.

Second, the spread of customer online activities on third-party platforms. The proliferation of customer online activities on third-party platforms is reflected in the uncertainty of the space for online activities. It can be said that on the entire Internet platform, customer online activities can exist. The Internet is a "global village," so customer online activities can theoretically spread arbitrarily on the Internet platform. At the same time, different consumers have different interests and hobbies, and the space of online activities diffusion generally conforms to the interests of customers. Because different consumers browse different platforms, the diffusion of customers' online activities has a strong uncertainty. Of course, due to its relative independence, customer online activities appearing on third-party platforms are essentially not under the control of brand marketing, but are also the self-expression of customers themselves. Therefore, in addition to the marketing of the network navy, the authenticity of the information on the third-party platform is relatively high. For example, customers often browse other platforms to learn about them when shopping, or use search engines to view online activities such as related product information of other brands. This article is drawn through a face-to-face questionnaire survey, as shown in Figure 7. 31.6%, 23.85% and 18.56% of its users agree that they will search for product information or product reviews on the Internet. This shows that their

purchasing decisions are largely influenced by the information on these third-party platforms. These online activities can reflect the value of customer online activities on third-party platforms. Therefore, online activities on third-party platforms also have an important impact on online brand sales.

(2) Offline Word of Mouth. In addition to third-party platforms, offline word-of-mouth communication from customers outside the Internet will also affect online brand sales. Of course, because the research perspective of this article is based on the Internet, the article only discusses some offline word-of-mouth activities related to online brands and their impact on online activities. Most customers will comment on this purchase after their online brand buying behavior occurs. Except for the evaluations on the Internet platform, this article believes that most of the customer's evaluations after shopping will be spread offline. This study also found through face-to-face questionnaire surveys that, in addition to online search, introductions by relatives and friends are also an important channel for customers to obtain product or service information. As shown in Figure 8, its proportion is as high as 29.87%.

Obviously, this kind of communication spreads the influence of online brands beyond the Internet, and has a significant impact on online brand sales. For example, after customers purchase a certain brand of goods online, they will spread word of mouth on real social relationships, such as relatives and friends. Of course, most of this kind of word-of-mouth communication obviously appears outside the Internet platform, which has a significant effect on attracting potential target consumers. If this word-of-mouth communication is positive, it will encourage more customers to buy a certain brand online. Conversely, negative offline word-of-mouth will affect online brand reputation.
Figure 7: Histogram of product information searched by third-party platforms or search engines.
Figure 8: Column chart of channels for online shopping groups to obtain information on goods or services.

If potential customers are attracted by offline word-of-mouth communication and enter the Internet space, the role of offline word-of-mouth communication has become prominent. And new potential customers often have the following two online behaviors:

The first is to seek online word of mouth.

Because the customer obtains the relevant information of the brand offline, the information about the brand has a high degree of uncertainty, and the customer is eager to seek more information to eliminate this uncertainty. Therefore, online activities for seeking brand reputation have emerged. Customers can obtain more relevant information by searching, posting, consulting and other means. Therefore, this kind of customer activity itself promotes the enrichment of online information resources, and can provide relevant information content to latecomers.

The second is to verify offline word-of-mouth behavior.

It is not difficult to see that on the one hand, customers search for online word-of-mouth information through various online methods, and on the other hand, customers will also verify offline word-of-mouth behavior. Because customers cannot be sure of the authenticity of the information provided by offline word-of-mouth, the process of seeking information is also a process of verification. If online word-of-mouth and offline word-of-mouth match, then the customer's brand impression will deepen, thereby forming trust in the brand. On the contrary, if the information that the customer seeks on the Internet platform does not match the information received offline, then the customer's sense of distrust will increase, which will affect the evaluation of the

brand. In summary, whether it is seeking online word-of-mouth behavior or verifying offline word-of-mouth behavior, the customer's activity itself has already constituted an impact on online brand sales. The results of the survey are shown in Figure 9.

The advent of the information age has made it easy for people to obtain various information resources. The survey shows that the majority of people obtain online brand-related information through other channels. As shown in Figure 9, men and women aged 25–35 will search for third-party platforms to learn relevant online brand information, and the number of them is more than 180. People aged 35–50, especially those over 50, prefer to obtain relevant brand product information through recommendations from relatives and friends, and the number of them is more than 130.

It can be seen that the influence of online brand sales comes from five aspects. The article only summarizes the five main factors that affect online brand sales. In the actual Internet environment, there may be other online activities that affect online brand sales. This article can only provide important influencing factors, and cannot completely describe all the influencing factors of online brand sales. In addition, the five aspects will interact and influence each other internally.

4.3. Suggestions on Online Brand Marketing Strategies. As mentioned above, the five factors of online evaluation, brand awareness, online shopping community, online news, and other channels affect online brand sales. Accordingly, this article summarizes the impact of five factors on online brand sales and give some marketing suggestions, which are mainly reflected in the following aspects:
FIGURE 9: Survey results from other channels (a) Men's survey results on other channels (b) Women's survey results of other channels.

First, it enriches potential online information resources.

In the era of new media, information about related products or services can be gathered together through hyperlinks and other means, so that users can obtain massive amounts of information about products or services. If a user finds an advertisement for a certain product or service on the Internet, he will use various Internet tools to understand the product. If the product does not have complete information, customers can search for it online. Therefore, from the perspective of online information content, potential online information resources will continue to be enriched due to the continuous contributions of customers. At the same time, a large number of customer online activities are gathered together in the form of keywords, providing customers with complete online information resources through hyperlinks. Therefore, based on the massive information of Internet products and the means of hyperlinks, customers can learn about all product systems from individual product information, as well as information about products and related brands. Therefore, in the era of new media, with the continuous integration of information, the content of online information resources has been greatly enriched. This has increased online brand sales to a certain extent.

Second, the promotion of online channels.

In the era of traditional media, the interaction between customers and businesses is extremely restricted due to the long time for feedback and limited feedback channels. For example, advertisement information in newspapers cannot provide timely feedback on the product. Even after the feedback, the time for the company to receive the feedback information is very long. Therefore, it is very important to make full use of various feedback channels in the new media era to interact with online customers in an integrated way. With the development of Internet technology, there are more and more ways to conduct product promotion online. For example, after consumers see relevant product information on the Internet, they can immediately click on the product's website or link to view it. At the same time, they will spread relevant product or brand information in real time through various media around them. In the current era of increasingly rich media methods, interactivity has become one of the prominent signs of communication between customers and brands. With the development and popularization of various applications on the Internet, the online activities of customers on various applications are interactive, multi-directional, and participatory, which greatly promotes the promotion of online brands or products. Therefore, the upgrading of online promotion channels is indispensable, such as blog promotion, WeChat promotion, and various application software promotion.

Third, offline word-of-mouth and online word-of-mouth are combined.

In addition to its own online promotion of brand reputation, customers also play a decisive role in the spread of brand reputation. Therefore, it is necessary to combine offline word-of-mouth with online word-of-mouth.

4.3.1. Offline Reputation of Online Brands. The offline reputation of a brand is formed through communication between people. In daily life, customers obtain online promotion information of related brands by communicating with people around them. Out of trust in people around them, they are more convinced of the authenticity and reliability of related brands. Each customer is actually playing the dual role of information disseminator and information receiver. The information that customers get about online brands is more likely to be the experience dissemination of the information disseminator through the experience of purchasing the online brand in person, or it may be the information about the online brand that the information disseminator obtains from other customers. Although there

are differences in the personal needs of each customer, this has also prompted customers to recognize the quality of related brands more. The spread of online brands by customers offline has gradually formed the offline reputation of online brands.

4.3.2. Online Reputation of Online Brands. The online reputation of online brands is mainly formed through online customer reviews. In the era of information sharing, after customers purchase related branded goods online, online platforms can make text comments on related branded goods or services, making relevant information about online brands more intuitive and transparent. Among these reviews, there are not only reviews of related brand products, but also those of shopping platforms, and there are both positive and negative reviews. The spread of these comments through the Internet has gradually formed the online reputation of online brands.

4.3.3. Combining Offline Word-of-Mouth with Online Word-of-Mouth. From the perspective of online brand communication, the development of a brand cannot rely on online or offline unilateral communication. Therefore, the word-of-mouth of an online brand needs to be formed by the combination of online and offline. Customers make reviews when doing purchases, and brands can continuously improve their services based on customer reviews to further meet customer needs. This shows that customers play a leading role in the formation and development of online brands.

Fourth, the communication of the online brand itself is combined with that of customers.

From the perspective of communication, customers are both consumers and communicators. Therefore, the combination of online branding and customer communication will generate a better effect. For example, when customers search for relevant brand product information, they will communicate with brand staff in a timely manner to obtain the information they want. Of course, customers can also consult various experts through various communities and forums, and all this information can only be obtained by searching for them. The propagation process is shown in Figure 10. At the same time, on the Internet platform, all consumer information can be disseminated a second time, and customers can forward it through various platforms such as Weibo, WeChat, and communities. For example, through various self-media means, customers can forward the information content of their favorite products or services to relevant people or recommend them to other friends. This kind of dissemination that customers actively forward will make the secondary dissemination wider to a certain extent. Therefore, customer communication is as important as the brand's own communication, which requires special attention.

Fifth, customers collaborate to participate in online brand communication.

Online brand communication activities require the active participation of customers, so the brand needs to mobilize the enthusiasm and enthusiasm of customers. At the same time, it is also necessary to strengthen the interaction with customers, so as to provide useful information to the brand during the interaction process in order to better carry out brand communication activities. For example, A is a popular search client. When general consumers do not understand brand information, they can search for answers to related brand information through A, and A generally has similar questions or answers from previous consumers, which can meet the needs of consumers. Of course, customers can also open an account A to provide their views on the brand, and it is precisely because of this that makes A's information more comprehensive and true, and provides more comprehensive information for future customers. It can be seen that the collaborative participation of customers in online brand communication has become a norm on the Internet, and the process of participation is also the process of brand information integration. Online brands can also extract the essence of relevant information. Customers can feed back good products or services to the brand, so that relevant brand information can be better displayed to customers, thereby increasing the credibility and promotion of the brand.

5. Discussion

This article conducted 200 effective online questionnaires for six groups of college students and young people aged 25–35 to collect relevant data to analyze the influencing factors of online shopping brand sales. The main findings of this article are analyzed as follows:

(1) Online evaluation. More than 180 men and women aged 25–35 said that they would pay attention to the evaluation of related brand products when shopping;

(2) Brand awareness. Young people aged 25–35 will pay more attention to brand awareness, and college students also express that they prefer branded products with brand awareness, and the number of them is more than 110. Compared with women, men will recognize the quality of branded goods better, and the number of men from college students to men over 50 years old is more than 110;

(3) Online shopping community. The survey results in this article show that young people are more active and proactive in participating in the community. People after 35 years old, because of different interests and low mobile phone usage, platforms such as communities are not the main channels for understanding product information;

(4) Network information. In the era of information sharing, adults will quickly learn about online news through platforms such as TV and have corresponding likes and dislikes. Therefore, online brands need to actively guide the brand's correct and true online news to increase the credibility of the brand to customers.

(5) Channels to learn about other brand products. It mainly focuses on the two aspects of third-party
FIGURE 10: Online communication process.

platforms and offline word-of-mouth communication. The 25–35-year-old youth association learns about relevant brand information through the third online platform, and the number of them is more than 180. The majority of men and women aged over 35 learn about relevant product information through the introduction of relatives and friends, and the number is more than 170.

It is not difficult to see that five aspects, including online evaluation and brand awareness, all affect online brand sales.

6. Conclusion and Outlook

Based on the big data processing technology of the Internet of Things, this paper analyzes the influencing factors of online shopping brand sales. It conducts an online questionnaire survey of people from junior high school to over 50 years old. According to the survey, the five aspects of online evaluation, brand awareness, online shopping community, related brand network news, and other brand product information acquisition channels all affect online brand sales. This article puts forward some marketing strategies in a targeted manner. First, by enriching online resources, customers can retrieve and consult relevant brand product information and learn about related services through major platforms. Second, through online promotion, customers can see brand product information on their frequently active platform, and can learn product information by clicking on the link to complete the purchase behavior. Third, through the combination of online and offline to spread brand reputation, customers will share and evaluate on third-party platforms after purchase, and the brand can make corresponding adjustments based on customer reviews to further meet the needs of the market. Fourth, in addition to self-dissemination, we should also pay attention to customer communication. Brand staff can conduct publicity based on answering customer questions, and customers will disseminate relevant information on other Internet platforms. In this way, the promotion of the brand has been further increased. Finally, customers collaborate to participate in online brand communication. Online brands can mobilize the enthusiasm of customers, better promote the brand by understanding customer needs, and increase the credibility of the brand.

The article uses a questionnaire to quantitatively analyze the sales of online shopping brands based on the big data processing of the Internet of Things, but there are still many shortcomings. First, the depth of the article research is not enough, only five aspects of online evaluation, brand awareness, etc. Have been investigated and researched, and no more in-depth research has been conducted on a certain factor; second, the data of the article also has its shortcomings. There are many factors that affect online brand sales. The survey sample only selected five aspects as research data, such as consumer psychology, consumer care elements, and so on. These two aspects are the follow-up work of this article.

The aim of this study was to research the mechanism of proprotein convertase subtilisin-like kexin type 9 (PCSK9) inhibitor in neural protective effect on rat cerebral ischemic reperfusion injury (I/RI). The transient middle cerebral artery occlusion (tMCAO) model of rats was prepared by the suture method, and PCSK9 inhibitor was injected intraperitoneally immediately after I/R. The rats were scored for neurological deficits and the cerebral infarction volume was measured. The brain tissues were collected and western blot (WB) was used to detect the expression of PCSK9. The rat cortical neural stem cells were treated with oxygen glucose deprivation (OGD) to establish a cell model of ischemia/reperfusion. WB was used to detect the expression of PCSK9 and the apoptosis-related pathway proteins. After interfering with the expression of PCSK9 siRNA, the cell viability (cell counting kit-8 assay) and apoptosis (TUNEL staining, Annexin V/PI method) were detected, and the cell proliferation was detected by EdU staining and flow cytometry. The expression of PCSK9 in the brain tissue of the MCAO group was dramatically increased. PCSK9 inhibitor can improve neurobehavioral scores and reduce apoptosis and infarct volume. An OGD model of neural stem cells in vitro was constructed. Inhibiting PCSK9 with si-PCSK9 can increase cell viability, promote cell proliferation, and also reduce cell apoptosis. Inhibition of PCSK9 can decrease the cerebral infarct volume in rats with cerebral I/RI and improve the neural function. Mechanically, inhibition of PCSK9 can lead to the decrease of nerve cell apoptosis and promotion of cell proliferation.

1. Introduction

The current population aging has become a global problem. Correspondingly, ischemic stroke, as one of the main cerebrovascular diseases that threaten human health, has the characteristics of high morbidity, high recurrence, high disability, and high mortality [1]. Because of the existence of collateral circulation in the ischemic penumbra, it is not completely infarcted, and neuronal function is still possible to recover. It has always been a hot spot in the study of acute ischemic stroke. The early restoration of blood flow is of great significance for reducing the infarct size, restoring patient dysfunction, and reducing mortality and disability [2]. After the blood supply of the tissues and organs is interrupted and blood flow is restored, the functions of the tissues and organs are not restored or even worsened, and

the dysfunction and structural damage are more serious, which is called ischemic reperfusion injury (I/RI) [3]. The mechanism of I/RI is very complicated. It is currently believed that various mechanisms such as inflammation, apoptosis, necrosis, oxidative stress, calcium overload, and free radical generation are involved [4]. Thrombolysis is a clinically effective treatment method, but its limited time window limits its clinical application, making the development of new and effective targets and drugs for the treatment of ischemic stroke particularly important.

Proprotein convertase subtilisin-like/kexin type 9 (PCSK9) was discovered by Seidah et al. [5] in 2003, and it is the ninth molecule in the proprotein convertase (PC) family. PCSK9 is mainly produced by the liver and then released into the blood. It returns to the liver through the circulation and binds to the low-density lipoprotein receptor (LDLR) on

the surface of liver cells to form a LDLR-PCSK9 complex, which is digested by hepatocytes [6], leading to a decrease in LDL clearance and an increase in LDL-C in the blood. PCSK9 is mainly expressed in the kidney, small intestine, liver, and other organs. PCSK9 is also expressed in the cortex and hippocampus [7]. A large number of literature studies have pointed out that the mechanism of PCSK9 in the nervous system is different from that of the liver. It is involved in such as inflammation and oxidative stress [8]. In addition, foreign scholars believe that PCSK9 as a neuro apoptosis regulating converting enzyme is also involved in mechanisms such as apoptosis [8, 9].

Pep2-8 is a PCSK9 inhibitor, which can selectively bind to PCSK9 and block various biological effects of PCSK9 [10]. Therefore, we hypothesized that inhibition of PCSK9 expression after I/R may rescue neurons away from ischemia-induced apoptosis via downregulating caspase-3 pathway. In our study, we established a tMCAO model in SD rats to observe the interventional effects of PCSK9 inhibitor on neurobehavioral scores and cerebral infarct volume after ischemia/reperfusion in SD rats. A neural stem cell OGD in vitro was constructed to explore the effects and potential mechanism of PCSK9 on cell proliferation and apoptosis.

2. Methods and Materials

2.1. Experiment Animal.
A total of 30 adult male Sprague-Dawley (SD) rats (body weight 250–280g) and fetal rats at 18 days of gestation were provided by the Experimental Animal Center of North Sichuan Medical College, and adult male SD rats were used for in vivo animal experiments. Fetal SD rats are used for the extraction and culture of neural stem cells in vitro. This study was approved by the Animal Ethics Committee of North Sichuan Medical College Animal Center.

2.2. Animal Grouping and MCAO Model.
SD rats were randomly divided into the following: (1) sham group: rats underwent sham operation. (2) MCAO group: SD rats were reperfused after 2 hours of ischemia. (3) PCSK9i (Pep2-8) treatment group: reperfusion after 2 hours of ischemia, and intraperitoneal injection of $10 \mu g/kg$ PCSK9 inhibitor immediately after reperfusion. The operation method refers to the MCAO method: (1) after the rats were weighed, they were anesthetized by intraperitoneal injection with 4% sodium pentobarbital. (2) The anesthetized rat was fixed on the operating table in a supine position. After the neck was shaved and disinfected, an incision with a length of about 2 cm was cut in the middle. (3) The blood vessels and the vagus nerve were separated, and the left common carotid artery, external carotid artery, and internal carotid artery were exposed. (4) The proximal end of the external carotid artery and the common carotid artery were ligated, a single knot was tied at the distal end of the common carotid artery, and the internal carotid artery was clamped with an arterial clip. (5) A small gap was cut midway above the ligation of the proximal end of the common carotid artery, and the prepared nylon suture was slowly advanced through the

incision to the internal carotid artery. At the same time, the arterial clamp on the internal carotid artery was loosened. (6) When the length of the thread plug was 18 mm–20 mm, the resistance can be obviously felt. At this time, the opening of the middle cerebral artery was blocked and the thread plug was fixed. (7) After blocking for 2 hours, the single knot was loosened, the nylon thread plug was slowly pulled out, and the distal end of the common carotid artery was ligated, finally restoring blood circulation and achieving reperfusion. (8) After suturing the skin, debridement and disinfection were performed. Sham group: arterial embolization by inserting a thread plug was not performed, and the other operations were the same as those in the MCAO group.

2.3. Modified Neurological Severity Scores.
mNSS is one of the most commonly used scales for evaluating neurological function after stroke, including four categories: motor, sensory, reflex, and balance. The rat was assigned a value when it cannot complete the action or meets the item. The greater the score, the more severe the damage. The scoring system referred to the method in the previous literature [11].

2.4. Rotarod Test.
The Rotarod test was mainly used to evaluate the coordination and balance of rodents. The rat was placed on a roller, the speed was gradually increased from 4 rpm to 40 rpm within 5 minutes, and the incubation period was recorded from the beginning to the time of the rat falling. The rats were trained every day for three days before modeling, and the average was measured three times.

2.5. Frozen Section of Mouse Brain.
On the 7th day after modeling, the rats were anesthetized with 4% sodium pentobarbital. After opening the chest, the right atrial appendage was cut and slowly 50 ml of normal saline was infused through the left ventricle until the right atrial appendage was clear. Then, the brain tissue was taken out and quickly put in isopentane precooled in the ultralow temperature refrigerator for about 1-2 minutes. Then, the rat brain was taken out, marked, and put in the ultralow temperature refrigerator for later use. When slicing, the rat brain was taken out and placed in a microtome for about 1 hour. After adaptation, the slice was embedded in OCT (Keygen, Nanjing, China) with a thickness of $20 \mu m$.

2.6. TTC Staining.
The brain tissue sections were incubated with 2% TTC solution (Jian Cheng, Nanjing, China) at 37°C for 20 minutes, and then the excess TTC regent was drained. The brain slices were fixed with 4% paraformaldehyde. The Image J analysis system was used to quantify the infarct volume.

2.7. Western Blot.
After the brain tissue or neural stem cells total protein was extracted and determined, sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) and membrane transfer were performed. After blocking, the primary antibody (PCSK9, Abcam, Cambridge, MA, USA,

mouse, 1:1000; Bax, Abcam, rabbit, 1:1000; Bcl-2, Abcam, rabbit, 1:1000; caspase-3, Abcam, rabbit, 1:1000; and β-actin, Abcam, 1:5000) was added and incubated overnight at 4 °C. The secondary antibody conjugated with horseradish peroxidase was incubated for 1 hour at room temperature, and the membrane was washed 3 times with tris buffered saline-tween (TBST). Then,the membrane was incubated with electrochemiluminescence (ECL) solution (Camilo, Nanjing, China) for 1 minute and exposed for 5–20 minutes in the cassette for developing and fixing. AlphaEaseFC grayscale analysis software was used to analyze the band grayscale scanning, and the results were expressed as the target protein by the gray value of the sample band/corresponding internal reference gray value. In this study, β-actin was used as an internal reference.

2.8. Isolation of Primary Cortical Neural Stem Cells. Primary neural stem cells were taken from the cerebral cortex of rat embryos at 18 days of pregnancy. The cerebral cortex was digested with 0.25% trypsin (Camilo, Nanjing, China), and then the cell suspension was inoculated into a 6-well plate under 95% air and 5% carbon dioxide conditions. The cell culture medium was DMEM containing 10% fetal bovine serum (FBS) and cytosine-D-arabinofuranoside ($10 \mu M$). In OGD treatment, cortical neurons were cultured in Dulbecco's modification of Eagle's medium (DMEM, Thermo Fisher Scientific, Waltham, MA, USA) for 12 hours under normal conditions and then incubated for 2 hours under hypoxic conditions (95% N_2 and 5% CO_2) with 0.5 mmol/L of glucose and sodium dithionite, and the medium was changed every two days and cultured for 7 days.

2.9. Transfection. The neural stem cells in the logarithmic growth phase were seeded in a 96-well plate to grow the cell density to 60%~80%, and the cells were transfected according to the Lipofectamin^{2000} (Keygen, Nanjing, China) instructions. siRNA-PCSK9 and negative control were diluted with $250 \mu L$ serum-free medium and incubated at room temperature for 5 minutes. Lipofectamin^{2000} $5 \mu L$ was diluted with $250 \mu L$ opti-MEM without serum and incubated at room temperature for 5 minutes. Then, the above liquid was mixed, incubated at room temperature for 20 minutes, and then added to the cell culture well. Cells were incubated in a 37 °C, 5% CO_2 incubator for 6–8 hours. After culturing for 24–48 hours, subsequent experiments were performed.

2.10. Cell Counting Kit-8 (CCK-8) Assay. The treated neural stem cells (2×10^4 cells/$100 \mu L$) were inoculated for 96 hours and $10 \mu L$ of CCK-8 solution (Ye Sen, Shanghai, China) was added to each sample, 3 replicate wells were repeated. After incubating for 2–4 hours, the absorbance at 450 nm was measured with a microplate reader (BD-Biosciences Franklin Lakes, NJ, USA).

2.11. Cell Cycle Assay. The treated neural stem cells were cultured in a 6-well culture plate at 37 °C until the cells reached 80% confluence. The cells were collected with 70% precooled ethanol. After washing with phosphate buffered saline (PBS) twice, the cells were resuspended with 0.5 mL PBS and added with PI (Thermo Fisher Scientific, Waltham, MA, USA) for 30 minutes. Finally, the cells were analyzed by flow cytometry (BD-Biosciences, USA).

2.12. Flow Cytometry. The processed neural stem cells were collected first, and then the cells were suspended in a buffer containing $60 \mu g/ml$ PI and Annexin V (Ye Sen, Shanghai, China) and kept at room temperature in the dark for 15 minutes.Subsequently, cell apoptosis was detected by ACS-Caliber flow cytometer.

2.13. TUNEL Staining. After the sections or cell slides were incubated with 2% hydrogen peroxide for 30 minutes, the cell membrane was permeated with Trixon X-100 (Keygen, Nanjing, China) for 30 minutes. Then, the TdT enzyme buffer (Keygen, Nanjing, China) was used to incubate at room temperature for 15 minutes, and then $50 \mu L$ of TdT enzyme reaction solution was added dropwise and incubated at room temperature for 60 minutes. After washing with PBS, the reaction was terminated. Next, the peroxidase-labeled antibody was used for reaction at room temperature for 30 minutes. After 10 minutes of methyl green counterstaining, 4 fields of view were randomly selected with an image analysis system to count the number of positive apoptotic cells.

2.14. 5-Ethynyl-2'-Deoxyuridine (EdU) Staining. Neural stem cells treated with OGD were seeded in a 6-well plate at 1×10^5 cells per well. After culturing overnight, the original medium was replaced with a fresh medium containing EdU ($100 \mu M$, Camilo, Nanjing, China) for 2 hours, then the cells were fixed with acetone for 20 minutes. The Apollo reaction buffer with FITC fluorescein was incubated for 1 hour and then photographed with a laser confocal fluorescence microscope (Leica, Wetzlar, Germany).

2.15. Statistical Analysis. All data were expressed as the mean ± standard deviation ($\overline{X} \pm SD$) of three repeated experiments and analyzed by Statistical Product and Service Solutions (SPSS) 20.0 statistical software (IBM, Armonk, NY, USA). Student's t-test was used for comparison between the two groups. One-or two-way analysis of variance (ANOVA) was used for data analysis among multiple groups. The statistical analysis of behavioral data adopts repeated measure ANOVA. $p < 0.05$ is regarded as a statistically significant difference.

3. Results

3.1. Expression of PCSK9 Increases in MCAO Rats' Brain Tissue. In order to verify the success of MCAO model, we performed neurobehavioral scores on the rats after modeling. It was found that the mNSS score of the rats increased in the MCAO group rats (Figure 1(a)), and the incubation period of the rat Rotarod test decreased (Figure 1(b)). On the
FIGURE 1: The expression of PCSK9 increases in MCAO rats' brain tissue. (a) Modified Neurological Severity Scores (mNSS). (b) Rotarod test. (c) TTC staining detected the infarct volume of brain tissue. (d, e) WB detected the protein of PCSK9 in brain tissue. * *vs.* sham group <0.05.

7th day of I/R, the brains of the two groups (sham/MCAO) were taken for TTC staining. It was found that the cerebral infarct volume of the rats in the MCAO group increased dramatically than the sham group (Figure 1(c)). The above results show that MCAO model was successful. Next, we used WB method to detect the expression of PCSK9 in the subventricular zone of rats. Compared with the sham group, the expression of PCSK9 in the MCAO group was dramatically increased (Figures 1(d) and 1(e)).

3.2. Protective Effect of PCSK9 Inhibitor on MCAO Rats.
In order to explore the effect of PCSK9 on MCAO rats, we injected PCSK9 inhibitor into the intraperitoneal cavity. WB results showed that PCSK9 inhibitor can dramatically inhibit the expression of PCSK9 in brain tissue (Figures 2(a) and 2(b)). At the same time, we performed neurobehavioral scores on rats and found that PCSK9 inhibitor can reduce the score of mNSS and increase the incubation period of the Rotarod test (Figures 2(c) and 2(d)). TTC results showed that compared with the MCAO group, the infarct volume in the MCAO + PCSK9i group was dramatically reduced (Figure 2(e)). Next, we used TUNEL staining to detect apoptotic cells in rat brain tissue and found that compared with MCAO group, the percentage of apoptotic cells in MCAO + PCSK9i group decreased (Figures 2(f) and 2(g)).

The above results indicated that PCSK9i can improve the neurological function of MCAO rats and reduce the volume of cerebral infarction and cell apoptosis.

3.3. Inhibition of PCSK9 Partially Inhibits OGD-Induced Apoptosis via Bax/Bc-l2 Signaling In Vitro.
We used 18-day-old fetal rat cortical neural stem cells to establish an in vitro cell model of ischemia and hypoxia. To explore the effect of PCSK9 on OGD-induced in vitro ischemic-hypoxic cell models, siRNA was used to knock down PCSK9. WB was used to detect the efficiency of knockdown, the results showed that the expression of PCSK9 in the OGD + si-PCSK9 group was dramatically reduced compared with OGD + si-NC group (Figures 3(a) and 3(b)). Furthermore, the apoptosis-related pathway Bax/Bcl-2 signaling was determined by WB assay, showing that OGD treatment significantly increased the expression of Bax and caspase-3 and decreased the Bcl-2 expression, but inhibition of PCSK9 markedly reduced the ratio of Bax/Bcl-2 and the level of caspase-3 (Figures 3(c) and 3(d)). CCK-8 assay was used to detect cell viability and it was found that compared with the OGD group, the cell viability of the OGD + si-PCSK9 group was improved (Figure 3(e)). The result of TUNEL staining showed that the ratio of TUNEL positive cells in the si-PCSK9 group decreased greatly (Figure 3(f) and 3(g)), and

flow cytometry results showed that si-PCSK9 can dramatically reduce the rate of apoptosis (Figures 3(h) and 3(i)). The above results indicated that inhibiting PCSK9 partially inhibits OGD-induced cell apoptosis.

3.4. Inhibiting PCSK9 Promotes the Proliferation of Neural Stem Cells. EdU staining test results showed that compared with the control group, cell proliferation in the OGD group was dramatically inhibited. Compared with the OGD + si-NC group, si-PCSK9 alleviated the cell proliferation inhibition caused by OGD (Figures 4(a) and 4(b)). In the cell cycle analysis, compared with the control group, the number of cells in the OGD group was dramatically upregulated in the G0/G1 phase and dramatically downregulated in the S phase. Compared with the OGD + si-NC group, the number of cells in the OGD + si-PCSK9 group was dramatically downregulated in G0/G1 phase and dramatically upregulated in S phase (Figure 4(c)). All the results showed that inhibiting PCSK9 can promote the proliferation of neural stem cells.

4. Discussion

In this study, we first used the rat MCAO model to find that the expression of PCSK9 in brain tissue was increased. In in vivo experiments, we found PCSK9i can improve neurobehavioral

functions and reduce apoptosis and infarct volume. At the same time, neural stem cells were used to establish an OGD model, and si-PCSK9 was used to inhibit the expression of PCSK9 to clarify the role of PCSK9 in the OGD model in vitro. Our results showed that after OGD treatment, the expression of PCSK9 was dramatically increased, and si-PCSK9 inhibited OGD-induced apoptosis and promoted proliferation (Figure 5).

The mechanism of cerebral ischemia/reperfusion injury is very complicated, including inflammation, apoptosis, and mitochondrial damage. PCSK9 is a serine protease related to the regulation of blood lipids discovered in recent years [12]. It is mainly produced by the liver and then released into the blood to regulate LDL in the blood. However, recent studies have found that PCSK9 is also expressed in the cerebral cortex and hippocampus of mice. After making a mouse ischemia/reperfusion model, Rousselet et al. [13] detected that PCSK9 was dramatically upregulated. In addition, Tang et al. [14] found that PCSK9 can downregulate LDLR levels after an ischemic stroke in mice, leading to hyperlipidemia. Chiang et al. [15] also found that PCSK9 was upregulated after inducing neuronal apoptosis. The above series of experiments show that PCSK9 expression will increase after the onset of ischemic stroke, and some literatures pointed out that the role of PCSK9 in the brain and the liver may be different. In addition to participating in the regulation of

blood lipids, it also has a wider range of biological effects. It is also involved in insulin resistance, inflammation, cell development, and apoptosis.

Previous studies have found that the MAPK pathway is involved in mediating PCSK9-mediated cell apoptosis [16, 17]. Through the action of shRNA, a study found that PCSK9 dramatically inhibited the phosphorylation of p-p38MAPK and JNK, [18] thereby affecting cell apoptosis. Therefore, we can guess that PCSK9 can directly induce

p-p38MAPK upregulation through the MAPK signaling pathway, thereby mediating neuronal apoptosis. Our study found that si-PCSK9 inhibits OGD-induced cell cycle arrest in G1 phase, indicating that knockdown of PCSK9 may restore the normal progression of the cell cycle through its function as a spindle checkpoint in the cell cycle. However, there are some limitations in the present study. First, we only proved that inhibition of PCSK9 displayed a well correlation with I/R-induced neuronal apoptosis in vivo and in vitro, but the underlying mechanism concerning PCSK9 inhibition regulated neuronal apoptosis was hardly reported. Second, we just preliminarily evaluated the effect of PCSK9 inhibition on function and injured area in MCAO rat model, and more systematic analysis and detection are needed to assess the efficacy in in vivo MCAO rats. Thus, our further researches would aim to the in-depth investigation on the molecular mechanism and therapeutic evaluation of PCSK9 inhibition in ischemic stroke model in the future.

5. Conclusion

Inhibition of PCSK9 can improve the cerebral infarct volume in rats with cerebral ischemia/reperfusion injury,

improve the dysfunction caused by ischemia, and protect the nerve, and its mechanism may be related to the inhibition of nerve cell apoptosis and promotion of its proliferation.

The informatization of cities has been further promoted, and the construction of smart cities supported by technological innovation has been upgraded. The financial industry and data are closely related. Whether the financial industry can make good use of new information technology is the key to its successful transformation. The development of smart cities has a significant effect on the development of people's livelihood, the process of urbanization, the use of technology, the solution of urban problems, and the improvement of economic levels. This also provides a good choice for the development of cities in each country. For better development, it needs technical support. Therefore, it is very important to improve the technical level. This research mainly discusses the risk assessment and regulation algorithms of financial technology platforms in smart cities. This study divides the risk decision channels into two paths based on the smart city theory, considers the internal risk factors and external risk factors of the robo-advisory service platform from the three perspectives of platform characteristics, corporate characteristics, and investor characteristics and exploring the construction of a robo-advisory service platform risk prediction model based on the machine learning perspective. The design and implementation of a personalized financial investment prototype system, a Python-based web development framework Django, and a variety of toolkits have realized a B/S architecture robo-advisor. Among them, the function of buying and selling ETF and the trend recording function after buying are realized by simulating the transaction data collected by the data collection module. The study found that the key potential characteristics that constitute platform risks are mainly the listing year of the background company, the age of the platform, the investment threshold, and the search index. To a certain extent, this provides data support for investors and regulatory authorities to evaluate platform capabilities and platform selection. Investors should comprehensively consider platform qualifications when making platform decisions and pay attention to information such as the age of listing of companies with platform background, platform age, and investment thresholds. Only when the quality of people is improved, the quality of the population of this city improves, so that the development of the city has a broad room for growth. The accuracy of the similar formula calculation method in the big data proposed in this study reached 88%. This research provides new ideas for perfecting the black box regulatory system of robo-advisory algorithms.

1. Introduction

Based on the integration and utilization of resources, smart cities cooperate with terminal equipment through informatization to achieve the improvement of the level of urban governance, thereby enhancing the intelligence and technology of infrastructure. The acceleration of the network upgrade has further promoted the development of various fields. Financial information is constantly emerging, and a large amount of information can indeed help people understand the financial market more fully, but it also increases the difficulty for users to obtain effective information and reduces efficiency. Through the intelligent integration and analysis of data resources, it provides an important reference for government decision-making and has a significant role in urban governance, economic growth, and improvement of people's livelihood.

Internet finance can be regarded as the basic version of financial technology, and financial technology is its upgraded version. Compared with Internet finance, the

penetration and influence of technology elements on financial technology is more obvious. Financial development can accelerate the informatization development of smart cities through technological innovation, and the efficiency of financial development plays the most prominent role. In the long run, the coordinated and orderly development of the overall financial mechanism and the close integration of technology and finance play an important role in improving the level of informatization development and accelerating the pace of smart city construction [1]. On this basis, corresponding countermeasures and suggestions are put forward to promote the integration of financial development and technological innovation to accelerate the pace of construction of smart cities in various regions.

Financial and technological developments promote each other, and financial service trade and technological advancement cherish each other. From a historical point of view, the financial service trade has emerged on the basis of trade in goods and has developed rapidly under the influence of technological progress, regulatory reforms, and economic growth. As one of the traditional industries, the financial industry is closely related to data. Whether the financial industry can make good use of new information technology is the key to its successful transformation. Menouar believes that there is no smart city without a reliable and efficient transportation system, this necessity makes ITS a key component of any smart city concept. Although traditional ITS technologies have been deployed in smart cities globally, the implementation of next-generation ITS relies on the effective integration of connected cars and autonomous vehicles, and these two technologies are undergoing extensive field testing in many cities around the world. Although these two emerging technologies are critical to the realization of fully automated transportation systems, there is still a great need for the automation of other roads and transportation components. Due to its mobility, autonomous operation, and communication/processing capabilities, UAVs are envisioned for many ITS applications. Menouar et al. described possible ITS applications that can use drones and emphasized the potential and challenges of ITS that support drones in the next generation of smart cities [2]. Bo et al. believed that data-intensive analysis is the main challenge facing smart cities due to the ubiquity of various sensors. The natural nature of geographic distribution requires new computing paradigms to provide location-aware and delay-sensitive monitoring and intelligent control. Fog computing, which extends computing to the edge of the network, fits this need. In order to protect the future community, it is necessary to integrate intelligence in the fog computing architecture, for example, perform data representation and feature extraction, identify abnormal and dangerous events, and provide the best response and control. They used an intelligent pipeline monitoring system based on fiber optic sensors and sequential learning algorithms to analyze case studies to detect events that threaten pipeline safety. A working prototype was built to experimentally evaluate the event detection performance of identifying 12 different events. These experimental results prove the feasibility of the system to be implemented in the city in the future [3]. Brundu et al. introduced an IoT software infrastructure that supports new control policies for energy management and simulated urban areas. The platform Brundu et al. proposed enables (near) real-time building energy profile interoperability and correlation with environmental data from sensors and building and grid models. In the smart city environment, the platform realizes the integration of heterogeneous data sources at the building and regional levels, and the simulation of new energy policies at the regional level. It aims to optimize energy use and consider its impact. The platform Brundu et al. proposed has been deployed in a real area, and a novel heating network control strategy has been developed and tested [4]. Mosannenzadeh believed that smart energy cities are an emerging concept in urban development, aiming to optimize the urban energy system and improve the quality of life of citizens. However, the development of smart energy cities requires a well-defined and consistent conceptual core to ensure its accurate interpretation and successful implementation. He defined the development of smart energy cities not only in the theoretical context but also in terms of practical solutions. He adopted the 5W + 1H (why, what, who, where, when, and how) model, combined with literature review and expert knowledge acquisition, namely, focus groups and interviews. This leads to (i) clarifying the general interrelationships among smart energy cities, smart cities, and sustainable cities; (ii) a holistic, multidisciplinary, and comprehensive smart energy city conceptual framework that reveals its principles, goals, intervention areas, stakeholders, and time and space scales; and (iii) a set of smart energy practical solutions and technologies, divided into eight intervention areas [5]. Badii believes that a large number of activities have been carried out in defining smart city architecture to cope with this complexity, and a large number of different types of services and processes have been implemented. He introduced the work carried out in the context of the Sii-Mobility Smart City Project. His project defines a smart city architecture that solves a wide range of processes and data. To this end, by proving the use of semantic ontology and knowledge base in data aggregation in smart service production, the latest solutions of smart city architecture based on data aggregation and smart city API are compared. Baddi's solution proposes to aggregate and re-coordinate data (open and private, static and real-time) through the use of reasoning/intelligent algorithms to achieve complex service interactions through smart city APIs. His work was developed in the context of the Sii-Mobility National Smart City Project, which combines mobility and transportation with smart city services [6]. Daniel believed that technological advancements in multiple fields have promoted the development of smart city applications, which can improve the lifestyle of modern cities. When using a visual sensor in this situation, still images and video streams can be retrieved from the monitored area, which may provide valuable data for many applications. In fact, visual sensor networks may require highly dynamic conditions to reflect changes in parameters in smart cities. In this case, the characteristics of the visual sensor and the conditions of the monitored environment, as

well as the status of other concurrent monitoring systems, may affect the way the visual sensor collects, encodes, and transmits information. He proposed a fuzzy-based method to dynamically configure the operating mode of the vision sensor in sensing, encoding, and transmission modes, using different types of reference parameters. This innovative method can be considered as the basis for multisystem smart city applications based on visual surveillance, and is expected to bring significant results to this research field [7]. Smart cities ensure the sustainable economic and social development of cities by improving the efficiency of urban governance and operation. As each city faces different development foundations, the most important thing in the initial stage of smart city construction is to find a development model suitable for local characteristics. Therefore, all localities must face up to their own level of informatization development and choose a suitable road for smart city construction.

Research on the role of science and technology development in promoting cities: the development of cities mainly relies on the Internet, through which the Internet of Things and the Internet are closely combined to achieve technological innovation and application. Compared with the urban sustainability framework, the modern technology and "intelligence" in the smart city framework have received more attention. Based on the two major hidden dangers of the robo-advisory service platform's regulatory risk control dilemma and investor irrational emotions, this study innovatively proposes a platform governance analysis framework of "platform risk supervision + investor decision-making capabilities" [8]. From the two paths of platform supervision and investor irrational sentiment, build a robo-advisory service platform risk prediction model and an investor's emotional decision-making model for the robo-advisory service platform, so as to conduct targeted governance on the robo-advisor service platform from different perspectives. In addition, this research analyzes theories of financial development, technological innovation, and smart city construction, including the theoretical basis of financial development, technological innovation, and smart city construction [9–11], as well as the analysis of the mechanism of action among financial development, technological innovation, and smart city construction.

2. Fintech Platform Risk Assessment Regulation Algorithm Method

2.1. The Module Division and Overall Architecture of the Robo-Advisory System. Robo-advisor generally refers to robot financial management. Robot financial management is the introduction of artificial intelligence into traditional financial advisory services, instead of physical robots helping customers manage financial affairs. Instead, it provides automated investment portfolio recommendations through computer program algorithms based on the investment objectives and risk tolerance set by the demander through online interactions. Unlike traditional counter-counter face-to-face financial management services, which require many service personnel, the purpose is to improve efficiency. The

robo-advisor is divided into four major functional modules, as shown in Figure 1. The first functional module is the data collection module, which is responsible for the collection of Exchange Traded Fund (ETF) transaction data and the calculation of the recent rate of return [12]. The data flow from the information collection layer, and its main function is to collect analysis data related to the assessment object and the information technology risk, including assessment task information, basic information of banking business system, bank information technology management, business process status investigation, as well as vulnerability threats and asset value identification based on business system assets. ETF mainly involves three participating entities, namely promoters, trustees, and investors. The promoters and fund product founders are generally stock exchanges, large fund management companies, and securities companies. The trustee is entrusted by the promoter to custody and control all the assets of the stock trust portfolio. Since the index ETF adopts an indexed investment strategy, unless the index changes, the trustee generally does not need to adjust the stock portfolio from time to time, but the trustee of the management investment company ETF has a certain degree of freedom of investment decision-making power. Trustees are generally financial institutions such as banks, trust, and investment companies. The second functional module is the user management module, which is responsible for the management of user accounts, the management of user risk tolerance ratings, and the management of user investment portfolios. The third functional module is the portfolio recommendation module, which is responsible for the preprocessing of transaction data, the calculation of the recommended portfolio (completed through the portfolio model), and the storage of the recommended portfolio. The fourth functional module is the monitoring and rebalancing module, which is responsible for simulating the value trend of the investment portfolio, monitoring the deviation of the portfolio fund allocation ratio during the calculation of the trend, and adjusting the ratio back to the recommended state when the deviation exceeds the threshold.

The article studied the supervision of robo-advisors, but as far as the existing robo-advisors papers are concerned, more research focuses on the fields of finance and information engineering. Therefore, in the writing process, the research results of robo-advisors in economics, finance, and other related disciplines are integrated, starting from law or economic law, and understanding robo-advisors from as many angles and dimensions as possible.

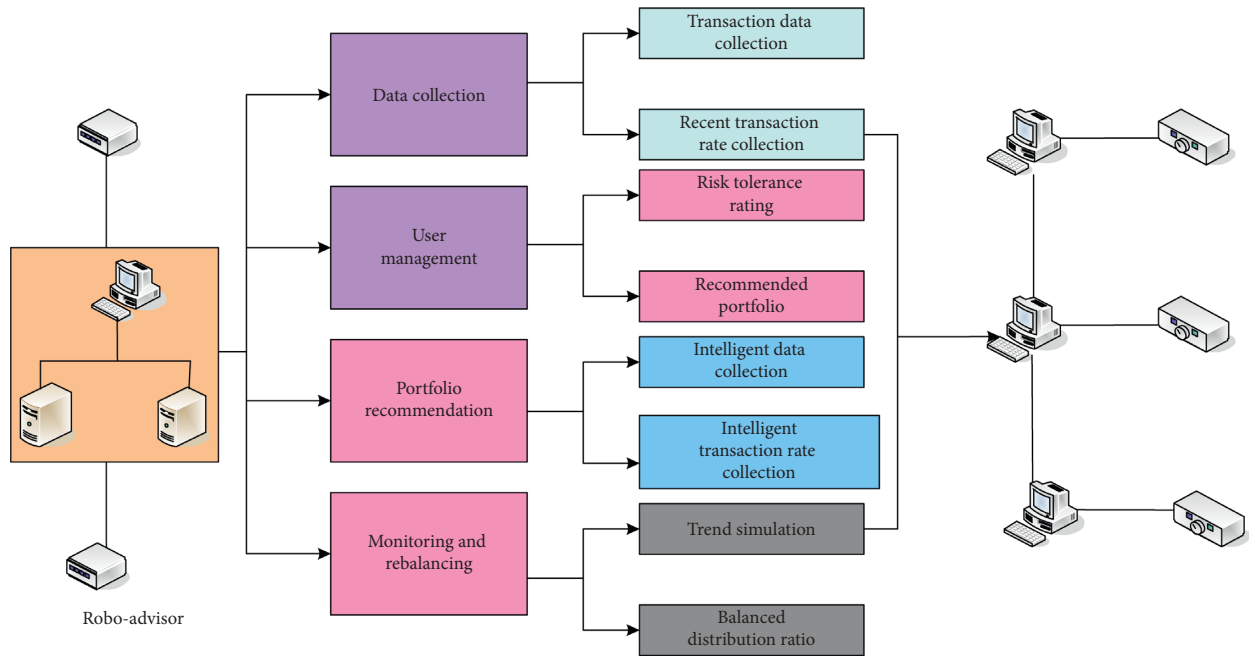
The main logic processing and calculation work in robo-advisors are concentrated on the server, and the front-end is mainly responsible for sending requests and processing a small amount of data, which are a typical application type suitable for B/S architecture [13–15]. Based on this, the entire system is divided into three parts: data storage, server, and Web front-end. The overall system architecture is shown in Figure 2. Among them, the data storage part is responsible for storing user information, historical ETF transaction data, the recent daily rate of return of each ETF, and information about recommended investment portfolios and user investment portfolios. The server is responsible for receiving


FIGURE 1: Module division of the four major functional modules.
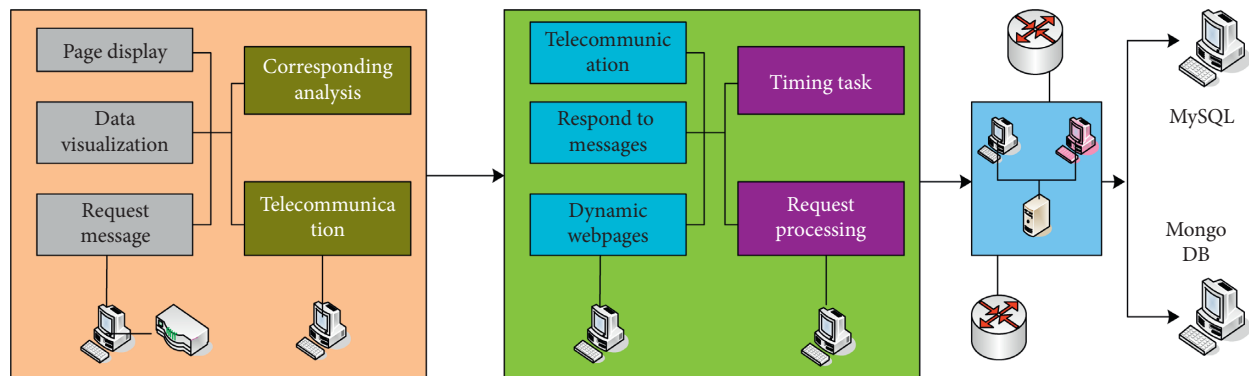

FIGURE 2: Overall system architecture.

front-end requests, performing logical processing, reading and writing data, and sending responses to the front-end. The web front-end is responsible for providing users with operating interfaces, sending requests to the server, and receiving and displaying the results returned by the server to users.

2.2. Adaptation Module Design. Intelligent analysis is divided into user analysis and investment analysis. User analysis is to analyze according to the evaluation questionnaire filled by the user during the user data acquisition stage, to classify different customers, and to allocate the proportion of large-scale assets according to the results of the rating.

When securities companies develop robo-advisor projects, they collect the "views" of retail customers through the analysis of retail customer historical data, market peer experience, and massive transaction data mining, complete the establishment of customer characteristic factors, and analyze and summarize the customer characteristic factor library. And through the subdivision of factors, it can be summarized into categories such as customer's overall characteristics, transaction characteristics, investment style, investment strategy, investment skills, and position status, including multiple characteristic factors. The process of collecting customer characteristic factors is shown in Figure 3.

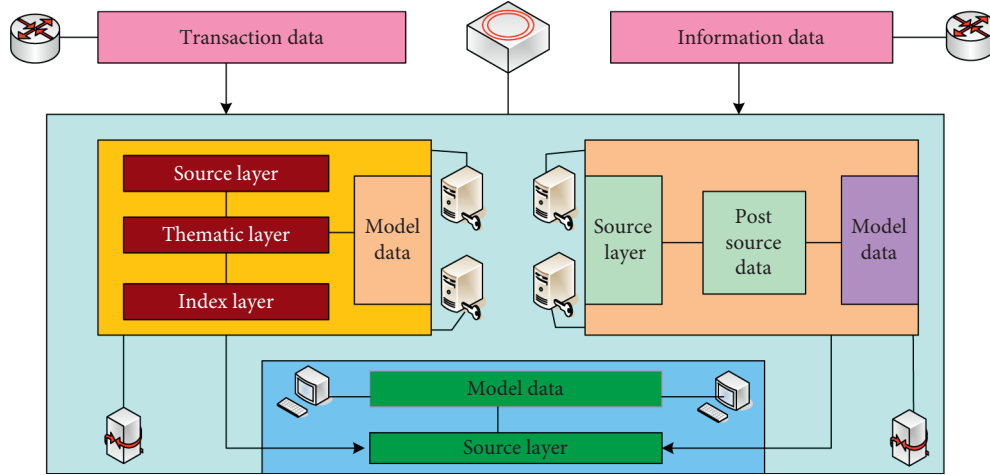
At the same time of user analysis, investment analysis is also carried out. Investment analysis is based on the analysis of fund data obtained in the data acquisition stage. Investment analysis is divided into two steps. The first step is to select the investment target. When selecting the target, it can first determine the broad categories of assets, and select several outstanding funds of various assets to join the asset pool through data analysis. The specific choice can be based on fund company ranking, fund manager ranking, fund performance ranking, and some fund evaluation indicators, such as Sharpe ratio and maximum retracement of the


FIGURE 3: The process of collecting customer characteristic factors.

interval, through these methods to select the best funds. A comprehensive analysis of the customer's historical investment characteristics and investment skills will be carried out, and the customer's trading operations will be recorded in the customer's characteristic factor system, and the investment characteristic factors of the company's investment consultants will also be collected [16]. The characteristic factors of the two include industry selection, individual stock selection, profit and loss ratio, high-frequency trading period, timely stop loss rate, timely profit settlement ability, risk control ability, industry preference, position control, individual stock preference, and other characteristic vectors. Using the similar formula calculation method in big data, the vector distance between the customer and the investment adviser is calculated, and the distance represents the similarity between the two. The size of the distance and the level of similarity are positively correlated, that is, the closer the distance, the higher the similarity between the two. For comparison, the system will focus on recommending top five investment advisors with matching degrees to customers, showing their views, simulated investment portfolios, investment advisory products, and self-selected stocks. In strict accordance with the relevant measures for the management of industry investment advisors, investment advisors can provide clients with securities advisory services and investment advisory portfolio products.

The calculation method of matrix element $D(i, j)$ in the similar formula calculation method in big data is as follows:

$$D(i, j) = d(i, j) + \min\{D(i - 1, j), D(i, j - 1)\}, \quad (1)$$

where $d(i, j)$ represents the distance between the i-th point in the sequence X and the j-th point in the sequence Y.

For the similarity distance of two time series:

$$\Delta D = \min\{D(i - 1, j - 1), D(i, j - 1), D(i - 1, j)\},$$
$$D(i, j)_\beta = d(i, j) + \Delta D. \quad (2)$$

In addition, the stock market is very time-sensitive. Most of the research on the historical trend of stocks is to have a better prediction of the future. It is hoped that similar stocks will have

similar trends in the future. Although the future trend of stocks cannot be fully estimated, it is possible to make appropriate guesses from recent information dynamics. Therefore, the more similar the two stock sequences are in the later time, it means that the two time series are more similar. Therefore, this research improves the similarity calculation method, introduces exponential weighted moving average, enhances the similarity of recent patterns, and weakens the similarity weight far away from the current time. The weighted formula is as follows:

$$D(i, j) = \beta(i, j) + (1 - \chi)\min\{D(i - 1, j), D(i, j - 1)\}, \quad (3)$$

where β is the weight coefficient.

The formula for attractiveness is as follows:

$$X(m, n) = s(m, n) - \max\{a(i, k) + s(i, k)\}, \quad (4)$$

where (m, n) is the similarity between points m, n.

In the iterative update, similar clustering of big data may oscillate due to some noise data, so the smoothing factor α is introduced for control, which is also called the damping coefficient, and the previous trend is considered in the current trend direction. The formula for one iteration of attraction X and belonging A is as follows:

$$X = (1 - \alpha)X_{T-1} + (1 - \lambda)X_{T-1},$$
$$A = (1 - \alpha)A_{T-1} + (1 - \lambda)A_{T-1}. \quad (5)$$

The similarities between stocks are described in different ways, and then the stocks are divided into categories by splicing different clustering algorithms. Exploring the pros and cons of the similarity of different methods for stock time series data, and the differences between different clustering algorithms, select the most suitable clustering algorithm for stock classification, and enhance the accuracy of stock classification.

In Markowitz's modern portfolio theory, indicators to measure returns and risks are proposed:

$$R = \sum_{i=1}^{n} wr, \quad (6)$$

R is the expected return of the asset portfolio.

The formula for portfolio risk is as follows:

$$\lambda^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} w_i w_j \lambda_{ij}. \tag{7}$$

Establishing an effective investment portfolio by finding the minimum portfolio standard deviation under the condition of a given expected return R:

$$\min \lambda^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} w_i w_j \lambda_{ij} + \gamma,$$

$$\text{STR} = \sum_{i=1}^{n} w_i r_j. \tag{8}$$

Using the risk parity model to optimize the combination formula is as follows:

$$\min f = \sum_{i=1}^{n} \sum_{j=1}^{n} \left[w(\Omega w)_i - w(\Omega w)_j \right]^2. \tag{9}$$

The formula for calculating the consistency CI is as follows:

$$\text{CI} = \frac{(\lambda - N)}{(N - 1)},$$

$$\text{RI} = \frac{(K - N)}{(N - 1)}. \tag{10}$$

where N is the order of the judgment matrix.

Calculation consistency CR:

$$\text{CR} = \frac{\text{CI}}{\text{RI}}. \tag{11}$$

2.3. Portfolio Recommendation Module.

Existing investment advisory platforms generally use two methods for user analysis to determine the investment ratio. One is to give a few fixed investment ratios for users to choose, such as the Betterment website. This result is actually more inclined to the user's subjective risk perception and ignores the user's objective conditions. It is very likely that the investment results will not match the customer's own situation. The second method is to divide the product portfolio's effective frontier in equal proportions to match the user's risk level. The result of this is not rigorous, and the difference in the choice of products in the effective frontier will also cause great deviations in the configuration results.

The portfolio recommendation module is the core of the entire robo-advisor. It is responsible for preprocessing the recent returns of each ETF, calculating the recommended portfolio through the portfolio model calculation, and storing the recommended results to disk. The optimized investment portfolio model is adopted in the implementation. The preprocessing of the recent returns of each ETF, including the processing of missing data items, and the calculation of the mean and covariance matrix of the returns based on the data. First, take the JSON string of the recent

return rate of each ETF from the MongoDB collection return-recent and convert it to the Data Frame type in the memory to obtain the return rate of 82 ETFs in the last 200 trading days. If there are missing items, it means that the corresponding single ETF stopped trading on the trading day due to some reasons of its own. Therefore, the return rate of the day is 0, and 0 can be directly added to the missing items. After dealing with the missing items in the data, it is necessary to calculate the mean return rate and the covariance matrix. Using Pandas to realize the EWM method to calculate the statistical characteristics of the mean and variance of the rate of return, and then use them as the input of the portfolio model, and run the model to get the recommended portfolio. The calculation of the portfolio model takes a lot of time, and it takes several hours in the serial case. The model needs to calculate the number of ETFs contained in the portfolio $K = 6, 7, 8, 9, 10$, respectively. Therefore, parallel operation can be realized for different K values. Because of the existence of the global interpreter lock in the Python language, only one thread can execute at any time, so the parallel implementation based on the multiprocess is adopted in the implementation, and the running time of the parallel implementation of the portfolio model has dropped to about half an hour.

There is a certain correlation between financial development and technological innovation:

$$\text{LNP} = C + \lambda_1 \text{SCID} + \lambda_2 \text{GS} + \lambda_3 \text{LNF}, \tag{12}$$

SCID is the smart city development index.

The dynamic panel model is as follows:

$$\text{SDI}_{\text{IT}} = \lambda_1 \text{SDI} + \lambda_2 \text{SDI}_2 + \lambda_3 \text{Lnp} + \lambda_4 \text{Finance} + \lambda_5 \text{Control},$$

$$\text{SDI} = \lambda_1 \text{LNP} + \lambda_2 \text{Control} + \gamma. \tag{13}$$

Among them, SDI and SDI_2 represent the SDI index lagging one and two periods, respectively.

2.4. Database Implementation.

The database of this evaluation system uses SQL-Server. In the implementation process, in order to facilitate the replacement of other database software in the future, this system uses SQL standard statements instead of calling SQL-Server specific functions. Designing a database is to classify tables according to dictionary tables and data tables. Among them, the dictionary table is used to define the data used in the coding. These data have been defined as rules at the beginning of the evaluation, such as asset importance assignment table, fragile assignment table, and asset type, and basically, no addition, deletion, and modification operations are performed. Data tables are often added and deleted during the evaluation process, such as asset identification tables, business system tables, and risk management tables. The asset value assignment information is shown in Table 1.

2.5. The Design of the Display Module of the Robo-Advisor System.

The robo-advisory system displays a "360-degree stereo view" of customers. The comprehensive investment ability of customers is scored through multiple dimensions

TABLE 1: Asset value assignment information.

Field name	Type of data	Length	Describe
ID	Int	4	Identification number
Name	Nvarchar	25	Asset materiality description
Rate	Int	4	Value of the asset
Description	Nvarchar	230	Description information

such as risk control ability, investment ability, ability to grasp opportunities, and operation ability, and the score is compared with the average score of stock customers to form a "customer profile," and fully mine customer transaction data to obtain customer investment habitual preference factors. Opening the page of the robo-advisor system to display the timing ability and risk control ability of the customer's investment ability analysis, and display the score and the average score of securities customers. It also displays customer characteristics obtained through testing: turnover rate, preferred industry, relevance of investment and research reports, preferred investment products, preferred risk, degree of concentration or divergence of holdings, and long, medium, or short-term investment risks, etc. Asset risk information is shown in Table 2.

After the investment advisory system configures the investment ratio, feedback is required. The result of the investment portfolio analyzed by the intelligent algorithm is fed back to the customer. The content includes the expected return rate, return volatility, investment asset types and their allocation ratios, and investment recommendations. The investment proposal states the basis of the investment portfolio and the customer's risk tolerance. Customers can invest according to investment recommendations.

Regarding how to recommend suitable financial products to suitable customers, it is assumed that the influence conditions of customers choosing to purchase financial products are customer investment experience, risk level, capital turnover rate, capital scale, expected rate of return, subscription threshold, investment cycle, and investment strategy. Through the simulation system, the purchase rate of different financial products, the order in which customers with the same capital scale purchase products and the product category with the highest purchase probability for customers with the same risk level are calculated. The intelligent model self-learns, trains, and tests the model to construct the most suitable model scheme. At the same time, the weight adjustment of subjective weighting method and the screening rules of customer suitability conditions are added to form a product recommendation list.

The similarity rate of rise and fall in the same category refers to the probability that stocks in the same category will rise and fall in the same direction for a period of time in the future. This article uses SDI to represent the same direction similarity rate of rise and fall, and its calculation method is as follows:

$$\text{SDI} = \frac{\sum_i^N \max\{I_1, I_2\}/m}{N}. \tag{14}$$

Among them, N is the number of categories.

The similarity rate of rise and fall in the same direction Z_D is as follows:

$$Z_D = \frac{\alpha * \text{SDI}/\lambda}{(\text{PVI} + \beta) * (\lambda + \beta)} = \frac{\alpha * \text{SDI}}{\lambda (\text{PVI} + \beta) * (\lambda + \beta)}. \tag{15}$$

Let Q denote the optimal value of the second-stage problem, which is related to the random parameters and the first-stage decision X.

$$\begin{aligned} Q &= \min q(y, \xi), \\ w(y, \xi) &= h(y, \xi) - G(y, \xi). \end{aligned} \tag{16}$$

Then the stochastic programming model S_G of the compensation problem has the following form:

$$S_G = \min f(x) + E(x, \xi). \tag{17}$$

Nested optimization model:

$$\begin{aligned} W(\xi)Z_1 &= H_1(\xi_1) - G(\xi_1), \\ W_T(\xi)Z_T &= H_T(\xi_1) - G(\xi_1)Z_{T-1}, \end{aligned} \tag{18}$$

where ξ is a random variable.

3. Results of Risk Assessment and Regulation of Financial Technology Platforms

Financial technology companies rely on advanced technology to settle in the market competition, and improper disclosure of internal technical personnel of the company, vulnerabilities in the internal technical system of the company, and improper release of corporate products and services that may all cause the leakage of key corporate technologies. Once the technology is leaked, imitated, or plagiarized by market competitors, what the company loses is not only the waste of the huge investment in research and development in the early stage but also the core competitiveness and potential business opportunities for survival in the market. This blow to enterprise development may be devastating. The main risks of financial enterprises are shown in Figure 4.

Due to various historical reasons, the financial industry will not be linked with "good user experience" and "focus on user needs" in people's vision. On the contrary, it will give people the impression of scarce resources and high service attitude. However, with the impact of the Internet, companies that pay more attention to convenient operation and timely service information will be more favored by users. With the development of Internet finance, according to statistics, it is estimated that in 2021, the number of online payment users will reach approximately 1.33 billion. The payment method statistics are shown in Figure 5. In recent years, the introduction of fast payment in more and more industries shows that the upper limit of the development of smart cities is more far-reaching than people think. Through the introduction of technical means, the convenience of urban residents' life has been further improved, and the use of scientific and technological means has given the government more choices in urban governance and prevention.

Table 2: Asset risk information.

Field name	Type of data	Length	Describe
ID	Int	4	Identification number, primary key

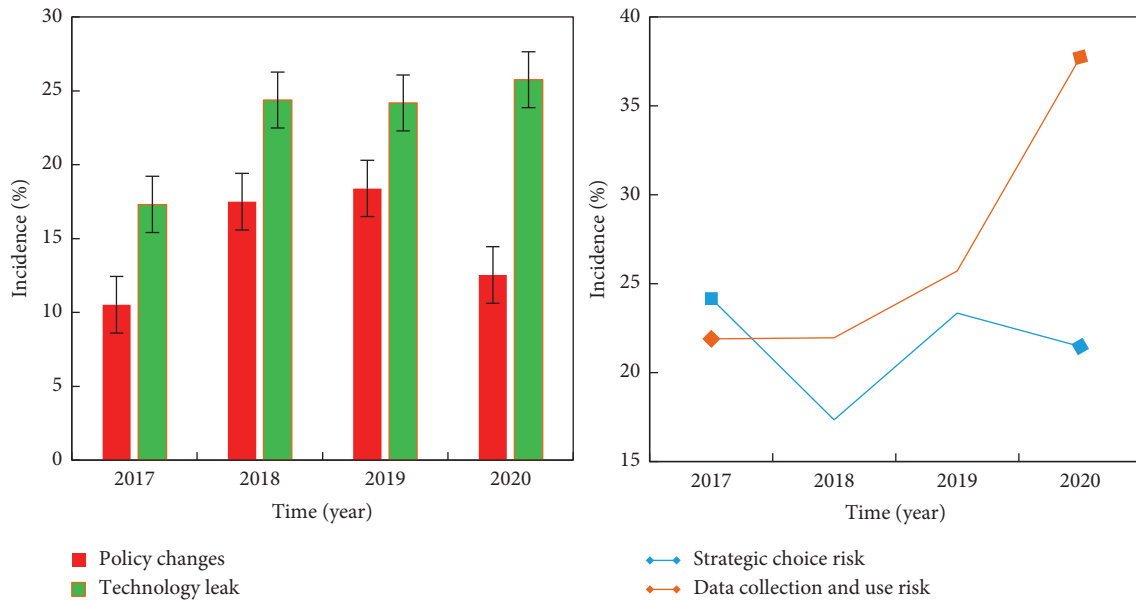

Figure 4: Main risks of financial companies.

For the spot silver from January 01, 2017 to June 05, 2017 on the precious metals exchange in City A and the spot silver 9995 on the precious metals trading center in City B, three K-line data of 60 min, 180 min,, and 240 min were used, use the similar formula calculation method in calculating big data to test the conventional accuracy of parameters, and simultaneously monitor the resource utilization of the server. Part of the result data is shown in Table 3.

During the test, the tested function of the system did not run abnormally under the system constraints, which affirmed the guiding role of the similar formula calculation model in the big data on the spot real market. Judging from the test results, the algorithm in this study has successfully made a profit for 25376 times in a total of 30564 transactions, and the accuracy rate is as high as 83.04%.

Based on the above, the risk values of the three major risk domains of bank information technology risk are 54.05, 51.63, and 64.28, respectively. The three risk domains are weighted by collecting opinions from multiple parties, and the final weighted risk assessment results are shown in Table 4.

When clustering data, it is necessary to calculate the distance between different time series separately. Usually, when calculating the distance, the base of the series is different, which will cause large errors. These errors sometimes lead to bizarre data results. The similar formula calculation

method in big data is used to solve such problems and speed up the calculation. The timing trend before and after standardization is shown in Figure 6.

The higher risk values in the management domain are information security (19%), information system development, testing and maintenance (21%), information technology operation (30%), and business continuity management (30%). The comparison of risk values in the management domain is shown in Figure 7.

Under the management support center, there are departments such as affairs, finance, project management, and the head of the department reports to the head of the management support center. There is no separate compliance department, intellectual property department, risk control department, and internal audit department that directly report to the board of directors. All compliance, intellectual property, risk control, and internal audit functions are currently concentrated in the legal department. The company's main intellectual property rights, personnel status, and financial status in the past three years are shown in Table 5.

Experiments found that a single LSTM and AVG algorithm is difficult to reduce the loss of the model, and under-fitting occurs. Therefore, the LSTM and AVG algorithms cannot effectively explain the investor emotional decision model. Due to the enhanced feature extraction
FIGURE 5: Payment method statistics.

TABLE 3: Part of the result data.

Variety name	Number of successful long signals	The number of successful short signals	Short-selling success rate
1	131	131	0.8771
2	111	13	0.8193
3	101	10	0.8193
4	101	13	0.8713
5	103	107	0.81
6	110	13	0.8783
7	117	11	0.8187
8	107	13	0.8731

TABLE 4: Final weighted risk assessment results.

Risk domain name	Risk domain weight	Risk domain risk value	Risk domain weighted risk value
Management domain	0.3	54.05	10.88
Business process domain	0.3	51.63	15.78
Business system domain	0.5	64.38	33.64

ability of the risk assessment regulation algorithm and the algorithm of this paper, which integrates Attention, it has a better fit to the investor's emotional decision data, the loss continues to decline, and achieves a relatively stable result. Among them, the risk assessment regulation algorithm model in this study makes the final loss smaller. The loss reduction degree of the four algorithms is shown in Figure 8.

The accuracy of various algorithms is shown in Table 6, which shows that the accuracy of the two-way LSTM and the similar formula calculation method in the fusion of big data has been greatly improved on the basis of a single LSTM and AVG network, by 17% and 10%, respectively. Although the similar formula calculation method in big data integrated with Attention has stronger feature extraction capabilities (with an accuracy of 88%), due to the lack of data on the robo-advisory service platform itself, there may be an overfitting problem. Therefore, the experimental results

show that the similar formula calculation method in big data can better explain the emotional decision-making ability of the robo-advisor service platform investors, which provide algorithmic support for the subsequent emotional calculation of platform investors.

Based on the similar formula calculation model in the fusion of big data with experimental training, this study uses Python language and Pytorch framework to calculate sentiment scores for the eight major platform reviews, takes the average value, evaluates the ranking, and compares it with the platform's own comprehensive strength ranking. The specific ranking and sentiment score are shown in Figure 9. The experiment found that investors' risk analysis and platform selection capabilities are still insufficient, and investors' emotional decision-making on the robo-advisor service platform has a large gap with the official platform's comprehensive strength. For example, Huitou Bank ranks
Figure 6: Time series trends before and after standardization.
Figure 7: Comparison of risk values in the management domain.

Table 5: The company's main intellectual property rights, personnel status, and financial status in the past three years.

Year	Net assets	Sales revenue	Total profit
2019	24172.17	440.21	−2441.41
2018	26611.91	121.47	−2161.49
2017	29777.29	5.67	−10022.72

very high in the official comprehensive strength announcement, but investors are not optimistic about its evaluation, only reaching a score of about 0.2. It is comprehensively found that investors still lack the ability of rational risk identification and platform selection for robo-advisory service platforms. This experiment explores the characteristics of relevant investor comments on the robo-advisory service platform and the concerns and emotional characteristics of investors on the robo-advisory service platform. First, construct a domain dictionary, segment words, remove stop words, and extract keyword frequencies

from the cleaned comment data. It can be found that keywords such as "income," "risk," "loss," "handling fee," and "fund" appear more frequently, which are the main points that investors pay attention to. The statistical results of investors' attention to keywords are shown in Figure 9.

4. Discussion

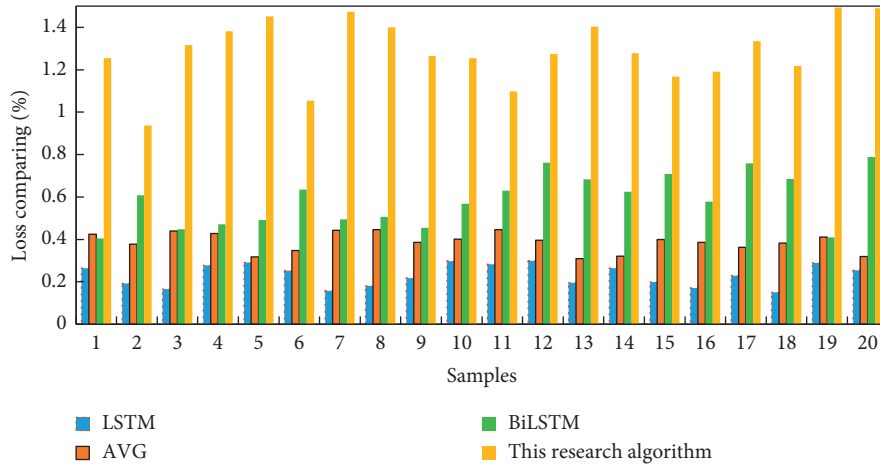
In the era of "AI for all people," computers, as the basic tools for processing work, can help people deal with various tedious and repetitive tasks, and they also have a place in the


Figure 8: Loss reduction degree of four algorithm learning.

field of financial information analysis. By categorizing this information, it is convenient for people to obtain information that is useful to them. The main research content of this subject is to use computer combined with machine learning methods to classify stocks, and on this basis, to dig out the relationship between stocks or categories, so as to better help users to invest. The market environment of perfect competition often stays at the ideal level, and the realistic market economy often shows the characteristics of imperfect competition. Traditional trade theory believes that in the case of monopolistic competition, open trade can not only expand the scale of the market, deepen industry

competition, and increase the degree of international specialization of production, but it can also alleviate the distortion of resource allocation caused by monopoly, make the product price and cost lower, benefit consumers, and improve the national income level.

The financial market plays an important role in the development of the country and the national economy. There are many types of financial products in the financial field. Stock is the most important part of securities, and it is one of the most common investment choices in people's daily life. However, stocks have the characteristics of high risk and high return. Therefore, how to avoid risks and

obtain returns when investing in stocks has been a topic of more concern in the society in recent years. Therefore, when studying the relationship between stocks, the relationship between stock categories is considered. Investing in stocks of different categories can be more conducive to reducing investment risks, and the relationship between categories is often more beneficial to investment, because the relationship between many stock categories is often more stable and lasting than the relationship between individual stocks, and a stable relationship can better avoid risks in investment.

Platform speculation and investor irrational sentiments are two important causes of platform risks and turbulence in the financial market environment. On the one hand, the robo-advisory service platform must provide investors with efficient and convenient robo-advisory services, and on the other hand, it must also restrain the uncertain speculative behavior in it and prevent the occurrence of tragic phenomena similar to a large number of P2P online loan investment platforms. This also brings challenges to the government and regulatory authorities. When the regulators provide incentives for robo-advisor concepts to enter China, they are also constantly exploring how to prevent and control the risks of bad investment platforms. For example, the current operation of the robo-advisory service platform needs to obtain the qualification certificate of the China Securities Regulatory Commission, but there are still the phenomena of platform speculation, running off or losing assets of investors.

For example, blockchain technology is based on the concept of "decentralized distributed transparent mechanism," which replaces the one-way linear relationship of "intermediary–customer" and introduces a highly democratic principle of decentralization into the financial market. Under the above background, the limitations of a single regulatory body, a single regulatory means, and a single regulatory model have become more and more obvious. In the context of financial technology, financial regulatory agencies will fall into a long-term trilemma that they can only achieve two of the three goals of seeking clear rules, maintaining market credibility, and encouraging financial innovation. "The drive of the information regulation model to the power of social regulation" provides a new way of thinking for the socialization and diversification of financial technology regulation. Therefore, information regulation can complement administrative regulation to achieve functional advantages, integrate regulatory resources from the government, market and society, and build a multilevel compound model of financial technology regulation.

The change from Internet finance to financial technology means that regulatory activities are becoming more complex and professional. However, with the rapid development of technical means, technology is subtly changing the way and value of information regulation, and it is an inevitable trend to reshape information regulation. In the context of financial technology, the content and structure of information regulation have become more and more complex, and instrumental rationality and value rationality have shown a dualistic and potentially unified contradiction in information regulation. As the current Internet financial market is undergoing a period of fierce changes and strong supervision, and a large number of Internet financial platforms are closed or cleared, the market is in a special period of transition from "Internet finance" to "financial technology." Investors still lack the ability of robo-advisory service platform selection and risk identification, and there are two key points in its governance: on the one hand, investors' irrational decisions account for a large proportion. Platform operators and the government or the Securities Regulatory Commission can enter from this to cultivate investors' sense of rational investment, including the popularization of relevant financial investment knowledge and attention to important risk characteristics. On the other hand, it is more important to supervise the compliance operation of the platform and restrict its disclosure of relevant characteristic information. For example, investors are concerned about the income, profit and loss, product structure, etc., and review them, which promotes the sound development of robo-advisors in China and builds a benign investment environment for investors.

Monitoring the problems and deficiencies in the financial markets of various regions, by introducing interactive items, helps to examine the degree of financial development's effect on technological innovation, and can discover and evaluate the degree of integration of financial development and technological innovation in various regions, check whether local financial institutions are in place in implementing the state's policy on financial support for innovation and development. On the basis of having a clear understanding of the financial development and technological innovation of various regions, it helps all regions to proceed from the actual situation and in-depth exploration of the specific path and the best way of the integration of technology and finance. Practicing the spirit of the "18th National Congress" promotes the realization of the goal of an innovative country by enhancing the role of finance in technological innovation. With the continuous in-depth research on smart cities, the focus of research is gradually starting from the nature and connotation of urban construction from what is a smart city and how to build a smart city. It not only evaluates the sustainability of urban construction but also pays more attention to the sustainable development of people. With the diversification and standardization of research, smart cities in particular have now developed into a national strategic plan; how to use better methods to construct and how to evaluate the performance of a complex system of smart city financial projects has become a research object that needs to be focused on nowadays.

5. Conclusion

Driven by digitization and informatization, financial technology plays an important role in promoting financial decentralization and financial democratization. The use of scientific and technological means and Internet technology to provide convenient and accurate inclusive financial services for long-tail customers has realized the decentralization and multicentralization of power in the financial

market. This article's research on Internet financial information regulation is still mainly based on the context of "Internet finance." The research on the paradigm of information regulation in the context of "financial technology" is still insufficient, and the research on the characteristics of the integration of information regulation and technology needs to be in-depth. In addition, the study of relevant Internet financial judicial cases still needs to be further excavated and sorted out. This study combines the latest developments of robo-advisory products, comprehensively analyzes the actual situation of robo-advisory platforms, and constructs a model of influencing factors about the use behavior of robo-advisors. This study analyzes the investor's emotional decision-making ability based on the information asymmetry theory and the bounded rationality theory of economic behavior. The existing domestic regulatory policies may not be able to effectively supervise robo-advisory service platforms. In such an environment, robo-advisory services are also difficult to meet the needs of investors. One of the important reasons for this is the irrational investment sentiment of investors. At present, investors' investment philosophy is not yet mature; for example, investors generally value short-term returns.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Conflicts of Interest

The authors declared no potential conflicts of interest with respect to the research, author-ship, and/or publication of this article.

Psychological troubles in training competitions mainly include worry about mistakes, long-term lack of improvement in sports performance, and lack of confidence in competitions. The main troubles in daily study and life are future career development and life planning, injury and illness, insomnia, and poor emotional control. Athletes are interested in psychological skills training, hobby training, interpersonal communication and other coaching content to improve sports performance. Athletes tend to prefer one-to-one psychological counseling and group counseling activities; there are differences in the psychological distress, coping styles and expected psychological counseling content of athletes in different age groups and events. This paper firstly introduces the important role of psychological quality education in modern competitive sports. The influencing factors of athletes' psychological quality were analyzed. At the same time, combined with relevant practical experience, it starts from various perspectives and aspects such as improving the scientific literacy of coaches and building a harmonious atmosphere for training and competition. This paper puts forward some effective strategies to strengthen athletes' psychological quality education and improve sports performance. In addition, it expounds the author's understanding of this, hoping to contribute to the practice of athletes' psychological quality education.

1. Introduction

In modern competitive sports, the intensity and difficulty of competition are getting bigger and bigger, which puts higher demands on the physical and mental health of athletes. Under the current situation, we must pay attention to the important role of psychological quality education in the application of modern sports. Objectively examine the many influencing factors affecting the mental health of competitive athletes, grasp the key points of the mental quality education of athletes, and promote the optimization and improvement of sports performance [1]. Based on the current situation of the needs and deficiencies of health monitoring and management of various types of athletes, athletes need to maintain a good mental state during training and competition. This is because a good mental state is conducive to its maximum potential and bear greater pressure. Generally speaking, they can be divided into three categories. The first

category, such as smart bracelets or watches, has the function of automatic health data collection, but lacks follow-up analysis and connection with health services. The second category, such as online health analysis and diagnosis platforms, can generate health reports based on big data, but data collection is not automatically connected to no health services. The third category, such as fitness or nutrition recommendation apps, passively provides health services, such as fitness courses, but is not based on intelligent recommendation and drainage based on data analysis [2]. Therefore, there is an urgent need for a digital platform that integrates real-time collection and monitoring of personal health data, automatic generation of health analysis reports, and follow-up intelligent recommendation to connect with health services. It is based on the above-mentioned status quo, to carry out research on the application of the Internet of Things and artificial intelligence to realize a health monitoring and management platform that spans time and
Figure 1: The occurrence of mental problems in athletes over the years.

space [3]. Based on the above analysis of the status quo and deficiencies, there is currently no platform or product that connects health data detection and subsequent health recovery services. Therefore, the *IoT* cutting-edge technology that integrates the Internet of Things, artificial intelligence deep learning and intelligent recommendation algorithms is proposed to realize the three-in-one process of "data based health monitoring and management service platform research based on the Internet of Things and deep learning" [4]. Research on health monitoring management service platform is significant for maintenance of athletes' health. When athletes use the platform, they can achieve accurate collection of health data and real-time update and view of health data through *IoT* collection devices. In addition, it will also recommend a series of health service management such as one-to-one live teaching by fitness coaches, one-to-one consultation with professional nutritionists, tweeting services on health forums, and Internet + diagnosis and treatment services based on the athletes' current physical health data. The health monitoring and management service platform based on the Internet of Things and deep learning can serve everyone who cares about their own health, and is precisely positioned for athletes with fierce competition and difficult psychological construction. Automatic real-time health data detection of users through IoT devices, big data analysis, and intelligent generation of user health monitoring analysis reports [5]. As shown in Figure 1, they are also students with rapid physical and mental development, and they will also face the problems that ordinary teenagers will encounter in their growth, such as academic pressure and internal contradictions in physical and mental development. The two influence each other and have their own particularities. In the previous International Olympic Committee, experts also emphasized that while paying attention to the psychological quality of athletes' competitive performance, it is necessary to pay attention to the mental health problems that often occur in athletes [6–9].

The full use of information technologies such as the Internet of Things in athletes' service management can effectively improve the technical quality and safety assurance of athletes' mental health management services. This approach can effectively enhance the high importance of effective management of their own health for all types of athletes. While effectively reducing the cost of psychological medical expenses, it can also change the bad mental life and behavior of athletes, and can effectively prevent the occurrence of mental diseases in athletes. In this way, it can effectively promote the recovery of athletes after various diseases, and further improve the economic, material and spiritual life of college teachers and students [10]. The Internet of Things project includes infrared sensors, laser scanners, and information sensors. According to the relevant protocol requirements, the connection between items and the Internet is realized, and the information flow between them is realized, so as to achieve the purpose of monitoring, tracking, identification, positioning and management. With the gradual increase in the number of sports and competitions in our country, there are higher requirements for venues, security and athlete training facilities. With the development of the Internet of Things project, it has brought more interactivity to the development of sports in our country, and has a very good development situation. It can be said that the development of the Internet of Things project. It will definitely bring significant changes to the development of sports in our country [11]. Athletes' mental health issues are getting more and more attention. Previous researchers have generally used tools such as clinical screening tools or mood state scales from a 90-item symptom list to assess the mental health of athletes. Although these tools are widely used and have shown good reliability and validity in many groups, their use in the field of sports has exposed the difficulty of daily monitoring and screening of sports teams and the irrelevance of the content of the scale to the sports context. Rice developed the Athlete's Psychological Stress Questionnaire from the perspective of the most obvious psychological stress on the development of athletes' mental health symptoms for daily monitoring and screening of professional athletes' mental health status [12]. Psychological stress refers to a state of feeling stressed and difficult to cope with, and is a state of constant emotional exhaustion and reaction to stressful experiences. Compared to internalized symptoms that other clinical diagnostic tools focus on, psychological stress can screen athletes for early signs of possible mental health problems for early professional support [13, 14]. In recent years, there have been more and more mental health problems among adolescents, which is worrying and has attracted attention from all walks of life. The relevant functional departments of the state, provinces and cities have also issued documents on the mental health of young athletes for many times, and the research on the mental health of young athletes is also in-depth. However, there are relatively few studies on the mental health of young athletes. Based on this, this study starts from the Internet of Things technology to investigate the mental health of athletes in youth sports training centers, establishes a health analysis system model. The real-time stream of data from IoT sensors, combined with historical data from other
FIGURE 2: Percentage of athletes with mental problems over the years.

FIGURE 3: Psychological evaluation score curve of participating athletes.

projects, can be used to monitor the current work site and provide an ever-increasing set of data that can be used for simulating system to monitor athletes' mental health. This study aims to investigate the mental health status of athletes based on the Internet of things technology, establish a health analysis system model, and compare the effects of different factors on Athletes' mental health by horizontal and vertical simulation.

2. A Brief Introduction to the Internet of Things

The concept of the Internet of Things was first proposed by the *MIT Auto-ID* Research Center in 1999. This technology is a technology that can use radio frequency identification technology to identify and manage the researched affairs and laws anytime and anywhere under network conditions, which is what we call the interconnection between items. The essence of the technology is mainly to effectively integrate radio frequency identification (*RFID*) technology and the Internet, and to effectively apply the integrated products. *RFID* is a wireless communication technology that can use radio signals to identify a specific target and read and write relevant data without the need to establish mechanical or optical contact between the identification system and a specific target.

As shown in Figure 2, the emergence of the Internet of Things can effectively solve the interconnection between objects to objects, people to people, and people to objects. The Internet of Things is also quite different from the traditional Internet. For example, the interconnection between people and objects we are talking about mainly refers to the connection between people and objects through the use of some common devices. The interconnection between people mainly means that the process of interconnection between people no longer only depends on the connection method of personal computers [15].

$$E_k = 0.5 \sum_{i=1}^{q} \left(Y_i^k - C_t^k \right)^2. \tag{1}$$
In the formula, E_k represents the error between the expected value and the actual value of the neural network.

The application of the Internet is based on optical fiber, to form a network of multiple computers to realize the communication and sharing of information. However, the network environment established by the Internet is actually virtual, and people can only apply the virtual information existing in it, but cannot change the form of real objects in the world. The emergence of *IoT* technology is to remedy this problem. At the same time, the Internet of Things can also realize the unmanned driving of vehicles, so that they can automatically avoid vehicles and congested roads. Thereby avoiding the occurrence of other situations such as traffic jams and saving more time for people. Based on this, we can find that the application of Internet of things engineering has high requirements for relevant equipment and devices. It needs a certain effectiveness and stability to improve people's work efficiency and quality of life [16].

The Internet of Things realizes the Internet between objects, through sensing devices, *RFID* technology, and identification technology. As shown in Figure 3, according to relevant protocols, the network connection between objects is realized, and the information exchange between objects is realized, so as to achieve the purpose of intelligent tracking, positioning, management and monitoring. This intelligent system will be combined with media, services and enterprises in the future to form the future Internet model [17]. The exact methods of data processing based on the SPSS software are data trend analysis, data contrast analysis and data subdivision analysis.

The essence of the Internet of Things is a convergent application in the development of information technology, and its characteristics mainly include the following aspects. First of all, the Internet of Things has the characteristics of the Internet, and it needs to be connected to the Internet before the intercommunication between objects can be realized. Secondly, a supervision cloud platform for environmental protection functional departments is established. Finally, the Internet of Things must be intelligent. The
FIGURE 4: Psychological and behavioral impact levels.

FIGURE 5: Health status of male and female athletes over the years.

intelligence mentioned here refers to self-feedback ability, intelligent control ability and automatic application ability. According to the above description, the application of the Internet of Things project in the mental health of athletes will greatly promote the development of sports in my country. In sports, it is necessary to bring out the potential of people's physical, psychological, athletic ability and physique, so it is necessary to formulate a series of training programs and methods [18].

$$F_i = \frac{(x_i - \overline{x})}{\overline{x}} \times 100\%. \qquad (2)$$

In the formula, F_i represents the deviation of the index from the mean value of the index group. The larger the value, the higher the mean value, and the lower the mean value on the contrary.

At present, most of the health management work in my country is carried out by physical examination institutions and medical institutions, but in actual work, their focus is disease control rather than health management in the true sense. As shown in Figure 4, with the popularization of the concept of the Internet of Things, some people are now focusing on monitoring various indicators of the human body in real time through the use of computer and mobile phone software. As a result, the factors threatening the mental health of athletes are simulated and analyzed in the early stage, and effective solutions are proposed. Make a huge contribution to the development of the sports industry. The Internet of Things has become a game changer for all sports. The IoT sensors are now being used to measure minute details of all aspects of performance to help athletes improve their performance, such as running, swimming, cycling and so on [19, 20].

3. Operation of Mental Health Management Based on Internet of Things

According to the market survey and relevant statistical results of relevant research institutions in our country, it is
known that in recent years, the mental and physical quality of various athletes in many countries around the world needs to be further improved. This is because with the rapid progress of the people, the competitiveness in sports competitions is also increasing. Correspondingly, it will also bring huge psychological pressure to many athletes, so many relevant institutions and organizations have made great efforts to increase the importance and degree of education on athletes' mental health literacy. Mental health test management needs to include a lot of test content, among which athletes' mental health management test and physical fitness evaluation management are very critical parts. Therefore, to seriously and effectively improve athletes' physical and psychological quality, we must work hard. Create a rational model for the management of mental health testing of athletes [21, 22]. The continuous real-time stream of data from IoT sensors, combined with historical data from other projects, can not only be used to monitor the current work site. However, it also provides a set of data that can be used for machine learning for predictive analysis to make athletes' mental health monitoring system smarter.

3.1. Correct Choice of Frequency.
According to the performance classification and characteristics of its operating frequency, electronic tags can be divided into low frequency (*LF*: 30–300 kHz), high frequency (*HF*: 3–30 MHz), ultra-high frequency (*UHF*: 300MHz-3 GHz) and microwave frequency band (*MW*: 2.45–5.8 GHz) four frequency bands. *RFID* applications in the international are generally based on *LF* and *HF* tags as the main implementation. As shown in Figure 5, at this stage, the relevant institutions has mastered the core design technology of *HF* chips, and has already put it into actual mass production applications on a large scale. The data in Figure 5 comes from public data resources published on the Internet. Meanwhile, the *UHF* chip has also successfully completed the research and development process and development stage [23].

3.2. Privacy and Security Protection Measures.
RFID product labels have their own unique characteristics, but in fact they

should all have a unified product code based on the global electronic product label code standard or a unique product code in the world. And this product label has been written into a corresponding product label before their packaging work is completed or before they leave the factory, and it is not allowed to read and write settings at will. At the same time, all the databases in the core chip are fully encrypted in parallel and have passed international security certification indicators, which can fully ensure the security of data sources and processed information. This can not only effectively prevent the artificial cracking of encrypted links and other databases, but also automatically lock some of our important confidential data information according to the sector mechanism, further ensuring that our data security will not be leaked.

$$\Delta v_j = -\alpha \left(\frac{\partial E_k}{\partial v_j} \right) = \alpha d_i^k b_j. \tag{3}$$

In the formula, the correction value of the network weight is Δv_j, which represents the influence strength of the neural network error change on the output result.

3.3. System Cost Analysis.

In the context of the social Internet, the cost of electronic tags has become lower and lower. Since 2006, the price of each tag has dropped to 5 cents. At the same time, because the tag can realize the functions of reading and writing data, and can also be recycled many times, the cost of the tag becomes lower and lower.

$$\Delta w_{ij} = -\beta \left(\frac{\partial E_k}{\partial w_{ij}} \right) = \beta E_j \alpha_i. \tag{4}$$

In the formula, $\triangle w_{ij}$ represents the change value of the connection weight from the hidden layer to the input layer.

3.4. International Standard Issues.

At present, the 2009 edition of *RFID* and other related information technology and electronic equipment development and application standard specifications and related data information of the standard are being researched and formulated internationally. These sources mainly use the International Organization for Standardization (*ISO/IEC*), and currently the main standards for my country are all based on the 2009 edition of *ISO/IEC* 15693. Basically, the specific research or drafting of the industry technical standards related to the national standards of the industry has been successfully completed. With reference to the relevant national standards formulated by *ISO/IEC*1800 in 2009, their standards have also been officially included in the industry standard national key project implementation plan.

$$\Delta \theta_j = -\beta \left(\frac{\partial E_k}{\partial \theta_{ij}} \right) = \beta E_j. \tag{5}$$

In the formula, θ represents the threshold change of the hidden layer.
FIGURE 6: The relationship between mental and social health in sports.

3.5. Implementation of System Design Plan.

Take advantage of some current hospital management systems and professional local area networks. Such as the *HIS* and *LIS* of large universities, institutions and government public administration departments, and on this basis initially complete the treatment of hospital patients, equipment and medical equipment. The system is mainly used in clinical medicine, constitutes the main part of the system, and is the system hardware and related software for optimizing the management of commonly used drugs. We can see from Figure 6 that the most important parts of the hardware include *RFID* network tags, *RFID* network antennas, file readers, *RFID* operating systems, servers, terminals, and related network cables. And each component is mostly connected in larger shapes by different network devices, all of which are equivalent to a broad network running an operating system. However, software functionality generally refers to the software applied to all *RFID* tag servers and tag users for each mobile station.

Through the use of the Internet of Things method, the real-time management of sports equipment can be realized, thereby helping athletes to reasonably allocate time and methods during exercise. We can see from Figure 7 that real-time monitoring of the warehousing and delivery of sports equipment, record the application of equipment and equipment, and share the records to improve the application efficiency of sports equipment. In this way, it can effectively improve the training efficiency of athletes and greatly reduce their psychological burden.

$$p(y|x) = \frac{e^{yx^T w}}{1 + e^{yx^T w}}. \tag{6}$$

This formula represents the mathematical definition of logical distribution under this model, which is a method to complete the classification based on the discriminant of logical distribution.
Figure 7: System structure diagram.

4. Application of Internet of Things Engineering in Sports

Using the Internet of Things project to monitor sports is actually monitoring the physical conditions of athletes in real time, because these physical conditions can reflect psychological changes to a certain extent. The terminal data collection method is used for information analysis. Once abnormality is found in the relevant parameters, an alarm will be issued immediately, thereby reminding the coaches and team doctors to take corresponding psychological counseling to avoid the occurrence of sports accidents during training. We can see from Figure 8 that this monitoring method can be applied to sports training as well as competitive competitions. Athletes can use the Internet of Things to monitor their physiological parameters during the usual training process. For example, for sprinters, they need to have strong explosive power, and in the process of sprinting, the heart will instantly enter. In the state of high-speed operation, how to train to improve the ability of the heart is very important.

$$f(w; X, y) = L(w; X, y) + R(w). \tag{7}$$

The above formula represents a model that rewrites the objective function in the form of a loss function.

Compared with training, athletes will continue to be in a state of high-intensity exercise in competitive competitions, and we can sometimes see athletes die suddenly during competitions. So far, hundreds of athletes have died suddenly during the competition due to too intense exercise. A very important reason for this phenomenon is that athletes do not pay attention to psychological adjustment during high-intensity training. If real-time monitoring of organs in athletes can be carried out, athletes can be warned before organ problems occur. Thereby, it can stop exercising, and effectively improve the psychological counseling, thereby
Figure 8: Comparison of the two algorithms.

avoiding the phenomenon of excessive exercise of athletes. Athletes cannot directly perceive their own mental state, so IoT engineering is needed to provide technical support.

$$c_j^* = \frac{1}{n_j} \sum_{i=1}^{n_j} x_i^j. \tag{8}$$

In the formula, the number of mental health data objects in the c_j cluster is n_j.

As the continuous development of Internet cloud computing technology and various hardware facilities, some equipment systems using the Internet of Things cloud technology have emerged. This is a health management system that includes various subsystems such as various biological detection instrument systems, wireless signal

transmission and reception systems, terminal data processing systems, and background database storage and processing systems. In S mode, the data on the server can be added, modified and deleted through their own terminal machine, and the analysis results and exercise intervention plan fed back to the terminal by the background server can also be obtained. Users can exercise according to the plan. The data during the exercise will be transmitted to the background server to further guide psychological counseling.

$$J^* = \sum_{k=1}^{n_j} \sum_{j=1}^{k} \left\| x_k^j - c_j^* \right\|^2. \tag{9}$$

If $|J^* - J| < \xi$, it means that the clustering criterion function converges, and the final clustering result is obtained, and ξ is the criterion for judging the convergence of the function.

The mental health monitoring work process of athletes generally generates a huge amount of data, and the analysis of these health monitoring data has extremely important practical significance. More work mistakes make the mental health monitoring work of the athletes lose its value.

$$A_i = \frac{\sum_{i=1}^{3} a_y \partial_y}{\sum_{i=1}^{3} y}. \tag{10}$$

In the formula, A_j is the value corresponding to each feature layer index calculated, and the coefficient of each base layer is determined, and the value is 0–1.

The popular science service provided by the athlete mental health tracking system is no longer the original one-way indoctrination, but it is changing to two-way interaction, that is, the two-way communication between the disseminator and the recipient of the popular science service is realized by using the product of the athlete mental health tracking system as the communication medium. In addition, while the athlete mental health tracking system provides popular science and services to all sports circles, these health data can become the basis for the investigation of athletes' mental health quality. The athlete mental health tracking system is a service-oriented popular science system, which provides a good opportunity for the development of future popular science exhibits. The design of this system fully reflects the people-oriented concept, and the design is more in line with the actual needs of athletes advantages of the Internet.

5. The Important Role of Psychological Quality Education in Sports Competition

With the development of economy and society, sports competition has been continuously improved and has become a key part of human social life. In the complex, ever-changing and exciting competitive arena, only with stable and strong psychological quality can we better play our due level and achieve better sports results. In sports, the contest between athletes is not only a contest of their own technical level, but also a contest of psychological quality. When
FIGURE 9: Average risk assignment for different ages.

athletes of the same level compete on the same field, the ups and downs of psychological state become the decisive factor for the performance of athletes.

Mental health is a key component of a person's overall quality. The level of modern competitive technology has generally improved, and the audience's viewing ability has also undergone profound changes. We can see from Figure 9 that if the mental health quality is lacking, it is bound to be difficult for the athletes to better adapt to the competition rhythm. Practice shows that the importance of athletes' psychological quality in their comprehensive quality is becoming more and more prominent, and it plays a pivotal role in competitive performance. Therefore, improving the level of psychological quality education and strengthening the psychological quality of athletes can better face failure and success, joy and tears.

Competitive sports under the commodity economy and social environment presents many new features, of which economy and utility are typical representatives. Under the impact of economic interests, some athletes pay too much attention to their own performance, put too much energy into utilitarianism, and even distort their self-values and outlook on life. Development requirements, unable to realize self-worth. Therefore, in the economic society, it is necessary to make athletes face fame and fortune more correctly and adapt to the needs of social development through systematic psychological education.

$$\chi^2 = \sum \frac{(f_o - f_e)^2}{f_e}. \tag{11}$$

Among them, f_o represents the observed frequency; f_e represents the expected frequency.

Today's sports competition is no longer a purely physical competition, but a comprehensive competition in psychology, training, economy, technology, anti-stress and other aspects. The traditional one simply relies on infinitely extending training time and improving training intensity
Figure 10: Risk value comparison of two targets.

The method is out of date. At the same time, the age requirements for training and participating in competitive athletes tend to decrease, and their psychological development is relatively lagging behind. All of the above conditions put forward higher requirements for the overall quality of the coaches.

$$I(X, Y) = \sum_{x \in X} \sum_{y \in Y} P(x, y) \log \frac{p(x, y)}{p(x)p(y)}. \quad (12)$$

Among them, $p(x, y)$ represents the joint distribution of two random variables (X, Y) of the observed frequency; $p(x)$ represents the marginal distribution; $p(y)$ represents the marginal distribution.

6. Application of BP Neural Network in Intelligent Analysis

First, the wavelet transform is used to denoise the athletes' psychological monitoring data, and the denoised data is used as the input of the *BP* neural network. The number of nodes in the input layer depends on the dimension of the data source degree, such as the athlete's mental fitness index plus gender, age, height, and weight. The number of output layer nodes is 3, which are poor, medium, and excellent. The number of hidden layer nodes affects the learning time and training effect. We can see from Figure 10 that the formula is used to determine the number of nodes. Finally, make sure the number of nodes is 6. The network performance is relatively stable. At the same time, the threshold and weight in the network structure are used as the objective function, and the error value between the expected output and the predicted output is used as the fitness function. The optimal solution is obtained by continuous optimization calculation.

In this paper, wavelet analysis is used to denoise, to keep the wavelet coefficients of the effective signal to the greatest extent, and remove the wavelet coefficients of noise. At the same time, in the process of denoising, the smoothness and similarity of the original signal should be kept as far as possible, indicating that the variance estimation of the signal before and after denoising is the minimum value in the worst case. Wavelet analysis has strong denoising ability. The steps of the wavelet analysis method are to select the appropriate wavelet basis function, to decompose the original sample by wavelet, and to obtain the wavelet coefficients of each layer. The wavelet coefficients are processed by the soft threshold method to minimize the maximum mean square error of the estimated signal. The Internet of Things in sports shows the potential to collect and analyze data to improve the performance of spaces, things and athletes. Driven by the competitive nature of sport, iot has the potential to fine-tune its ability to take sports mental health monitoring to a new level.

7. Conclusion

For competitive sports, the ultimate goal of sports training is to create excellent sports performance, and the psychological quality of athletes is the most basic factor to improve competitive ability. After training with the training set, the *BP* network and the *PSO-BP* network are tested respectively using the data in the literature, which can accurately reflect the efficiency and accuracy of the *BP* neural network after particle swarm optimization. Aiming at the popularization of smart devices and the needs of athletes' training monitoring, a deep learning-based athlete's physique assessment algorithm was designed. The advantage of IoT technology is that the athletes can remove faults in time and reduce the occurrence of safety accidents in competitive sports. The

algorithm scores different athletes by selecting factors such as vertical jumping, high-speed leg raising, sitting and stretching, height, chest circumference, body fat percentage, and uses particle swarm optimization algorithm to optimize the *BP* algorithm to establish athlete psychology. The evaluation model of the situation comprehensively reflects the physical and mental quality of athletes. Through simulation experiments, it is concluded that the optimized *BP* network has high efficiency and accuracy. It is obviously superior to the traditional *BP* network in the evaluation and prediction of athletes' psychological quality.

The corpus is applied to compare and analyze three elements of the third personal pronoun endophora in English abstracts of Chinese and foreign theses. It is discovered that there is no significant difference in the total frequency of third personal pronoun endophora used by Chinese and foreign masters, but there is a significant difference in three elements of third personal pronoun endophora. Native Chinese-speaking masters tend to choose "it" as the anaphor, while native English-speaking masters are inclined to select "them" as the anaphor; antecedents used by native Chinese-speaking masters are mostly consistent with keywords of theses, while antecedents used by native English-speaking masters are rarely consistent with keywords of theses; distances between antecedents and anaphors set by native Chinese-speaking masters are much longer than those set by native English-speaking masters. These findings are beneficial for Chinese masters in terms of better understanding the writing conventions of English abstracts of foreign theses and further improving the language quality of English abstracts in their theses.

1. Introduction

Endophora refers to the phenomenon that writers make use of words or phrases to substitute previous or subsequent elements. Endophora seems to be a simple language phenomenon, but actually it not only shows the substitution relation in grammar but also displays the coreferring relation in semantics. Moreover, endophora, as a cohesive means, plays the main constraint on cohesion. Halliday pointed out that anaphors are mostly enacted by personal pronouns [1]. Haiyan LU comparatively analyzed the usage of personal pronouns in general English writing by native Chinese-speaking students and native English-speaking students, and discovered that native English-speaking students tend to choose third personal pronouns as anaphors, while native Chinese-speaking students are inclined to select first personal pronouns to replace complicated and redundant antecedents [2].

In recent years, some Chinese and foreign studies have focused on comparing personal pronoun endophora in English sentences or general English discourses written by native Chinese-speaking students and native English-speaking students. According to Helen and Renate, it is learned that all types of personal pronouns are used as anaphors in general English writing, while in academic English writing, third personal pronouns rather than first and second personal pronouns are preferred [3]. However, the study on third personal pronoun endophora in academic English discourses is relatively rare. Compared with first or second personal pronouns, third personal pronouns not only follow the economic principle of language as they avoid repetitions of complicated antecedents, but also play the role of cohesive means as their comprehension relies on the discourse context. Therefore, third personal pronoun endophora is both a textual language phenomenon and a textual cohesive tool. It is currently a research topic in the spotlight for comparing and analyzing third personal pronoun endophora in academic English writing written by native Chinese-speaking students and native English-speaking students.

This paper employs the tool of corpus to study third-personal pronoun endophora in English abstracts of Chinese and foreign theses. On the basis of the analysis of similarities and differences in third personal pronoun endophora, it is expected to help Chinese masters better understand the writing conventions of English abstracts of foreign theses and to further improve the language quality of English abstracts in their theses.

2. Theoretical Framework

According to Halliday, endophora is complicated in that it needs to refer to some elements that have appeared or will appear in the discourse so as to make the whole discourse coherent. When the reference of an element is used to refer to its previous element in the discourse, this phenomenon is called anaphora; when the reference of an element is used to point to its following element in the discourse, this phenomenon is named cataphora [1]. In his dissertation, Jiangli XU claimed that anaphors and antecedents are two inherent elements of anaphora and cataphora [4]. Michael Strumpf demonstrated that anaphors in discourse are mostly expressed by objective third personal pronouns instead of subjective first and second personal pronouns [5]. Forms of personal pronouns consist of subject case form, objective case form, possessive determiner form, possessive pronoun form, and reflexive pronoun form. Compared with other forms, the possessive pronoun form owns double antecedents. For example, "hers" may have the antecedent of "Mary" and the antecedent of "book". Hua WANG described that those forms of third personal pronoun anaphors are as follows: "He," "His," "Him," "Himself," "She," "Her," "Herself," "It," "Its," "Itself," "They," "Their," "Them," and "Themselves" [6].

Antecedents in the discourse are generally served by nouns or noun phrases. Since the combination of nouns or noun phrases is infinite, the identification of antecedents is a complicated procedure. Chomsky attempted to propose a series of explanatory rules at the sentential level about antecedents' identification with the aid of the c-command theory of transformational grammar [7]. On the basis of the node analysis and tree-diagram presentation, Levinson claimed that antecedents that have a coindexed relation with anaphors can be identified in the discourse smoothly [8]. Fukumura also adopted c-command as the core idea and claimed that third personal pronouns usually have a coreferring relation with the definite noun phrase in independent sentences [9]. For instance, "Mary thinks she has been late." If this sentence is an isolated sentence, the third personal pronoun "she" will definitely be regarded as a variable bound by the definite noun phrase "Mary."

It is clear that Chomsky and Fukumura are restricted to the syntactic level. H.G. Widdowson strode the syntactic node to control the jurisdiction level and confirmed anaphora in discourses by analyzing the semantic characteristics of anaphors and antecedents [10]. However, his method requires a lot of time and energy to analyze the semantic features of third personal pronouns and noun phrases. In order to pursue the labor-saving principle, Levinson and Yan HUANG have raised the antecedent confirmation to the pragmatic level by analyzing partial interpretations, disjoint hypotheses, and salient information interfaces of the coreferring relation [8, 11], but two scholars never touch upon readers' cognitive motivation in the process of discourse comprehension. Ariel and Yulong XU classified anaphors into accessibility levels from the cognitive perspective, and they maintained that pronouns belong to high accessibility markers in that pronouns are closely related to the context in which short-term memory usually works [12, 13].

In comparison to anaphora, the reason why cataphora has not been extensively explored by scholars lies in its rareness. Halliday holds that cataphora is a special linguistic phenomenon which is often discovered in rhetorical or literary writing [1]. For instance, "Through their fiction, the Brontes consider Victorians' treatment and understanding of animals, as well as the human implications and consequences of cruelty." In this instance, the antecedent "the Brontes" appears after the anaphor "their", so this phenomenon is genuine backward anaphora. In addition to western scholars, Chinese scholars also make great efforts to investigate cataphora. Through analyzing materials, Yuan GAO and Canlong Wang discovered that although there indeed exists a third personal pronoun cataphora in news titles or subtitles, its application in English writing is still rare [14, 15]. For example, "It may not be great, but Footstep is not that bad". The anaphor "it" and the antecedent "Footstep" are coindexed in this news title. Therefore, in this research, much attention will be paid to the analysis and discussion of third personal pronoun anaphora instead of cataphora.

Those mentioned researches related to the third personal pronoun endophora indicate that endophora confirmation procedures in discourses should integrate all levels to form a comprehensive endophora confirmation principle. Specific procedures of endophora identification proposed by the author in this paper are as follows:

(1) The first step is to seek out the current topic before the anaphor. In the process of topic searching, pronouns are considered as high accessibility markers, so their antecedents are current topics.

(2) The second step is to judge whether the anaphor and the current topic are identical in semantic features or not. If they are identical, they have a coreferring relationship; if they are not identical, they do not have a coreferring relationship.

(3) The third step is to infer previous and subsequent antecedents based upon contexts at a pragmatic level, and specific contexts are of great importance to identify antecedents.

3. Research Design

3.1. Research Questions. Three research questions will be answered:

(1) What are the similarities and differences in the total frequency of third personal pronoun endophora in the English abstracts of Chinese and foreign theses?

(2) What are the similarities and differences in three elements including anaphors, antecedents, and distances used by native Chinese-speaking masters and native English-speaking masters?

(3) What are the underlying reasons for discrepancies in the total frequency and specific usage of third personal pronoun endophora applied by Chinese and foreign masters?

3.2. Research Instruments.

240 English abstracts of Chinese theses are selected from CNKI (China National Knowledge Infrastructure) and 240 English abstracts of foreign theses are selected from PQDT (ProQuest Dissertations & Theses) respectively. CNKI and PQDT are outstanding representatives of Chinese and foreign academic resource databases. AntConc software is applied to transform 480 English abstracts into a corpus. Those English abstracts with more than 100,000 words cover the disciplines of history, literature, sociology, and anthropology. With the aid of concordance, word list, file view, collocates, and other functions in AntConc software, relevant contexts of third personal pronoun anaphors are retrieved. On the basis of the "Hit" column on the left side of the software, the author annotated and analyzed three elements, including anaphors, antecedents, and distances.

3.3. Research Procedures.

Procedures of data collections consist of three steps:

(1) The first step is to automatically search "He," "His," "Him," "Himself," "She," "Her," "Herself," "It," "Its," "Itself," "They," "Their," "Them," and "Themselves" as third personal anaphors in the corpus.

(2) The second step is to artificially analyze the consistency of semantic components between current topics and third personal anaphors by applying the specific pragmatic context and the reader's cognitive capacity. Then the author marks the antecedent as "1" (1 means the antecedent is consistent with keywords of the thesis), and "2" (2 means the antecedent is inconsistent with keywords of the thesis).

(3) The last step is to measure the number of words between anaphors and antecedents and consider the distance as the third element, except for anaphors and antecedents.

4. Data Analysis and Discussion

4.1. Frequency of Third Personal Pronoun Endophora.

As endophora is divided into anaphora and cataphora, the total frequency of third-personal pronoun endophora in this research has been counted by the summation of anaphora and cataphora. In 240 English abstracts written by native Chinese-speaking masters, the total frequency of third personal pronoun endophora is 1329, in which there are 1258 anaphora examples and 71 cataphora examples. In 240 English abstracts written by native English-speaking masters, the total frequency of third personal pronoun endophora is 952, of which there are 899 anaphora examples and 53 cataphora examples. In order to test if there exists a significant difference in the frequency of third personal pronoun endophora used by Chinese and foreign masters, the author made use of the Chi-square test in that it mainly deals with the 2×2 table for testing the significant difference.

Because of $n > 40$ and an expected count > 1, the result of continuity correction[b] is emphasized in Table 1. The Sig. value of continuity correction[b] is 0.889, which is much larger than 0.05, hence there is no significant difference in the frequency of third personal pronoun endophora. In other words, both native Chinese-speaking masters and native English-speaking masters tend to apply third personal pronouns to refer to antecedents that appear in the previous or subsequent discourse.

In CNKI and PQDT, the frequency of third personal pronoun anaphora in the disciplines of history and literature accounts for the largest proportion. In CNKI, the cumulative percent in the two disciplines is 58.3%, and in PQDT, the cumulative percent is 65.9%. Masters who major in the disciplines of history and literature are inclined to employ the third personal pronoun endophora. The reason is that the discipline of history mostly involves historical figures, events, and places, and the discipline of literature frequently consists of characters, most of which are proper nouns. When Chinese and foreign masters refer to proper nouns that have appeared in English abstracts, they would like to make use of third personal pronouns to replace redundant antecedents. Only in this way, can the purpose of following the economic principle of language and guaranteeing discourse coherence be achieved.

Eg1. Based on close reading and text analyses of about 40 historical novels published around 1962, this thesis investigates the differences between these novels, as well as their values and limitations, and demonstrates the profound impact of two of Chen Xiang-he's novels on Chinese literature (sentence from the discipline of literature in CNKI).

Eg2. This thesis broadly analyzes the principles of Dante's aesthetic in the poem while analyzing the Sibyl, the Hanged Man, and the Prajapati for their relevance to Eliot's aesthetic theory (sentence from the discipline of literature in PQDT).

In two instances, the third personal pronoun "their" is the economic and succinct anaphor, but "40 historical novels published around 1962" and "the Sibyl, the Hanged Man, and the Prajapati" play the roles of complex and lengthy antecedents. Anaphors acted by third personal pronouns can not only make language succinct in form but also benefit readers in comprehension. That's why third personal pronoun endophora accounts for such a large proportion of the total, no matter in CNKI or PQDT. Both Chinese and foreign masters pay attention to the economic principle of language and focus on the least amount of effort in language and the greatest effect in communication. They tend to apply third personal pronouns in English abstracts so as to reduce complicated and redundant antecedents.

TABLE 1: Chi-square tests of third-personal pronoun endophora in CNKI and PQDT.

	Value	df	Asymp. Sig. (2-Sided)	Exact sig. (2-sided)	Exact sig. (1-sided)
Pearson Chi-square	0.055a	1	0.815		
Continuity correction[b]	0.020	1	0.889		
Likelihood ratio	0.054	1	0.816		
Fisher's exact test				0.852	.443
Linear-by-linear association	0.055	1	0.815		
N of valid cases	2281				

a. 0 cells (0.0%) have an expected count of less than 5. The minimum expected count is 51.75. b. Computed only for a 2×2 table.

With the aid of AntConc software and SPSS, 71 genuine cataphora cases were discovered in 240 English abstracts selected from CNKI, and 53 genuine cataphora cases were found in 240 English abstracts selected from PQDT. The author concludes that there exist two types of antecedents. The first type of antecedent is the infinitive form like "to describe..." and the second type of antecedent is the that-clause, like "that the history of Yingzhou Fu has a...". There is only one type of third personal anaphor. It is the third personal pronoun, "it". Summarized patterns and specific examples of cataphora in English abstracts written by native Chinese-speaking masters and native English-speaking masters are as follows:

It is +adj. (like impossible/necessary/...) + to do

Something makes it + adj. (like significant/important...) + to do

It is +v-ed (like argued/published/...) + that-clause

It is +adj. (like significant/important...) + that-clause

Something makes it + adj. (like significant/important...) + that-clause

Eg3. It is not normal to do research that associates preschool teachers with professional gender segregation (sentence from the discipline of sociology in CNKI).

Eg4. Through comparisons of the Broome County Department of Social Services end-of-year caseload reports of 2005 and 2010, it is clear that the number of caseloads has approximately doubled during this time period (sentence from the discipline of sociology in PQDT).

Eg5. Secondly, the disunity among Jewish organizations made it difficult to put them together as one voice to defend against the destruction of European Jews (sentence from the discipline of literature in CNKI).

Eg6. To sum up, a comparative study of these two books makes it clear that human beings can only build an ecological society by building a harmonious relationship with nature (sentence from the discipline of literature in PQDT).

After analyzing and discussing third personal pronoun anaphora and cataphora in English abstracts selected from CNKI and PQDT, it is concluded that the usage of the third personal pronoun endophora in English abstracts of theses should be encouraged. On the one hand, third personal pronouns, unlike first or second personal pronouns, are more objective, therefore they are in concordance with the objectivity of theses. On the other hand, the central idea of endophora is to use shorter language representations to substitute longer antecedents. Hence the phenomenon of endophora is the inevitable result of language objectivity and language economy.

4.2. Three Elements of Third Personal Pronoun Endophora. In order to test if there is a significant difference in the usage of three elements, including anaphors, antecedents, and distances, used by native Chinese-speaking masters and native English-speaking masters, the author performed an MNOVA test on three elements. The MNOVA test mainly deals with the relationship between two or more fixed factors and various dependent factors. However, according to statistical principles, before the MNOVA test is conducted, the test of homogeneity of variances has been accomplished. As the Sig. value of the test of homogeneity of variances is 0.000, which does not meet the standard of homoscedasticity, in the MNOVA test, "Tamhane's T2" below the line of equal variances not assumed is emphasized. Sig. values in Table 2 show that there exists a significant difference in the usage of anaphors, antecedents, and distances of third personal pronoun endophora used by Chinese and foreign masters.

In terms of anaphors used by Chinese masters, the anaphor "it" has the largest number of 97 in history, the largest number of 93 insociology, and the largest number of 87 in anthropology. The anaphor "it" used by native Chinese-speaking masters is frequently to describe some proper nouns. With regard to anaphors used by foreign masters, the anaphor "their" has the largest number of 70 in history, the largest number of 75 in sociology, and the largest number of 63 in anthropology. The anaphor "they" used by native English-speaking masters is frequently to depict some social spotlights. There are significant differences between the usage of anaphors in the discipline of literature and the usage of anaphors in the other three disciplines. In English abstracts written by Chinese masters, the frequency of the anaphor "it" is the highest in the disciplines of history, sociology, and anthropology, while the frequency of anaphor "his" is the highest in the discipline of literature. In English abstracts written by foreign masters, the highest frequency of anaphor in the disciplines of history, sociology, and anthropology is "they," while the highest frequency of anaphor in the discipline of literature is "her."

Table 2: Multivariate tests[b] of three elements of third personal pronoun endophora in CNKI and PQDT.

	Effect	Value	F	Hypothesis df	Error df	Sig.
Intercept	Pillai's trace	0.962	13684.131[a]	3.000	2152.000	0.000

a. exact statistic and b. design: intercept + source.
Figure 1: Distances between antecedents and anaphors in CNKI and PQDT.

It is discovered that Chinese and foreign masters majoring in the discipline of literature tend to prefer the third personal pronoun, "his" or "her," which is determined by professional characteristics. The discipline of literature mostly covers proper nouns for characters in works of literature. In order to avoid cumbersome repetitions of proper nouns, Chinese and foreign masters will use third personal pronouns. As the other three disciplines mostly involve proper nouns and social spotlights, Chinese and foreign masters would like to choose "it" or "their" to replace antecedents in English abstracts for achieving the objective purpose.

At the mention of antecedents applied by native Chinese-speaking masters and native English-speaking masters, there are significant differences in the usage of antecedents among disciplines. In English abstracts, antecedents used by Chinese masters are mostly consistent with keywords of the thesis, but antecedents used by foreign masters are mostly inconsistent with keywords of the thesis. Compared with native Chinese-speaking masters, native English-speaking masters are more inclined to direct readers to experience the whole theme of the thesis rather than simply highlight the topic of the thesis by using repetitions. This difference is traced back to discrepant mindsets and is consistent with the research conducted by Frauen and Shuneng LIAN.

According to two scholars, the mindset of Chinese masters displays holistic and inductive characteristics, while the mindset of foreign masters shows analytic and deductive features [16, 17]. The fundamental difference between Chinese and foreign mindsets lies in the perceptual thinking model and the reasonable thinking model. The former employs images to organize perceptual materials so that integral characteristics are portrayed. The latter makes use of logic and reasonable thinking to explore the essence and internal connections of materials so that analytical characteristics are depicted. The phenomenon that native Chinese-speaking masters frequently repeat keywords of the thesis reflects the intuition-oriented mindset, highlighting the whole-to-part pattern and the inductive thinking model. The phenomenon that native English-speaking masters rarely repeat keywords of the thesis embodies the experience-oriented mindset, highlighting the part-to-whole pattern and the deductive thinking model.

With regard to distances between antecedents and anaphors set by native Chinese-speaking masters and native English-speaking masters, there are significant differences in the usage of distances among the four disciplines. No matter the Kurtosis or Skewness of distances, both values exceed the normal distribution value of 3 or 0. In statistics, if values of Kurtosis and Skewness are larger than normal distribution

values, the histogram of distances definitely shows the features of the aiguille and fat tail branch.

According to Figure 1, there exist centered frequency distributions and large ranges of distance between antecedents and anaphors. Specifically, the number of words set between antecedents and anaphors by Chinese and foreign masters is controlled within a range of 0–50 words, but the average distance between antecedents and anaphors set by Chinese masters is 20.26 words, which is much longer than that set by foreign masters. The average distance set by foreign masters is merely 12.95 words. If the distance of 12.95 words is regarded as the distance threshold between antecedents and anaphors, the average distance set by Chinese masters exceeds this threshold.

5. Conclusion

The corpus is applied to compare and analyze the third personal pronoun endophora and its three elements in English abstracts of Chinese and foreign theses. Underlying reasons for similarities and differences are explored in order to help native Chinese-speaking masters have a better understanding of international writing conventions of English abstracts and to further improve the language quality of English abstracts in their theses.

In 480 English abstracts, there is no significant difference in the total frequency of third personal pronoun endophora used by native Chinese-speaking masters and native English-speaking masters. Driven by the economic principle of language, Chinese and foreign masters tend to avoid redundant words, reduce the memory burden of encoding and decoding, and finally improve the efficiency of language communication. Chinese masters pay attention to the cognitive schema from the whole to the part, and therefore the antecedents they use are usually consistent with keywords of the thesis. The direct repetition not only achieves the overall consistency of the thesis and the prominence of the theme, but also demonstrates the integrity and induction of the mindset. On the contrary, foreign masters show solicitude for the cognitive schema from the part to the whole, and hence the antecedents they apply are hardly consistent with the keywords of the thesis. The indirect description can not only lead readers to explore the whole topic when they experience different parts but also reflect the analytical and deductive mindset. Although the distance between antecedents and anaphors set by Chinese and foreign masters displays the same feature as the aiguille and fat tail branch, the distance set by Chinese masters far exceeds the threshold set by foreign masters. This finding has some implications for Chinese masters. When they use third personal pronoun endophora in English writing, they are suggested to shorten the distance between antecedents and anaphors in order to achieve discourse coherence.

It is concluded that native Chinese-speaking masters had better make efforts in terms of language representation and deep cognition in order to get closer to the international English abstract writing conventions. With regard to the language representation, Chinese masters are suggested to reduce the distance between antecedents and anaphors

because the excessive distance will increase the memory burden of encoding and decoding for readers and have an influence on the readability and coherence of the discourse. In terms of deep cognition, 30 Chinese masters interviewed realize that they should pay attention to the cognitive schema of exploration and analysis and imitate the mindset of foreign masters. To be specific, the repetitiveness relationship between antecedents and keywords should be adjusted to the relevance relationship in order to comply with foreign masters' English abstract writing convention. Only the language representation and deep cognition are concerned, the language quality of English abstracts in their theses will be ultimately enhanced.

In order to enhance the classification accuracy and the generalization performance of the SVM classifier in cable partial discharge (PD) pattern recognition, a firefly optimized sparrow search algorithm (FoSSA) is proposed to optimize its kernel function parameters and penalty factors. First, the Circle-Gauss hybrid mapping model is employed in the population initialization stage of the sparrow search algorithm (SSA) to eliminate the uneven population distribution of random mapping. Sparrows tend to fall into local extremums during the search process, while the firefly algorithm has a fast optimization speed and strong local search ability. Thus, a firefly disturbance is added in the sparrow search process, and the fitness value is recalculated to update the sparrow position to enhance the sparrow's local optimization ability and accuracy. Finally, based on the SSA, a dynamic step-size strategy is adopted to make the step size dynamically decrease with the number of iterations and improve the accuracy of convergence. Six benchmark functions are employed to evaluate the optimization performance of the FoSSA quantitatively. Experiment results show that the recognition accuracy of the PD patterns using the SVM optimized by the FoSSA could reach 97.5%.

1. Introduction

Power cable is the key infrastructure equipment for urban distribution networks and large-scale clean energy access, and its reliability is vital to the safe and stable operation of the power system [1]. The defects of insulation material, manufacturing process, and structural defects, coupled with the aging of insulation material caused by harsh electrical, thermal, and mechanical stresses environment, will result in a partial discharge (PD) and even dielectric breakdown, which lead to insulation failure [2]. Accurate and instant identification of the fault pattern by mining and analyzing operation fault records and all types of test data of the power cable can significantly improve the efficiency for the maintenance and overhaul of a cable system.

Due to the low frequency of faults during operation, imperfect records of fault, and abnormal information, the size of fault samples is usually limited. Benefitting from the

structural risk minimization (SRM) criteria and the kernel methods, support vector machines (SVMs) [3] have shown significant superiority to deal with the classification problems of few samples and nonlinear high-dimensional data. Thus, it has been widely applied in the fault pattern recognition of large-scale electrical equipment, such as cables, transformers, and power grids [4–7]. However, the classification performance of the SVM is highly dependent on the selection of kernel function parameters and penalty factors, so how to optimize the parameters is crucial for its further applications.

For deterministic optimization algorithms, such as sequential minimal optimization (SMO) [8] and stochastic gradient descent (SGD) [9], if the objective function is discontinuous and nondifferentiable, their convergence speed is usually slow and they will easily fall into the local optimum. As a stochastic optimization method, the swarm intelligence optimization methods introduce a brand new

path to solve global optimization problems by taking advantage of randomness. The particle swarm optimization (PSO) algorithm [10] and the ant colony optimization (ACO) algorithm [11] are the most representative of these.

The PSO algorithm has few parameters and a fast convergence speed, but it tends to fall into local extremes due to premature convergence. This can be improved partly by introducing inertial weighting factors and taboo detection mechanisms. However, for complex high-dimensional problems, usually, it is impossible to guarantee convergence to the global optimum. The ACO algorithm uses the positive feedback mechanism of ant colony pheromones to strengthen the learning ability. Its heuristic probabilistic search mode makes it not easy to trap in the local optimum. However, the parameter settings are complicated and searching speed is slow; furthermore, the convergence property is pretty poor. In order to further strike a balance between the search range and the convergence accuracy in optimization algorithms, a series of bionic intelligent optimization algorithms, such as gray wolf optimization algorithm [12] (GWO), artificial bee colony algorithm [13] (ABC), and the bacterial foraging algorithm [14] (BFA), have been proposed in recent years. Sparrow search algorithm (SSA) [15] is a novel swarm intelligence optimization algorithm that is inspired by foraging and antipredation behaviors of sparrows. Testing results on unimodal and multimodal functions demonstrate its superiority over PSO, ACO, and GWO in terms of accuracy, convergence speed, stability, and robustness.

This paper proposes a FoSSA-optimized SVM for the recognition of partial discharge patterns in HV cables. First, the feature vector is constructed based on the partial discharge $\varphi - q - n$ pattern. Second, in the standard SSA, the Circle-Gauss hybrid mapping model is introduced to initialize the population to improve the diversity. In the sparrow search process, the dynamic step strategy and the firefly interference strategy are introduced to make the sparrow escape from the local optimum and find the global optimal combination of support vector machine parameters. Finally, an optimized SVM classification framework is constructed for the partial discharge recognition in the HV power cables.

2. Problem Description

The basic principle of a nonlinear SVM is to map the input space x to a feature space $\Phi(x)$ through a nonlinear transformation which results in a hyperplane model in the feature space corresponding to the hypersurface model in the input space. The hyperplane in the feature space is divided as follows:

$$f(x) = \omega^T \Phi(x) + b, \tag{1}$$

where ω is the weighting vector and b is the threshold.

For a given nonlinear separable data set, considering the existence of errors ξ, the optimization problem with the constraint conditions is as follows:

$$\min \frac{1}{2} \|\overrightarrow{\omega}\|^T \omega + c \sum_{i=1}^{l} \xi_i, \tag{2}$$

$$\text{st.} y_i \left(\overrightarrow{\omega}^T \Phi(x_i) - b \right) \geq 1 - \xi_i (\xi_i > 0).$$

The optimization of equation (2) can be transformed into a dual problem by introducing the Lagrange factor, and the solution of equation (1) can be obtained as follows:

$$f(x) = \sum_{i=1}^{l} \alpha_i \kappa(x, x_i) + b, \tag{3}$$

where α_i is the Lagrange factor, l is the number of support vectors, and $\kappa(x, x_i)$ is the kernel function. A radial basis function (RBF) in equation (4) is generally adopted.

$$\kappa(x, x_i) = \exp \left(-g \|x - x_i\|^2 \right). \tag{4}$$

It can be seen from the derivation that the parameter selection of c and g directly affects the classification performance of SVM. In the traditional SVM model, they are usually selected according to expert experience or k-fold cross verification. In the process of cable fault classification, the input data are diverse and complex. The parameter selection based on experience not only takes time but also brings some randomness to the calculation process. The K-fold cross-verification method is dependent on the parameter range; if this range is inappropriate, it is impossible to determine the optimal parameters.

3. Firefly Optimized Sparrow Search Algorithm (FoSSA)

3.1. SSA Principle. SSA is a novel swarm intelligence algorithm that has evolved from the foraging and antipredation behaviors of sparrows. The algorithm is simple and efficient, and it can achieve global convergence. According to the mathematical model of the algorithm, virtual sparrows are used for foraging behavior and the position of sparrows can be expressed as follows:

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \\ \vdots \\ \mathbf{X}_n \end{bmatrix} = \begin{bmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,d} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,d} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n,1} & x_{n,2} & \cdots & x_{n,d} \end{bmatrix}, \tag{5}$$

where d is the dimension of the variable in the optimization question, n is the number of sparrows, and $x_{i,j}$ is the position of the i-th sparrow of the j-th dimension.

The fitness value of all sparrows can be calculated as the following vector:

$$\mathbf{F}_x = \begin{bmatrix} f(x_{1,1}, x_{1,2}, ..., x_{1,d}) \\ f(x_{2,1}, x_{2,2}, ..., x_{2,d}) \\ \vdots \\ f(x_{n,1}, x_{n,2}, ..., x_{n,d}) \end{bmatrix}, \tag{6}$$

where f represents the individual fitness value.

A sparrow population can be divided into producer and scrounger according to the relative role of each sparrow. Producers are in charge of looking for food for the whole population; they provide foraging directions for the scroungers. Producers can obtain a larger foraging area than the scroungers. According to the foraging rules of sparrow population, the moving position of the producer is calculated as follows:

$$\mathbf{X}_i^{t+1} = \begin{cases} \mathbf{X}_i^t \cdot e^{-\left(i/\alpha.t_{\max}\right)} & \text{if } V_a < V_s, \\ \mathbf{X}_i^t + r_d \cdot \mathbf{U} & \text{if } V_a \geq V_s, \end{cases} \quad (7)$$

where $\mathbf{X}_i^t$ is the position of the i-th sparrow in j-dimension space at iteration t, $i \in [1, 2, \dots, n]$, t indicates the current iteration, $t_{\max}$ is the maximum iteration number, $\alpha \in (0, 1]$ is a random number, r_d is a random number that obeys a normal distribution, U represents a unit matrix of $1 \times d$, and $V_a \in [0, 1]$ and $V_s \in [0.5, 1]$ are the alarm and safety value relative to the predators, respectively, and they determine the sparrow's moving range.

During the foraging process, the scroungers keep eyes on the producers. Once the producers find something better, they fight for it immediately. According to the rules, their moving position can be updated as follows:

$$\mathbf{X}_i^t = \begin{cases} r_d \cdot e^{\left(\mathbf{X}_{wst}^t - \mathbf{X}_i^t\right)/i^2} & \text{if } i > n/2, \\ \mathbf{X}_{op}^{t+1} + \left\| \mathbf{X}_i - \mathbf{X}_{op}^{t+1} \right\| \cdot \mathbf{A}^+ \cdot \mathbf{U} & \text{others,} \end{cases} \quad (8)$$

where $\mathbf{X}_{op}$ is the optimal location of the producers, $\mathbf{X}_{wst}^t$ is the current global worst location, $\mathbf{A}$ is the matrix of $1 \times d$ with elements are all 1 or -1 randomly, and $\mathbf{A}^+ = \mathbf{A}^T (\mathbf{A}\mathbf{A}^T)^{-1}$.

In the search process, some sparrows called guards will be aware of the danger from the predators, according to the antipredation rule, and the mathematical expression of their moving positions can be obtained as follows:

$$\mathbf{X}_i^{t+1} = \begin{cases} \mathbf{X}_{bst}^t + \beta.\left\| \mathbf{X}_i^t - \mathbf{X}_{bst}^t \right\| & \text{if } f_i > f_b, \\ \mathbf{X}_i^t + \gamma.\left(\dfrac{\left\| \mathbf{X}_i^t - \mathbf{X}_{wst}^t \right\|}{\left((f_i - f_w) + \varepsilon\right)} \right) & \text{if } f_i = f_b, \end{cases} \quad (9)$$

where $\mathbf{X}_{bst}^t$ is the current global optimal value, β is a random parameter obeying standard normal distribution that constraints step size, $\gamma \in [-1, 1]$ is a random number, f_i is the fitness value of the current sparrow, f_b and f_w are the best and worst fitness value, and ε is a regulatory factor.

3.2. Initialization by Circle-Gauss Hybrid Mapping.

The distribution of the initial population is important for SSA. A uniform and fully mapped initial distribution will effectively improve the convergence speed of the optimization process. Due to the lack of initialization strategy for uniform population distribution in SSA, simple random distribution cannot guarantee the breadth of the search range, and it is easy to produce "super sparrows" in the iterative process that

cause other individuals to gather to them, resulting in a "premature" phenomenon and reducing the diversity of the population.

In this study, a Circle-Gauss hybrid mapping model is introduced to initialize the SSA. By combining the advantage of the regularity and uniformity of Circle mapping and the randomness and ergodicity of Gauss mapping, the chaotic sequence can be transformed into the solution space of the SSA algorithm to replace the original population by Circle-Gauss hybrid mapping model. The Circle-Gauss hybrid mapping model not only avoids the overdensity of the population but also retains the diversity of the population to a large extent, which is the key factor for the global optimization of the SSA algorithm. The mathematical expression of the Circle-Gauss hybrid mapping model is as follows:

$$\mathbf{M}_{i+1} = \begin{cases} \mathbf{M}_i + a - \text{mod}\left(\dfrac{b}{2\pi} \sin\left(2\pi\mathbf{M}_i\right), 1 \right) & \text{if } i = 2k; \\ \\ \dfrac{1}{\mathbf{M}_i} - \left[\dfrac{1}{\mathbf{M}_i} \right] & \text{if } i = 2k+1; \end{cases} \quad (10)$$

where $\mathbf{M}_i \in \mathbb{R}^{1 \times d}$ is the mapping position of i-th sparrow, $\mathbf{M} = [\mathbf{M}_1, \mathbf{M}_2, \dots, \mathbf{M}_n]^T \in \mathbb{R}^{n \times d}$ is the mapping position of the whole population, n and d have the same meaning as in equation (5). a is 0.5, b is 2.2, and $k = 0, 1, 2\dots$. mod() and [] represent modulation and rounding operation.

Figure 1 shows the 2D scatter diagram generated by the Circle-Gauss hybrid mapping model and the other two mappings in (0, 1). As shown in Figure 1, the Circle-Gauss hybrid mapping model combines the characteristics of both uniformity and randomness, improves the ergodicity and effectiveness of the initialization, and ensures the diversity of the population.

3.3. Firefly Perturbation.

Firefly perturbation is introduced in SSA here to improve its global convergence ability while the sparrow falls into the local extremum. In the two-dimensional solution space of SVM parameter combination (c, g), analogous to the idea of the firefly algorithm, each sparrow is initialized by the attractiveness of ρ_0. During the disturbance process, the degree of attraction decreases with the increase of the spatial distance. When the sparrow traps in a local optimum, the perturbation will be introduced as follows:

(1) The spatial distance r between the sparrow position $\mathbf{X}_i^t$ and the optimal position $\mathbf{X}_{bst}^t$ is calculated as follows:

$$r = \frac{\sqrt{d_m}}{b_l - b_u} \left\| \mathbf{X}_i^t - \mathbf{X}_{bst}^t \right\|. \quad (11)$$

In the expression, b_l and b_u represent the lower and upper boundary, respectively, and d_m is the space dimension.
Figure 1: Population initialization scatter plot of three methods. (a) Circle map. (b) Gauss map. (c) Circle-Gauss map.

Table 1: Expressions of characteristic parameters.

Symbol of parameters	Meaning
sk_m^+	$\varphi-q_{\max}$ pos(+) half-cycle skewness
sk_m^-	$\varphi-q_{\max}$ neg(−) half-cycle skewness
sk_m	$\varphi-q_{\max}$ full-cycle skewnesss
sk_n^+	$\varphi-q_{\mathrm{mean}}$ pos(+) half-cycle skewness
sk_n^-	$\varphi-q_{\mathrm{mean}}$ neg(−) half-cycle skewness
sk_n	$\varphi-q_{\mathrm{mean}}$ full-cycle skewness
kt_m^+	$\varphi-q_{\max}$ pos(+) half-cycle kurtosis
kt_m^-	$\varphi-q_{\max}$ neg(−) half-cycle kurtosis
kt_m	$\varphi-q_{\max}$ full-cycle kurtosis
kt_n^+	$\varphi-q_{\mathrm{mean}}$ pos(+) half-cycle kurtosis
kt_n^-	$\varphi-q_{\mathrm{mean}}$ neg(−) half-cycle kurtosis
kt_n	$\varphi-q_{\mathrm{mean}}$ full-cycle kurtosis
r_m	$\varphi-q_{\max}$ ratio of the sum of pos(+) and neg(−) half-cycle discharge amplitudes
r_n	$\varphi-q_{\mathrm{mean}}$ ratio of the sum of pos(+) and neg(−) half-cycle discharge amplitudes

(2) The attractiveness value ρ of each individual sparrow is calculated:

$$\rho = \rho_0 e^{-\theta r^2}. \tag{12}$$

In the expression, ρ_0 is the maximum attractiveness and θ is the attractiveness coefficient.

(3) The sparrow position with perturbations $\mathbf{X}_i^t$ can be obtained as follows:

$$\mathbf{X}_i^{t'} = \mathbf{X}_i^t + \rho\left(\mathbf{X}_i^t - \mathbf{X}_{bst}^t\right) + \tau\left(\mathbf{R}_d - 0.5\right). \tag{13}$$

Here, τ is the step-size factor and $\mathbf{R}_d \in \mathbb{R}^{1 \times d}$ is a matrix with all elements obeying uniform distribution within $[0, 1]$.

3.4. Dynamic Step-Size Updating.
In the SSA, the step-size control parameters are constant, which cannot make the SSA achieve a balance between the local optimization and the global optimization in the iterative process. It will affect the effect and speed of the optimization.

In the initialization process, a longer step-size factor is adopted to enhance the algorithm's global search capability. In the later process, a smaller step is adopted to enhance the local optimization capability. Therefore, in this study, a dynamic updating strategy of step size is adopted to make

the step size decrease nonlinearly with the increase of iteration number for the guards in equation (9). The dynamic step size can be optimized as follows:

$$\lambda(t+1) = i_{\mathrm{m}}\lambda(t)e^{t/i_m}\left(\frac{\lambda_0}{\ln t} + r_d\left(1 - \lambda_0\right)\right), \tag{14}$$

where λ_0 is the initial step-size factor and i_m is the maximum iteration number.

4. Cable PD Pattern Recognition Based on FoSSA-SVM

4.1. Feature Vector Extraction.
Phase resolved partial discharge (PRPD) spectrum reveals the relationship between the number of PD signals with different peak values and the phase angle. Since the PRPD spectra of different defects achieve different distribution characteristics, statistical characteristic parameters based on PRPD can be used to recognized different insulation faults. In this study, 14 statistical characteristic parameters are employed for the feature extraction of the PD data. The expressions and the meanings of the characteristic parameters are shown in Table 1.

According to the calculation of statistical characteristic parameters, 9 key features are extracted as PD patterns, as shown in Table 2.

TABLE 2: Symbol definition of characteristic quantity.

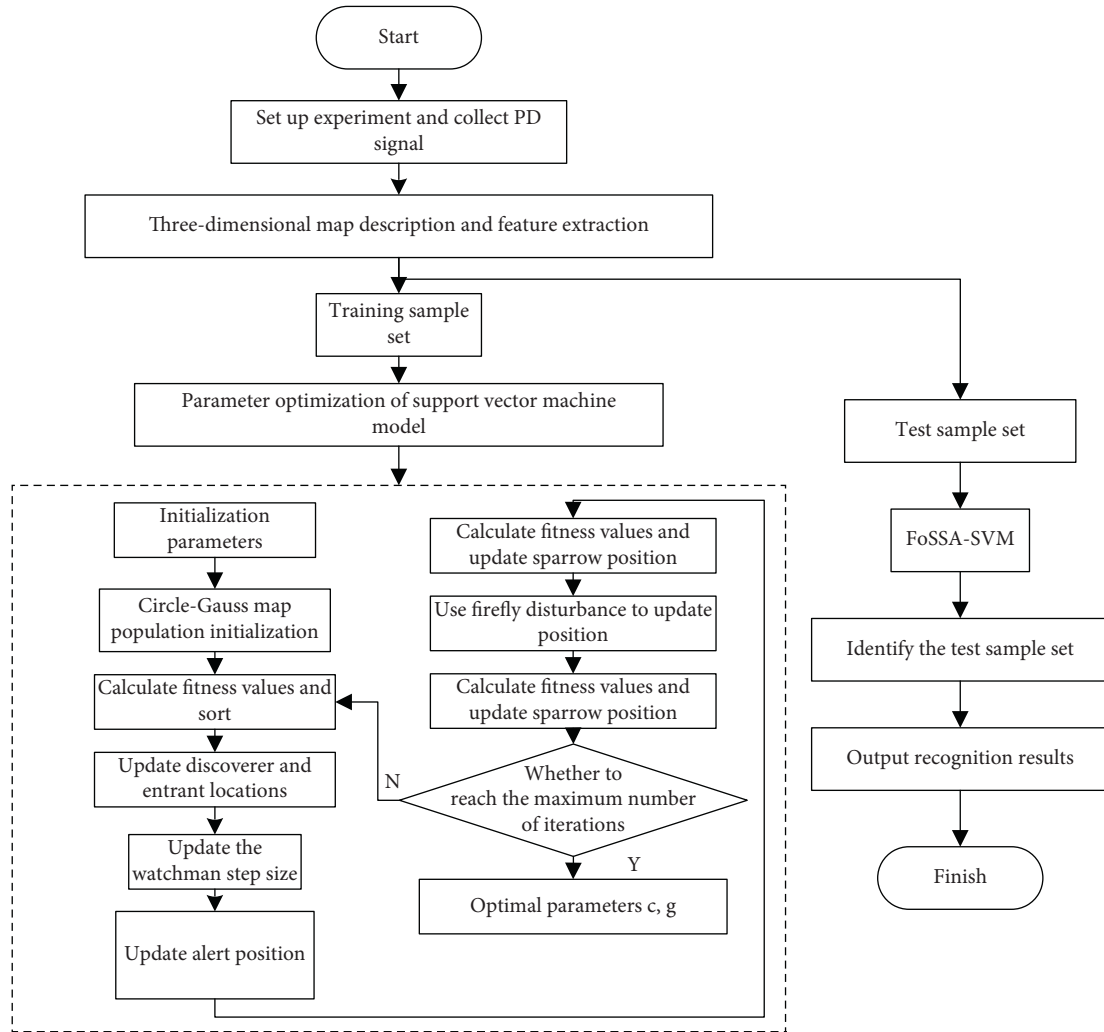
Characteristic	Symbol description
Mean	μ
Variance	σ^2
Skewness	S_k
Steepness	K_u
Local peak number	P_e
Discharge factor	Q
Degree of phase asymmetry	$\varnothing$
Cross-correlation coefficient	C_c
Corrected cross-correlation coefficient	m_c


FIGURE 2: Flow chart of PD pattern recognition based on FoSSA-SVM.

The skewness S_k reflects the skewness of the spectrum shape compared with the normal distribution. The steepness K_u is used to describe the protrusion degree of the distribution of a shape compared with the normal distribution shape. The factor Q reflects the difference of the average discharge in the pos(+) and neg(-) half-cycle of the $\varphi - q$ spectrum. The phase asymmetry degree $\varnothing$ reflects the difference of the initial phase of the discharge within different half-cycles of the $\varphi - q$ spectrum. The cross-correlation coefficient C_c reflects the degree of shape similarity of the spectra in different half-cycles.

4.2. PD Pattern Recognition Based on the FoSSA-SVM Model. The FoSSA-optimized SVM model for cable PD pattern recognition proposed in this paper is shown in Figure 2. The whole scheme can be divided into feature extraction, parameter optimization, and pattern recognition:

(1) Four kinds of PD defects are manually prepared for data acquisition on a test platform. Then, the 3D PRPD spectrum is drawn for key feature extraction using statistical characteristics.

TABLE 3: Discharge voltage of different defects.

Defect type	Discharge voltage
Outer semiconductive layer creepage	5.6 kV, 6.6 kV
Internal air gap	5.3 kV, 11.3 kV, 18.3 kV
Scratch of insulation surface	5.6 kV, 9.6 kV, 13.6 kV
Metallic filth on insulation surface	6 kV, 20 kV, 34 kV

FIGURE 3: PRPD spectra of four type defects. (a) Outer semiconductive layer creepage (5.6 kV). (b) Internal air gap (5.3 kV). (c) Scratch of the insulation surface (5.6 kV). (d) Metallic filth (6 kV).

(2) The parameters of FoSSA and SVM are initialized, and the penalty factor and kernel function parameters of SVM are taken as the optimization objective of FoSSA. During the initialization stage, the Circle-Gauss hybrid mapping model is employed to initialize the population of sparrows.

(3) FoSSA algorithm is used for parameter optimization. The recognition error rate is set as the objective function for iterative calculation. The optimal parameter combination obtained is imported into the SVM model and verified by the test set. The detailed steps of the FoSSA to optimize the combination parameters are as follows:

Step 1: the size of sparrow population, number of iterations, producer and scrounger ratios, step-size parameters, and SVM parameters are initialized.

Step 2: the Circle-Gauss hybrid mapping model is used to generate the initial population of sparrows.

Step 3: the fitness value is computed and sorted.

Step 4: the positions of producers and scroungers are updated according to equation (7) and equation (8), respectively.

Step 5: the step size of the guards is updated according to equation (14).

Step 6: the position of the guards is updated according to equation (9).

TABLE 4: Test function expressions and their range.

Test function	Range

Step 9: if the stop conditions are met, the algorithm is exited and the results are output. Otherwise, repeat Steps 3–8.

5. Experimental Results and Analysis

5.1. PD Sample Set Construction. According to the designed experiment, the cable PD data are acquired. The sampling rate of the oscilloscope used in the experiment is set at 10 MS/s, and the sampling length is 1s each time; that is, the signal containing 50 power frequency cycles is taken as one sample. The number of samples from each type of defect is 50; that is, each PD defect contains 50 samples. The voltage levels corresponding to the measurement of the four PD defects are shown in Table 3. After the collection of sampling points, the PRPD spectra with four defects are drawn, as shown in Figure 3. The training set is 80% of these defect samples and the test set is 20%.

5.2. Comparison and Analysis of Convergence Performance

5.2.1. Transverse Comparison and Analysis. Compared with other traditional algorithms such as PSO and GA, the FoSSA has obvious improvements in the convergence speed and optimization accuracy. In this study, three thirty-dimensional test functions are used to compare the convergence speed and optimization ability of FoSSA, GA, PSO, and GWO algorithms. The expressions of the test functions are shown in Table 4.

To make the results more convincing, each test function is tested 30 times independently. The population is set to 100 and the maximum number of iterations is 1000. For FoSSA,

Function	Optimizer	Optimal value	Worst value	Mean
$f_4(x)$	SSA	−10139.98	−6154.46	−8145.43
	FoSSA	−36168.05	−28325.41	−34049.27
	LevySSA	−30725.72	−26342.56	−28072.35
	tSSA	−29325.62	−23210.74	−28705.26
	RandSSA	−23257.82	−19072.23	−21072.43
$f_5(x)$	SSA	−15642.13	−13425.62	−14568.18
	FoSSA	−35653.03	−31971.04	−34895.24
	LevySSA	−16725.12	−14236.42	−15742.84
	tSSA	−16732.45	−14584.72	−15643.72
	RandSSA	−17325.42	−14346.28	−16435.65
$f_6(x)$	SSA	−3.2432	−3.0898	−3.1042
	FoSSA	−3.8947	−3.8628	−3.8725
	LevySSA	−3.7243	−3.2649	−3.4634
	tSSA	−3.7254	−3.6234	−3.6927
	RandSSA	−3.3274	−3.1324	−3.2736

TABLE 7: Optimal parameter combination of different classification models.

Classifier	c	g
SSA-SVM	0.12	14.50
FoSSA-SVM	4.45	0.76
LevySSA-SVM	6.31	14.56
tSSA-SVM	1.77	8.11
RandSSA-SVM	0.14	8.34

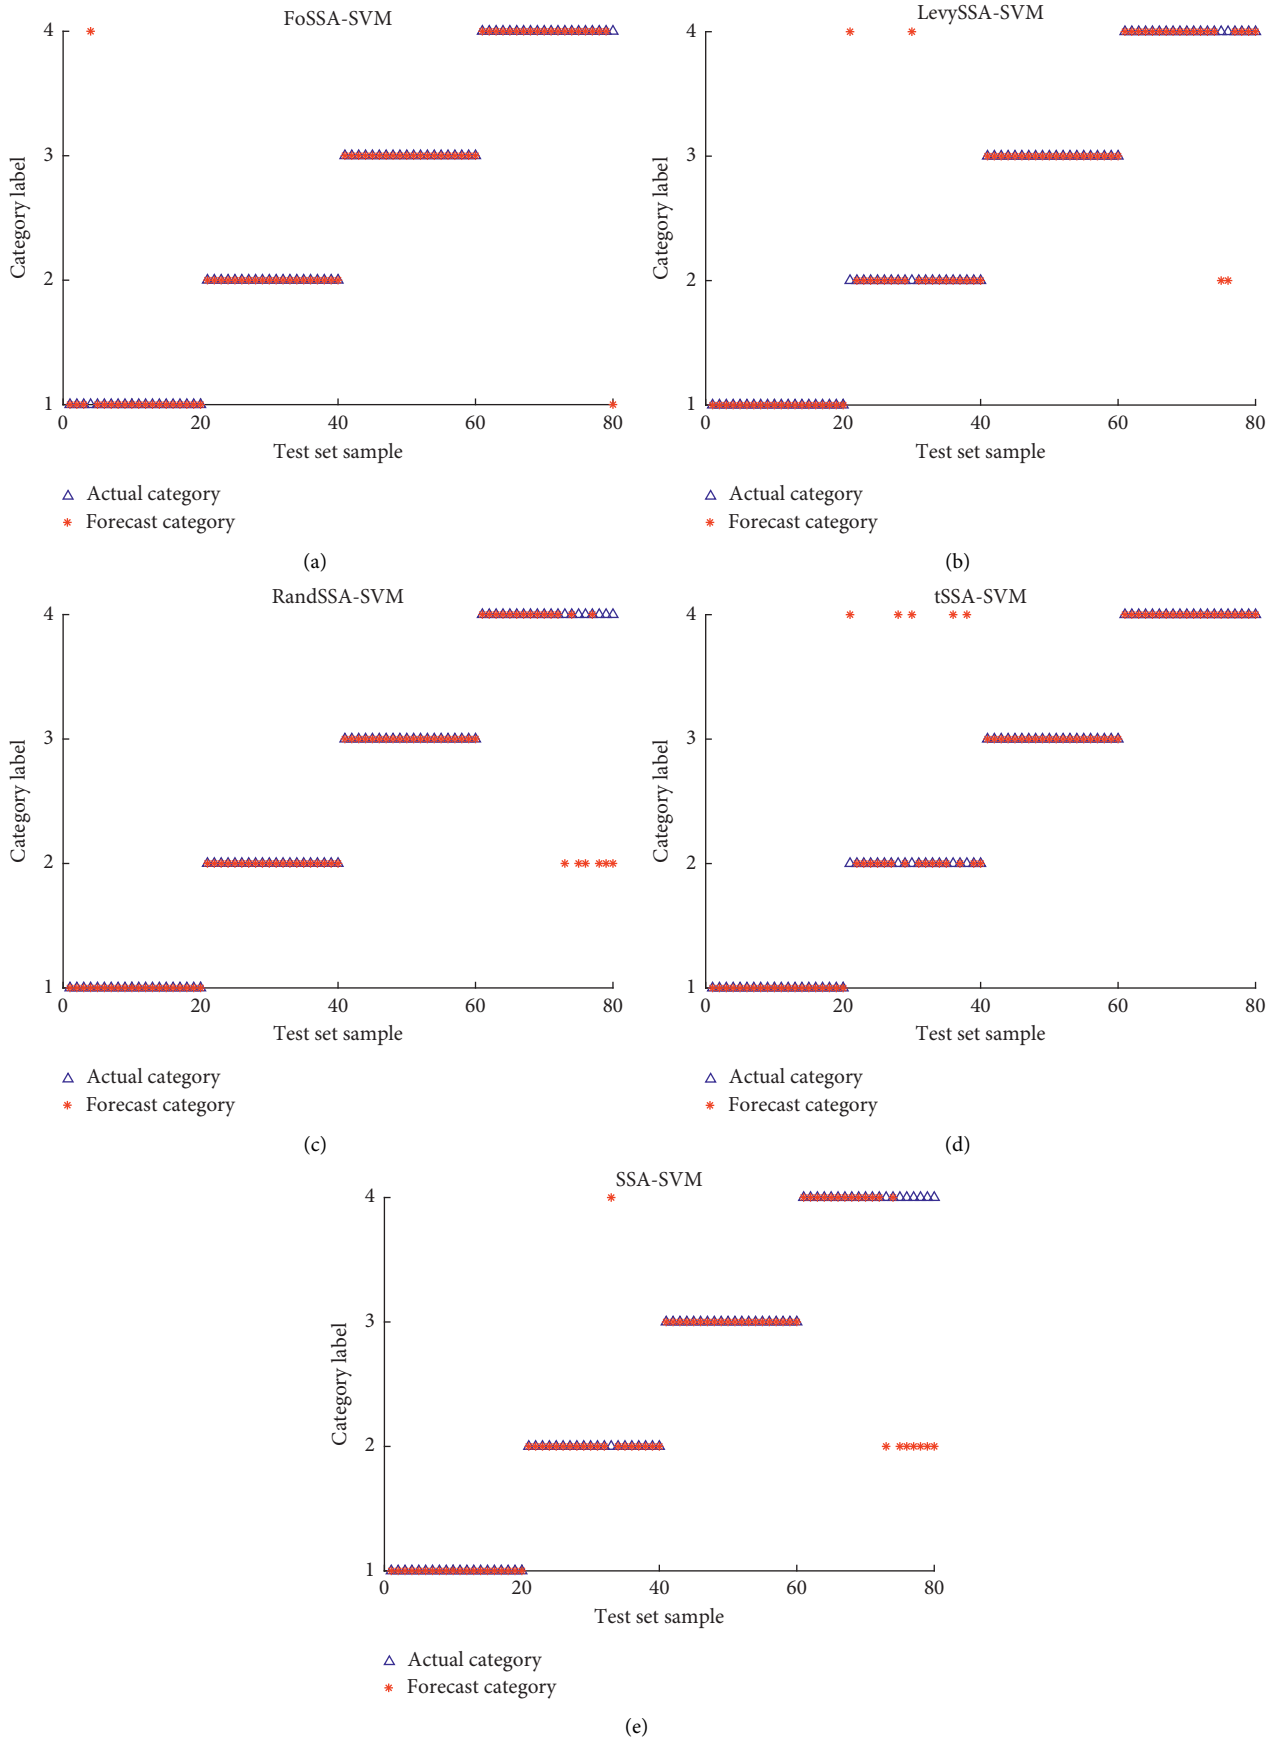
the accounts of producers and sparrows aware of danger are set as 20% and 10% of the whole population and v_s is 0.8. Crossover probability c is 0.9, mutation probability μ is 0.03 in GA, $\omega = 0.728$ and $c_1 = c_2 = 1.49442$ in PSO, $r_1, r_2 = \text{random}(0, 1)$, and $a \in (0, 2)$ with a linear decrease


Figure 6: Classification results of different classification models. (a) FoSSA-SVM. (b) LevySSA-SVM. (c) RandSSA-SVM. (d) tSSA-SVM. (e) SSA-SVM.

in GWO. The optimization results of the four algorithms on the test function are shown in Figure 4.

The minimum values of the test functions are all zero. The results show that the PSO method has a fast convergence speed, but the convergence accuracy is very low. The GA and GWO are prone to local optimality. The FoSSA achieves the best convergence speed and convergence accuracy at the same time.

5.2.2. Longitudinal Comparison and Analysis. SSA, LevySSA [16], RandSSA [17], and tSSA [18] are studied separately to compare with our FoSSA to demonstrate the optimization effect and convergence ability. For SSA, the accounts of producers and sparrows aware of danger are set as 20% and 10% of the whole population and the safety threshold value V_s is 0.8. For FoSSA, additional parameters of the step-size factor τ is 0.2 and the maximum attractiveness ρ_0 is 2. The parameter β in LevySSA is 1.5. The parameter $r(t)$ in RandSSA is set as 0 or 1 randomly. The parameter p in t-SSA is 0.5.

In this study, a six-dimensional single-peak function is employed to test the optimization ability of the function, and two thirty-dimensional multimodal functions are employed to test the ability to escape from the local optimum. The three test functions are shown in Table 5.

Figure 5 shows the comparative analysis effect of five optimization algorithms on the minimum optimization of the test function. It is obvious that the FoSSA achieves the fastest convergence speed for the single-peak function of $f_6(x)$ and the strongest ability to transfer from local optimum for the multipeak functions of $f_4(x)$ and $f_5(x)$.

Each method optimizes 100 times for test functions, and the mean value, optimal value, and worst value are recorded, as shown in Table 6.

After comparing the FoSSA with the other four optimizers, it is found that the FoSSA obtains the strongest performance to get over the local optimum for the multipeak function and the fastest convergence speed of the single-peak function. The optimal value, worst value, and mean value of the FoSSA are the smallest, which means the best performance.

5.3. PD Pattern Recognition Results and Analysis. Based on the FoSSA algorithm, in order to find the optimal kernel function parameters g and the penalty factor c, the corresponding combination which achieves the minimum classification error rate after 30 iterations is chosen as the optimal parameter combination of g and c. The optimal parameter combination of different optimization algorithms is shown in Table 7.

The SSA-SVM, LevySSA-SVM, tSSA-SVM, RandSSA-SVM, and FoSSA-SVM classification models described in this paper are employed to recognize cable defects patterns with their optimal parameter combination. The results are shown in Figure 6 and Table 8.

Compared with the SSA-SVM, FoSSA-SVM improves the classification accuracy by 7.5%, and with the other

TABLE 8: Comparison of accuracy and times consumption of different models.

Classifier	Accuracy	t (ms)
SSA-SVM	90%	512
FoSSA-SVM	97.5%	362
LevySSA-SVM	95%	494
tSSA-SVM	93.75%	394
RandSSA-SVM	92.5%	402

TABLE 9: Prediction accuracy of different models.

Classifier	FoSSA-SVM	PSO-SVM	GA-SVM
Error number	2	7	9
Accuracy	97.5%	91.25%	88.75%

classification models, it improves the accuracy by 2%–5%. In terms of time, the FoSSA-SVM requires the shortest iteration time, which is 32–150 ms shorter than that of other algorithms. In short, the FoSSA-SVM achieves a faster optimization speed and the highest recognition accuracy at the same time.

In order to further verify the prediction accuracy, the FoSSA-SVM model is compared with PSO-SVM and GA-SVM models. 80 samples are used for testing, and each model is employed to predict 30 times; the optimal prediction result is taken into account. The final results are shown in Table 9, in which it is obvious that the FoSSA-SVM model achieves a predictive accuracy of 97.5%, which is better than that of the other two algorithms.

The results of the experiment demonstrate that the proposed FoSSA-SVM model improves the prediction accuracy significantly in cable PD pattern recognition and it achieves obvious advantages in potential applications.

6. Conclusion

FoSSA is proposed in this paper to optimize the kernel function parameters and penalty factors of SVM for PD pattern recognition of cables. A novel Circle-Gauss hybrid mapping model used in the initialization stage of SSA improved the diversity of the sparrow population. Dynamic step-size and firefly disturbance strategy help SSA out of local optimum and then improve the convergence accuracy. Compared with SVM optimized by SSA, the classification accuracy is increased by 7.5% and the time consumption is shortened by 150 ms. The introduction of firefly perturbation and dynamic step strategy enhances the global convergence ability of SSA.

In this paper, we conduct in-depth research and analysis by building an IoT data-driven intelligent law classroom teaching system and implementing it in the actual teaching process. Firstly, the application requirements and main functions of the classroom interactive system are analysed and studied in depth; the overall design of the classroom interactive system based on wireless communication is carried out; and the classroom interactive system consisting of teacher's receiver, wireless receiver, student's handheld terminal, teacher's receiver upper computer software, student's handheld terminal upper computer software, and data management website is developed. Platform and communication part: middleware comprises multiple modules such as real-time memory event database, task management system, and event management system. The system uses USB communication, serial time-sharing communication, Zigbee wireless communication, WebSocket, and other technologies to realize data communication between several modules, and some key technologies are studied and improved in detail. Finally, the system is deployed to the actual experimental application scenario, and the software and hardware construction of the IoT innovation lab is completed. The lab equipment is officially put into use, the information platform is also in the trial run stage, and the system is tested in time during the operation stage to provide the basis for the improvement of the system functions. Use data to conduct an in-depth analysis of learning situations and learning process analysis, optimize the reasonable construction of a personalized learning environment, serve personalized learning, and achieve the most optimal learning effect. The secondary development of the Turing robot provides a personalized auxiliary Q&A system for teaching, allowing artificial intelligence-assisted teaching to be integrated into the curriculum. With the help of teaching law courses, the empirical study demonstrates that the personalized learning environment has significant advantages in improving teaching effectiveness.

1. Introduction

The rapid development of information technology has accelerated the deep integration of information technology and education teaching, information technology platforms, and artificial intelligence-assisted teaching; other information technology resources have emerged; and a variety of new learning methods have emerged to show that education is making headway towards the information technology process. However, due to the complexity of information tools, teaching reform often tends to go astray, and very often information technology tools become just a landmark application to highlight new learning styles, staying only for information technology competitions, or open or observed classes, and not falling into the classroom reality for students

[1]. The main research purpose of this paper is to select, integrate, and develop informatization resources under a data-driven perspective and build a personalized informatization learning environment that meets the school, teaching, and learning conditions. Network nodes are required to have the self-adjustment ability, self-adaptation ability, and robustness and complete tasks such as network initialization and fault self-repair through topology control mechanisms, network protocols, and cooperation to maintain the normal operation of the network. Traditional school education cannot teach each student according to his or her ability, but the information age has brought new education opportunities [2]. With artificial intelligence and big data, the whole process of student learning can be monitored and tracked in real time, and the problems and

deficiencies of students can be analysed so that teachers can tailor their learning plans to the specific situation of students. The emphasis on process-oriented data on student learning guides students to adjust their learning styles promptly, making large-scale personalized learning possible. While offline traditional education allows teachers to impart knowledge and solidify the foundation, online education breaks the time and space constraints from which students can access personalized resources and learning styles.

Changing the traditional education model through new educational technology equipment has received increased attention from schools [3]. At present, the information management system for teachers and students has been widely used in colleges and universities, realizing the functions of integrated management of teacher and student information, online course selection, online grade entry and query, and integrated query of school information. In particular, the online grade entry and query function of students is especially widely used among teachers and students. However, the current teaching situation in domestic universities is still the traditional irrigation method interspersed with multimedia teaching methods such as PPT. Teachers still count students' knowledge proficiency through traditional after-class assignments and randomly checking students' answers to questions in class [4]. At the same time, according to the student's learning data feedback, the learning environment resources are adjusted in real time, and finally, a dynamic and personalized learning environment that conforms to the academic conditions is constructed. Once students do not keep up with the teacher's teaching ideas, it is difficult to listen to the later knowledge. As for the student's attendance, teachers usually still confirm it through the roll call.

About the methodological aspects of rule of law education, rule of law education is most often based on problem-based and case-based approaches [5]. The problem-based approach requires students to identify, construct, and analyse problems, and students, therefore, spend more time on learning activities and perform better than those in the case-based approach. Based on the needs of laboratory management and practical training teaching, it is necessary to research and explore laboratory intelligence and informatization for the management of university laboratories. If the requirements are met, open the serial port communication switch for communication, and close the serial port switch after the communication is completed. If it does not meet the requirements, wait for a period, continue to query until there is no other coordinator communication, and then turn on the serial port switch. In this paper, based on the existing perfect facilities, the structure and characteristics of IoT technology in smart home and smart building are applied to the laboratory management system, exploring the model of intelligent laboratory, constructing IoT innovation training room, and developing smart campus class terminal management system, which integrates the use of IoT, mobile Internet, big data, intelligent perception, and other emerging information technologies, on the basis of traditional campus, to provide timely feedback to parents and teachers on students' safe attendance and abnormal attendance; to

organically combine all aspects of home-school interaction, campus information, announcement release, class culture, teacher-student interaction, class walking teaching and teaching management; to build an information management platform for campus and class management and student growth; enrich the overall school information technology environment and information dissemination channels; efficiently and conveniently deliver various knowledge information and notice information; provide timely feedback on classroom information; realize transparent management of classes; and provide strong technical support for the digitization and information of education and teaching in our school.

2. Status of Research

The spreading factor and the communication rate are found to have a significant impact on the coverage capability of the LoRa network through field tests. The limitations of the Lora WAN protocol are proposed through the analysis of Lora WAN protocol, the size of the Lora WAN network is much smaller than the theoretical value under the limitation of duty cycle transmission, and the adoption of transmission acknowledgment answering mechanism for reliable transmission also makes the network capacity smaller in the same way [6]. Through different IoT application cases, the advantages and disadvantages of Lora WAN in different scenarios are analysed and its applicability scope is illustrated. The authors argue that the random-access method of Aloha for nodes in Lora WAN networks is not the optimal solution and a more complex TDMA access method can be considered. By modelling and simulating a large Lora WAN network using the NS-3 network simulator, the simulation results show that the limited downlink communication in the Lora WAN network reduces the packet delivery rate of the uplink communication that needs to be acknowledged and adding gateways can improve but not eliminate this effect [7]. A comprehensive analysis of the features and limitations of Lora WAN gives the current problems of the Lora WAN protocol, that is, high data loss rate at high data concurrency and long retransmission time for the timely arrival of data [8]. The physical layer transmission characteristics of the Lora WAN network are analysed, the packet loss rate and conflict probability of different data frames at the gateway are derived by building a signal reception model, and the variation of packet loss rate and conflict probability with different spreading factors and sending cycles are illustrated by simulation results [9].

With the development of communication technology, classroom interactive systems have gradually entered university campuses and are playing an increasingly important role in student learning. Multimedia teaching has also become a standard part of daily university teaching activities [10]. Many university research project groups and some social research institutions at home and abroad have also conducted a series of research on education informatization [11]. There are currently two ideas for developing classroom interactive systems. One idea is to upgrade the hardware facilities completely and transform them into intelligent

classrooms [12]. However, these devices require a large-scale and comprehensive upgrade of the classroom hardware; the amount of engineering, time costs, and transformation costs are relatively large. Moreover, if a certain aspect needs to be upgraded at a later stage, it will be more difficult [13]. The data management web terminal is mainly used to bind the user's school number and the MAC address of the student's handheld terminal. The teacher downloads the student list and the corresponding MAC address list of the class to be taught, stores and analyses the students' classroom answer and question data collected by the teacher, and visualizes these data. For the student user, it can display the students' usual classroom performance in real time and show it in a chart; for the teacher user, it can display his classroom performance in real time [14]. For teachers, they can display the class performance of students in their classes in real time and display it in charts [15].

With the continuous development and updating of computer technology, big data, cloud computing, and artificial intelligence will be widely used in all areas of social life. For example, big data can be used to predict the occurrence of crimes; companies can analyse the sales of products based on customer reviews on shopping websites; the National Centre for Disease Control and Prevention can analyse the spread of diseases based on Internet users' search records; and so on [16]. For the large amount of data generated, the integration and analysis of the data allow people to discover new knowledge and create new value. As the volume of IoT business increases, the amount of data storage and computation will bring the need for "computing" power to the cloud. Cloud computing will provide the appropriate services in infrastructure, platforms, and software. Artificial intelligence is a branch of computer science and new technical science that combines the application of computers and other disciplines, which focuses on the study of theories, methods, and technologies to simulate, extend, and expand human intelligence [9].

3. IoT Data-Driven Intelligent Law Classroom Teaching System Design

3.1. IoT Smart Classroom Teaching System Design. There is no doubt that the communication among many nodes in IoT involves addressing the problem, and IPv4 addresses are getting scarce. Its address space can hardly meet the demand for address space in today's IoT. Moreover, IPv4 has a shortcoming for the mobility of the Internet, and the MIPv4 mechanism proposed in the IETF to support the mobility of nodes will lead to rapid consumption of network resources for many nodes, resulting in network paralysis [17]. IPv6 technology not only has a huge address space but also adopts a stateless address allocation scheme to solve the problem of allocation efficiency of massive addresses. For node mobility, IPv6 proposes the concept of IP address binding buffer and introduces a method to detect node movement. At the same time, IPv6 design considers the quality of service, such as defining the traffic class field and flow label field in the packet structure and using the flow label carried by the packet to do a detailed division of services. It is a protocol designed for

communication between remote sensors and control equipment that have limited computing and storage resources and work on low-bandwidth, unreliable networks. It has the characteristics of simplicity, strong scalability, and low traffic.

The IoT application layer is the ultimate purpose layer, which is the combination of IoT and industry needs, by docking IoT technology with industry technology and using various solutions to provide a good IoT business experience for a wide range of users to achieve a wide range of intelligent applications, so that people can feel the great impact that IoT brings to real life. The main function of the IoT application layer is to process the massive information coming from the network layer and use this information to provide relevant services to users. The key issue of the application layer is how to achieve information sharing and security. Among them, the rational use, as well as efficient processing of relevant information, is an urgent IoT problem, and to solve this technical challenge, the IoT application layer needs to utilize technologies such as middleware, Machine to Machine (M2M), and edge cloud computing. In building the information network of IoT, middleware is mainly applied to distributed systems to connect various technologies and share resources. Middleware can be divided into two parts: the platform and the communication part. The middleware consists of various modules such as a real-time memory event database, task management system, and event management system, which can be implemented to connect two independent applications, as shown in Figure 1.

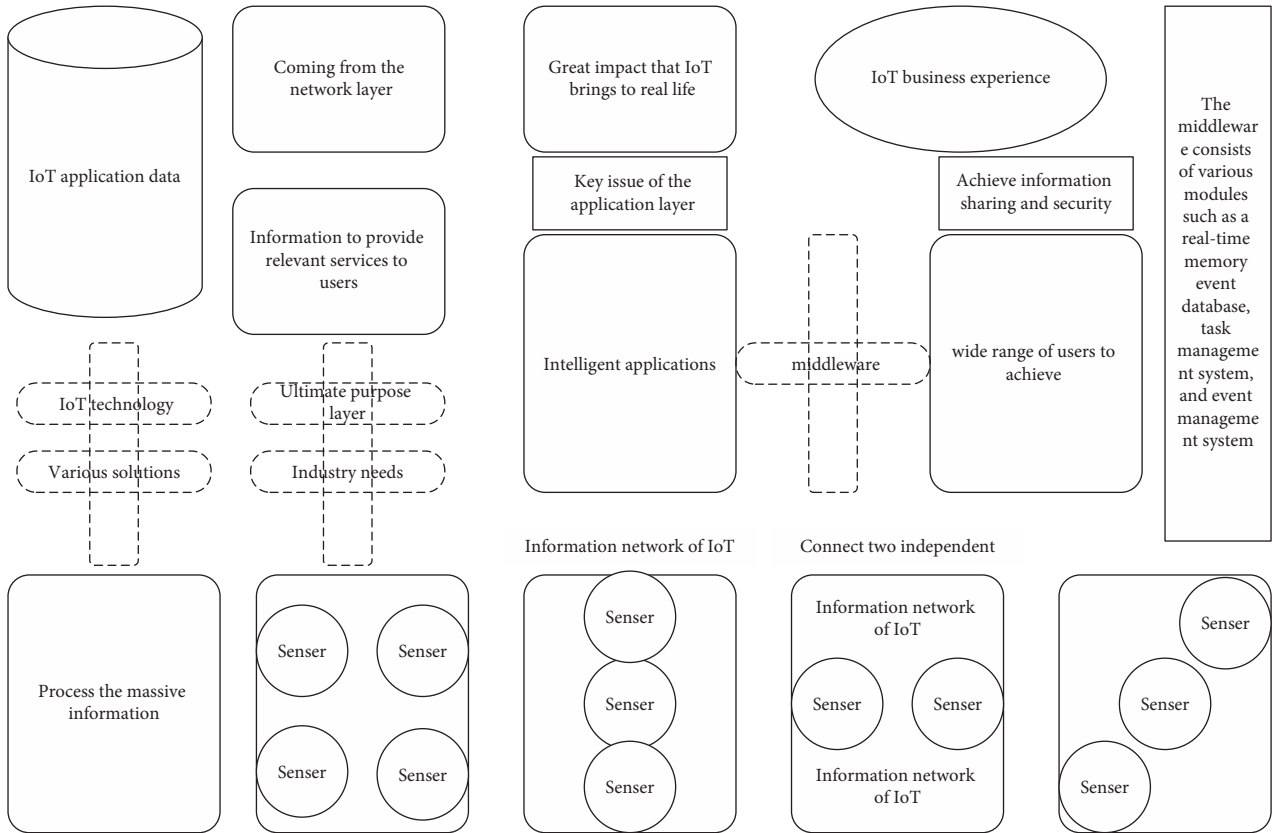
It is a protocol designed for communication between remote sensors and control equipment that have limited computing and storage resources and work on low-bandwidth, unreliable networks. It has the characteristics of simplicity, strong scalability, and low traffic. A wireless sensor network consists of tiny nodes deployed in the monitoring area with data processing units, miniature sensors, and communication modules through a self-organizing wireless self-organizing network system. With the help of the nodes' built-in sensors measuring the signals of the objects around their location, the observer can obtain information about the sensed objects in the network coverage area. The three elements of wireless sensor networks are sensor, sensing object, and observer [18]. The characteristics of wireless sensor networks are mainly reflected in the size of scale and the purpose of application. In the application of a wireless sensor network, the location of sensor nodes cannot be set precisely in advance. Therefore, the network nodes are required to have self-regulation ability, self-adaptive ability, and robustness to maintain the normal operation of the network through topology control mechanism and network protocols and mutual collaboration to complete such work as network initialization and fault self-healing. The basic structure of wireless sensor networks can be divided into node types, node structures, and function-based models of wireless sensor network structures. Its technical research is to be mainly focused on medium access control protocols, network topology control, routing protocols, node positioning, clock synchronization, data management, data fusion, embedded operating systems, and network security.


Figure 1: IoT framework design.

Based on the in-depth analysis of constructivist theory, we propose the theory of realm pulse learning and build a personalized learning environment with an information platform and AI teaching assistance. It is a new paradigm to guide the transformation of learning, which allows the interaction between the many learning elements of the learner and the external elements of the teacher's guidance to form a self-renewal force. In many cases, informatization methods have only become an iconic application for demonstrating new ways of learning. They only serve for informatization competitions or open classes and observation classes and have not been implemented in the classroom to serve students. The AI-assisted teaching of the information platform can undoubtedly provide a better learning environment for the student-cantered teaching model while adjusting the learning environment resources in real time based on the feedback of students' learning data, finally building a dynamic and personalized learning environment in line with the learning situation.

Then, to make data-driven decision-making applied to teaching in addition to the basic elements, some conditions are needed. One is based on the concept of big data teaching, education data as a practical tool, and means to promote the improvement and perfection of teaching continuously. Second, for the correct understanding of the application of data in teaching, the big data should have a cautious attitude; there may be some personal privacy, data security, and other issues; and we should adhere to the principle of science and objectivity, combined with the actual situation and flexible

choice. The third is the construction of an effective platform for data collection and application, to be able to use the platform to carry out teaching activities inside and outside the classroom, collect learning data, carry out learning tracking, and make data decisions truly applied to teaching, as shown in Figure 2.

To ensure that more student handhelds can be connected in a wireless-based classroom interactive system, we need a teacher receiver and 4 Zigbee coordinators to transmit information to each other. Reasonably use educational data to customize a personalized learning environment to meet the learning needs of students at different levels so that artificial intelligence and big data can truly promote more personalization, thereby increasing the attractiveness of the classroom. The teacher receiver uses one serial port to connect to 4 wireless receivers, respectively. At the same time, there are 4 LCD lights connected to each hardware channel to show which coordinator of the wireless receiver the teacher receiver is communicating with. There is also a serial communication switch connected to each serial path, which can only be communicated when the switch is closed. When the teacher needs to send a message to the 4 serial ports with the receiver, the 4 serial communication switches can be turned on and off in sequence to ensure that only one serial communication switch is on for each communication. When a coordinator needs to send a message to the teacher receiver, it also needs to make sure no other coordinator is communicating first. If the requirements are met, then turn on the serial communication switch to communicate and
FIGURE 2: Time-sharing communication serial port principle.

turn off that serial switch when the communication is complete. If the requirement is not met, then wait for some time and continue to query until no other coordinator is communicating before turning on the serial switch.

Reasonably use educational data to customize a personalized learning environment to meet the learning needs of students at different levels so that artificial intelligence and big data can truly promote more personalization, thereby increasing the attractiveness of the classroom. A typical Lora WAN network architecture consists of four parts: nodes, gateways, web servers, and application servers. The nodes are mainly responsible for the collection and reporting of sensing data and the reception and execution of command data on the server side. The nodes adopt the ALOHA access method to randomly access the network and send data on demand. The data reported by a node can be received by multiple gateways, thus forming a star network topology with the gateways, which can ensure the reliability of the connection and realize the access of a larger number of devices in the network. The gateway is the relay device between the node and the network server in the Lora WAN network as the central node of the star network, forwarding the LoRa RF data from/to the node and TCP/P network data for processing. The network server is an important part of the Lora WAN network for data processing and device access, responsible for LoRa node data parsing and encapsulation, encryption, decryption, LoRa node entry authentication, Adaptive Date Rate (ADR) regulation, and other functions. The application server is built and developed by the user side and has different application functions for different IoT applications. Building a database to process and store the application data, providing an application logic interface, and using a visual interface such as WEB or APP to connect the user side with the application server mean building a LoRa IoT system from the sensing layer to the application layer.

3.2. Data-Driven Intelligent Law Classroom Analysis.
Depending on the starting point for considering the problem, research scholars have proposed model-driven, goal-driven, product-driven, business-driven, technology-driven, decision-driven, task-driven, and other forms of drivers. Data analysis emanating from the model side is called model-driven, and the mode of operation with the technology side as the trigger is called technology-driven. With the advent of the intelligence and data era, knowledge acquisition is no longer entirely dependent on expert experience. The use of some intelligent methods can start from the data, mining to get the valuable information behind the data, which is data-driven and one of the main reasons why data-driven methods have developed more rapidly than other methods and attracted widespread attention from scholars [19]. From the perspective of the generation environment, the concept of data-driven is a product of the era of big data, inspired by data-intensive scientific discoveries. Data has become the starting point and perspective for people to understand, analyse and solve problems, resulting in the idea of using a data mindset to solve problems. Furthermore, the scientific preprocessing of data, the constant statistics of data, the real calculation of data, data modelling, machine learning, data visualization, data management, and other technologies provide the technical support for data-driven, in addition to these data science methods, data mining, neural networks, artificial intelligence, metadata, and all other technologies and methods of data-based design are the technical guarantee of data-driven. Reasonably use educational data to customize a personalized learning environment to meet the learning needs of students at different levels so that artificial intelligence and big data can truly promote more personalization, thereby increasing the attractiveness of the classroom:

$$T_p = \frac{\sqrt{x^2 + y^2 + z^2}}{C},$$

$$T_s = \frac{L}{V} - \frac{\sqrt{x^2 - y^2 - z^2}}{C}. \tag{1}$$

The essence and value of big data are to eliminate uncertainty, and the value of data drive lies in the kinetic output of the drive and the means to realize the value of big data: data analytic thinking, data-driven applications in different scenarios, the formation of data-driven decision-making, data-driven design, data-driven procedures, data-driven products, data-driven innovation, and other results output. Among them, the so-called data-driven decision-making is to help patronize through data, including product improvement, operation optimization, marketing analysis, and business decision-making. With data support, we can better determine which channels convert better and which feature styles are more popular with users and support the decision through data. Data-driven product intelligence is the ability to empower products to learn through data models. The so-called intelligence can be understood as a model with a certain database, setting an algorithm model on it; then, the results of the data obtained back to the product are intelligent. In this way, the product has a certain learning ability and can constantly update and iterate itself, for example, the literature recommendation system, by analysing the user's historical behaviour records, discovering the user's interest points, building a targeted user model, and finally realizing personalized recommendations, as shown in Figure 3.

Scientific discovery has shifted from the traditional hypothesis-driven to a scientific approach based on scientific data for exploration. For some scientific problems that are difficult for humans to understand, researchers are gradually unravelling the mystery of these scientific puzzles through data monitoring and analysis, using data as a tool and object of research and designing and conducting research from data. Data are no longer just the result of scientific research but have become the living foundation of scientific research. People are concerned with not only modelling, describing, organizing, preserving, accessing, analysing, reusing, and building scientific data infrastructure but also how to use the ubiquitous network and its inherent interactivity and openness to construct an open and collaborative discovery and creation model with the help of massive data, thus giving birth to data-intensive scientific discovery. There is a lack of effective and detailed information interaction between students and teachers. Teachers cannot specifically and comprehensively understand students' knowledge proficiency. They can only arrange teaching content and teaching progress based on their own teaching experience and random checks in the classroom. The development of a data-intensive scientific research paradigm offers new opportunities for collaborative efforts between academia, industry, and government. This research paradigm relies on sensing tools to acquire data or computer

simulations to generate it, process it through software for cleaning, store it in computers, and analyse it using data analysis software. Data from scientific research can be grouped into four categories: data generated by experimental instruments, data generated by computer simulations, data collected by observation, and data generated on the Web. Data generated on the Web include historical behavioural data of Internet users and data on Web transactions:

$$a(h_m) = (1.25gf + 0.7)h_m - (1.25gf - 0.7),$$

$$P_{\text{coll},sf} = 1 + e^{2G_{sf}}. \tag{2}$$

Data visualization is an interactive visual representation of data using the intelligence of the human brain and the perceptive ability of the human eye to convert data that is difficult to display directly into graphics, symbols, and so on to convey useful information efficiently. Through this visual representation of data, the information hidden in the data, including various attributes, is presented in some summary form. From the point of view of aesthetic requirements and functional requirements, data visualization requires the same for both and guarantees a balance between design and functionality by directly expressing special aspects and special features, and thus gaining insight into very sparse but particularly complex data collections.

The conflict model of the Lora WAN protocol shows that the probability of conflict during transmission of data packets sent by nodes using ALOHA access is closely related to the combination of bandwidth, coding rate, and the proportion of nodes using the same spreading factor. When the Lora WAN protocol is simulated in the LoRa network created in this paper, the corresponding proportion of nodes using the same spreading factor, bandwidth, coding rate, and other parameters are substituted into the formula, and the probability of conflicts occurring in the data transmission process of nodes using different spreading factors is close to 1. At this time, the conflicts in the network are more frequent, the data loss caused by communication conflicts is more serious, and the reliability of network communication is poor at this time:

$$G_{sf} = \lambda^2 \partial_{sf} T_{sf}. \tag{3}$$

As the information transfer channel in the whole IoT architecture, the network layer is responsible for transferring the information obtained from the sensing layer and submitting it to the application layer for processing. The application layer is the interface between the IoT system and the user, which mainly solves the problems related to information interaction, human-machine processing, and so on. It combines the needs of various IoT industries to complete specific business functions and realize the intelligent application of the whole IoT industry. The main tasks of the application layer include data analysis and processing, data storage and mining, and communication handover between people and things, and things and things [20]. To adapt to the ubiquitous situation of devices and at the same time play the powerful computing ability, storage ability, and network communication ability of cloud
FIGURE 3: Data-driven intelligent law classroom architecture.

computing platform, the cloud platform is used as the application layer in the IoT architecture to build the IoT cloud platform architecture; establish the unified management of people and things in the IoT application; establish and maintain the communication channel between people and things; and realize the functions of remote control, data management, business logic processing of industry applications, and so forth. The IoT system architecture based on the cloud platform is shown in Figure 4, which mainly consists of terminal layer, network access layer, and cloud platform.

For aesthetic effect, adjust the label size to be <10 so that the information about the research user can be better presented. The base feature is more important in understanding the researcher's information and is also the least variable. Set the base feature label size to 10. It is necessary to research and explore the intelligence and informatization of laboratories. This article takes the Computer Engineering Department of Fujian Institute of Information Technology as an example. Based on the existing facilities, the structure and characteristics of the Internet of Things technology in smart homes and smart buildings are applied to the laboratory management system:

$$i_t = \sigma\left(W_i \left|h_t x_t^2\right| + b_i\right). \tag{4}$$

Research preference label and research relationship label: the user portrait of the digital library knowledge discovery platform designed in this paper is essentially a labeled formal description of the user model of the platform users, and the user portrait is constructed using the user's basic attributes, research results, and search target information and displayed through the word cloud visualization. Finally, the real users of the knowledge discovery platform are selected for the method validation. The user portrait of the digital
FIGURE 4: Label weights.

library knowledge discovery platform constructed in this paper can depict user information in all aspects and intuitively display user information to accurately provide personalized services and accurate recommendations and provide a real and effective reference basis for the decision-making layer.

4. Results and Analysis

4.1. IoT Smart Classroom Teaching System Performance. The key to achieving remote management from the cloud to the device side is to establish and maintain instantaneous and reliable communication between the cloud and the device side. Instant communication requires that the device

side can report data to the cloud, receive messages from the cloud in real time, and ensure that the communication has low latency. Since in the actual application environment, the network environment at the device side cannot ensure stability and reliability, so based on establishing the connection between the device side and the cloud side, a heartbeat mechanism is required to maintain the long connection from the device side to the cloud side, and at the same time, TCP-based protocols are preferred to select the communication protocols to ensure the reliability of the connection. Based on the above analysis, this paper selects the MQTT protocol to solve the problem of end-to-end instant and reliable communication during remote communication. MQTT protocol is a lightweight, agent-based publish/subscribe model messaging protocol designed for communication of remote sensors and control devices with limited computing and storage resources and working in low bandwidth and unreliable networks, with features of simplicity, scalability, and traffic saving. The MQTT protocol enables network communication between multiple clients by specifying topic subscriptions and message distribution, with the server acting as a proxy to forward messages based on the topic number. By decoupling the senders and receivers of messages in space and time, the system has good scalability and scaling capability.

The rapid development of IoT applications has led to the emergence of various types of IoT products. In various IoT products, the nodes can be either sensing devices/actuation devices with sensing data collection modules and control modules or subsystem devices connected through field buses. By accessing different functional module devices, different IoT products can be quickly constructed to achieve functional expansion of IoT applications. For the characteristics of multiple and complex product functions in IoT applications, this paper completes the description of device functions by defining attributes, services, and events for devices, referred to as the object model, to construct data models of device entities under different products, digitize the entity objects in physical space, and digitally represent them in the cloud, as shown in Table 1 for the definition of attributes and services events. By linking the Internet of Things technology with industry technologies, various solutions are used to provide users with a good Internet of Things business experience to achieve a wide range of intelligent applications, so that people can truly feel the huge impact of the Internet of Things on real life.

Different IoT products are used in different application scenarios, and the hardware architecture and software environment of the devices in the products, as well as their functions, show great differences, which determine different forms and functions of the device side, leading to the gradual "fragmentation" of IoT applications. Any user-oriented IoT product needs to break the full-stack communication protocol of "device–network platform application," but the "fragmented" IoT feature leads to great differences in the format, length, and precision of data from different devices. The communication protocols of different products are also very different, which will lead to the problem of interconnection between IoT products and become a bottleneck for

further development of IoT. In the traditional IoT application development mode, first, the device developer needs to define the communication protocol from the device side to the application side according to the system function. The application side has a strong dependency on the device side development, so the device side must be done first and then the application side, which cannot be developed synchronously. The application developer must wait for the device developer to complete the development of the device side and then carry out the development and testing of the application side, which undoubtedly increases the development time and cost and consumes huge human and material resources, as shown in Figure 5. Data-driven decision-making, data-driven design, data-driven programs, data-driven products, and data-driven innovations are formed.

In order to avoid the communication conflict caused by multiple nodes communicating with the gateway at the same time on the same channel, CSMA presentation monitoring and random delay backoff strategy are used to avoid the conflict. Presend listening is to detect the presence of packet leading code on the channel through CAD. If the CAD detects the presence of leading code transmission in the current channel, then the current channel is occupied. Otherwise, the current channel is in an idle state. If the channel is idle, then the service transmission can be carried out. Otherwise, random back-off is performed. When the channel is occupied, the timer is set to wait for a random delay; after the delay, the current channel state is detected until the channel is idle and the data is sent successfully, or the number of random evasions reaches the upper limit. If the number of random evasions reaches the upper limit, the competing channel is randomly switched, and the data is sent again.

Since the SNR values of the three groups of nodes to the gateway are similar in this test, the gateway assigns the three nodes to the same TDMA channel after admission. They are assigned communication time slots consecutively in the order of admission. The three nodes continuously occupy the time slots for periodic service reporting. Use data as research tools and objects, design, and conduct research from data. Data is no longer just the result of scientific research but becomes the living foundation of scientific research. Theoretically, there is a difference of 3 seconds between the time slots of each node for periodic reporting. However, the test data shows that there is a delay of several tens of milliseconds due to the software and hardware factors. The corresponding communication cycle has a certain delay, but in general, it is verified that the LoRa network communication with TDMA access is feasible, and different nodes will actively report at different times without conflict with each other to ensure the reliability of communication is ensured.

4.2. Results of the Data-Driven Smart Law Classroom Experiment. Finally, classroom observations revealed a strong interest in the course, most notably in the reluctance of students to leave the classroom after class and continue to

FIGURE 5: Comparison of the communication bloc.

modify the code to create their work. Several problems were also revealed: firstly, the lack of basic computer skills due to the low exposure to computers, which was a major obstacle to the completion of the first three weeks of the assignment, and secondly, the repeated shouting at the teacher during the class. In the teacher workshop after the class, we analysed two reasons behind this: students were afraid of using the software badly because they were not familiar with the use of Scratch programming, so they were afraid to try boldly when there were problems with the code; students needed the teacher to affirm the quality of their work and encourage and evaluate it before they would proceed to the next stage of the task after completing their work. Show it in some form of summary. From the perspective of aesthetic requirements and functional requirements, the requirements of data visualization are the same for both, and by directly expressing special aspects and special characteristics, we can gain insight into very sparse but particularly complex data sets to ensure balance between design and function. The data collected was divided into three parts: the first part was about mathematical achievement, evaluated with a pre- and posttest of mathematical academic achievement related to project progress; the second part was computational thinking, divided into three areas (computational concepts and computational practices were evaluated by Bibras competition questions, computational perspectives were tested by scales, and collaborative perceptions in computational perspectives were analysed separately); and the third

area was a problem-driven learning environment perceptual analysis, as shown in Figure 6.

Use the template to design a display page for the new seasonal products of Sun King Sportswear. According to the web design imitation + microinnovation concept, students can imitate the teacher's work or modify their preclass work. Moreover, according to their actual learning situation, they can choose a learning method that suits them; for example, students with weaker abilities can log on to the Super Star platform to watch tutorials and microlessons on demand and dialogue with robot assistants to help them learn, keep up with the pace of the class, and exercise their independent inquiry skills. Students upload the designed layout in real time to an online discussion group to exchange ideas with group members. This session uses online resources and a robot assistant to assist students in their task exploration, exercising their independent inquiry skills. Students discuss the layout online to improve their collaborative learning skills. The "shake it up" spot check of task completion adds interest to the classroom and instantly determines the level of proficiency in key content, recording student errors for more intuitive analysis and summary. The information resources include Super Star Online Learning Space, Turing Robot, Learning Pass "Shake One," and Super Star Interactive Group. After the teacher's lecture, students can access the online learning space to learn more or ask questions to the robot assistant according to their proficiency. In this session, students can access the Superstar platform video to watch the learning data and discussion, and the students' personalized learning mode is greatly reflected. Online group interaction makes group learning more convenient. The use of "shake" instead of roll call to check the completion of tasks increases the interest of the classroom and improves students' participation in the classroom, as shown in Figure 7.

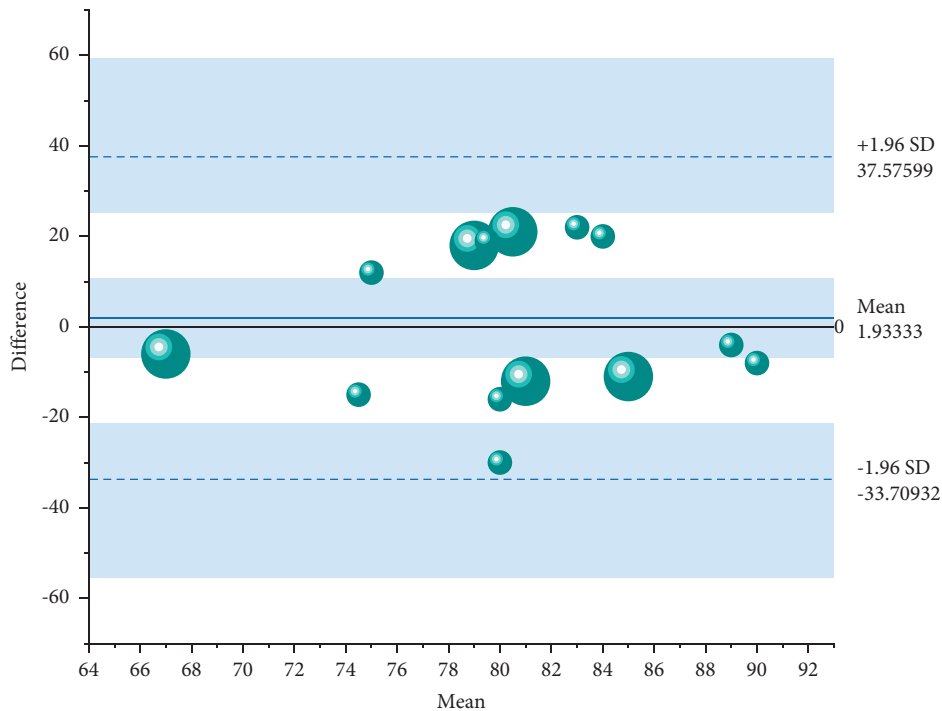
As can be seen from Figure 7, the accuracy of the research object is 0.90, the recall is 0.84, and the F1 value is 0.87. The research object category is higher than the other categories in all indicators of discrimination because the research object generally has an established authorized name. For example, in the case of research objects in specific feature domains, the corresponding conventions can usually be found, and the model can better identify and determine them. Research questions and research methods, on the contrary, are more variable and complex in their formal composition, so the discriminative F1 values are relatively low. The change of knowledge discovery services in data-driven digital libraries has put forward higher requirements on the semantic understanding of data resource contents, especially the full text of scientific research papers. Complete specific business functions and realize intelligent applications in the entire Internet of Things industry. The main


FIGURE 6: Test performance statistics.
FIGURE 7: Comparison of inspection results.

tasks of the application layer include data analysis and processing, data storage and mining, communication between people and things, and things and things. To assist in achieving semantic identification, annotation, and understanding of data resource content, this section designs a keyword-based approach to identify the problems, methods, and research objects of data resource content using keywords of full-text scientific research papers and implements the approach in the field of agriculture. Experiments show that the method achieves satisfactory identification results.

This section focuses only on identifying the research object, problem, and method vocabulary, without exploring the functions assumed by the vocabulary in the text and whether the problem corresponds to the method. Therefore, future research will further explore which specific function the vocabulary assumes in the text and what the corresponding solution to the problem is. Through the experiments, the effectiveness of the deep learning model is verified, which provides an effective general idea for the research design fingerprint extraction of the full text of scientific papers in the knowledge discovery service platform of the digital library and methodological references for other types of data content extraction and identification studies.

5. Conclusion

The LoRa IoT system is designed with the help of IoT platform, the access process from the device side to the cloud side is developed, and the authentication mechanism is used to ensure the legal access of the device side. The front-end web page of the data management website design is not beautiful enough, and the functions are not perfect. The jQuery and Bootstrap frameworks used in developing the front-end of the web page are not beautiful enough, and the website currently only does some simple data processing and visualization. Now, it does not support the function of big data analysis. The MQTT protocol is used to achieve reliable remote long connection communication between the cloud and the device; the device function is abstracted through the object model, and the object model is described using the JSON data interaction format so that the relevant communication protocol can be developed to realize the data transmission between the end and the end. The wireless

communication-based classroom interaction system designed in this paper can help teachers realize the collection of feedback data, data visualization display and storage of students' roll call, multiple-choice questions of classroom quizzes, and Y/N judgment questions in classrooms. The data management website also allows students and teachers to view the actual classroom performance of students in their class or the teacher's class. Although the system can achieve the basic functions of the classroom interactive system, due to the limited personal ability, there are still numerous shortcomings, and there are some gaps between the research work of the thesis and the actual use of the needs, which need to be continuously improved at a later stage.

This article has first presented an overview and a brief design to the system, and then analyzed the system design goal and design principle. The role of the resource representation model in the Internet of Things is more important than the significance of the database schema for the web information system. In the current "vertical" application model, the device resources of the perception layer and the application entities of the business layer are in a tightly coupled relationship. In the process of system operation, it changes flexibly as the situation changes. This article will combine the characteristics of resources in the Internet of Things, from the perspectives of resources and services, and refer to the basic structure of the traditional Internet resource reference model OWL-S to appropriately expand and tailor it, and describe the relationship between Internet of Things device resources and application services. Therefore, the resource representation model oriented to the Internet of Things service in this article is proposed and simulated and verified. To a certain extent, this model can provide support for the unified description of IoT resources and services, so as to better adapt to the development needs of diversified IoT services. Based on the application and service in the Internet of Things environment restricted by time and space correlation and limited resources, the article discusses and proposes a multiterminal selection algorithm for Internet of Things business, and converts it into a mathematical combination optimization problem. Based on the ant colony optimization algorithm, a solution is given, which can realize the optimization of equipment combination scheme under resource-constrained conditions to maximize the total benefit value of the service, and can effectively improve the utilization rate of terminal resources. In the research on the analysis of the development strategy of China's industrial design industry in the era of intelligent interconnection, the analysis of the development strategy of the industrial design industry in the era of intelligent interconnection through analysis tools of industrial strategy reveals the new trend of industrial design in the era of intelligent interconnection. The analysis and formulation of industrial strategy are complicated, and it is a systematic project involving all aspects. The rational use of corresponding strategic analysis tools can further enhance the scientificity and rationality of industrial design strategy.

1. Introduction

The concept of "Internet of Things" was originally developed in the late twentieth century. The top laboratories in the field of networked RFID and emerging remote sensing technologies, the Auto-ID Laboratory of the Massachusetts Institute of Technology, automatically identify art and industrial products in the supply chain [1, 2]. With the "ITU Internet Report: Internet of Things" published by the International Telecommunication Union, the Internet of Things has been promoted to the public eye, and there has been an explosive growth in the research and application of

the Internet of Things worldwide [3]. The technical guide pointed out that the era of interconnection and interoperability of the Internet of Things is coming. Any object in real life, from toothbrushes and needles, to cars and houses, can rely on the Internet of Things technology for active interaction and data sharing [4]. With the rapid development of the Internet of Things technology, key basic technologies such as wireless electronic label technology, wireless sensor network technology, and intelligent embedded technology have matured, and the cost of related commercial equipment has fallen, and the Internet of Things has received more and more attention from more and more fields [5]. Concepts

such as smart home, smart grid, smart transportation, smart industry, and smart medical care are all concepts and technological development routes that result from combining the Internet of Things technology with this field [6].

At present, almost all IoT platform architectures are vertical application architectures; that is, they are mainly oriented to applications and closed-loop applications in the relevant fields of the industry [7]. This type of architecture has poor reusability, huge investment in one-time construction, poor data sharing and operational interaction capabilities between devices and applications, and difficulties in interconnection and intercommunication between different application systems. The main reason for this problem is the prominent problem of device heterogeneity and network heterogeneity, and the serious differentiation of IoT applications in different fields has led to the research of existing IoT applications and architectures [8]. Although with the growth of the actual application and deployment of the Internet of Things, there have been many research studies and results that combine the Internet of Things and the cloud in recent years [9, 10]. The format is uniformly regulated, and the powerful processing capabilities of cloud technologies such as cloud computing and cloud storage are used to process large data volume device data to form a backend centralized architecture system [11]. However, the research direction of the Internet of Things of this kind of system architecture is also oriented to the research of the Internet of Things technology in this field [12]. The relative equipment types are fixed and unified, and the equipment data are single. It can better deal with the problem of equipment and data unification. At the same time, this type of architecture has harsh requirements for the network and cloud servers, and a stable and reliable connection is required to obtain Internet of Things services and computing capabilities [13]. There are also certain requirements for bandwidth, and the data transmission pressure of equipment capable of carrying large amounts of data is required.

This article gives an overall overview of the Internet of Things device access system, and describes the design goals and principles of the system. From different aspects, namely, functional and nonfunctional, a detailed demand analysis of the Internet of Things device access system is carried out. In terms of the architecture design of the Internet of Things device access system, the overall design of the system is analyzed, and the functional architecture design of the system is described in accordance with the functional modules of the system. This article proposes a multiterminal selection algorithm for IoT services. Under the condition of limited resources in the Internet of Things environment, reasonably we configure the best terminal set for each user business in the business layer to improve the efficiency of the use of ubiquitous peripheral resources in the Internet of Things. A large number of users requesting services in the same time period will cause competition for equipment resources. Therefore, efficient multiterminal collaboration needs to ensure that the overall service benefit value reaches the best value, without the imbalance of user service quality. For this reason, the problem is modeled as a multiterminal selection process based on the service model and resource model. Finally, the problem is simplified into a combinatorial optimization process, and a heuristic ant colony optimization algorithm is introduced to solve the problem. Through simulation, the random allocation algorithm and the greedy algorithm are compared in terms of comprehensive benefits, utilization rate, and business success rate. Based on the diamond model to study the development of China's industrial design industry under the background of the era of intelligent interconnection, this article analyzes the production factors, demand conditions, related and supporting industries, corporate strategy, organizational structure, and factors of competition in the industry, government, and opportunities of China's industrial design industry. The industry should improve the efficiency of division and cooperation in the industry, promote competition and cooperation among enterprises, stimulate design creativity, and scientifically enhance the competitiveness of the national industrial design industry.

2. Related Work

Relevant scholars believe that the development of the Internet of Things not only requires comprehensive consideration of the security and technical issues closely related to its industry, but also needs to make a detailed future development plan for the Internet of Things industry and raise it to a strategic height [14]. The researchers pointed out that the development of core industries has become the top priority of the development of the Internet of Things industry, and it is necessary to fully support leading companies and use them to drive related industries to form a complete industrial chain [15]. Based on existing conditions, application demonstrations are mainly carried out in key areas such as strong industry driving, high relevance, and good demonstration effects, such as people's livelihood services and infrastructure. Relevant scholars believe that "the two ends are weak and the middle is strong" is the main problem in the development of China's Internet of Things [16]. The breakthrough of core technology and the realization of independent innovation are the focus of the development of the Internet of Things. Scientific and reasonable industrial layout, regional coordination and unity, avoiding duplication of construction, and focusing on regional advantages are indispensable conditions for the sound development of the Internet of Things industry.

Relevant scholars believe that it is better to regard the Internet of Things industry as an innovation system, use the method of innovation system element linkage, and build a conceptual analysis model of multi-element linkage of the Internet of Things industry innovation system from the perspective of "linkage" [17]. By analyzing the development history of the Internet of Things industry, it is concluded that the role of the government is the main innovation fulcrum of the development of the Internet of Things. Therefore, in the development of the Internet of Things, the government must create a good external environment to guide the scientific development of the Internet of Things industry. Based on the theory of value, the researchers put forward the theory of value creation of the Internet of Things and the theory of

value creation of the Internet of Things from the perspective of industrial clusters and industrial chains [18]. This theory explains the essential question of how the Internet of Things creates value as a new production tool. Relevant scholars believe that it is necessary to rely on the industrial advantages of each region to handle the relationship between traditional industries and strategic emerging industries, so as to realize the adjustment of the regional economic structure, and rely on industrial advantages to strengthen technological innovation and promote the transformation of its results [19].

Related scholars have proposed that the Internet of Things and the sensor network are actually different representations of the same thing [20]. The comparison between the networking and the sensor network and the conclusion that the two are larger and the smaller are one-sided. The researchers pointed out that the ubiquitous integrated sensors, the subtle nodes of the communication unit, and the data processing unit form a wireless network in a self-organizing manner [21]. The items are given "wisdom" by these subtle details, and they interact and influence each other according to the instructions received, so as to achieve the integration of human economic society and the physical world. Based on the above viewpoints, it can be known that the Internet of Things is defined mainly based on two technologies in the research of Chinese scholars, namely, radio frequency identification technology and sensor network technology.

Related scholars' interpretation of the concept of the Internet of Things includes the above two theories [22]. He pointed out that the Internet of Things is an intelligent sensor that places radio frequency identifiers in objects that need to be monitored, and then recognizes GPS and other technologies, and communicates with the Internet through interfaces. The definition of the concept of the Internet of Things by domestic and foreign scholars will vary according to the focus, that is, the core technology involved [23]. But no matter from which point of view it is defined, the core connotation is basically the same; that is, the Internet of Things is a combination of the Internet and information sensing equipment. Through the construction of an intelligent network connected to things, communication and information exchange in an agreed manner are finally realized.

Relevant scholars have summarized the application fields of the Internet of Things technology, including industrial automation, smart agriculture, pollution prevention, public management, medical and health, communication logistics, smart home, and other major fields [24]. The changes brought about by the Internet of Things in the four fields of agriculture are described in detail. Relevant scholars looked forward to the application of the Internet of Things technology in agriculture and pointed out that the application of the Internet of Things technology to agricultural production in China, a large agricultural country, is a good opportunity to solve the "three rural" problems. Relevant scholars believe that the application of the Internet of Things has involved food traceability, industrial monitoring, intelligent transportation, environmental protection, environmental

monitoring, government work, public safety, enemy investigation and intelligence collection, smart fire protection, safe home furnishing, and water system monitoring [25]. It can be seen that most domestic scholars are studying the application of the Internet of Things in a wider range of industries, but they have not made further detailed and indepth studies on the specific application of the Internet of Things in these industries. The common characteristics of the application have not been clearly mentioned.

3. IoT Device Access System Design

3.1. System Requirements Analysis. The smart building monitoring system collects information such as temperature, air conditioning location, and carbon dioxide concentration through the underlying sensor equipment to achieve comfortable management of the working environment and improve work efficiency. In IoT applications, there are a large number of underlying sensor devices, and the transmission protocols are different and diverse. The IoT device access system provides a system for the access management of underlying sensor devices and provides the service of encrypting data before transmission.

The topic proposed in this article is based on the IoT smart IoT sensor equipment project. In this project, the IoT equipment is connected to the system and is responsible for the management of the sensor equipment at the lower level perception layer, and provides services such as data transmission to the upper layer. Figure 1 shows the architecture of the smart IoT sensor device. The underlying sensor equipment is composed of traditional IoT sensor equipment plus NB modules. After the IoT equipment is connected to the system, it will be managed by the system, and the collected information usage and other data will be safe and complete. It is transmitted to the upper application server, and the data are processed and then visualized into the intelligent information management system.

When uploading data to the system, the system will select the corresponding protocol according to the transmission protocol used and then parse the original protocol data to obtain intuitive environment perception data, and re-encapsulate the data into a unified data format for transmission to the system. In the process of transmission, in order to ensure the security of data transmission, the data are encrypted and then transmitted, and the upper management system can obtain the data completely.

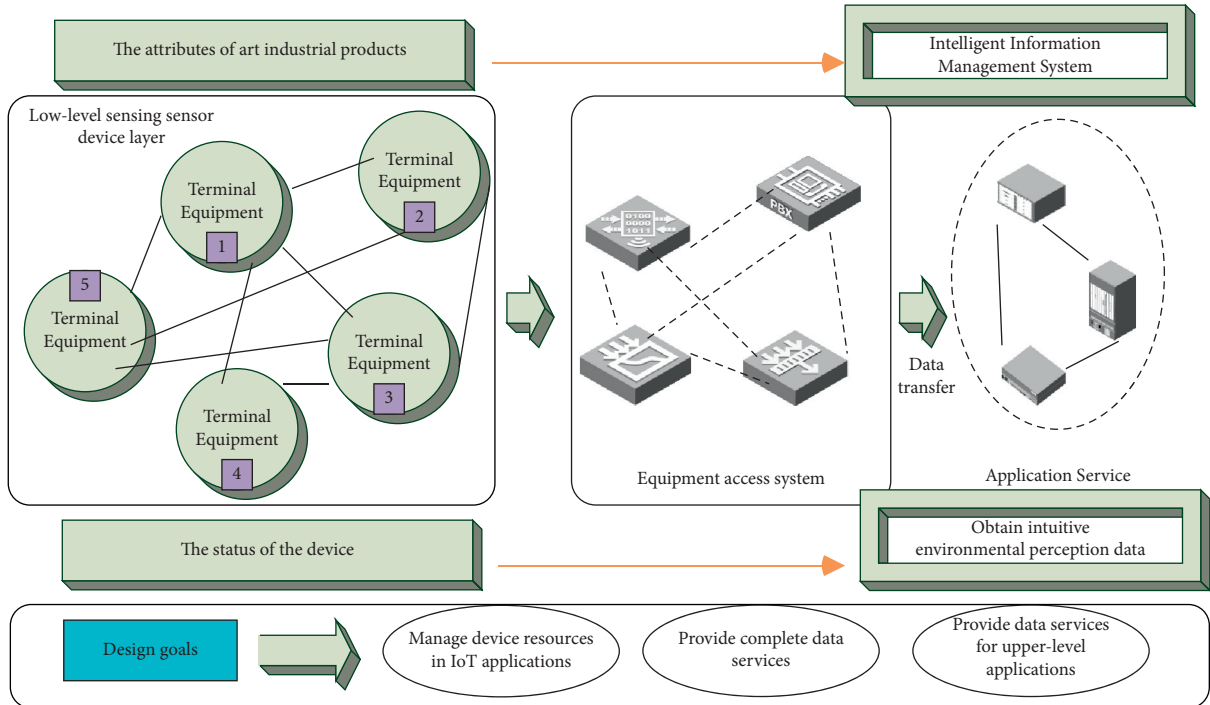
3.2. Demand Analysis of IoT Device Access System. The underlying sensor device network layer has the characteristics of multiple types of devices, limited computing and storage capabilities of the device, and so on. Therefore, for the communication protocol, the corresponding protocol should be used according to the characteristics of the underlying sensor device layer to ensure the accuracy and fluency of data transmission. The Internet of Things device access system has functional modules such as user management, application product management, device management, protocol management, data analysis and


Figure 1: Smart IoT sensor device architecture.

encapsulation, and data encryption transmission. The specific requirements are analyzed as follows:

(1) User information management is mainly responsible for managing the basic information stored by users when they use IoT devices to access the system. It has the following basic functions: user registration and login—this function is responsible for entering the system; and password modification and retrieval—this function is responsible for the management of user passwords. In addition, the management of user information also contributes to the management of modules such as application product information and equipment.

(2) The basic information of the Internet of Things device access system management application products mainly includes the creation of application products, the modification of application product information, the deletion of application products, and the query of application product information. Moreover, the management of application product information also contributes to the management of equipment modules.

(3) In IoT applications, different application requirements lead to different sensor devices. In the IoT device access system, devices are managed according to their application information. In an IoT application, there will be multiple sensor devices serving it. Multiple sensor devices can be saved under the same application product information. The equipment management module is based on the management of application product information and is responsible for functions such as adding and modifying equipment attribute

information, deleting equipment, and querying equipment information.

(4) Different sensor equipment manufacturers will lead to different communication protocols supported by the equipment. The Internet of Things equipment access system supports mainstream communication protocols, such as HTTP protocol, MQTT protocol, and CoAP protocol, so as to support multiple sensor equipment.

(5) After the IoT device access system collects the original data from the sensor device network of the underlying perception layer, it will parse the original data according to the data transmission protocol supported by the sensor device and then encapsulate it into a unified, standardized, and intuitive data. When the data are transmitted, it is encrypted and then uploaded to ensure the accuracy and integrity of the data.

(6) The Internet of Things device access system stores the user's information, the information of the Internet of Things application products and the information of the sensor equipment in the database, so that the user can modify, query, and delete these data information.

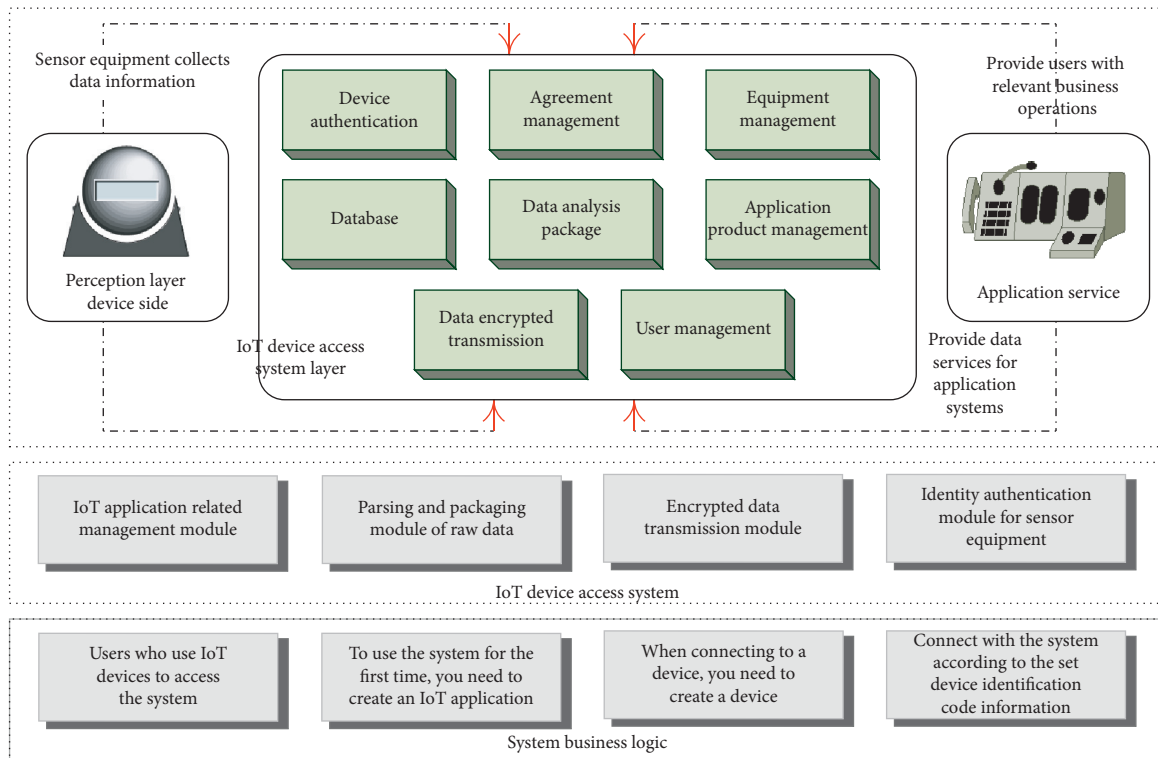
3.3. Design of the Internet of Things Device Access System Architecture. The Internet of Things device access system is an important part of the entire Internet of Things applications. It solves some of the problems that will be involved in the development of Internet of Things applications, such as the access management of multiple different resource devices, and the analysis and packaging of raw data. Figure 2


FIGURE 2: Functional architecture diagram of IoT device access system.

shows the overall architecture of the Internet of Things device access system.

In this architecture, sensor devices are responsible for collecting data information. In the application scenario of this topic, the data information related to the IoT sensor equipment are collected, which is the most basic and core part of the IoT application implementation process. Wireless communication technology is mainly used to realize the collection of related information and other operations. The IoT device access system layer is mainly responsible for providing data for the upper layer, combining with database technology to manage the sensor devices in the underlying perception layer, and adapting appropriate IoT application protocols to parse the collected raw data. The application server is mainly responsible for providing data services for the upper-layer application system, and parses and processes the received lower-layer data for use by the upper-layer business system.

4. Multiterminal Selection Algorithm of Artistic Industrial Products for IoT Sensor Devices

4.1. Problem Description. The execution of ubiquitous services of the Internet of Things often requires the collaborative combination of multiple terminals on the perception layer to achieve. Because of the differences and differences in the configuration of application scenarios, resources, etc., compared with traditional Web services, IoT services have very different characteristics, such as heterogeneity and the execution of services are restricted by device resource conditions. It is precisely because of these different characteristics that the collaborative combination of multiple terminals in the ubiquitous environment of the Internet of Things faces the following challenges:

(1) Since devices and network links are shared in a ubiquitous environment, it is a more complicated problem to configure corresponding device sets and link sets for multiple ubiquitous services in a bandwidth-constrained network reasonably and efficiently.

(2) Due to the influence of mobility and other aspects, the state of terminal equipment in the ubiquitous environment of the Internet of Things is usually unstable, such as processing delay, equipment reliability, and other availability of equipment. Therefore, periodic dynamic adjustments are required to meet user requirements for service quality.

Due to the limited network resources and terminal capabilities, a large number of users requesting services at the same time period will lead to equipment resource competition. Therefore, efficient multiterminal collaboration needs to ensure that the overall service benefit value is optimal, and there should be no imbalance in user service quality. Multiterminal selection should focus on solving the problem of how to maximize the sum of the benefits of business-layer service requests under the condition of limited underlying perception resources and network resources, so as to improve the use efficiency of terminal equipment and network links.

Most of the mapping models between the business layer and the resource layer in the multiterminal collaborative

aggregation mechanism in the ubiquitous environment build constraint functions from the perspective of resource constraints. There are relatively few studies on the abstract modeling work of IoT business layer and resource layer.

To this end, this article will first abstract and model the IoT business layer (service model) (SM) and the perception resource layer (resource model) (RM), and establish a multiterminal selection management layer between the network layer and the business request layer (resources aggregation management layer) (RAML); the description information of the underlying resources will be automatically mapped to the terminal aggregation management layer. This layer will realize the combination and allocation of resources based on the multiterminal selection algorithm ACO-MTS for ubiquitous services of the Internet of Things proposed in this article to ensure the maximum and smoothness of comprehensive benefits. In order to adapt to the heterogeneity and instability of terminals in the ubiquitous environment of the Internet of Things, a comprehensive benefit function based on the maximum business success rate and benefit is designed. Finally, through experimental simulation and random selection (RS) algorithm, the comprehensive benefits, the total consumption of resources, and the effective utilization of resources are compared to show the effectiveness of the mechanism.

4.2. Mathematical Model of Multiterminal Selection Problem.

The resource layer is a comprehensive modeling of the network layer and the ubiquitous perception layer in the overall architecture of the Internet of Things. The models are all represented in the form of logic diagrams, which are, respectively, represented as GSM and GRM, and the problem to be studied for multiterminal selection for IoT services is how to map GSM to GRM to select the best terminal set to provide services.

TAS means that for each ubiquitous service i, there are multiple optional terminal collaboration sets corresponding to it, denoted as $C_{i,s}$, where s represents the s-th terminal collaboration set corresponding to the ubiquitous service Pi. At the same time, the TAS corresponding to each ubiquitous service must meet the corresponding resource capacity constraints, mainly including terminal capacity and link capacity limitations, where w represents the type of terminal k's capacity, and e represents which one is occupied link:

$$\prod_i T_{kw} > t_{i,kw} \quad w \longrightarrow (0, W),$$
$$\prod_i L_e > l_{i,e} \quad e \longrightarrow (0, E). \tag{1}$$

Combining the above concepts of business model, resource model, and terminal collaborative aggregation model, it can be seen that the key to the multiterminal selection problem for IoT services lies in the SM to RM mapping algorithm in the resource aggregation management layer (RAML). RAML is responsible for multiple universal applications at the application layer.

4.3. Selection Algorithm Analysis.

In order to further abstract the mathematical model of the mapping from SM to RM, the benefit function is mainly measured by business quality here. Assuming that each ubiquitous business i corresponds to a total of Si TAS, in order to avoid the supervisor dependence of the benefit evaluation function, the TOPSIS criterion of the multi-attribute decision-making scheme is also introduced to calculate the benefit index of each TAS.

After determining the evaluation criteria of the benefit function, the Multi-Terminal Selection Problem (MTSP) can be expressed as

$$Max \quad \prod_{i=0}^{l-1} \prod_{s=0}^{S_i-1} U(C_{is}, i) = \prod_{i=0}^{l-1} \prod_{s=0}^{S_i-1} (x_{is}\varphi_{is}),$$

$$s.t. \begin{cases} \prod_{i=0}^{I-1} \prod_{s=0}^{S_i-1} \prod_{e=0}^{E-1} z_{i,se} l_{i,e} > L_j, \qquad j \longrightarrow (-1, J), \\ \prod_{i=0}^{I-1} \prod_{s=0}^{S_i-1} \prod_{v=0}^{V_i-1} y_{i,svk} t_{i,vw} > T_{kw}, \quad w \longrightarrow (0, W) \cup k \longrightarrow (-1, K). \end{cases} \tag{2}$$

From the analysis of the above formula, it can be seen that the MTSP problem is an integer linear programming problem with multidimensional constraints. Due to the difficulty and complexity of solving this type of combinatorial optimization problem, in order to simplify the solution process, it is necessary to reduce the dimensions of the multidimensional constraints in the formula, that is, to convert multiple limited constraints into unique constraints. Therefore, the MTSP problem can be transformed into a Multi-dimension Multi-choice Knapsack Problem (MMKP) through dimensionality reduction processing; that is, the two constraints on terminal capacity and link capacity in MTSP are combined into one-dimensional constraints. The conversion formula is

$$r_{i,sk} = \begin{cases} \prod_{e=0}^{E-1} (k' z_{se} l_{i,e}), \qquad k' \in [KW - 1, KW + J], \\ \prod_{v=0}^{V_i} (k' t_{i,v} y_{i,sv}/w), \quad k' \in [-1, KW - 1], \end{cases} \tag{3}$$

$$R_{k'} = \begin{cases} L_{KW+k'}, \quad k' \in [KW - 1, KW + J], \\ R_{k'/W}, \quad k' \in [-1, KW - 1]. \end{cases}$$

Thus, the MTSP problem can be transformed into a one-dimensional constrained MMKP mathematical model:

$$Max \quad \prod_{i=0}^{I-1} \prod_{s=0}^{S_i-1} U(C_{is}, i) = \prod_{i=0}^{I-1} \prod_{s=0}^{S_i-1} (x_{is} \bullet \varphi_{is}),$$

$$s.t. \begin{cases} \prod_{s=0}^{S_i-1} x_{is} = 1, \qquad i \longrightarrow [1, KW], \\ \prod_{i=0}^{I-1} \prod_{s=0}^{S_i-1} x_{is} r_{vk'} < R_{k'}, \quad k' \longrightarrow [-1, KW + J]. \end{cases} \tag{4}$$

MMKP is an NP-hard problem with a broad engineering background. Many practical application problems can be described as MMKP models, such as inventory compression problems and distributed computing system processor allocation strategy problems. Here, the ant colony optimization (ACO) algorithm is introduced to solve the MMKP problem, and the ant colony algorithm model is appropriately modified according to the characteristics of the multiterminal selection problem model to form the ACO-MTS algorithm to adapt it to the MMKP problem model.

When the ACO algorithm is applied in different scenarios, the pheromone update model in the multiterminal selection algorithm is often different. The pheromone update process of each TAS of the ACO-MTS algorithm is shown in the following formula:

$$\tau_s(t-n) = \prod_{k=0}^{K-1} \tau_{k,s} + (1+p)\tau_s(t-2n), \quad (5)$$

$$s.t. \quad \tau_{k,s} = Q\varphi_{is}/C^k,$$

where Q is a constant and can be set to 1, $\triangle\tau$ is the pheromone increment produced by the k-th ant passing through the s-th TAS terminal set, p represents the volatilization degree of the pheromone, and C^k represents the total benefit value of all TAS selected by the k-th ant. It can be seen from the above formula that the higher the benefit value of TAS, the larger the corresponding pheromone increment. At the next iteration, all ants will calculate the probability of each TAS being selected based on the latest pheromone vector. The calculation method is

$$p_s(k) = \begin{cases} \tau_{a,s}(t)\eta_{\beta,s}(-t), & s \subset tabu(k), \\ -1, & s \not\subset tabu(k). \end{cases} \quad (6)$$

In the dynamic ubiquitous peripheral environment of the Internet of Things, due to the limited resource capabilities of devices such as terminals and links in the network, it is often impossible to undertake all the requested ubiquitous services at the same time. However, there are many types of services in the Internet of Things, with outstanding heterogeneity characteristics, and different services have different requirements for indicators such as delay, bit error rate, and packet loss rate.

5. Analysis of the Development of Industry Models

5.1. The Impact of the Era of Intelligent Interconnection on the Development of Art and Industrial Products. Products will no longer be a combination of engineering structure and CMF, and more and more products are evolving into smart terminals. When we design a new product, it is far from enough to only consider the ergonomics and practical functions of the past. What we are facing is the features and capabilities of computing power, smart application, information interface, interconnection, and cross-border integration. Moreover, they often have a powerful data backend, and continue to provide users with updated and iterative service content. On the other hand, consumers have been integrated with

intelligence and services. Users put forward beautiful experience and simple and easy-to-use expectations for complex smart products, and it is an important task of design to transform complex scientific logic into a beautiful experience. Figure 3 shows the comparison chart of total business benefits.

Intelligent design has been widely and deeply applied in the field of visual communication. Giants such as Alibaba, Jingdong, Google, and Amazon have developed their own computing designs. Among them, the intelligent design robots of Alibaba and JD.com have made great progress in intelligent analysis of user data, automatic generation of pictures, and intelligent push based on user big data. In the field of product design, the integration of user big data and design modules, technical parameters, collaborative platforms, etc., intelligent design is still in its infancy. The integration of IoT and industrial design forms an innovative model of intelligent design.

Intelligent manufacturing puts forward many new requirements for industrial design. Industrial design is changing from the optimization of a single product to the full life cycle of design, production, management, and service. Industrial design is closely related to intelligent manufacturing.

5.2. The Important Role of the Transformation and Upgrading of the Industrial Design Industry in the "Dual Cycle" Strategy. The economy and society are in a dynamic and circular process, and the various elements are closely connected. Only when the elements are communicated smoothly can the economy develop healthily. In view of the current stage of economic development and the internal and external environment of economic development, the Party Central Committee proposed a development situation where domestic economic cycles are the mainstay, and domestic and foreign economic cycles are supplemented by mutual promotion. Therefore, the formulation of industrial design industry development strategies should firmly grasp the "double cycle." Under the long-term downturn of the world economy, grasp the main characteristics of the current turbulent external environment, rising protectionism, and shrinking international markets. Speeding up the "dual cycle" strategy is an important measure for China to stabilize the domestic economic environment and seek development opportunities. The "inner loop" shows China's market size and absolute advantages. Second, the integrity of China's industrial system is not available in other countries. Therefore, expanding domestic demand, increasing domestic market demand, and focusing development on the domestic market can be better. Through the "dual cycle" strategy, China's relative advantages in cooperation and competition with other countries will be enhanced, and domestic economic development will be promoted. Figure 4 shows the comparison of the role of the transformation and upgrading of the industrial design industry in the "dual cycle" strategy.

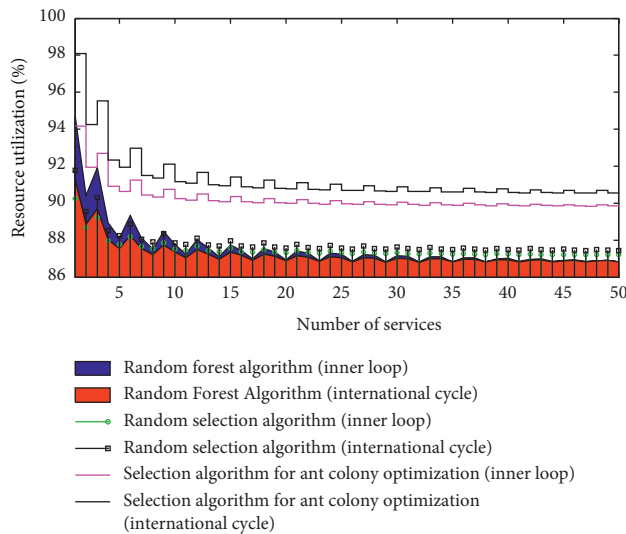
From the perspective of international circulation, excellent industrial design can enhance the international
FIGURE 3: Comparison of total business benefits.


FIGURE 4: Comparison of the role of the transformation and upgrading of the industrial design industry in the "dual cycle" strategy.

competitiveness of domestic independent products, seize a place in the global market, help to promote the development of national innovation level, and enhance national competitiveness. The scale advantage of the industrial design industry has been formed, but there is still huge room for improvement in the quality advantage. Therefore, in order to further enhance China's position in the international industrial chain and ensure the effective circulation of foreign economies in the "postepidemic" era, developing the industrial design industry is an important focus for the development of China's industrial industry.

5.3. The Important Role of the Transformation and Upgrading of the Industrial Design Industry in the Supply-Side and Demand-Side Upgrading.
From the supply side, in order to adapt to the changes in people's consumption concepts, it is necessary to enhance the status of industrial design in

China's economic production. Industrial design can endow products with new added value in consumption upgrades to meet growing consumer demand. Improving the level of industrial design can promote the innovation level of the manufacturing industry. Only continuous innovation can guarantee the competitive advantage of Chinese manufacturing and increase the added value of products. It is not only necessary to increase design investment, but also to focus on the cultivation of design innovation talents, promote design investment, and protect design patents. Figure 5 shows the comparison between the transformation and upgrading of the industrial design industry in the supply-side and demand-side upgrading.

From the demand side, as people's living standards continue to improve today, the transformation and upgrading of the design industry is a huge driving force for the release of effective demand and can promote demand-side changes. With the increasing material and spiritual needs of people, the reform of consumption structure, people are pursuing a high-quality life, so that the design industry has a huge room for development. In order to meet the huge consumer market demand and provide high-quality products and services, continuous innovation is required. While meeting the needs of consumers, it has also stimulated the optimization and upgrading of the design industry, making capital continue to flow to the design innovation industry. The design innovation industry radiates to other industries to increase the added value of other industries and promote the overall innovation and upgrading of China's industrial system. The design industry not only meets consumers' growing material needs, but also meets their spiritual needs. The design industry provides consumers with differentiated and personalized services, while giving consumers a sense of identity, which is a diversification of society and the importance of social relations.

5.4. Analysis Based on the Diamond Model.
Industrial design enterprises are divided into enterprises that provide industrial design services to enterprises that provide industrial design services to industries based on production targets. The former is to directly create economic benefits for enterprises through resource integration, sharing platforms, and technical services, such as professional product design and interaction design enterprises; the latter is to provide design services for enterprises, industries, or industries at the same time, as shown in Table 1.

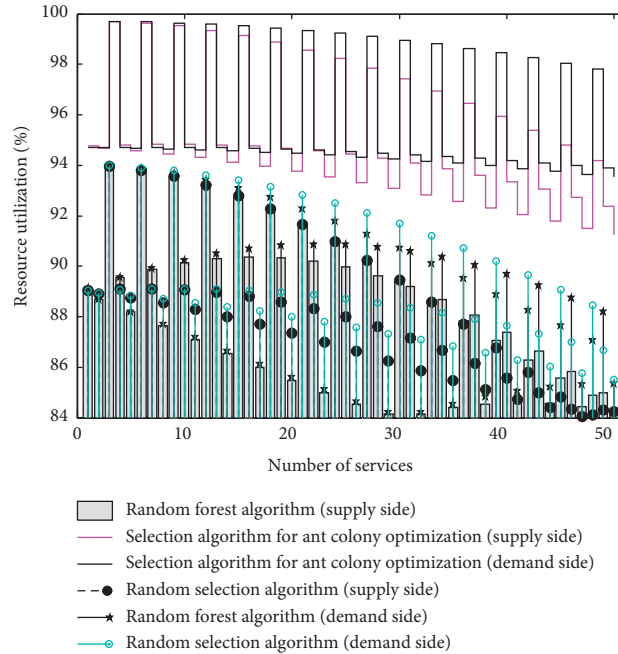
In the era of intelligent interconnection, China's industrial relations and economic structure have undergone drastic changes. Under the new demand and new background of domestic manufacturing development, China's industrial design industry is also facing new plans for industrial structure adjustment and industrial development. In the era of smart interconnection, industrial design will be injected with digital technologies such as smart technology and big data. Industrial design includes the characteristics of innovation and creativity-intensive,


Figure 5: Comparison of the role of industrial design industry transformation and upgrading in supply-side and demand-side upgrading.

Table 1: Classification of industrial design companies.

Classification based on production objects	Classification based on the main body of production	According to the production content as the standard classification
Companies that provide industrial design services for companies	Industrial design service company	An enterprise centered on physical product design
Companies that provide industrial design services for industries and industries	Industrial design collaboration enterprise	An enterprise focusing on information product design
Art industrial product industry model	Industrial design application enterprise	An enterprise centered on product service system design

knowledge-intensive, and other characteristics. The development of industrial design has a powerful role in promoting innovation in the manufacturing industry and the entire country. Based on the diamond model to analyze China's industrial design industry in the era of intelligent interconnection, it can fully position and analyze the development of the industry, make a long-term plan for the healthy development of China's industrial design industry, and highlight the competitive advantage of China's industrial design industry in the world. The factor analysis of China's industrial design industry based on the diamond model is shown in Figure 6.

Internet technologies such as the Internet of Things and big data are widely used, making people's lives more convenient, improving people's work efficiency, and changing people's lifestyles. Under the background of this era, the application of industrial design is particularly important. Through industrial design, high-end technology can become more grounded. At the same time, intelligent technology also promotes the development of industrial design. The intervention of the Internet of Things has changed the way of working in traditional industrial design. Therefore, the industrial design industry should make

corresponding adjustments and upgrades to meet the new demands of consumers in the era of intelligent interconnection. The demand condition analysis of the industrial design industry in the era of intelligent interconnection is shown in Figure 7.

With the development of social economy, the industrial design industry chain has been gradually improved, and related supporting industries and policy planning have also been further improved. Industrial design has gradually formed a good industrial environment. At present, an industrial design industry composed of upstream industries, industrial design industries, and downstream industries has been formed. Related and supporting industries are shown in Figure 8.

Industrial design consulting companies began to transform to "design house" and other models. This model first appeared in the mobile phone industry. They cooperated with software and hardware suppliers and did not require mass production, and paid more attention to development efficiency. They can develop their own conceptual mobile phones, carry out prototype tests, and modify plans according to customer needs to produce small batches in order to cope with the current market situation with urgent
Figure 6: Analysis of China's industrial design industry factors based on the diamond model.

Figure 8: Analysis of related supporting industries in the industrial design industry. (a) Upstream industry. (b) Industrial design industry. (c) Downstream industry.

needs at the time and the shortcomings of domestic enterprises with low R&D capabilities. Industrial design has developed rapidly, and enterprise-level industrial design centers have gradually been established. In addition, these industrial design centers will also provide related design services externally (within the industry).

6. Conclusion

In this paper, the requirements of IoTs device access system are analyzed in detail from functional and nonfunctional perspectives, and the software system is optimized. Some principles that need to be followed in the design have been designed for the system. Based on the dimensionality reduction processing and ant colony optimization algorithm, a multiterminal selection algorithm ACO-MTS for Internet of Things business is proposed, and it is compared with the random allocation algorithm (RS) and greedy in terms of total business benefits, resource utilization, and business success rate. Compared with GA, the algorithm is improved. However, because the simulation experiment was carried out under several premises and assumptions, it failed to simulate the multiservice batch processing scenario, which still has a gap with the actual IoT multiservice request environment; at the same time, the number of evaluation indicators of the benefit function is relatively less. The next step will be to strengthen simulation experiments for multiservice batch processing scenarios and at the same time design more complex benefit functions to lay the foundation for the optimal allocation of resources in the ubiquitous network peripheral environment of the Internet of Things. The study found that the attribute of industrial design purely as a productive service industry has changed. A large number of designers and design companies are transforming from traditional design services to the design industry under the new situation and new opportunities analyzed and researched in the previous article, that is, from selling ideas at a low price. And the solution to the manufacturer is transformed into the integration of industry chain resources through the information network, creating a better and high-quality life for users, and realizing their own value at the same time.

Considering that collision accidents happen sometimes, it is necessary to predict the collision risk to ensure navigation safety. With the information construction in maritime and the popularity of automatic identification system application, it is more convenient to obtain ship navigation dynamics. How to obtain ship encounter dynamic parameters through automatic identification system information, assess ship collision risk, find out dangerous target ships, and give early warning and guarantee for ship navigation safety, is a problem that scholars have been studying. As an index to measure the degree of ship collision risk, CRI, namely, collision risk index, is usually obtained by calculating ship encounter parameters and comprehensive analysis. There are many factors that affect CRI, and the values of many parameters depend on expert judgment. The corresponding CRI has nonlinear and complex characteristics, which is highly correlated with the time sequence. In order to enhance the prediction accuracy and efficiency, PSO-LSTM neural network is applied in the paper to predict CRI. Experiments show that PSO-LSTM neural network can effectively predict collision risk and provide a reference for navigation safety.

1. Introduction

Ship collision accidents are the main type of marine accident, and are more likely to occur in port areas with dense ship traffic. It is usually accompanied by casualties, property losses and marine environmental pollution, which often attracts extensive attention. For example, according to Reference [1], at approximately pm 7:50, Jan.6th, 2018, the Panamanian tanker "Sanchi" collided with the bulk carrier "CF CRYSTAL," resulting in ship sinking, casualties and oil pollution. Due to the serious consequences, people pay special attention to ship collision, which is assessed, forecast and forewarning, so as to avoid the occurrence of collision accidents and reduce the related losses. Some scholars have proposed the ship collision risk index (CRI), which is widely used to quantify the degree of collision risk [2]. Generally, parameters such as DCPA and TCPA are used to quantify ship collision risk [3–5]. Then, the ship domain, which is a safe area around the own ship, is applied to measure the

collision risk [6–9]. In Reference [10], once the target ship enters the own ship's domain, there may be collision risk. With the popularity of AIS data and the convenience of data acquisition, more and more new methods have been used to evaluate ship collision risk. In References [11, 12], AIS data are used to measure the risk level of ship collision in the waters. Reference [13] uses evidence theory to evaluate ship collision analysis. According to Reference [14], the artificial neural network method is used to quantify ship collision analysis. Fuzzy inference method is used to calculate ship collision risk by Reference [15]. In Reference [16], a quantitative assessment algorithm based on SVM technology can obtain collision risk according to ship sailing status. From Reference [17], images are constructed by AIS data, and then a method based on CNN and image recognition is used to classify ship collision risks. In short, with the trend of intelligent navigation, more and more intelligent technologies have begun to be applied in the field of marine transportation to serve and ensure the safety of ship

navigation. Considering that the ship driver not only needs to know the current collision risk of the ship, but also wants to predict the possible risk, it is necessary to predict the collision risk. Taking an example as follows: reference [18] deduces an ordered probabilistic regression model to study perceived collision risk. In Reference [19], the domain method is adopted to carry out dynamic risk warning for ship encounter process.

LSTM neural network, as an excellent deep learning model, has been widely used. An automatic collision avoidance algorithm based on LSTM for ship continuous motion space is proposed in reference [20], and the experiment shows that it is effective. PSO can optimize hyperparameters of LSTM. Therefore, PSO-LSTM neural network can be used for more accurate prediction. For instance, according to reference [21], ship traffic flow prediction is currently faced with problems of high randomness, many influencing factors and low accuracy, so PSO-LSTM prediction model is proposed to improve the prediction accuracy. In reference [22], due to the high randomness and complexity of ships sailing at sea, it is difficult to make accurate prediction. PSO-LSTM is applied in forecast ship's comprehensive posture. Considering that the measurement of collision risk depends on expert judgment, the ship collision risk index has the characteristics of nonlinear, random, empirical, fuzzy and complex, etc. Meanwhile, as ship encounter process parameters are a time sequence with correlation, this paper proposes using PSO-LSTM model for prediction analysis.

The main contribution of this paper is as follows: PSO-LSTM model is applied to predict collision risk. The feasibility of the prediction method is analyzed through the design of single-ship and multi-ship encounter situation experiments. The change characteristics of CRI during ship encounter are studied and visualized. AIS data is collected by ship maneuverability simulator test to ensure the correctness, integrity and synchronization of data, so as to ensure the accuracy of CRI prediction data sources. By comparing with pilot's experience in BRM practical operation test, the conformity of CRI and its prediction with the actual situation is verified.

The rest of this paper is organized as follows: in Section 2, the quantitative methods of collision risk are discussed, including ship collision parameters and fuzzy membership quantification methods. In Section 3, the basic principles of PSO algorithm and LSTM model are introduced, and the ship collision risk prediction model using PSO-LSTM is established. Simulation experiments are taken in Section 4. Finally, the conclusion is drawn in Section 5.

2. Quantitative Method of Ship Collision Risk

At present, ship collision risk quantification methods include the collision theory analytical calculation method, ship domain method, fuzzy mathematics method, artificial neural network method, data statistics method, evidence theory method, support vector machine method, etc. Because collision risk index is a fuzzy concept, the fuzzy mathematical method is widely used. In this paper, AIS data is used to calculate ship encounter parameters. On this basis, CRI is obtained by the fuzzy membership degree, so as to obtain the time sequence data set required for ship collision risk prediction.

2.1. Calculation of Ship Encounter Parameters. In the process of ship encounter, DCAP, TCPA and other parameters are usually used for quantitative analysis, so as to quantify collision risk. Suppose that the own ship's geographic coordinate is (x_o, y_o), the speed is V_O, and the course is φ_o; the geographical coordinate of the target ship is (x_t, y_t), the speed is V_t, and the course is φ_t. The geometric relation of the parameters is shown in Figure 1, and the calculation formula of relevant parameters [23] is as follows: where D is the relative distance (unit: nautical mile), V_r is the relative ship speed (unit: knot), φ_r is the relative heading (unit: degree), and q is the relative bearing (unit: degree). The value of the arc-tangent function needs to be based on the position relationship, and the range is $[0, 360°]$. In Reference [24], DCPA is the minimum encounter distance (unit: nautical mile), and TCPA is the minimum encounter time (unit: minute). Considering the calculation requirements of the membership function, DCPA and TCPA are greater than zero in this paper, and absolute values are taken when there are negative values.

$$D = \sqrt{(x_t - x_o)^2 + (y_t - y_o)^2},$$

$$V_r = V_O \sqrt{1 + \left(\frac{V_t}{V_O}\right)^2 - \frac{2V_t}{V_O}\cos(\varphi_t - \varphi_o)},$$

$$\phi_r = \cos^{-1}\left(\frac{V_O - V_t\cos(\varphi_t - \varphi_o)}{V_r}\right),$$

$$q = \arctan\left(\frac{x_t - x_o}{y_t - y_o}\right),$$

$$\text{DCPA} = D.\sin(\phi_r - q - \pi),$$

$$\text{TCPA} = D.\cos\frac{(\phi_r - q - \pi)}{V_r},$$

$$\tag{1}$$

DCPA and TCPA are the main parameters used to measure collision risk. When DCPA and TCPA are less than the safety value, there may be a collision. However, to obtain the collision risk, it is not enough to consider only DCPA and TCPA. Other factors, such as distance and relative orientation, etc., should also be considered.

2.2. CRI and Membership Function. CRI is used to measure ship collision risk. Usually, the value range can be $[0, 1]$. The higher the value, the more dangerous it is. DCPA, TCPA, D, q and k (ratio of the speeds of the other and own ship) can be used as the constituent index to measure collision risk, which is obtained by weighting the membership degree in fuzzy mathematics. This paper refers to the membership
FIGURE 1: Geometric relation diagram of ship encounter parameters.

function in Reference [13] and the weighting coefficient which is the survey results of the experts in Reference [25].

The membership function and weighting coefficient of the above parameters are as follows:

$$
\mu(\text{DCPA}) = \begin{cases} 1, & \text{DCPA} \leq d_1, \\ \dfrac{1}{2} - \dfrac{1}{2}\sin\left[\dfrac{\pi}{d_2 - d_1}\left(\text{DCPA} - \dfrac{d_1 + d_2}{2}\right)\right], & d_1 < \text{DCPA} < d_2, \\ 0, & d_2 \leq \text{DCPA}, \end{cases} \tag{2}
$$

$$
\mu(\text{TCPA}) = \begin{cases} 1, & \text{TCPA} \leq t_1, \\ \left(\dfrac{t_2 - \text{TCPA}}{t_2 - t_1}\right)^2, & t_1 < \text{TCPA} \leq t_2, \\ 0, & t_2 < \text{TCPA}, \end{cases} \tag{3}
$$

$$
\mu(D) = \begin{cases} 1, & 0 < D \leq D_1, \\ \left(\dfrac{D_2 - D}{D_2 - D_1}\right)^2, & D_1 < D \leq D_2, \\ 0, & D_2 < D, \end{cases} \tag{4}
$$

$$
\mu(q) = \dfrac{17}{44}\left[\cos(q - 19^\circ) + \sqrt{\cos^2(q - 19^\circ) + \dfrac{440}{289}}\,\right], \tag{5}
$$

$$
\mu(k) = \dfrac{1}{1 + (k_0/k)^2}, \tag{6}
$$

where d_1 is the minimal safe encounter distance, and d_2 is the absolute safe encounter distance in (2). t_1 and t_2 are the time to reach the corresponding positions of D_1 and D_2 by relative motion in (3). D_1 is the latest steering distance, and D_2 is the moving boundary in (4). The above parameters are calculated according to Reference [12] and Reference [23]. In (5), when q is equal to 19°; the collision danger degree is the highest. k_0 is usually taken as one in (6).

Weighting the membership degree of the above parameters, the collision risk index formula is as follows:

$$
\text{CRI} = \mu(\text{DCPA}) * w_1 + \mu(\text{TCPA}) * w_2 + \mu(D) * w_3 + \mu(q) * w_4 + \mu(K) * w_5, \tag{7}
$$

where the values of weight coefficients $w_1, w_2, w_3, w_4,$ and w_5 are 0.36, 0.32, 0.14, 0.10, and 0.08, respectively.

3. Collision Risk Prediction Model

3.1. LSTM Model. LSTM neural network, namely long and short memory neural network, is an improved network of RNN [26]. According to Reference [27], LSTM model can remember past information and store it for a long time by adding additional memory units, which has strong generalization ability, good learning ability for both large and small data sets, and strong advantages in dealing with nonlinear problems. LSTM model can reflect the time dependence and correlation in time sequence data of AIS date and predict ship collision risk. The main structure of LSTM model has three gates. Its basic structure is shown in Figure 2.

The forget gate f_t determines the information to be discarded and retained according to the unit state C_{t-1} at the previous moment, and the input x_t determines the value to be updated through σ and tanh respectively and generates new candidate values for updating [27]. The value after the updating operation will be updated together with the Forget Gate f_t, and the updated unit state C_t is computed with the tanh function and Output Gate o_t and then outputs h_t [28]. The state update equation of LSTM basic unit are equations (8)–(13).

$$f_t = \sigma\left(W_f.[h_{t-1}, x_t]\right) + b_f, \tag{8}$$

$$i_t = \sigma\left(W_f.[h_{t-1}, x_t]\right) + b_i, \tag{9}$$

$$a_t = \tanh\left(W_c.[h_{t-1}, x_t]\right) + b_c, \tag{10}$$

$$C_t = f_t.C_{t-1} + i_t.a_t, \tag{11}$$

$$o_t = \sigma\left(W_o.[h_{t-1}, x_t]\right) + b_o, \tag{12}$$

$$h_t = o_t.\tanh\left(C_t\right), \tag{13}$$

where x_t is the input at time t; f_t, i_t, o_t represent forget, input and output gate respectively. a_t is the input node state at the corresponding moment; C_{t-1} and C_t are the unit states at the corresponding moment. h_{t-1} and h_t are the outputs at corresponding moment. σ is the sigmoid activation function, and tanh is a hyperbolic tangent function [28]; $W_f, W_i, W_c,$ and W_o and $b_f, b_i, b_c,$ and b_o are the corresponding weight matrices and offsetting vectors.

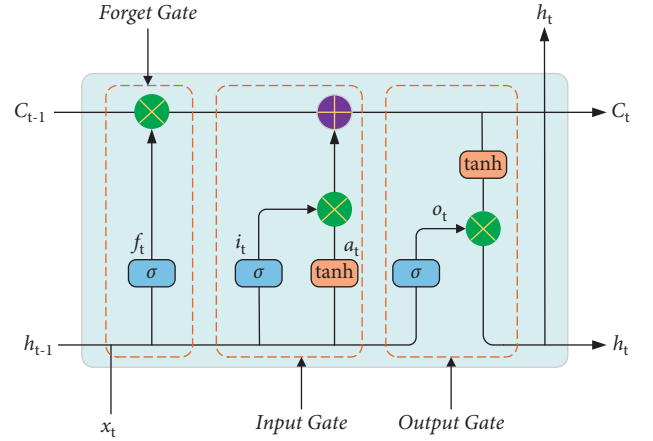
3.2. PSO Algorithm. PSO algorithm is an optimization technology proposed according to the foraging behavior of birds, which updates the formula with speed to make the particles in the population constantly close to the historical optimal value [29]. Firstly, the particle is given an initial velocity and position information in the solution space in a random way, and then the local and global optimal solutions are tracked and their velocities and positions are updated in time through the defined Fitness function. In this process,


FIGURE 2: Basic structural unit of LSTM.

the Fitness value is calculated through each iteration, so as to achieve the set target Fitness value, and then the optimal solution can be obtained.

In the search space, several particles form a population, and after the t iteration, the velocity and position of particles are formed, which are represented by $X_{i,t}$ and $V_{i,t}$ respectively. During the search process, the position and velocity are updated constantly, and two optimal solutions are formed: one is the individual extremum $pbest_i$, and the other is the global optimal solution $gbest_i$. In the process of searching for the optimal solution, the particle updating formulas of velocity and position [30] are (14) and (15), respectively.

$$\begin{aligned} X_{i,t+1} = {}&\omega X_{i,t} + c_1 \text{rand}\left(pbest - X_{i,t}\right) \\ &+ c_2 \text{rand}\left(gbest - X_{i,t}\right), \end{aligned} \tag{14}$$

$$X_{i,t+1} = X_{i,t} + \lambda V_{i,t+1}, \tag{15}$$

where ω is the inertia factor; c_1 and c_2 are individual and global learning factors, respectively. *rand* is a random number in $[0, 1]$. λ is the velocity coefficient.

3.3. PSO-LSTM Model for Collision Risk Prediction. As hyperparameters greatly impact on the results, PSO algorithm can improve the accuracy of LSTM model by optimizing parameters [31]. The flow chart of PSO-LSTM prediction model is shown in Figure 3. The steps are as follows:

Step 1: According to the AIS data, the ship motion parameters are obtained and the ship encounter parameters are calculated.

Step 2: CRI is obtained by calculating the membership function value and weight coefficient by fuzzy mathematics, and the training and test data are constructed according to the time sequence. Since the range of CRI is already $[0, 1]$, normalization is not required.
Figure 3: Flow chart of collision risk prediction by PSO-LSTM model.

Step 3: The particle swarm parameters are initialized, including the population size, maximum number of iterations, learning factor, particle positions and velocity ranges [32]. Meanwhile, the hyperparameters of LSTM neural network are initialized, including the number of hidden layer neurons, the learning rate, the maximum number of iterations of LSTM network, and the number of steps in the input layer.

Step 4: The LSTM model is established, which is trained with the data of the training set. The results are compared with the training set, and RMSE is used as the Fitness function in PSO algorithm. The calculation formula is as follows:

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^{n} \left(\hat{Y}_i - Y_i \right)^2}, \tag{16}$$

where Y_i and $\hat{Y}_i$ are the real value of the CRI time sequence and the corresponding predicted value of the model respectively.

Step 5: The global optimal position *gbest* and local optimal position *pbest* are determined by the initial Fitness value of the particles [33], and they are regarded as the historical optimal positions. According to the speed and position of the updated particles, the corresponding particle Fitness

value is calculated and then updated to improve the prediction accuracy.

Step 6: The termination condition is judged to be satisfied (the Fitness value of particles tends to be stable or reaches the maximum number of iterations with iteration [33]). If the termination condition is satisfied, optimal parameters are assigned to PSO-LSTM model; otherwise, step (4) is returned.

Step 7: PSO-LSTM prediction model is constructed from the optimal parameter values, which is applied to predict CRI of the test sets. The predicted result curves are drawn, and the ship collision risk is visualized.

4. Experiment

This paper is based on AIS data of pilot's BRM (bridge resource management, which is included in the Mandatory Enforcement Part A of the STCW convention by IMO in 2010) practice test on ship handling simulator, and the actual operation site is shown in Figure 4. The main reasons for choosing the ship maneuvering simulator for the test are as follows: first, different encounter situations are simulated by setting the same environmental parameters. In the case of the same other conditions, interference is eliminated so as to compare the difference of different encounter situations. Second, the AIS data collected by the simulator have a complete structure and high data frequency, which can well solve the problem of a lack of AIS data and time synchronization. All these are conducive to better process analysis. Finally, experienced pilots perform practical operation experiments, which can not only ensure the professionalism of the experiment, but also ask pilots how they feel in the process of ship encounter, which can be verified and compared with the results of the test data analysis. In addition, the disadvantages of the simulator test also need to be explained, mainly as follows: the environmental conditions in a certain water area are relatively fixed, and are not as complex as the actual water area. The pilot's sense of urgency for dangerous situations is not as strong as the actual situation, which has a certain influence on the judgment of collision risk.

Through data acquisition and processing, ship encounter parameters and fuzzy collision risk index are calculated, PSO-LSTM network is trained to predict CRI, and single-ship encounter situation and multi-ship encounter situation tests are carried out. Considering that disadvantage of PSO-LSTM neural network is that it requires a long period of training, it is necessary to set reasonable parameters to avoid PSO optimization parameter setting too large search range and iteration times, to improve operation efficiency. Therefore, during the experiments, the PSO parameters are set as follows: the learning factors c_1 and c_2 are both set to 2, the range of the inertia factor ω is from 0.8 to 1.2, the maximum number of evolution is 20, and the size of the particle population is 5.

The selected water area for the test is the approach channel of Shanghai Yang Shan Port. The main reasons for

FIGURE 4: Pilot's actual operation in ship handling simulator.

the test in this area are as follows: Shanghai Yang Shan Port is a world-famous container terminal, and its inbound and outbound channels have certain typicality. At the same time, due to the large scale of navigable ships, the navigation safety of their waters is also a concern. The parameters of the own ship and target ships are shown in Table 1. The environmental parameters are shown in Table 2, which need to be marked, because environmental conditions, especially strong winds and waves, will affect the navigation difficulty of ships, affect the pilots' judgment of collision risk, and then affect the generation and prediction results of training datasets.

4.1. Single-Ship Encounter Experiment. AIS data are collected with an interval time of 6 seconds during the encounter between ship OS01 and ship TS05. In the experiment, approximately 255 groups of data is collected and processed, with the first 175 groups of data as training sets and the others as test sets. A complete group of data includes AIS data of the two ships, encounter parameters calculated by the formula, and CRI calculated by the fuzzy method. Taking 10 groups of data as time intervals, corresponding to one minute, are used in the rolling window. After the training and testing PSO-LSTM network, the experimental result curves of DCPA, TCPA and CRI and Fitness, etc., are smoothed and the relevant curves are drawn as follows:

Analysis of the single-ship experiment results is as follows:

(1) Figure 5 reflects the track of ship OS01 and ship TS05 in the encounter process. The arrow represents the direction of the track, and the colour filled in track dots of the target ship TS05 reflects CRI which is obtained according to the Fuzzy calculation method. It can directly reflect the change in collision risk in the encounter process. The redder the colour is, the more dangerous it is.

(2) From Figure 5, the risk index of the target ship leaving the port turns red many times during the encounter with its own ship, indicating that the collision risk of the target ship increases significantly during the close encounter. At this time, the ship's pilot needs to be vigilant and pay close attention to the dynamics of the target ship in the encounter until it passes clear.

(3) According to Figures 6 and 7, in the process of ship encounter, DCPA and TCPA decrease and then increase rapidly as the two ships get closer and farther away. The corresponding collision risk also increases and then decreases.

(4) The Fitness curve in the training process of PSO-LSTM network is reflected in Figure 8, which is also the RMSE convergence process. The experiment shows that the deviation is rapidly reduced and stable in the iterative optimization process of PSO, and PSO-LSTM network training process is effective.

(5) The deviation of PSO-LSTM test prediction results is reflected in Figure 9, which indicates that the CRI prediction accuracy of PSO-LSTM is high, and the overall deviation range is ±0.1.

(6) Figure 10 intuitively reflects the prediction effect of PSO-LSTM model by comparing the original data, the predicted data of training process and the predicted data of testing process. The experimental results show that PSO-LSTM model has strong prediction ability and good prediction effect. It also shows that PSO-LSTM model can be well adapted to ship collision prediction in single-ship encounter situation.

(7) Figure 11 shows the visualization of CRI prediction results. The changes of CRI in ship encounter can be intuitively seen in relative coordinates, where the arrow is the velocity vector of the target ship TS05. From the figure, it can be easily found that when ship TS05 approaches ship OS01, its CRI increases rapidly, and the colour of the position point of ship TS05 turns red rapidly.

(8) After the experiment, the pilots are consulted about their feelings. In the process of meeting with the target ship TS05, the pressure is obviously felt when approaching, which is due to the close distance and the large ship size. The psychological danger perception of the driver at that time is consistent with the situation reflected by the CRI curve in this test.

4.2. Multi-Ship Encounter Situation Experiment. References for the single ship test, the same test parameters are set except for the target ship. AIS data are collected with an interval time of 6 second during the encounter between

TABLE 1: Main parameters of the ships in experiments.

AIS number	Attribute	Length (m)	Width (m)	Draught (m)	Ship type	Encounter situation
OS01	own ship	274.7	40	10	5000TEU container ship	—
TS05	Target ship	347	42.8	14.4	8000TEU container ship	Head-on
TS08	Target ship	81.8	13.8	4.4	3000 ton river ship	Starboard crossing
TS19	Target ship	263.2	32.2	8.5	3000TEU container ship	Portside crossing

TABLE 2: Environmental parameters during the simulation test.

Wind direction (degree)	Wind scale	Flow direction (degree)	Flow velocity
45	Level 4	310	1 knot
FIGURE 5: Visualization of collision risk between ship OS01 and ship TS05 with head-on situation.
FIGURE 6: DCPA curve of single-ship encounter process.

ship OS01 and ships TS08 and TS19. In the experiment, approximately 255 groups of data is collected and processed, with the first 175 groups of data as training sets and the others as test sets. Taking 10 groups of data as time intervals, corresponding to one minute, are used in the rolling window. After the training and testing PSO-LSTM network, the
FIGURE 7: TCPA curve of single-ship encounter process.
FIGURE 8: Fitness curve of PSO-LSTM training process.
FIGURE 9: CRI deviation curve of PSO-LSTM prediction.

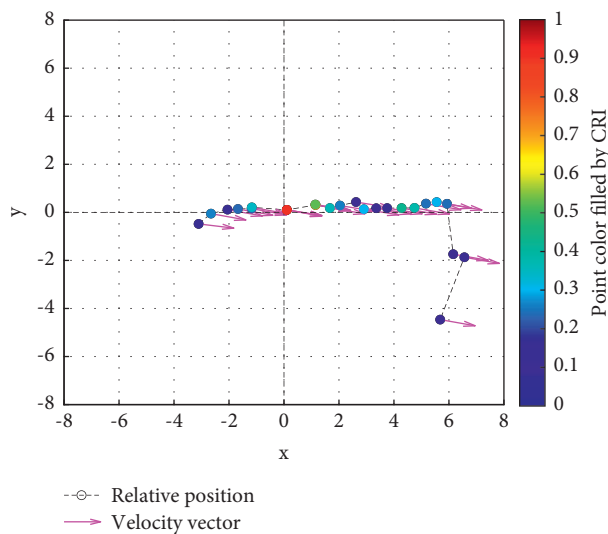

Figure 11: Visualization of collision risk prediction of ship TS05 in relative coordinates of own ship center.

experimental result curves of DCPA, TCPA, CRI and Fitness, etc., are smoothed and the relevant curves are drawn as follows:

The analysis of the multi-ship experiment results is as follows:

(1) Figure 12 reflects the track of the ship and the target ships TS08 and TS19 in the encounter process. According to the colour changes of the position points, the CRI of the target ship TS08 is relatively stable, and the risk increases slightly when the target ship crosses and approaches the own ship from the starboard side, indicating that the collision risk is small. By comparison, the CRI of the target ship TS19 changed relatively greatly, resulting in several sudden increases. In the process of the target ship crossing and approaching from the port side, the corresponding position points turned red several times, indicating the danger of collision. The pilot needs to pay attention to the target ship TS19 until it passes and clears. In the experiment, the overall collision risk of the target ship from the port side is greater than that of ship from the starboard.

(2) Figures 13 and 14 reflect the change characteristics of the DCPA and TCPA, respectively, in the process of multi-ship encounter. By comparison, it is found that with the approach and departure of the target ship, the TCPA decreases roughly and then increases rapidly, while the DCPA shows the characteristics of fluctuation.

(3) In Figure 15, the Fitness curves of target ships TS08 and TS19, also known as RMSE curves, can converge, indicating that the training process of PSO-LSTM is
FIGURE 12: Visualization of collision risk in multi-ship encounter situation.
FIGURE 13: DCPA curve of multi-ship encounter process.

effective and that the deviations are gradually reduced under the action of PSO optimization. The Fitness curves show that starboard ship is faster than port ship in PSO optimization and that deviation convergence is faster.

(4) In Figure 16, the CRI prediction curve analysis of the test set shows that the prediction accuracy of PSO-LSTM is high, with the starboard prediction deviation range of ±0.05 and port prediction deviation range of ±0.15.

(5) Figures 17(a) and 17(b) show the performance of PSO-LSTM in the training and testing processes.

There is a high degree of fit between the results and the original data, and the predicted results are close to the actual ones. The results show that PSO-LSTM can effectively and accurately predict ship collision risk, and adapt to the CRI prediction of multi-ship encounter situation.

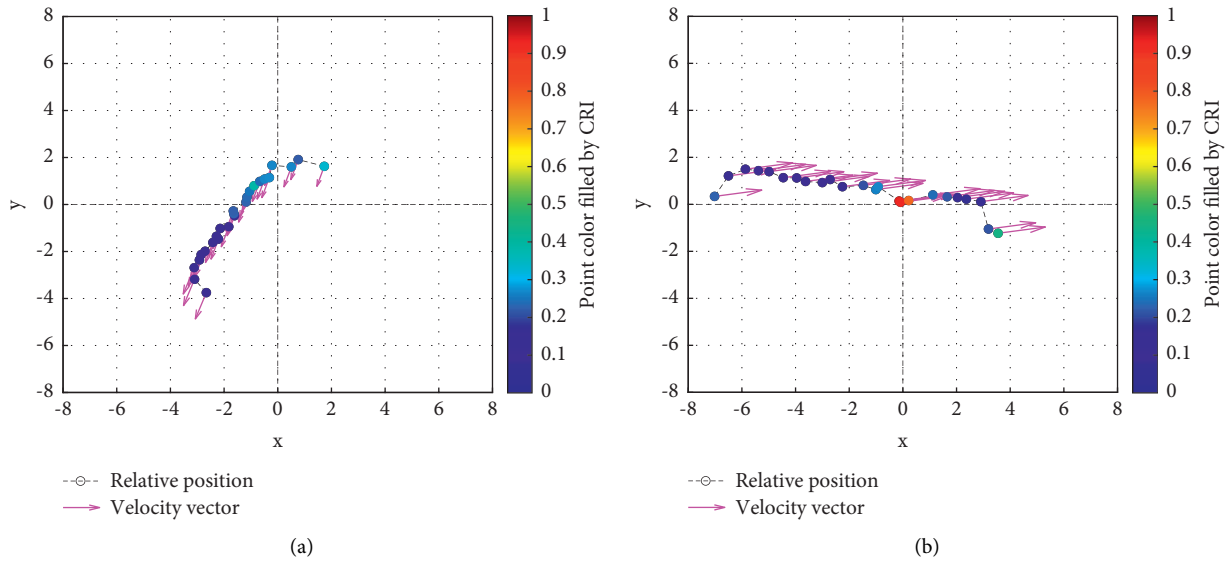
(6) In Figures 18(a) and 18(b), the CRI change process of target ships TS08 and TS19 is visualized. Figure 18(a) shows that when ship TS08 passed the bow of ship OS01, CRI rapidly and gradually decreased and remained at a low level, indicating a low overall risk. From Figure 18(b), during the encounter between
FIGURE 14: TCPA curve of multi-ship encounter process.
FIGURE 15: Fitness curve of PSO-LSTM training process.
FIGURE 16: CRI deviation curve of PSO-LSTM prediction.
FIGURE 17: Predictive results of CRI in training and testing. (a) Target ship TS08 from Start broad. (b) Target ship TS19 from Portside.


FIGURE 18: Visualization of collision risk prediction in relative coordinates of own ship center. (a) Target ship TS08 from Start broad (b) Target ship TS19 from Portside.

the target ship TS19 and the own ship, there is a very close process, and CRI turns red many times, so there is a collision risk, which should be considered.

(7) After the experiment, the pilots are consulted about their feelings. During the course of the ship encounter, they clearly felt that the ship from the portside was more urgent, closer and more dangerous, which is consistent with CRI and its prediction.

5. Conclusion

Collision risk analysis is an important for ship navigation safety assurance. It is necessary to make collision risk forecast and forewarning. CRI, namely ship collision risk index, is mostly considered with DCPA, TCPA and other parameters in the process of ship encounter. These parameters are time sequences, which in performance before and after time are interrelated, and the corresponding CRI also shows time correlation characteristics. The rolling

prediction mechanism and time memory ability of LSTM model can well reflect the related characteristics. PSO algorithm can optimize the hyperparameters of LTSM model, and better prediction results can be obtained. In this paper, through single-ship encounter and multi-ship encounter tests, PSO-LSTM model was used to obtain good results in CRI prediction. The Fitness curve of PSO in the training process converges rapidly, and the prediction deviation range of the test results is small. The results show that PSO-LSTM model can adapt to complex encounter situations and show high efficiency and accurate ship collision risk prediction.

In the future, we will consider using the multi-ship prediction capability of PSO-LSTM model to access real-time AIS data, and train a more powerful network through massive data learning to provide assistance for collision risk prediction for ship pilots earlier and in a timely manner. In addition, combined with the external environment, the deep learning model will be more effective in predicting and warning ship collision hazards. It is believed that with the development of navigation intelligence in the future, more intelligent deep learning methods will be more widely applied in the navigation field to ensure navigation safety and promote the development of the unmanned vessel and navigation intelligence.

Sciatica has been widely studied, but the association of sciatica with immune infiltration has not been studied. We aimed to screen key genes and to further investigate the impact of immune infiltration in patients with sciatica. The bioinformatics analyzes were performed based on the GSE150408 dataset. Subsequently, we used CIBERSORT to study the immune infiltration in the disease group. Results showed that 13 genes were with differentially expressions in the sciatica group compared to healthy participants, including 8 up-regulated and 5 down-regulated genes. Through the LASSO model and SVM-RFE analysis, a total of 6 genes have intersections, namely SLED1, CHRNB3, BEGAIN, SPTBN2, HRASLS2, and OSR2. The ROC curve area also confirmed the reliability of this method. CIBERPORT analysis showed that T cell gamma delta infiltration decreased and neutrophil infiltration increased in the disease group. Then the association of these six key genes with immune infiltration was further verified. We found six overlapping genes and found that they were closely associated with the total immune infiltration in the sciatic nerve disease group. These findings may provide new ideas for the diagnosis and therapeutics of patients with sciatica.

1. Introduction

Sciatica is commonly caused by lumbar disc herniation involving peripheral neuropathy [1, 2]. According to statistics, the incidence of sciatica in one's life is as high as 40%. The common treatment methods for sciatica include nonsurgical conservative treatment and nonsurgical treatment. 90% of acute sciatica can be effectively relieved by nonsurgical treatment [3].

Proteomic analysis has identified proteins related to sciatica or intervertebral disc degeneration, which may be involved in the pathophysiological process of sciatica [4]. It is generally believed that mechanical compression combined with immunity and inflammation can lead to sciatica during lumbar disc herniation. Many cytokines related to immunity and inflammation are activated in lumbar disc herniation [5, 6].

In this study, we used two machine learning methods to explore and identify the key genes of patients with sciatica and preliminarily analyzed the immune cell infiltration.

Then further evaluate the correlation between immune cell infiltration and the central gene in sciatica so as to provide new research ideas for the treatment and early detection of sciatica.

2. Materials and Methods

2.1. Screening of Differentially Expressed Genes (DEGs). We downloaded GSE150408 in the GEO database (https://www.ncbi.nlm.nih.gov/geo/). The platform of the GSE150408 mRNA microarray is GPL21185, which was used for the following analyzes.

2.2. Identification of Feature Gene. The feature genes were screened by two machine learning algorithms, least absolute convergence and selection operator (LASSO) and support vector machine-recursive feature elimination (SVM-RFE) and validated in the validation dataset. Machine learning is a new type of algorithm analysis tool. This

study used the method of machine learning to identify features for algorithm analysis. Two machine learning algorithms, LASSO and SVM-RFE, were applied for marker screening. LASSO is a regression algorithm regularized through "*glmnet*" package in R. SVM-RFE is a supervised learning technique that can rank features based on recursion. We adopted the "e1071" package to complete the SVM algorithm.

2.3. Analyzes of Immune Infiltration. The CIBERSORT deconvolution algorithm was adopted for the estimation of different immune cell proportions. Totally, we obtained twenty-two types of immune cells. CIBERSORT filters data with $p < 0.05$. We then calculated each immune cell type's percentage and displayed it as a bar graph. The "pheatmap" package was adopted for the construction of the heat map of the twenty-two types of immune cells. Comparisons of levels of the twenty-two types of immune cells were done using a package.

2.4. Statistical Analysis. Analyzes of the association of immune cells with feature genes were performed using Spearman's rank via *R* software. We used the "ggplot2" package for the visualization of the plot. $P < 0.05$ indicated statistically significant.

3. Result

3.1. Diagnostic Feature Biomarkers Screening. After removing the batch effects, thirteen DEGs were screened out: 8 significantly up-regulated and 5 significantly down-regulated (Figures 1(a) and 1(b)). Using the LASSO regression algorithm, we found 8 potential Figure 1(b) variables for the disease group (Figure 2(a)). A total of thirteen features were determined in Figure 2(b). SLED1, CHRNB3, BEGAIN, SPTBN2, HRASLS, and OSR2 were finally selected in Figure 2(c). Then, ROC was performed for the evaluation of the value of the prediction of the 6 characteristic genes. The AUCs for all 6 genes were greater than 0.8 (Figure 3(a)). It showed that the characteristic biomarkers have a high diagnostic ability, Figure 3(f).

3.2. Analyzes of Immune Infiltration. Immune infiltration in control and sciatica groups was explored with the twenty-two subpopulations of immune cells. The percentage of the twenty-two types of immune cells was visually displayed in Figure 4(a). CIBERPORT analysis showed that T cells gamma delta infiltration decreased and the degree of neutrophils infiltration increased in the sciatica group (Figure 4(b)).

3.3. Relationship of Central Genes with Immune Cells. As shown in Figure 5(a), SLED1 was related to macrophages M0 ($R = 0.38$, $P = 0.025$), B cells memory ($R = 0.42$, $P = 0.014$), neutrophils ($R = 0.56$, $P = 0.00073$) positively and correlated with monocytes ($R = -0.43$, $P = 0.011$), T cells gamma delta ($R = -0.53$, $P = 0.0016$) negatively. CHRNB3 was positively

associated with T cells gamma delta ($R = 0.72$, $P = 3.8e - 06$) and negatively associated with neutrophils ($R = -0.39$, $P = 0.022$), T cells CD4 naive ($R = -0.45$, $P = 0.0081$) (Figure 5(b)).

SPTBN2 had a positive correlation with CD4 memory-activated T cells ($R = 0.38$, $P = 0.025$) and a negative correlation with neutrophils ($R = -0.37$, $P = 0.033$), T cells (CD4 naïve) ($R = -0.41$, $P = 0.017$) (Figure 5(d)). CHRNB3 had a positive correlation with gamma delta-T cells ($R = 0.72$, $P = 3.8e - 06$) and a negative correlation with neutrophils ($R = -0.39$, $P = 0.022$). No correlation was found between BEGAIN, HRASLS2, OSR2, and immune cell infiltration (Figures 5(c)–5(f)).

4. Discussion

So far, there is no specific diagnostic method for sciatica. Combining medical history with a physical examination is the most common diagnostic method [7]. As a common clinical syndrome, sciatica is caused by two causes: one is internal and the other is external factors [8, 9]. When sciatica occurs, it often causes pain in the legs, back and below the knee, usually accompanied by tingling in the legs, numbness or muscle weakness [10, 11].

This study showed that 13 genes were differentially expressed in patients with sciatica. Through two methods, we identified six key genes, which are SLED1, CHRNB3, BEGAIN, SPTBN2, HRASLS2, and OSR2. We determined the association of these differentially expressed genes and immune infiltration in patients with sciatica. CIBERPORT analysis showed that T cell gamma delta infiltration decreased and neutrophil infiltration increased in the sciatica group. Up to now, there has still been a lack of research on brain-enriched guanylate kinase-associated protein. Studies have shown that brain-enriched guanylate kinase-associated protein participates in chronic pain. We demonstrated in the SNI model that mechanical abnormal pain, an abnormal pain condition caused by harmless stimuli, was significantly attenuated in BEGAIN deficient mice [12, 13]. Another key gene found is SPTBN2. It is the research on SPTBN2. At present, it is mainly used in research on congenital cerebellar ataxia and various cancers. In the study of cancer, miR-424-5p was found to be able to accelerate the development of endometrial cancer through regulating SPTBN2 and then the cldn4/PI3K/Akt axis [14–16]. Combined with bioinformatics and cell experiments, SPTBN2 may become a novel target of lung adenocarcinoma. SPTBN2, highly expressed in LUAD, might indicate poor prognosis. Cell experiments confirmed that SPTBN2 could promote the proliferative, migrative, and invasive abilities of LUAD cells [17].

The researchers found that glia was significantly activated in the brains of patients who experienced chronic pain, indicating that immune cells can spread and maintain disease states, including neuropathic pain, through communication with neurons rather than being regarded as bystanders [18]. During nerve injury, neuronal activity will be activated, resulting in the recruitment of monocytes/macrophages (peripheral) to the injured site. At the same

time, microglia will release inflammatory-related mediators after activation, resulting in neuronal sensitivity [19].

The signal molecules of the immune system are cytokines. An increase of proinflammatory cytokines is related to the existence of pain after nerve injury, while antiinflammatory cytokines are related to the down regulation of the immune system and the relief of neuropathic pain

[20, 21]. Immune system activation has been shown to promote and increase neuropathic pain [22].

Immune cells play an important role in different pathophysiological processes in the state of neuropathic pain. It brings the pain field to different directions and provides opportunities for new methods for the treatment of chronic pain.
(a)
(b)

Figure 4: Visualization and evaluation of immune cell infiltration: (a) relative percentage of 22 kinds of immune cells, and (b) immune cells' violin plot image.

However, there are still some limitations to the present study. This is a purely bioinformatics study without further experiments for validation, which weakened the evidence level of our results. In the future, we will conduct in vivo and in vitro assays to further explore the exact effects of the abovementioned immune-related genes and the potential underlying mechanisms on sciatica.

Figure 5: Correlation analyzes between immune cells and SLED1, CHRNB3, BEGAIN, SPTBN2, HRASLS2, and OSR2. (a) Association of SLED1 with immune cells. (b) Association of CHRNB3 with immune cells. (c) Association of BEGAIN with immune cells. (d) Association of SPTBN2 with immune cells. (e) Association of HRASLS2 with immune cells. (f) Association of OSR2 with immune cells.

5. Conclusions

In summary, we systematically discussed the functions of immune-related genes of sciatica and provided new ideas for new methods for the treatment of chronic pain.

The traditional E-government big data system fills and classifies algorithms with low accuracy and poor work efficiency. With the development and wide application of big data, the internet of things, and other technologies, the integration of information resources has become the key to information construction. In the process of information resource integration, there are still outstanding problems such as incomplete government information resource system, different standards of government information resource management system construction, and serious threats to network and information security. In order to solve this problem, a new E-government big data system filling and classification algorithm is studied in the cloud computing environment; E-government big data filling is carried out on the basis of complete compatibility theory; and the E-government big data computing intelligence system in the cloud computing environment is constructed and its development impact, so as to parallelize the data, classify the data through decision trees, and realize incremental update decision forest parallelization processing. To verify the effectiveness of the method, comparative experiments are set, and the results demonstrate that experiment one is randomly built into the classification model, and according to the decision forest algorithm, the optimal number of decision trees is 24.

1. Introduction

With the rapid development and widespread use of big data technology, people are increasingly optimistic about the future of big data [1]. In particular, the increasing volume of data in recent years has made it difficult for existing software to process it effectively, and the quality of big data makes "big data" technology stand out from the crowd. Big Data can help people extract valid information from large amounts of data quickly and help them get answers quickly [2]. McKinsey & Company, the first to coin the phrase "big data era," has pointed out that data is everywhere and that its value today is not just information but also a factor of production. Deeper mining and organization of data can help people obtain data products. "Big data strategy" is also

on the agenda with the widespread use of big data [3]. Big data technology can be used to collect, process, and handle large amounts of data and analyze them from a professional perspective. People can obtain valuable information.

The use of big data technology for the construction of government information resources integration began to involve the construction of the platform, the construction of the information security system, the promotion of big data awareness, and other aspects, not a quick fix [4]. Big datum is more active in the construction of platforms, and many local governments are building local big data platforms to integrate government information resources across platforms and data types through the construction of big data platforms [5]. Big data platforms can help us gather a large amount of data and analyze and evaluate these data [6]. We

can understand the meaning behind these data. If we just look at the data, it is sometimes difficult to get useful information from it. Big data platforms help managers change the way they used to make decisions based on personal experience and personal knowledge, and through the analysis of data, decisions can be justified, and decision-makers can quickly understand the situation through data analysis [7].

Although big data technology is widely used in the integration of government information resources, there is still a lack of big data awareness in the concrete implementation [8]. Although claiming to use big data to solve problems, the original approach is still used in problem-solving. All these show a lack of awareness of big data and the need to fundamentally understand the importance of big data and the position it occupies in the process of government transformation. At the same time, data security has become an inescapable issue as we make extensive use of data today [9, 10]. The nature of big data allows it to respond quickly to government information, which is why it is so effective in advancing the integration of government information resources so quickly.

The amount of data in the data centre is huge; therefore, it is necessary to improve the efficiency of data processing. Therefore, the paper proposes an E-government big data system filling algorithm to address the problem of data loss that occurs when the government uses the E-government big data system, which solves the problem of missing data, and proposes a parallel optimization of E-government big data system filling based on the cloud computing environment, which greatly improves the efficiency of filling missing data [11]. A new classification model for E-government big data systems in a cloud computing environment is constructed in the paper. By using a decision forest algorithm to classify and process huge data and incremental update processing of the decision forest algorithm, the big data system can continuously change its model according to the continuous change of data, and finally, the parallel optimization of the algorithm is carried out, which makes the processing efficiency greatly improved [12]. The results of the experimental demonstration of the proposed method show that the E-government big data system in the cloud computing environment proposed in the paper has great advantages over the algorithms used in the traditional way.

2. Related Work

The application of big data in government information integration will promote efficient use and innovation of government information [13]. In conclusion, big data are data that transcend traditional data analysis and processing capabilities and are difficult to apply to existing database architectures, and traditional software tools are difficult to access, store, manage and analyze, and thus, new tools and processing methods should be adopted. At the same time, big data are changing the traditional sampling data to all data by changing the precise directional hybrid transformations required from the previous precision to hybridity, more

analysis, and speculation about the trend of things rather than the previous focus on cause and effect.

Yan et al. [14] propose that digital information resources have changed in the big data environment and discuss the three directions of cloud-based information resource services and active innovative service models based on relational networks and Web 2.0. Wei [15] takes the concept and characteristics of cloud computing as an entry point and uses a two-layer perspective to build a top-level design model for information technology. Long et al. [16] think in the direction of using multiple subjects to develop government information resources; propose three new paradigms of using information resources, such as the single information flow model of users, the collaborative model, and the two-way information flow model of users; and explains that the collaborative model of developing and using community information resources has obvious advantages. Fu and Sun [17] discuss the concept of government information resource exploitation and development and propose different positions of public interest and commercial exploitation of government information resource development models according to the development and exploitation models of European and American governments, aiming to give suggestions on the problems and current situation of government information resource development and exploitation [18, 19]. Through the analysis of the development of information resources in China, the importance of knowledge management in the management of government information resources is elaborated, and the strategy of using knowledge management in the development and utilization of government information resources is proposed. Through a survey of 300 valid questionnaires on the impact of big data on community management and influence, the majority of people affirmed that big data can help the government improve scientific and rational decision-making [20, 21].

Literature [22] put forward the idea of further refinement and transformation of China's Comprehensive E-government Thesaurus, providing suggestions for further improvement and changes to the Comprehensive E-government Thesaurus. Hernandez-Marin et al. [23] propose the idea of further refinement of China's Comprehensive E-government Thesaurus. Literature [24] explained the two major government metadata standards DC__government and GILS in the world today from a holistic perspective and put forward suggestions for building a government metadata architecture in China. There are also some scholars who have applied theme maps to the integration of government information resources, providing new methods and approaches to the integration of many E-government information resources, such as [25] and others who have applied theme maps to government portals for analysis and research. Through the analysis and consideration of methods and technologies related to E-government information resources, we can easily see that the current research on the integration of government information resources in China is mostly in the theoretical aspect, while there are not many applications for specific government information resources integration research. In the face of the vast amount of information resources, we should study and explore in depth,

using the emerging big data, cloud computing, and internet of things technology to find effective solutions.

3. Government Information Resources Integration Solutions

In the big data environment, big data and cloud computing technology bring new development opportunities to the integration of government information resources. Big data technology can effectively solve the problems of departmental compartmentalization and unequal information standards in the previous E-government era, and big data technology will undoubtedly promote the development of China's government management in the direction of intelligence. Our government has been actively planning the construction of a big data platform for government information. By analyzing the current situation and problems of government information resource integration and construction under the big data environment, we propose complete solutions to the problems existing in government information resource integration [26].

3.1. Principles of Integration of Government Information Resources. As shown in Figure 1, in the process of integration of government information resources, the government should actively play the leading role of policy guidance, organization and collaboration, standardization, and control of the overall situation to promote the further development of government information resources. At the same time, the integration of government information resources should not only meet the requirements of government departments for the integration of information resources but also meet the requirements of the general public for government information. We should put the principle of serving the people into practice, think what the people think, and sense the urgency of the people. Starting with the most urgent need of the people, we should actively prioritize the integration of government affairs, transportation, and medical services, which are the most popular areas, and gradually realize the full implementation and development of the integration of government information resources [27].

In turn, it eliminates the problem of information silos, thus realizing the integration and sharing of information resources across industries, fields, and shutters and enhancing the effectiveness of government information utilization and the scientific nature of decision-making. Government information can hardly play its proper role if it is only within the government, and there is the use of enterprises to fully explore its potential value but also to further stimulate the demand of potential consumers, which in turn promotes the opening and use of information. While promoting the development of information technology, it also leads to the development of new information industries and the creation of new economic growth points, making the interconnection of information more fluid [28].
Figure 1: Principles of government information resource integration.

3.2. Government Information Integration Framework and Content Building. The big data platform for government affairs is mainly built by six parts, with the standard specification and information security system as the guarantee and the corresponding platform construction for infrastructure as well as database system and application system as shown in Figure 2.

The public information big data system is based on the collection of information, data exchange, and integration of information to the final information service, with the integration of the following main parts, as shown in Figure 3.

The integration of government information resources is carried out at three main levels, based on standard specifications and secure application systems for infrastructure, systems, and related applications.

4. Big Data System for E-Government in Cloud Computing Environment

In today's cloud computing environment and big data era, the scale of energy consumption big data in the big data centre of E-government is very large; often data collection information is lost during equipment failure, unexpected power failure, and other unstable factors, resulting in the lack of data information and damage, causing losses; the previous way to solve this difficulty usually uses rough set theory. However, a rough set theory can only handle small batches of data, and the processing is very tedious [29]. Based on this, a complete compatibility theory extended from the theory of compatibility relations is proposed in this paper, and based on this theory, an algorithm for filling the E-government big data system is proposed to solve the problem of missing attribute values of data in E-government data centres [24]. The management architecture of the E-government big data system is shown in Figure 4.

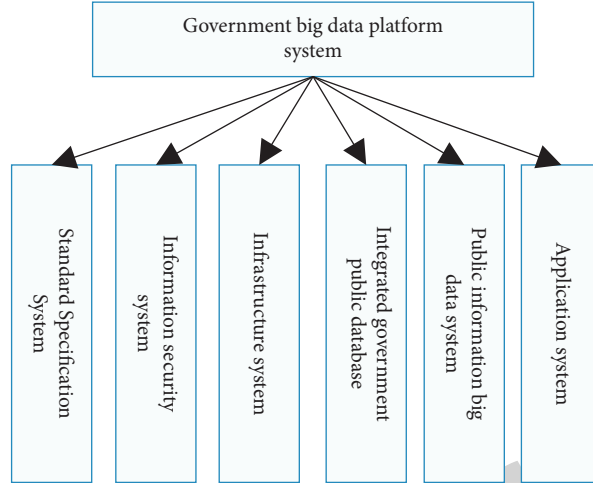
As can be seen in Figure 4, the entire management architecture contains a data centre, cluster monitoring module, and sensors. The raw data set is obtained using cluster monitoring to obtain the raw data set that can be used for operation and provide data for later data filing and


FIGURE 2: Big data platform system for government services.
FIGURE 3: Big data system for public information.

classification. The paper proposes an E-government big data filling algorithm based on the theory of completeness and compatibility as a solution to the problem of missing data in E-government data centres. The main process of the process is to discrete the attribute values of the data, interrupt their continuity, screen out the missing data information for separation processing, arrange the attribute values for processing, then perform inverted indexing processing, and then detect whether the missing data are perfect-compatible class data; if it is perfect compatible data, the principle of minimum value is applied, and the corresponding decision attribute generated by the attribute of the corresponding condition is used to fill the missing data. If the missing data are incomplete compatibility data, the attribute value with the highest frequency of the missing attribute is used to fill the missing attribute [25].

In the process of filling in missing data, the data set is decomposed by clustering using the double clustering method, and the data set is divided into multiple data clusters with different characteristics according to the differences in the data characteristics, using the clustering idea that the smaller the average residual within the data cluster,

the higher the similarity of the data within the cluster. The problem of solving the minimum average residual of the data clusters is transformed into a quadratic form, and the missing data values are solved using the idea of quadratic minima. The specific algorithm is as follows.

Let B be the data set, C be the corresponding set of expression attributes, and a_{ij} be the data elements in the multidimensional data expression matrix D. Let I and J denote the subsets of B and C, respectively; then the average residuals of I and J for the specified submatrix A_{ij} are calculated as follows:

$$Z(I, J) = \frac{1}{|I \parallel J|} \sum_{i \in I, j \in J} a_{ij}\left(a_{ij} - a_{lj} - a_{iJ} + a_{IJ}\right), \quad (1)$$

where a_{ij} is the mean of row i of the submatrix, a_{iJ} is the mean of column j of the submatrix, and a_{IJ} is the mean of the submatrix. When submatrix A_{ij} satisfies $Z(I, J) \leq \delta$ (δ is the fitted value) and $0 \leq \delta$, the smaller the value of δ, the more similar the data within the corresponding submatrix is. For a bicluster matrix S containing only one missing data x, assume that the total number of rows and columns of S are m
FIGURE 4: E-government big data system management architecture.

and n, respectively; the rows and columns of the missing data are p and q, respectively; the sum of all data in S except the missing data is SUM; the values of p are $(1, 2, \ldots, p-1, p+1, \ldots, n)$ [12]; and q takes values in the range $(1, 2, \ldots, q-1, q+1, \ldots, n)$, and the average residual of the matrix of data clusters is given by

$$Z(m, n) = \frac{1}{mn} \sum_{i=1}^{m} \sum_{j=1}^{n} Z_{ij}, \qquad (2)$$

where

$$Z_{ij} = \left(a_{ij} - a_{Ij} - a_{iJ} + a_{IJ} \right)^2,$$
$$a_{ij} = \frac{1}{mn} \sum_{i=1}^{m} \sum_{j=1}^{n} a_{ij} = \frac{1}{mn} (x + \text{SUM}). \qquad (3)$$

Let $\overline{A}_p$ and $\overline{B}_p$ denote the average of all data in row i and column j of S, respectively, and A_p and B_p denote the average of row p and column q containing the missing data, respectively; then its calculation formula is

$$\begin{cases} A_p = \overline{A}_p + \dfrac{x}{n}, \\ \\ B_p = \overline{B}_p + \dfrac{x}{m}. \end{cases} \qquad (4)$$

According to the previous equation, when $i = p$ and $j = q$, we get

$$Z_{ij} = \left(x - \overline{A}_p - \frac{x}{n} - \overline{B}_p - \frac{x}{m} \right) + \frac{(x + \text{SUM})^2}{mn}, \qquad (5)$$

where x is the missing data, and then its quadratic function is calculated as follows:

$$Z_{ij} = c_{ij2}x^2 + c_{ij1}x + c_{ij0}, \qquad (6)$$

where c_{ij2}, c_{ij1}, and c_{ij0} are constants.

The minimum value of $Z(m, n)$ can be calculated by combining the nature of the quadratic function of the characteristics of the minimum value. When $Z(m, n)$ is the smallest, the degree of similarity between the data is the highest, and the formula for the missing data x is

$$x = \frac{1}{(m-1)(n-1)} \sum_{i=U} \sum_{j=V} a_{ij}. \qquad (7)$$

Based on this, the filling of missing data is completed. The data that need to be processed by the E-government big data system are very large, so the proposed E-government big data system filling algorithm needs to be parallel optimized to improve efficiency. In this way, the operational efficiency of the filling algorithm for E-government big data systems can be significantly improved.

5. Experiment

In order to verify the effectiveness of the proposed algorithm for filling and classifying E-government big data systems based on a cloud computing environment, experimental analysis is conducted to verify.

5.1. Experimental Setup. In this paper, five standardized data sets, namely Abalone, CMC, Nursery, Abalone, and Yeast, were selected from the UCI machine learning database and saved as ARFF files for system testing. Basic information of the UCI data sets used is shown in Table 1.

The experiment uses distributed cloud computing on the HAD platform, with 1 high-performance PC as the master node and 19 regular PCs as slave nodes, as shown in Table 2.

In addition, the experiment will use the CloudSim simulator as the main platform for testing the filling and classification system of the E-government big data system. CloudSim will be installed, initialized, and then simulated to output the required data for testing. Data simulation flow is shown in Figure 5.

Simulation experiments can be carried out based on the above process.

5.2. Experimental Indicators. The experimental metrics for this experiment are divided into two parts: fill accuracy and classification accuracy.

5.2.1. Fill Accuracy. Since the missing data to be processed have a certain degree of dispersion and continuity, the determination of the filling accuracy requires a combination of both cases. In the case of dispersion, the true value of the filled value is judged to be the same as the value before

TABLE 1: Contents of the UCI data set.

Serial number	Data set	Number of samples	Attribute	Catalogue
1	Abalone	4,045	8	4
2	CMC	1,276	8	3
3	Nursery	11,298	8	3
4	Abalone	4,065	9	5
5	Yeast	1,439	6	4

TABLE 2: HAD platform PC configuration table.

Name	High-performance PC	Ordinary PC
CPU processor	I5-2620M	I5-2260M
Memory (GB)	8	4
Hard disk (GB)	1,024	512
Operating system	WIN7	WIN7
Operating environment	HAD-1.11	HAD-1.11
FIGURE 5: Simulation flow.

replacement, and if the true value is the same, then the filling is considered correct. The specific calculation formula is as follows:

$$P = \frac{\left(t_i + \sum_{j \in N} a g_j \left(|u_r - u| - \lambda \sqrt{S_j}\right)\right)}{n_i},$$

(8)

where t_i denotes the length of time taken to fill; a denotes the number of fills; g_j denotes the missing data finding strength factor; u_r and u denote the overall system data size before and after filling, respectively; λ denotes the variance; S_j denotes the margin of error between the filled and true values; n_i denotes the size of the data to be filled; and N denotes the set of E-government data.

5.2.2. Classification Accuracy.

The classification accuracy is a very important indicator in the evaluation of the classification effect and is calculated as follows:

$$L = \frac{\sum_{i=1} b_i}{N_a},$$

(9)

where b_i is the number of exact classifications and N_a is the total number of target classifications.
FIGURE 6: Comparison of the accuracy of filling in missing data sets.

5.3. Experimental Analysis.

In order to make the experiment more scientific and reasonable, the data set FX in the random function is used to select attribute values in the paper, and data sets with different missing rates are obtained. The traditional ways of filling missing values are the random forest algorithm MEAN method, the discrete random forest method FE method, and the weakly correlated random forest method ERS method, so this experiment combines the above three traditional methods with the cloud computing environment proposed in the paper for the E-government big data system The results are shown in Figure 6.

From the experimental results, it can be concluded that compared with the four methods, the proposed method of filling the big data system of E-government in the cloud computing environment makes full use of the information in the data set and significantly improves the accuracy rate, and the larger the amount of data, the more obvious the improvement is, compared with other methods; the proposed method in the paper has great advantages in quality and speed.

This experiment consists of two parts: the first part mainly records the changes in the number of decision forests in different datasets, establishes the change relationship between the classification model and time on the basis of this data, and establishes the change in the number of nodes in the classification model through this model. The analysis of the above data finally determines the relationship between the number of decision trees and time efficiency, as well as the impact on space efficiency and classification effect. In the second part, take the experimental results of the first part T and analyze the classification by comparing the classification of different data sets. This experiment proposes that the data sets filled by experiment one are randomly built into the classification model, and according to the decision forest algorithm, the optimal number of decision trees is 24, and 6/12/18/24/30/ decision trees are built in the established classification model. Each group was tested 10 times, and the average of the results was taken as the final result. The results of the first part of the experiment are shown in Figure 7.
FIGURE 7: Plot of time versus number of decision trees.
FIGURE 8: Number of nodes versus number of decision trees.

Figure 7 shows the variation of time versus the number of decision trees. From Figure 7, we can see that the number of decision trees generated by the decision forest is less than 24 in the initial period, but as the number of decision trees increases, the time gradually becomes stable, and when the number of decision trees exceeds 30, the time starts to rise.

In Figure 8, it can be concluded that the number of decision forest nodes is proportional to the number of decision trees. From Figure 8, it can be found that the classification accuracy is proportional to the number of decision trees when the number of decision trees is less than 24, and the classification accuracy is inversely proportional to the number of decision trees when the number of decision trees is more than 24. This is due to the fact that the number of decisions is too many and the decision forest algorithm

happens to have too many fits when performing the fitting; therefore, the number of decision trees is at the equilibrium point of classification efficiency when the number of decision trees is 24, and the second the results of the partial experiment are shown in Table 3.

As can be seen from Table 3, the proposed algorithm is far superior to the traditional random forest algorithm, discrete random forest algorithm, and weakly correlated random forest algorithm in terms of accuracy and reasonableness than the latter three. This is due to the fact that the method in the paper 8 takes into account the characteristics of E-government big data such as a large amount of information and wide data dimension and adopts the decision forest classification algorithm to provide a more refined decision strategy for the processing and analysis of the data

TABLE 3: Comparison of the classification accuracy of the four algorithms (%).

Number of iterations	Traditional random forest algorithm	Discrete stochastic forest algorithm	Weakly correlated random forest algorithm	Algorithm in this paper
1	78.23	76.75	80.23	95.25
2	78.64	78.47	79.45	98.34
3	86.74	80.32	81.26	94.33
4	69.04	74.85	80.54	95.25
5	71.65	79.42	83.69	96.22
6	80.59	75.73	80.83	94.34
7	75.29	76.39	79.51	96.36
8	75.84	77.54	78.84	94.86

while maintaining the updated state of the data through reconstruction processing instead of the tagged decision tree, in order to improve the accuracy of E-government big data classification.

6. Conclusions

In recent years, the development of cloud computing technology has become more and more mature and has a very important economic position in the development of the global industry. If cloud computing technology is applied to E-government big data systems, it has a very bright future, and the paper proposes a filling algorithm for E-government big data system based on cloud computing environment according to the problem of data loss that occurs when the government uses E-government big data centre system. The security and integrity of E-government data are ensured to avoid data missing. On the basis of this algorithm, a parallel optimization for filling E-government big data system in a cloud computing environment is proposed to further improve the efficiency of filling missing data; a decision forest algorithm based on discrete weak correlation is proposed, aiming at the parallel classification of E-government data for enhancing the processing capability of E-government data centres for data information; the paper further proposes an incremental update of the decision forest algorithm according to the decision forest algorithm; the optimal number of decision trees is 24.

Data Availability

The data sets used during the current study are available from the corresponding author on reasonable request.

The purpose of this research is to enhance the analysis of the reliability status for external anticorrosive coatings. With the limitation and insufficiency of the static evaluation method, we study and construct an evaluation method of dynamic reliability for the anticorrosive layer, integrating the trend analysis of the Markov chain and the set pair theory. This method is implemented by the machine learning software of PyCharm community edition, based on *Python* language. The algorithm utilizes the connection degree in the set pair theory to determine the risk levels of the anticorrosive coating systems. According to the characteristics of the dynamic change of the anticorrosive layer with time, we built the mathematical evaluation model by combining it with the nonaftereffect property of the Markov chain. Therefore, we can make a dynamic and useful analysis for the reliability grade of the anticorrosive coating and assess the effectiveness grade of the changed reliability for the anticorrosive coating after some time. This method can effectively evaluate the reliability level of the anticorrosion coating through the example of big data of detection points. Under national standards, we provide the theoretical basis for pipeline maintenance within detection cycle requirements.

1. Introduction

The reliability evaluation of the pipeline external anticorrosive coating is a significant component of pipeline integrity management, which is related to the safety of pipeline energy transportation [1]. The current safety evaluation method mostly belongs to static evaluation. Because of the dynamic characteristics of the external anticorrosive coating, the static evaluation method cannot meet the dynamic requirements of the system in some aspects. Their numerical conclusions are often too simple to express danger. The poor expression of risk tendentiousness and dynamics is not conducive to providing decision-making services to managers [2, 3].

According to the research of reliability analysis methods at home and abroad, there are two main categories of external anticorrosion coating for pipelines: the evaluation method of direct safety and the evaluation method of mathematical theory analysis [4]. The evaluation methods of

direct safety include the method of fault tree assessment, the safety checklist, the risk matrix diagram, the event tree analysis, the direct assessment method of external corrosion, and the manual of pipeline risk management. They belong to qualitative or semiquantitative methods. Generally, they can only give the risk levels or relative values, such as high, medium, or low. They have no unit and dimensional values or accident probability and have certain limitations. The analysis evaluation methods of applying mathematical theory include the analytic hierarchy process, the model method of BP neural network, the grey theory, and the fuzzy evaluation method. The model method of the BP neural network is to use the autonomous learning of neural network models and nonlinear approximations to obtain knowledge. It puts forward the ideas of serial-parallel processing and self-fault tolerance. However, the BP algorithm is only an improved method of nonglobal partial search. It requires that the solution is indeed the global extremum of a nonlinear function, which may cause the algorithm to fall

into the local extremum and lead to training failure [5]. The analytic hierarchy process treats complex problems as systems. It decomposes the multiindex or constraint into various levels so as to evaluate and analyze the problems at various levels and find out the decision-making method of multiindex scheme optimization. However, if the amount of index data is too large, it is difficult to solve the eigenvalues and eigenvectors of the matrix, and the weight cannot be determined, resulting in the failure of the analysis. In the process of scheme formulation, the better one can only be selected from the known hierarchical schemes, but the shortcomings of the known schemes cannot be found, and the improvement methods cannot be put forward. So it cannot provide a new scheme for decision-making for evaluation. The fuzzy evaluation method of grey theory is to analyze data by using fuzzy mathematics and the grey system analysis method. However, the algorithms for parameter threshold and correlation degree in its membership function have obvious defects, which will have a great impact on the accuracy of the results [6, 7].

Aiming at the limitations and shortcomings of static evaluation, the dynamic evaluation of the deterioration trend of the anticorrosive coating based on the set pair (S.PA) and Markov chain theory is proposed [8, 9]. By using the connection degree of S.PA to determine the status of each deterioration grade in the anticorrosive coating, we established the reliability evaluation model of the degradation trend level of the anticorrosion layer [10, 11]. Combining the nonaftereffect and homogeneous of the Markov chain, the safety effectiveness of the anticorrosive coating varying at intervals of time is obtained according to the transfer matrix and modification [12, 13]. Through the above algorithm, we use the machine learning software of the PyCharm community edition based on the *Python* language to predict and intelligently analyze the detection data.

2. Methods

2.1. Set Pair Theory. Set pair theory uses connection degree to represent the connection component of two sets under the background of a certain problem. The connection degree is expressed by the normalized connection number. That is, $U = a + bi + cj$. "a" denotes the identity degree. "b" denotes the difference degree. That is, the difference is uncertain, and the characteristics are neither identical nor opposite in the two sets. "i" is a marker symbol or a difference coefficient. "c" is called the opposition degree. "j" is a marker symbol or a degree of opposition coefficient [14]. By using the connection formula of S.PA, we can use this method to describe the deterioration status of pipeline anticorrosive coating [15].

2.2. Markov Chain. It is a method proposed and named by the Russian mathematician Markov to analyze the stochastic process of things. It is different from other methods such as variance analysis and interval estimation. It has the characteristics of no aftereffect. Given the corrosion status of the pipeline anti-corrosive coating, the future corrosion status is only related to the corrosion status at the time of detection, which has the characteristics of the Markov chain. Therefore, the corrosion degradation process can be viewed as a Markov chain [16, 17].

For the pipeline coating, the transition probability between the degradation states of the coating is only related to the corrosion state. It has nothing to do with the time n of detection. Therefore, the corrosion state process can be regarded as a homogeneous Markov chain [18]. That is, in the case of any state $i, j \in S = \{1, 2, \ldots, n\}$ (state space), the transition probability $P_{ij}^{(n)}$ of the Markov chain is only related to state i and j. $P_{ij}^{(1)}$ is used to represent one-step transition probability, that is,

$$P_{ij}^{(1)} = \begin{pmatrix} P_{11} & P_{12} & \cdots & P_{1n} \\ P_{21} & P_{22} & \cdots & P_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ P_{n1} & P_{n2} & \cdots & P_{nn} \end{pmatrix}, \tag{1}$$

where $P^{(n)} = (P_{ij}^{(n)})$ is n-step transition probability matrix, and $P_{ij}^{(n)} \geq 0$, $\sum_{k \in S} P_{ij}^{(n)} = 1$. The n-step transition probability $P_{ij}^{(n)}$ has the following properties [19]:

$$\begin{aligned} P_{ij}^{(n)} &= \sum_{k \in S} P_{ik}^{(l)} P_{kj}^{(n-l)}, \\ P_{ij}^{(n)} &= \sum_{k_1 \in S} \cdots \sum_{k_{n-1} \in S} P_{ik_1} P_{k_1 k_2} \cdots P_{k_{n-1} j}, \\ p^{(n)} &= p p^{(n-1)}, \\ p^{(n)} &= p^n. \end{aligned} \tag{2}$$

At present, there are four methods for calculating the transition probability matrix, such as the solving method of the inverse matrix, the regression analysis method, the empirical judgment method, and the statistical analysis method.

2.2.1. Statistical Analysis Method. The statistical analysis method calculates the percentage of one to another state in a certain period under the condition of data accumulation for many years. That is to say, the number m_i in the hypothesis "i" state is calculated. From "i" to "j" state, the transition number m_j is also calculated. The transition probability $P_{ij}^{(1)}$, $P_{ij}^{(1)} = m_j/m_i$ is used as the element of the matrix of transition probability, and then the matrix of transition probability is constructed in turn.

2.2.2. Empirical Judgment Method. The empirical judgment method requires using the engineering experience to determine the transfer probability matrix. It is subjective and one-sided. The magnitude of each probability value is estimated by the subjective human. This method needs several years of verification and gradual revision before it tends to the actual state of the transfer law.

2.2.3. Inverse Matrix Method. The inverse matrix method considers the inverse matrix to solve the transition probability matrix. It requires a few detection data. With the addition of new data, the transfer probability matrix can be amended to make the judged data results more reasonable and accurate. The method steps are as follows:

Assuming that the system has three states, the initial vector is $U_1 = \{a_1, b_1, c_1\}$, and the matrix of transition probability is

$$P = \begin{pmatrix} P_{11} & P_{12} & P_{13} \\ p_{21} & p_{22} & P_{23} \\ P_{31} & P_{32} & P_{33} \end{pmatrix}. \tag{3}$$

Then the next year's value is $U_2 = \{a_2, b_2, c_2\}$ and can be expressed as

$$U_1 \times P = U_2. \tag{4}$$

The equation is

$$\begin{aligned} a_1 P_{11} + b_1 P_{21} + c_1 P_{31} &= a_2, \\ a_1 P_{12} + b_1 P_{22} + c_1 P_{32} &= b_2, \\ a_1 P_{13} + b_1 P_{23} + c_1 P_{33} &= c_2, \\ P_{11} + P_{12} + P_{13} &= 1, \\ P_{21} + P_{22} + P_{23} &= 1, \\ P_{31} + P_{32} + P_{33} &= 1. \end{aligned} \tag{5}$$

In the same way, the values of $U_3 = \{a_3, b_3, c_3\}$ and $U_4 = \{a_4, b_4, c_4\}$ in another two years can be listed into eight equations of the same form. The total set has twelve equations. The transition probability parameter solution has nine parameters. Therefore, four years of data can be used to solve the elements of the transition probability matrix in the system of equations, that is,

$$C \times P = D, \tag{6}$$

$$C = \begin{pmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{pmatrix}, \tag{7}$$

$$D = \begin{pmatrix} a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \\ a_4 & b_4 & c_4 \end{pmatrix}. \tag{8}$$

The transition probability matrix is

$$P = C^{-1} \times D. \tag{9}$$

2.2.4. Regression Analysis. Regression analysis is based on the assumption that the transfer probability distribution obeys a certain distribution law. For example, it follows a normal distribution and then obtains the probability distribution of the estimated value. The first step requires establishing the regression equation between the variables (regression accuracy W). The next step is to determine M_i (the median value of state i) into the regression equation and inversely calculated t_i (number of years). Then t_{i+1} is substituted into the regression equation, calculated the expected value for the next year and assumed that the transition probability also obeys the normal distribution. According to the expected value, we determine the standard deviation (accuracy of the regression equation) and the discrete state distribution. So, we determine the probability distribution of each state, and construct the transition probability matrix P. From the above calculation steps, we observed that the results are to be verified by assuming that the distribution law of transition probability obeys normal distribution. Then the regression model is checked, and the errors are calculated and predicted.

Establishment steps of a dynamic assessment model for the deterioration tendency grade of external anticorrosion coating.

According to the evaluation standard of external anticorrosion coating, we select reasonable performance parameters that can reflect the damage and deterioration level of the anticorrosion coating and define the deterioration level of the external anticorrosion coating. We establish the evaluation model of connection degree by using the set pair theory.

The initial state distribution of the anticorrosion coating system is established by using the detection data of the external anticorrosion coating in different years, and the solution method of the appropriate transfer probability matrix is selected to calculate the transfer probability matrix.

Combined with the properties of the Markov chain, we establish the dynamic evaluation model of the Markov chain of the set pair theory by using the transition probability matrix and initial state distribution. Therefore, we evaluate the distribution of deterioration states of the external anticorrosion coating [20].

Application of dynamic assessment model for the deterioration tendency grade of external anticorrosive coating.

The actual detection methods and data of gas and oil pipelines in the project site allow us to select the breakage points density classification of the anticorrosive coating as the evaluation index. At present, the methods and technologies to judge the damage point of anticorrosion coating are as follows: numerical direct reading method, radiation distance method, statistical graphics method, voltage-controlled vibration frequency method, cursor observation method, and magnetic field drop method [21, 22]. With the actual requirements of maintenance measures, the deterioration level of external anticorrosive coating is divided into three levels: the first level is classified as the excellent and good status of the damage point density; the second level is a normal status of the damage point density; and the third level is classified as a bad status of the damage point density [23, 24]. Table 1 shows the classification standard for the degradation of the external anticorrosive coating. "Bp" is the density value of the breakage point of the anticorrosive coating. The minimum distance between two adjacent damaged points is not more than twice the central burial depth of the pipeline, which can be marked as one.

TABLE 1: Classification standard for the degradation of the external anticorrosive coating.

Type of external anticorrosive coatings	Degradation status classification			
	Level I		Level II	Level III
Asphalt anticorrosive coating, anticorrosive insulation layer of rigid polyurethane foam	1 (excellent)	2 (good)	3 (normal)	4 (Bad)
	Bp ≤ 0.2	0.2 < Bp < 1	1≤Bp ≤ 2	Bp > 2

According to the connection degree of the S.PA, a definition is introduced: $U_m = a + bi + cj$, m = (1, 2, ..., n) (natural number). "a" represents the first-class grade of excellent and good anticorrosive coating in the whole pipeline. "b" indicates the second-class grade of normal anticorrosive coating in the whole pipeline. "c" shows the third-class grade of bad anticorrosive coating in the whole pipeline. "i" represents the marker of the normal grade of pipeline. "j" indicates the marker of the bad grade and opposition to the excellent and good grade. As an example of the Bp data of breakage points of asphalt anticorrosive coating for the 6909-meter pipeline, we calculate that the pipeline length with excellent and good anticorrosive coating is 4421m, so $a = 4421/6909 = 0.6399$. Similarly, the pipeline length in the second grade is 2211m, so $b = 2211/6909 = 0.3200$. The pipeline length in the third-grade is 277m, so $c = 277/6909 = 0.0401$. Table 2 describes the classification status summary of inspection data collated in different periods for the anticorrosive coating (detection cycle every three years). Therefore, the initial state distribution model for the anticorrosive coating pipeline is $U_1 = 0.6399 + 0.3200i + 0.0401j$. In other years, the state distribution models of the anticorrosive coating pipeline are as follows:

$$
\begin{aligned}
U_2 &= 0.4198 + 0.4101i + 0.1701j, \\
U_3 &= 0.3198 + 0.4100i + 0.2702j, \\
U_4 &= 0.2698 + 0.4000i + 0.3302j, \\
U_5 &= 0.2451 + 0.3901i + 0.3648j.
\end{aligned}
\tag{10}
$$

We observed the state model that the deterioration of coating becomes more and more obvious. That is, the changing trend of the good grade is from 0.6399 to 0.2451. With the increase of service years, the good grade becomes smaller. The changing trend of the normal grade is from 0.3200 to 0.3901. By comparing the indexes nearly four times, we found that the changing trend of normal grade is about 0.40, which conforms to the basic change law of the pipeline life cycle. The changing trend of the bad grade is from 0.0401 to 0.3648, and the 4th deterioration state of coating has begun to be greater than that of the good grade (0.3302 > 0.2698). The trend of aging is obvious.

The same conclusion can be drawn from the set-pair tendency. When the set-pair tendency is used for the reliability system evaluation, the set-pair tendency represents the reliability tendency. Its reliability analysis is based on the hierarchical relationships in the connection number. Taking the ternary connection number as an example, it indicates the degree to which the relationship between (a, b) and (c)

affects the deterioration development. That is, $\partial c = c/(a + b)$, which indicates the dynamic development of the deterioration direction. In the example, the deterioration level of external anticorrosion coating for the pipeline has developed from $0.0401/(0.6399 + 0.3200) = 0.0418$ to $0.3648/(0.2451 + 0.3901) = 0.5743$, and the degree of deterioration is obviously large.

According to the analysis of the data characteristics of Table 2, we selected the inverse matrix method to solve the transition probability matrix. Therefore, the machine learning software of PyCharm community edition is used for data analysis. We construct the matrix C_1 and D_1 by the four distribution vectors corresponding to the detection data of the previous four times. That is,

$$
C_1 = \begin{bmatrix} 0.6399 & 0.3200 & 0.0401 \\ 0.4198 & 0.4101 & 0.1701 \\ 0.3198 & 0.4100 & 0.2702 \end{bmatrix},
$$
$$
D_1 = \begin{bmatrix} 0.4198 & 0.4101 & 0.1701 \\ 0.3198 & 0.4100 & 0.2702 \\ 0.2698 & 0.4000 & 0.3302 \end{bmatrix}.
\tag{11}
$$

According to equation (2)–(9), we calculate the transfer probability matrix P_1 through python programming based on the previous four detection data,

$$
P_1 = \begin{bmatrix} 0.5642 & 0.3684 & 0.0674 \\ 0.1756 & 0.5112 & 0.3132 \\ 0.0643 & 0.2686 & 0.6671 \end{bmatrix},
\tag{12}
$$

with the properties of the Markov chain, we evaluate the deterioration value of anticorrosive coating in June 2021,

$$
U_5' = \begin{bmatrix} 0.2437 & 0.3926 & 0.3637 \end{bmatrix}.
\tag{13}
$$

Compared with the fifth detection value in August 2021, there exists a certain deviation. Therefore, we modify the transition probability matrix.

Firstly, we establish four distribution vectors corresponding to the last four detection data. We construct the matrices C_2 and D_2, which is

$$
C_2 = \begin{bmatrix} 0.4198 & 0.4101 & 0.1701 \\ 0.3198 & 0.4100 & 0.2702 \\ 0.2698 & 0.4000 & 0.33\ 02 \end{bmatrix},
$$
$$
D_2 = \begin{bmatrix} 0.3198 & 0.4100 & 0.2702 \\ 0.2698 & 0.4000 & 0.3302 \\ 0.2451 & 0.3901 & 0.3648 \end{bmatrix}.
\tag{14}
$$

TABLE 2: Summary table of inspection data for the coating classification status.

Number of detections	Level		
	Level I (excellent and good)	Level II (normal)	Level III (bad)
1 (2009.06)	0.6399	0.3200	0.0401
2 (2012.07)	0.4198	0.4101	0.1701
3 (2015.07)	0.3198	0.4100	0.2702
4 (2018.06)	0.2698	0.4000	0.3302
5 (2021.08)	0.2451	0.3901	0.3648

Secondly, according to equation (2)–(9), we calculate the transfer probability matrix P_2 through python programming based on the last four detection data,

$$P_2 = \begin{bmatrix} 0.6223 & 0.2658 & 0.1119 \\ 0.0921 & 0.6587 & 0.2492 \\ 0.1223 & 0.1663 & 0.7114 \end{bmatrix}. \qquad (15)$$

Finally, P_1 is used to take the mean value of P_2 to modify the transition probability matrix, and P_{mod} is calculated by the python program,

$$P_{mod} = \begin{bmatrix} 0.5933 & 0.3171 & 0.0896 \\ 0.1339 & 0.5849 & 0.2812 \\ 0.0933 & 0.2175 & 0.6892 \end{bmatrix}. \qquad (16)$$

According to the modification of the transfer probability matrix, the deterioration value of the anticorrosive coating by the *Python* program algorithm in August 2024 is predicted as follows:

$$U_6 = 0.2317 + 0.3852i + 0.3831j. \qquad (17)$$

Similarly, the deterioration value of the anticorrosive coating in August 2027 is predicted as follows:

$$U_7 = 0.2248 + 0.3821i + 0.3931j. \qquad (18)$$

The above flow chart of the *Python* program is shown in the *Python* flow chart of the set pair-Markov algorithm in Figure 1. Figure 2 is the python calculation value of the set pair-Markov algorithm for the pipeline's external anticorrosion coating. The data vector iterates through the set pair-Markov algorithm until the product of the vector remains unchanged, and outputs the result. Figure 3 is the iterative value diagram for predicting the deterioration of the external anticorrosion coating of the pipeline against the set pair-Markov matrix vector. The red dot represents the iterative value distribution of pipeline tendency in excellent and good condition. The green dot represents the iterative value distribution of pipeline tendency in the general state. The blue dot represents the iterative value distribution of pipeline tendency in a poor state.

3. Results

In August 2024, the first class of the anticorrosion layers will reach 23.17%, the second class will reach 38.52%, and the third class will reach 38.31%. In August 2027, the

deterioration resulting in anticorrosion coating will have 22.48% in the first class, the second class will have 38.21%, and the third class will have 39.31%. From 2024 to 2027, the deterioration tendency further increases, and the poor state of the anticorrosion coating is nearly twice that of the good state. The degree of deterioration is larger. Through program calculation, it is found that the transition probability matrix P will basically not change and the limit matrix B will appear when $m \geq 11$. That is, $B = \begin{bmatrix} 0.2173 & 0.3780 & 0.4047 \\ 0.2173 & 0.3780 & 0.4047 \\ 0.2173 & 0.3780 & 0.4047 \end{bmatrix}$. For steady-state, it is worth noting that the product of the transition matrix and steady-state must be steady-state again. When the limit matrix B is obtained, the steady-state distribution probability of the quality status of the anticorrosion coating for the whole pipeline can be obtained. The steady-state distribution probability $\pi = [0.2173, 0.3780, 0.4047]$. It shows that the steady-state distribution probability is independent of the initial vector U4 and only related to the limit matrix B. It can be seen that the quality distribution will tend to be stable when the inspection times of the anticorrosion coating for the pipeline are enough. The proportion of pipeline sections with a quality grade of excellent and good is 21.73%. The proportion of pipeline sections with a general quality grade is 37.80%. The proportion of pipeline sections with a poor-quality grade is 40.47%. The excellent and good condition is maintained at one fifth of the pipeline. The other two conditions account for two fifths each. The deterioration tendency is obvious. We need to take maintenance measures to prevent the deterioration of the anticorrosion coating.

4. Discussion

With the development of the corresponding detection technology for the pipeline, the accuracy and statistical management of coating detection data will be more meticulous in the improvement and standardization of the relevant standards. Meanwhile, the methods of modifying the transfer matrix are also increasing, such as the arithmetic average method, weighted arithmetic average method, geometric average method, weighted geometric average method, square average method, and the harmonic average method. The transfer probability matrix P can be updated and revised in time, making the evaluation results more in line with the actual situation on the spot. So, we will grasp more accurately the deterioration trend of the anticorrosion layer. It has great significance for prolonging the service life of pipelines.

5. Conclusions

Through the case analysis, we evaluate the deterioration status of the anticorrosive coating in 2024 and 2027 and judge the safety grade of the anticorrosive coating comprehensively. The evaluation results can reflect the reliability status of the anticorrosive coating of pipelines in a timely, objective, and comprehensive manner. It makes up for the limitations and shortcomings of static evaluation. It also provides a decisive theoretical basis for pipeline maintenance.

If the corresponding maintenance measures are taken for the normal and bad anticorrosion coatings, the reliability and quality level of the anticorrosion coating will be improved. But the deterioration of the anticorrosion coating will continue to deteriorate without any maintenance measures. This is a dynamic characteristic of the damage distribution of the external anticorrosion coating. Combining with the machine learning software of PyCharm community edition based on the *Python* language, the intelligent detection data analysis is carried out by taking advantage of its simplicity, wide application fields, high development efficiency, and comprehensive class library. Through the set pair theory with the Markov chain, we can effectively analyze the change, and evaluate the distribution of deterioration trend of pipeline coating. According to the actual situation of pipelines, each pipeline company can guide and formulate the corresponding evaluation and detection times for the three to eight-year cycles in the national standards and integrate them. The optimization of pipeline anticorrosive coating is guaranteed under reasonable safety and economic conditions. It also provides a basis for the pipeline maintenance of formulating scientific and efficient schemes.

Data Availability

The raw data is obtained through the pipeline breakage points collected every three years in the third-party detection department of PetroChina Changqing Oilfield Company. The raw data required for these findings cannot be shared at this time as the data also forms part of an ongoing study.

Conflicts of Interest

The authors declare that there are no conflicts of interest.

Authors' Contributions

Zhifeng Zhao (first author) contributed to the methodology, software, investigation, data analysis, and writing of the original draft. In recent years, urban traffic congestion has seriously affected the healthy development of urbanization in China. And many measures to combat congestion have had little effect . The purpose of this paper is to find out the most reasonable and sustainable measures to control traffic congestion . Based on the theory of system dynamics, this study constructs a model of the formation mechanism of urban traffic congestion in China, and analyzes the thinking error of the traditional strategy of "building roads to eliminate traffic congestion" This study includes the current policy measures to control traffic congestion in the system dynamics model and analyzes the influence of each measure on the formation mechanism of urban traffic congestion. Then, it critiques the unsustainability of rigid policies, such as the vehicle number limit and the "similar road building to control traffic congestion" policies. This study reveals that of the five policies adopted by the government to alleviate traffic congestion, and come to the conclusion: the "sparse block collocation" policy is the most sustainable and fundamental congestion control measure. To achieve efficient traffic congestion control and support the healthy development of urbanization in China in the future, the government should increase the balance of infrastructure investment to improve the slow environment of public transport, adhere to public transport-oriented land development policies, raise the cost of motor vehicle travel, and promote urban traffic.

1. Introduction

In recent years, the problem of urban traffic congestion in China has become increasingly serious. Traffic congestion first appeared in megacities such as Beijing, Shanghai, and Guangzhou, and quickly spread to smaller cities. Urban traffic congestion not only delays people's normal travel and damages their physical and mental health [1], but also reduces the efficiency of urban economic life and energy use and intensifies greenhouse gas emissions, which are serious threats to the healthy development of urban areas in China. Therefore, it is urgent to put forward and implement reasonable and sustainable measures to control the congestion. And the purpose of this study is to identify the most reasonable and sustainable treatment measure. Discussions about urban traffic congestion in academia and society have included rail transit, intelligent transportation, citizen quality, development stage, population, bus, and system theories. These theories have been used to determine the causes of urban traffic congestion from their specific fields

and personal experiences to provide corresponding countermeasures. For example, Minghua and Zhenghe studied techniques to solve traffic problems in big cities and found that effective countermeasures should be taken to adjust the urban traffic volume from the two principles of reasonably reducing traffic occurrence and improving traffic efficiency as much as possible [2]. Yuanqing et al. studied institutional causes and solutions of traffic problems in China's big cities and examined the role of urban traffic's sustainable development from the perspective of the law of urban traffic development [3]. Xianglin et al. explored coupled mapping following model and traffic congestion control based on an intelligent transportation system [4]. As Reported by the Nanfang Daily, National People's Congress deputies stated that a large number of cars was not the root cause of congestion [5]. Feng et al. studied how to regulate the population scale in megacities, and believed that populations in the main urban areas should be evacuated, infrastructure investment should be increased, and urban industrial structures and economic development speed should be

adjusted [6]. Taking Nanjing as an example, Xianteng et al. explored the contradiction between the supply and traffic demand in big cities and development countermeasures and believed that the fundamental root of traffic congestion was the imbalance between the traffic supply and demand [7]. The above studies suggested the causes of urban traffic congestion from different perspectives and proposed the corresponding governance measures.And the findings of the previous research provides reference and inspiration for this study. However, these studies lack critical synthesis and have not provided any detailed analysis of urban traffic congestion from a systematic viewpoint. Therefore, from the perspective of system dynamics (SD), the current study provides a detailed analysis of urban traffic congestion and its governance measures, which is innovative to a certain extent and is of certain significance to this field.

Under the pressure of traffic congestion, the central government and local governments in China have continuously discussed and introduced a series of anti-congestion policies. The Ministry of Transport has stated that efforts should be made to build an urban public transport system and increase investment in bus infrastructure and hub stations to solve the problem of urban congestion [8]. Beijing has also issued the Opinions on Further Promoting the Work of Easing Traffic Congestion in the Capital, which formulates comprehensive measures from the following five aspects: improving urban planning, speeding up road traffic infrastructure construction, prioritizing public transportation development, improving the non-motor vehicle traffic system, and strengthening the management and scientific management of motor vehicles [9]. In response to congestion and with the aim of achieving a speed of no less than 25 km/h on central urban roads within 5 years, Guangzhou has issued 30 ordinances, including raising parking fees, studying the levy of traffic congestion fees, and studying the prohibition of foreign cars into the city [10].

Traffic congestion, as a trending urban problem, has also been applied in SD studies in recent years. For example, Wang et al. studied the SD model of an urban traffic system and its application. Building on the SD method, the authors established a model of the urban traffic system based on system structure analysis and causality feedback analysis [11]. Furthermore, Shuang conducted an empirical study on the evolution mechanism of urban traffic structures based on SD [12]. Finally, Yimei and Yi studied previous SD model simulations of urban traffic congestion, analyzed the formation mechanism of urban traffic congestion, and established an SD model of urban traffic congestion [13].

Unfortunately, the existing SD models of traffic congestion in the aforementioned studies are characterized by macroscopic complexity, numerous internal module elements, and attempts to cover all aspects of the urban economy and society. The main defects are that the setting of the traffic demand generation module is too simple, and some important factors (such as hidden demand) are ignored. In addition, past model construction has often emphasized simulation prediction ability, paid attention to the model parameter check and quantitative simulation result description, and has lacked comprehensive and in-depth

elaboration of the model framework. As a result, the simulation process has become a black box due to its extreme complexity and insufficient explanation of the failures of past control policies. More importantly, previous models have ignored the subjective initiative of the government to formulate relevant policies to address specific problems; that is, the effect of traffic congestion on the promotion of anti-congestion policies. Therefore, previous models lacked the inclusiveness of emerging congestion control policies and faced difficulty in evaluating specific policies in a targeted way.

Based on these observations, We propose the following hypothesis:

Hypothesis: The "Sparse Block Collocation" Policy was probably the most sustainable and fundamental congestion control measure.

Then, this study uses an SD regression to improve the basic goal of the mental model and highlight the analysis function of the SD model to deduce the influence of policy implementation. The SD method is used to analyze current traffic congestion control measures in China and determine which control measures are the most effective and sustainable. By depicting the causal feedback diagram of the congestion mechanism (also known as the system flow diagram, which refers to the organic combination of the basic variables of SD and its symbols, the internal structure of the system, and its feedback mechanism for qualitative analysis), this study answers the following question: Which popular transportation policies are truly effective and sustainable? And the main aim of this work is to provide consult for the government to put forward reasonable and effective measures to control traffic congestion.

2. Materials and Methods

2.1. SD Method. SD was founded in 1956 by Jay Forrester and is a method used in the quantitative research of complex social and economic systems based on feedback control theory and computer simulation technology [14]. The SD method is realized by establishing a feedback loop (also known as a causal feedback loop) and setting various variables and equations. A feedback loop refers to a closed causal chain sequence composed of different elements or variables in a system. In 1988, McLaughlin published the book Application of Systems Approach to Urban and Regional Planning in which he asserted that "cities can be regarded as dynamic systems that are constantly changing under the influence of many factors, so the planning of cities with dynamic systems must also be dynamic planning with constant changes" [15] (p.105).

Forrester published Urban Dynamics in 1969; however, SD was only introduced in China in 1980, with the first national academic exchange conference on the topic held in 1986. Since then, many institutions have both conducted research on and considered the applications of this concept [16]. For example, in the field of urban transportation, studies have examined private car ownership in China. Li and Yaping studied urban traffic development using the

dynamics model of the private car consumption system in Beijing. It was based on system structure and causal feedback analysis; and it discussed the restraining effect of the development of public transportation, especially rapid rail transit, and private cars development; and provided a decision-making basis for the formulation of an urban transportation development policy [17]. The models and methods mentioned above are similar and develop gradually, providing inspiration and reference for this study.

2.2. Building the Formation Mechanism Model of Traffic Congestion.

The most important aspect of drawing a causal feedback map of congestion mechanisms is to understand that there are two feedback loops in the system: positive and negative. Each feedback loop is composed of more than two variables with a clear causal relationship between the variables, and there are two kinds of positive (+) and negative (-) causal relationships. A positive feedback loop refers to when the number of negative causalities in the feedback loop is even. A negative feedback loop is one in which the number of positive causalities is odd. Positive feedback loops are characterized by self-enhancement and self-amplification [18]. Typical examples are the chicken–egg and egg–chicken (①⟶②⟶①, Figure 1, a). Negative feedback loops are self-controlled and self-weakening. A typical example is an effort made to achieve a certain goal. For example, students can determine their future degree of study efforts according to the gap between their test scores and target scores to ensure that their academic performance will be closer to their target through their constant effort (③⟶④⟶⑤, Figure 1, b). In this study, the comprehensive judgment of traffic congestion is the result of a cycle caused by urban construction and traffic environment deterioration under the guidance of a self-enhancement mechanism.

2.3. Method of Analysis

2.3.1. Operational causal chain

Definition 1. If the simulation equation of the causal chain from the variable X(t) to the dependent variable Y(t) is the function Y(t) = f(X(t)), wherein f is the operation symbol of the function, then the causal chain $X(t) \longrightarrow^f Y(t)$ that gives the simulation operation symbol is called the operation causal chain.

Definition 2. If we run the causal chain $X(T + k * DT) \longrightarrow^f Y(T + k * DT)$, it is called the causal chain of simultaneous operation of simulation step size. If the operation causal chain is $X(T + (k-1) * DT) \longrightarrow^f Y(T + k * DT)$, it is called the causal chain of simulation step length heteroscale operation.

Flow level variable simulation step length multi-layer operation causal chain. Since the flow bit $L_i(t)$ has the following function relationship:

$$L_i(T + k * DT) = L_i(T + (k-1) * DT) +$$
$$DT * R_{i1}(T + (k-1) * DT) \qquad (1)$$
$$- DT * R_{i2}(T + (k-1) * DT).$$

Then T is the starting time of simulation, and the left side of the function of the flow bit variable $L_i(t)$ is the simulation step length of $t = T + k * DT$, and the right side is the simulation step time of $t = T + (k-1) * DT$, with a difference of one simulation step DT.

The value of $L_i(T + k * DT)$ on the left side of the flow potential variable is the algebraic sum of the three terms on the right side of $L_i(T + (k-1) * DT)$, the inflow rate $R_{i1}(T + (k-1) * DT)$, and the outflow rate $R_{i2}(T + (k-1) * DT)$. There are three corresponding causal chains from right to left:

$$L_i(T + (k-1) * DT) \longrightarrow L_i(T + k * DT),$$
$$R_{i1}(T + (k-1) * DT) \longrightarrow L_i(T + k * DT), \qquad (2)$$
$$R_{i2}(T + (k-1) * DT) \longrightarrow L_i(T + k * DT).$$

The three chains from right to left of the flow potential variable are endowed with different operations to form the algebraic sum of the three terms and the functional expression:

① $L_i(T + (k-1) * DT) \longrightarrow L_i(T + k * DT)$, which is the addition of the three algebraic sums, the "+" operations, and the causal chain with the "+" symbol:

$$L_i(T + (k-1) * DT) \xrightarrow{+} L_i(T + k * DT). \qquad (3)$$

In this study, "+" in the causal chain represents the "plus" operation symbol, but this does not mean that the causal chain polarity is positive. The "-" is in the middle of the causal chain and represents the "minus" sign in the operation. The same applies to the operations below.

② $R_{i1}(T + (k-1) * DT) \longrightarrow L_i(T + k * DT)$ is the addition to the algebraic sum of three terms and is also the plus term. However, there is an operation term of $*DT$ again, so there is a causal chain with a "+ " and " $*DT$" double operation symbol. It is marked as follows:

$$R_{i1}(T + (k-1) * DT) \xrightarrow{+, *DT} L_i(T + k * DT). \qquad (4)$$

③ $R_{i2}(T + (k-1) * DT) \longrightarrow L_i(T + k * DT)$ is the subtraction item in the three-term algebraic sum and is the "-" operation item and also the operation item with $*DT$, so there is a causal chain with a "-" and " $*DT$" double operation symbol.

$$R_{i2}(T + (k-1) * DT) \xrightarrow{-, *DT} L_i(T + k * DT). \qquad (5)$$

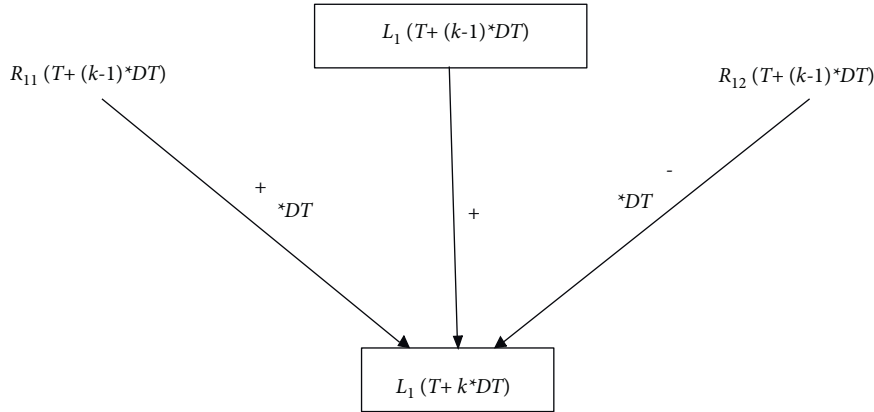
The above three operation causal chains reveal that the causal chain of the flow potential variable $L_i(T + k * DT)$ is composed of the following three causal chain diagrams of the different layer operations. Figure 2 shows that the vertex of the flow potential variable in the calculation causal chain graph is the frame vertex in the hold flow graph.
FIGURE 1: Example of reinforcing loop (a) and balancing loop (b).


FIGURE 2: Flow level variable $L_i(T + k * DT)$ of the different layer operation causal chain diagram.

Proposition 1. *The causal chain of flow potential variables operation in the system dynamics flow diagram is all 3-layer operation causal chain of flow potential variables $L_i(T + k * DT)$. It is the combination of the causal chain of the flow potential variables in the flow diagram and the simulation equation:* $L_i(T + k * DT) = L_i(T + (k-1) * DT) + DT * R_{i1} (T + (k-1) * DT) - DT * R_{i2}(T + (k-1) * DT)$.

Intuitively revealing the causal chain of different level operation, the value of the flow level variable $L_i(T + k * DT)$ is its last moment $L_i(T + (k-1) * DT)$ value, plus the inflow rate times the step size $DT * R_{i1}(T + (k-1) * DT)$ value, and the minus outflow rate times the step size $DT * R_{i2}(T + (k-1) * DT)$ value. Combining the causal chain with the simulation equation, the internal relationship between the causal chain and the simulation equation can be established, and the intuitiveness of the model can be enhanced.

Flow rate variable simulation step length time simultaneous operation causal chain. After the simulation calculation of flow level variable of the system dynamics model, the simulation calculation of flow rate variable is carried out, and the simulation calculation of flow rate variable is the same as the simulation step length calculation. For example, the quotient equation of outflow rate $R_{i2}(t)$: $R_{i2}(t) = L_i(t)/D_1$. The independent variables on both sides of the equation are t, and in the flow diagram, there exists a causal chain from the flow potential variable to the outflow rate:

$$L_i(t) \longrightarrow R_{i2}(t). \tag{6}$$

The operator of this quotient equation is $1/D_1$, at the $t = T + k * DT$ simulation step length, the causal chain of its parallel operation is:

$$L_i(T + k * DT) \overset{1}{\longrightarrow} /D_1 \; R_{i2}(T + k * DT). \tag{7}$$

The flow rate causal chain is the combination of the flow level variable to the flow rate causal chain and its simulation equation.

According to the definition, in the flow diagram of system dynamics, flow rate to flow rate, flow rate to auxiliary variable, auxiliary variable to flow rate, and auxiliary variable to auxiliary variable are all causal chains of the same layer operation.

Proposition 2. *In the dynamic flow diagram of the system, the causal chain of the most operation of flow level change is the causal chain of the simulation step length and time different layer operation, and the causal chain of the other variable operation is the causal chain of the simulation step length and time the same layer operation.*

Proposition 3. *System dynamics any simulation step length time $t = T + k * DT$. First of all, according to the causal chain of each flow potential variable with 3 different levels of operation, the $T + (k-1) * DT$ correlation multiplier of the*

previous simulation step is used to calculate the causal chain of each flow potential variable, and the values of all flow potential variables $t = T + k * D$ time are calculated. Then, do the same level operation for the other variables, the causal chain calculation, and calculate the values of $t = T + k * D$ time for all the other variables.

The above three propositions are the default requirements of the system dynamics simulation program.

2.3.2. Operation process diagram

Definition of operation process diagram. Let $G = (V(t), X(t))$ be an ordered binary, $V(t)$ is the vertex set, $V(t) = \{V_1(t), V_2(t), \ldots, V_{n-1}(t), V_n(t)\}$; $X(t)$ is the directed arc set, an arc is an ordered pair of $(V_i(t), V_j(t))$ composed of different elements of $V_i(t) \cdot V_j(t)$ of the vertex set $V(t)$. Then $G = (V(t), X(t))$ is called a directed graph.

Definition 3. directed graph $G = (V(t), X(t))$, t is the simulation step length time $T + K * DT$, $V(T + K * DT)$ is the vertex set of data process, arc set $X(T + K * DT)$ is the set of operation causal chain of assignment operation symbol, an ordered binary set of vertex sets of data procedures and causal chain sets of operations is called an operation procedure graph, recorded as $G = (V(T + K * DT), X(T + K * DT))$.

Definition 4. The computation process diagram of the simulation model is an ordered binary of the vertex set of the data process and the causal chain set of the computation.

The establishment steps of operation process diagram

Step 1. Based on the simulation table or some known conditions, the causal chain of flow graph variable is combined with the simulation equation, and the operational causal chain graph without calculating the vertex value is established layer by layer.

Step 2. The variable data process of calculating the uncalculated vertex values of each layer of the causal chain graph, showing the calculation process of variable vertex values.

3. Results and Discussion

3.1. The Logic of Traditional "Road Construction and Congestion Control" Policies. From the perspective of SD, this section describes two disadvantages of traditional road construction and congestion control strategy: the release of short-term hidden demand and the generation of medium - and long-term demand. To some extent, this opens the analysis and evaluation of several congestion control measures in the following discussion.

The direct cause of traffic congestion is an imbalance between the demand for car travel and the supply of road facilities. In recent decades, China's urbanization process has accelerated. An increasing number of people have entered cities, and living standards have been continuously improved. Private cars have gradually transformed from high-

end luxury goods to mass-consumption goods. Under the combined force of an increase in the population base and a rise in the private car ownership rate, the demand for car travel has increased, thereby rendering transportation infrastructure in many cities insufficient to support this shift, resulting in added traffic congestion [19].

Regarding public complaints, the government's pressure on congestion control has increased, and road construction has long been the dominant solution. Road widening, viaduct construction, expressway construction around the city, and other unimpeded projects are common in various cities in China. In addition, driven by the desire for image projects and urban expansion, Chinese city governments invest billions in road planning, construction, and management annually. This infrastructure is given to the car group free of charge, along with many modern traffic managers and management methods. Furthermore, 70% to 80% of traffic researchers' efforts serve car users [20].

From the perspective of SD, the causality of ①⟶②⟶③⟶④ groups form a closed negative feedback loop, thereby indicating that road construction can alleviate local traffic congestion in the short term (Figure 3). If traffic was simply a self-debilitating mechanism as many government officials and technologists imagine it to be, then the problem would be solved. However, this is not the case because there is a series of self-reinforcing mechanisms that play a more dominant role.

3.1.1. Post-Road Effect 1: The Release of Short-Term Hidden Demand. When the government was occupied by the positivity of road construction and ribbon cutting, urban congestion was alleviated immediately. However, in the short term, the appeal of car travel was rapidly improved, which directly encouraged people to drive both more frequently and for longer distances, thereby leading to the increase of car travel and the subsequent congestion of new roads (negative feedback loop ①⟶②⟶③⟶④, Figure 4). Conversely, the appeal of car travel became the most important factor in encouraging citizens to buy private cars, other than an increase in income, which also led to an increase in car travel volume and the deterioration of road congestion (negative feedback loop ①⟶⑤⟶⑥⟶⑦⟶④, Figure 4). Figure 4 shows that there are two negative feedback loops in the process of eliminating the congestion control effect caused by road construction, which indicates that the suppressed hidden demands of the original congestion period are released and transformed into explicit demands, thus aggravating the road burden.

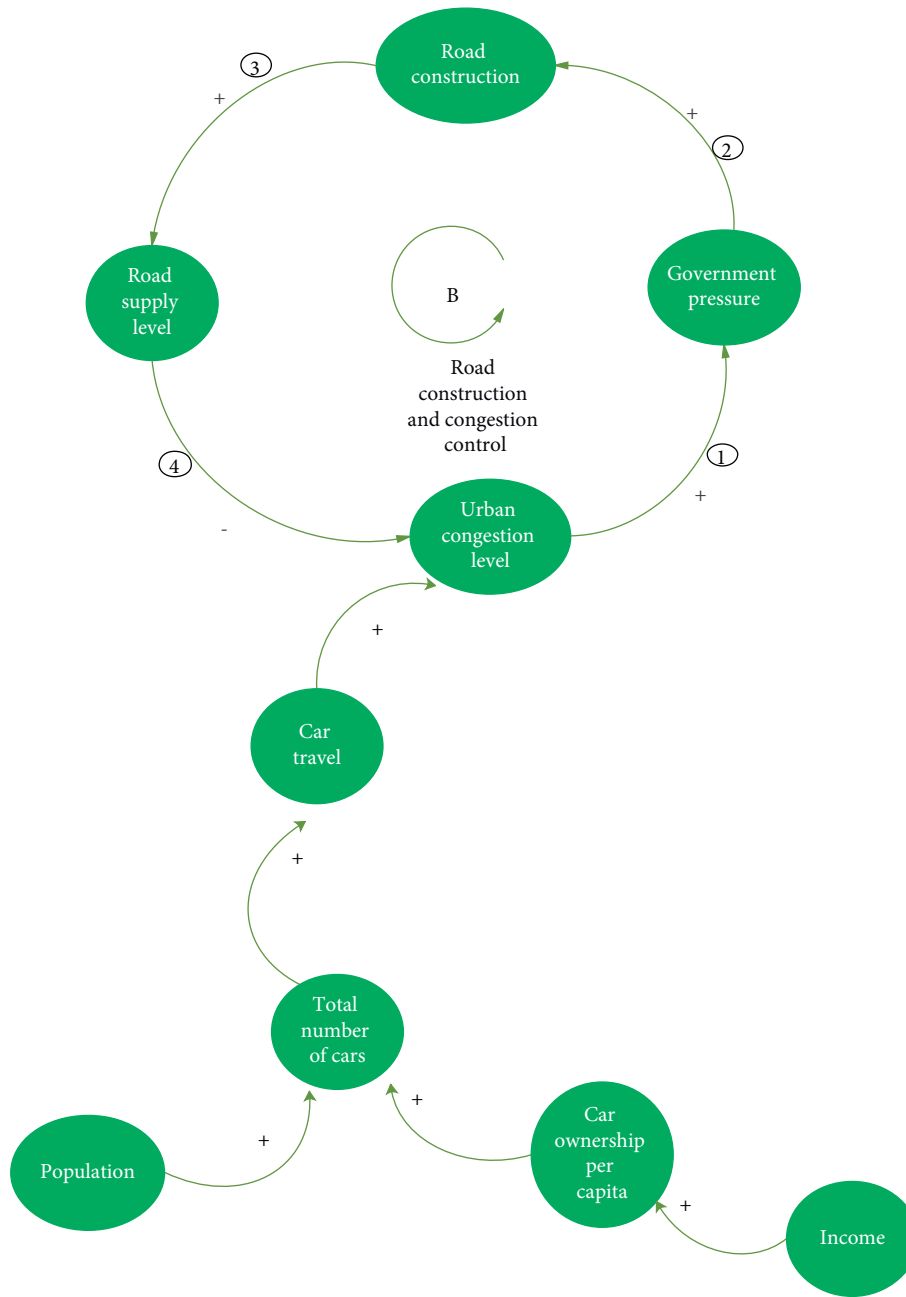
However, the four-stage traffic model of "trip generation - trip distribution - mode division - road network allocation," widely adopted by transportation professionals, cannot accurately simulate the hidden demands, which leads to the conclusion that more roads can solve congestion. Although traffic modelers assume future increases in travel demand in traffic forecasting scenarios, these demands are often considered the product of economic growth and car ownership. In this model, expanding the supply of road


FIGURE 3: Conventional logic of building more roads to relieve congestion.

infrastructure does not affect the forecast of future transport demand growth [21]. In other words, the importance of latent demand has been ignored.

3.1.2. Post-Road Effect 2: Generation of Medium- and Long-Term Derivative Demand.

In the medium- and long-term perspectives, road construction will also lead to a cycle of "congestion, road construction, congestion, and road construction" (Figure 5) because the government builds roads on the outer edge of the city to enclose land. This construction usually adopts a car-led development model, thereby resulting in a large amount of induced demand.

Three positive feedback loops account for the rapid deterioration of urban traffic congestion in China, as follows.

First, the imbalance between jobs and housing in new areas led to the emergence of several sleeping cities around central cities (such as Huilongguan and Tiantongyuan in Beijing). The migration of residents has greatly increased the daily commuting distance, which causes congestion. However, the government continues to build roads to control congestion, which causes a vicious cycle (positive feedback loop ①⟶②⟶③⟶④⟶⑤⟶⑥⟶⑦⟶⑧⟶①, Figure 5).

Second, large new urban areas accommodate more urban populations, thereby objectively increasing the total
FIGURE 4: Short-term release of latent demand after road building.

population base of urban travel and the congestion of the traffic system. Highstreets and large road networks lead to low permeability of bus systems, and meeting client satisfaction regarding speed and efficiency is a common problem. Regarding the slow traffic environment, the dredging and construction of the main roads block the microcirculation of the slow traffic network, resulting in the need for a long-distance detour to avoid crossing the road. However, intersections of wider roads form larger intersections, which causes excessively long waiting times at red lights, traffic disorder at intersections, and the need to climb the overpass under the underground passage; all of which causes inconvenience. Additionally, the car parking management in the new districts is loose, and the phenomenon of bicycle lanes and sidewalks being occupied by parked cars is prominent. Furthermore, because of the lack of bicycle parking facilities, parking is difficult, and it is easy to lose bicycles at destinations due to poor parking management. Subsequently, bicycles have become the second transportation choice, even for short- and medium-distance travel, thereby augmenting the reliance on car travel (positive feedback loop ① ⟶ ⑫ ⟶ ⑬ ⟶ ⑭ ⟶ ④ ⟶ ⑤ ⟶ ⑥ ⟶ ⑦ ⟶ ⑧ ⟶ ①, Figure 5).

Similarly, the third loop involves the deterioration of public transportation and slow-moving environments and has also led to a surge in the car ownership rate in new districts. Many people regard staying in large districts and buying private cars as binding lifestyle transition nodes (positive feedback loop ① ⟶ ⑫ ⟶ ⑬ ⟶ ⑮ ⟶ ⑯ ⟶ ⑪ ⟶ ⑤ ⟶ ⑥ ⟶ ⑦ ⟶ ⑧ ⟶ ①, Figure 5).

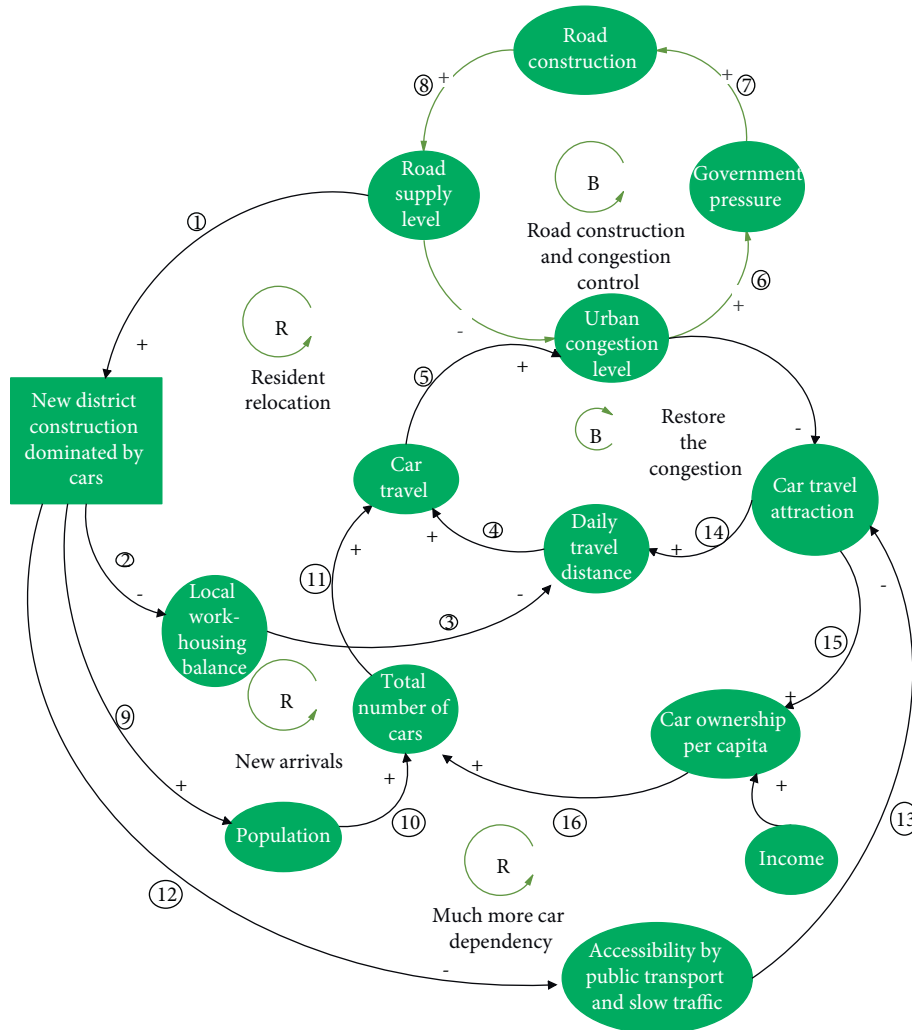
The three positive feedback loops outlined above are the main reasons for the rapid deterioration of urban traffic congestion in China. Taking Beijing as an example, in the last 10 years, the functions of Beijing have been concentrated in the central urban area, thereby resulting in a large increase in the proportion of long-distance travel that is difficult to complete on bicycles. According to a survey by the Beijing Transportation Development Research Center, the


FIGURE 5: Medium- and long-term generation of induced demand after road building.

proportion of bicycle trips in Beijing dropped from 30.3% in 2005 to 17.9% in the first half of 2019 [22]. Among the car trips, the proportion of short-distance trips within 5 km was more than 40% [23]. The reason for driving is because the environment for walking and cycling is deteriorating, which is closely related to the new urban form that is dominated by large blocks and wide roads.

The above analysis shows the mechanism of the release of implicit demand for car travel and the generation of the derivative demand in the post-road construction period. It can be predicted that when per capita income reaches a point where it is no longer a major barrier to household car consumption (for a significant portion of households), by allowing the ability to choose to travel by motor vehicle, traffic congestion will follow a barrel effect with slow bus accessibility as a shortcoming.

3.2. Analysis of Several Congestion Control Policies. According to the framework in the above section, the congestion control policies can be divided into five categories: similar road construction, rigid intervention, supply

adjustment, demand guidance, and sparse block collocation. Using the framework established in the previous section, we next analyze the congestion control policies.

3.2.1. Similar Road Construction Policies. Such policies include increasing the supply of parking spaces, improving the service level of intersections (building flyovers and pedestrian overpasses), enhancing the efficiency of road networks (using intelligent transportation systems and creating green wave corridors for vehicles), and so on [24]. The goal of these policies is to increase the space supply of motor vehicles or expand the capacity of road traffic by summarizing them as "similar road construction and congestion control" policies. Similar to road construction, closing the negative feedback loop indicates that the road supply level can indeed increase in the short term. However, it will soon be consumed by the released hidden demand and the newly-derived demand, thereby exacerbating traffic congestion further (Figure 6).

3.2.2. Rigid Intervention Policies. Rigid intervention policy measures include population control, license plate lottery,

FIGURE 6: Consequences of adopting similar road construction policies.

and car license plate restrictions, which are characterized by direct and forcible interventions in the growth of key elements within the traffic system (such as population and cars or car travel volume). Although these measures will have an immediate effect in the short term, they are often conducted at the expense of higher personal and social costs and are suspected of tending toward groups with vested interests. For example, after the restrictions on these key elements were implemented, the need to shift to the public transport system made the already crowded situation worse [25]. Meanwhile, such policies only temporarily transform part of the explicit demand into implicit demand, which is likely to be re-released when the policy is relaxed, thereby resulting in the rapid recovery of the system and the aggravation of congestion.

Many drivers and traffic police groups attribute traffic congestion to the low civilization quality of pedestrians and cyclists (such as running red lights, jaywalking, etc.), and believe that traffic civilization construction can be strengthened to alleviate traffic congestion [26]. However, without discussing the effectiveness and lag of the construction of traffic civilization, this can be attributed to the following reasoning. If from tomorrow, citizens begin to strictly observe the traffic order (such as not running red lights), then the traffic order may be greatly improved in a short time, thereby significantly improving the driving efficiency of motor vehicles. However, this improvement can only be made possible by inconveniencing pedestrian or cycle travel (such as the introduction of a long wait at traffic signals),

which, in the long term, will encourage people to drive, once they are able to buy a car, thus adding to the congestion[27].

3.2.3. Supply Adjustment Policies.

In contrast to the "rigid intervention type" policies, supply adjustment policies start from the "supply side," prioritize slow or public transportation and attempt to introduce a new negative feedback loop to achieve a self-reduction mechanism of congestion (Figure 7). By reducing unnecessary vehicle space (such as avoiding excessively wide vehicle lanes, reducing the turning radius of intersections, and adding safety islands), the crossing distance for slow pedestrians can be shortened, the speed of vehicles can be reduced, and the safety and convenience of walking and cycling can be improved. This result will indirectly improve the accessibility of the public transportation system and reduce the dependence on cars, cars' travel distances, and the rate of private car ownership, thereby reducing the number of car trips and alleviating traffic congestion (negative feedback loop ①⟶②⟶③⟶④⟶⑤⟶⑥⟶⑦, Figure 7; negative feedback loop ①⟶②⟶③⟶④⟶⑧⟶⑨⟶⑩⟶⑦, Figure 7).

The slimming of roads may seem to reduce the amount of space available for vehicles, but it does not. So, by optimizing the organization of roads and effectively reducing the interference of mixed traffic, it is possible to achieve a win-win situation for slow traffic and motor vehicles. In recent years, some foreign cities (such as New York, Copenhagen, Seoul, etc.) have boldly transformed urban motorways into slow lanes or bus lanes. As a result, they have not only improved the vitality of the city and the quality of public spaces but have also eased traffic congestion, which has been welcomed by citizens. For example, the renovation project of Broadway Avenue in New York transformed a congested road into a special strip for pedestrians to walk and rest (Figure 8). According to a recent evaluation study, the speed of vehicles in the area increased by nearly 17% after the project was implemented [28].

Another example is the Bus Rapid Transit (BRT) test line in Guangzhou, which was built in the most congested area where buses and social vehicles had serious interaction before its reconstruction. By turning the motor lane in the middle of the road into a bus lane, the running speeds of both public and social vehicles were improved (Figure 9). After the BRT corridor was put into operation in February 2010, the average speed of social vehicles along Zhongshan Avenue increased by 28% compared to before [29].

3.2.4. Demand-Oriented Policies.

From the perspective of demand management, the policies of economic leverage to increase cars' travel costs have increased parking fees, levied congestion charges, and strengthened the restrictions on unregulated parking. These measures can effectively restrain the uncontrolled use of cars during rush hour (negative feedback loop ①⟶②⟶③⟶④⟶⑤⟶⑥, Figure 10) and can simultaneously slow down the popularity of cars, reduce the number of car trips, and alleviate the degree of congestion (negative feedback loop ①⟶②⟶③⟶⑦⟶⑧⟶⑨⟶⑥, Figure 10).

Another benefit of increasing parking fees and congestion pricing is the amount of economic revenue that the city government can generate, which can then be used to subsidize the construction or improvement of the efficiency of the public transport system [30]. It can also improve the slow travel environment, increase the attractiveness of short- and medium-distance slow travel, and solve the last mile problem for long-distance bus travel. All these changes will reduce citizens' reliance on cars for travel, the distance traveled by cars, the rate of private car ownership, and car trips, thereby alleviating congestion (negative feedback loop ①⟶②⟶⑩⟶ 11 ⟶12 ⟶④⟶⑤⟶⑥, Figure 10; negative feedback loop ①⟶②⟶⑩⟶ 11 ⟶12 ⟶⑦⟶⑧⟶⑨⟶⑥, Figure 10). Similar measures have been adopted in London since February 2003, where part of the revenue from traffic congestion fees have been used to improve public transport in the region. As a result, not only did 20% fewer cars enter the city center every day, but buses were also 25% faster than before, thus reducing the delay time of motor vehicles in the congested charging areas during peak hours by 30% (Figure 10) [31].

3.2.5. Sparse Block Collocation Policies.

With the aim of increasing the construction of public transport systems and adopting the transit-orientated development (TOD) model in the construction of new areas around bus stations, the policies are to: (1) design walkable streets and pedestrian-scale blocks to enhance pedestrian traffic; (2) incorporate pedestrian safety and convenience requirements into architectural design; (3) reduce the demand for motor vehicles by creating bicycle-friendly road networks; (4) increase the use of public transport by building public transport-oriented streets and communities; (5) advocate mixed land-use patterns to disperse public travel destinations; and (6) establish public green spaces and services within walking distance of each other [32].

The impact of such policies can be explained by the following series of negative feedback loops (Figure 11).

Mixed land use enables more balanced employment and housing, shortens commuting distances, and reduces traffic demand. Simultaneously, it is possible to use bicycles and walk for short and medium distances, which increases the proportion of green travel and reduces car travel (negative feedback loop ①⟶②⟶③⟶④⟶⑤⟶⑥, Figure 11).

Increasing the construction of public transportation facilities and attractions of public transportation can reduce the dependence on cars. Owing to the distribution of attraction points along the bus corridor, pendulum traffic flow can be avoided. The reduction of the one-way distance per person can improve the bus carrying turnover rate and avoid one-way traffic congestion during peak hours. The development of small blocks can reduce bottlenecks along major and secondary roads and large intersections, thereby enhancing the permeability of public transportation services and solving the problem of the last mile by improving the
Figure 7: Consequences of adopting adjusting supply policies.

Figure 8: Before/after comparison of the Broadway renovation project in New York.

slow traffic environment. The impact of these aspects can reduce the attractiveness of car travel by lowering the private car ownership rate, car use intensity, and a number of car trips, thereby alleviating traffic congestion (negative feedback loop ①⟶②⟶⑦⟶⑧⟶⑨⟶⑤⟶⑥,

Figure 11; negative feedback loop ①⟶②⟶⑦⟶⑧⟶⑩⟶ 11 ⟶12 ⟶⑥, Figure 11).

If the number of parking spaces is reduced and the private car ownership rate of residents in TOD areas can be

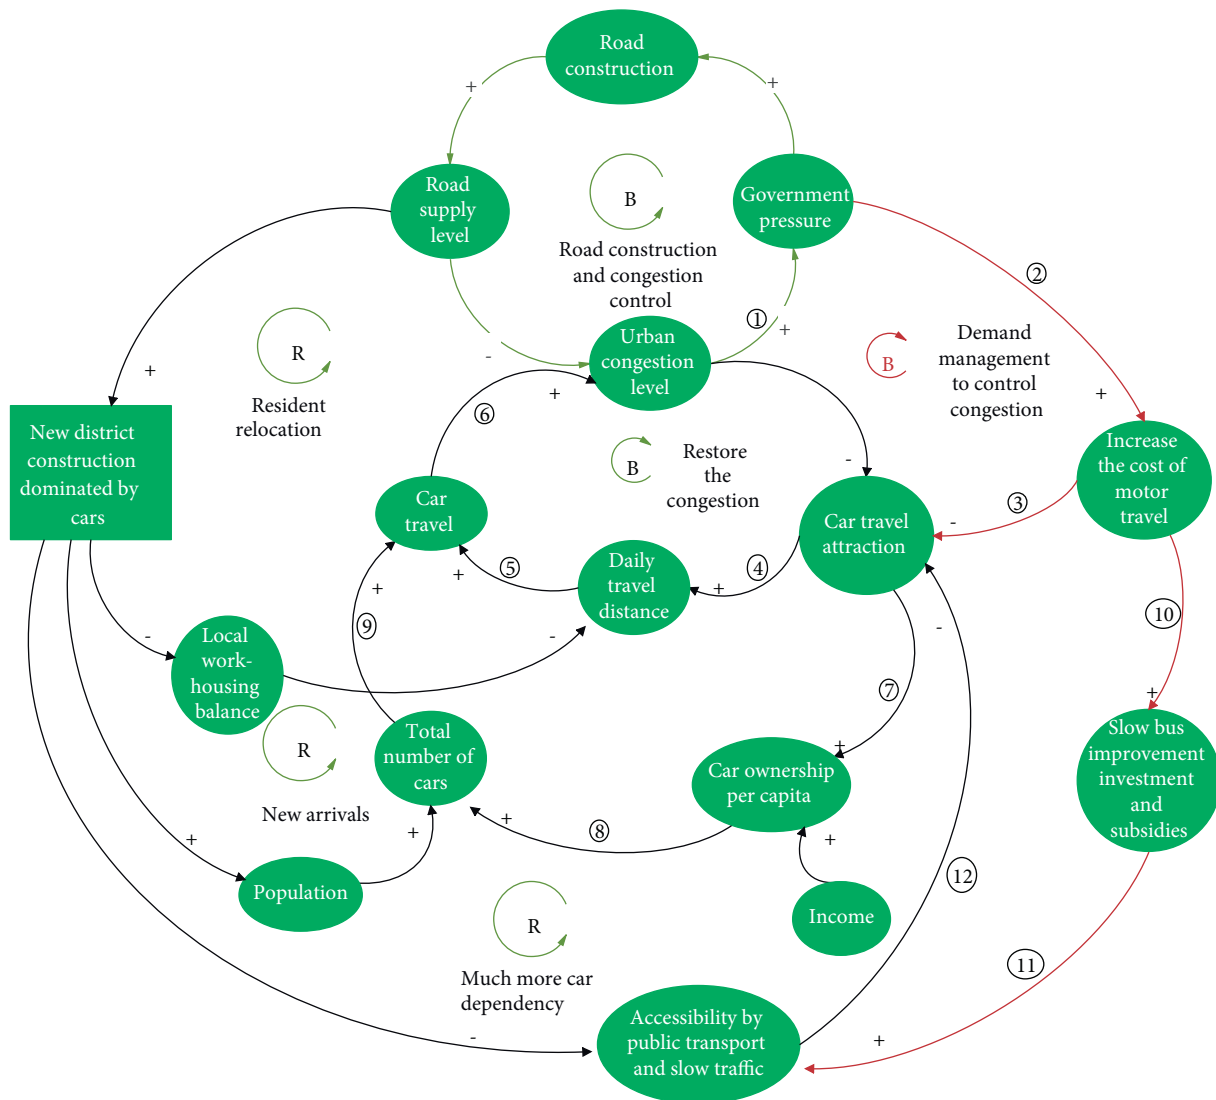
Figure 9: Before/after comparison of the Zhongshan Avenue renovation in Guangzhou.


Figure 10: Consequences of adopting demand-oriented policies.

effectively controlled to a low level, the number of car trips can be reduced and congestion alleviated (negative feedback loop ①⟶②⟶ 13 ⟶14 ⟶11 ⟶12 ⟶⑥, Figure 11).

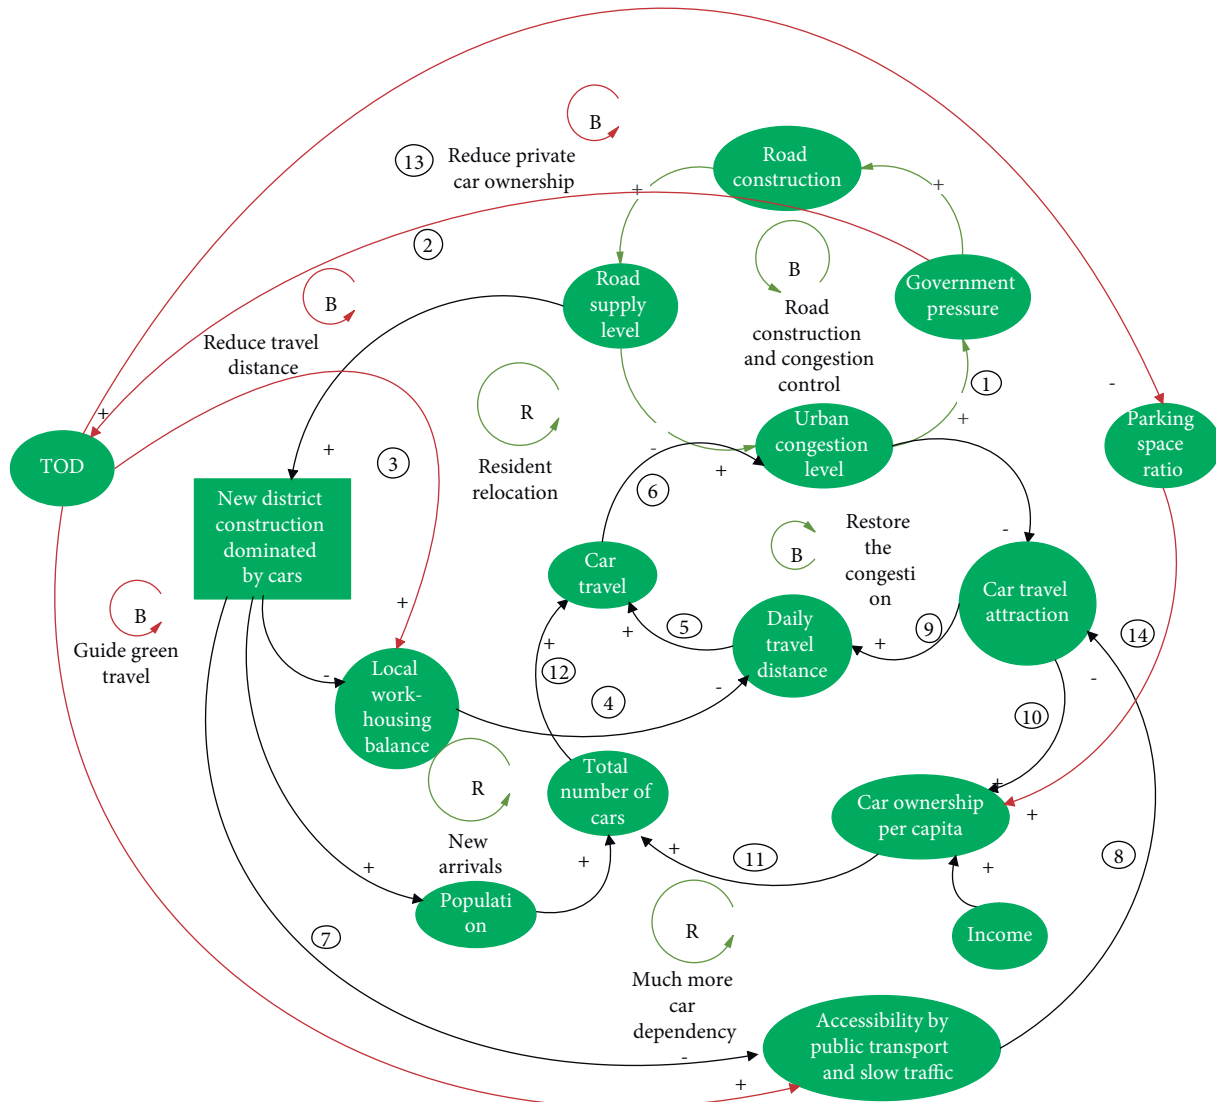
Compared with previous types of congestion control policies, public transit-guided development and sparse block collocation policies can establish multiple and effective congestion mitigation mechanisms from "open sources" (attracting car travel to other modes of transportation) to "throttling" (reducing basic travel volume), thereby creating more comprehensive and further-reaching traffic control.


Figure 11: Consequences of adopting TOD policies on the traffic demand and supply simultaneously.

4. Conclusions

This study builds an urban congestion mechanism model based on SD theory. The analysis shows that although traditional road construction and control congestion methods can alleviate congestion in a short period of time, the huge hidden demand and the development of car-oriented new districts caused by road construction will be prevalent in the future. Under the dual influence of the derived demand, traffic congestion will quickly recover and intensify. Unfortunately, traffic congestion cannot be solved by traffic engineers alone, as traditional traffic model predictions cannot simulate these interactions.

Faced with the pressure to control congestion, the government has adopted five policy types: similar road construction, rigid intervention, supply adjustment, demand guidance, and sparse block collocation. This study introduces the SD model to analyze these policies and shows that

similar road construction policies continue to misunderstand traditional road building to prevent traffic congestion. Although rigid intervention policies have immediate effects in the short term, they will be at the expense of personal convenience and social cost, and the suppressed hidden demand will eventually be released, making it unsustainable overall. The supply-adjusted policies and demand guidance policies are relatively more effective, not only for short-term results but also for long-term sustainability. Meanwhile, the sparse block collocation policies are the most sustainable and fundamental congestion control measure, with public transport-oriented land use and development as its core. It forms multiple negative feedback loops to relieve traffic congestion from both the supply and demand aspects. Although the land development policy is often regarded as a long-term policy, it is both urgent and necessary to take effective measures to curb its use, and instead, implement the concept of public transport-oriented development in urban

planning policy formulation in view of the rapid development of new areas dominated by cars in China at present.

The fundamental idea of congestion control should be people-oriented, not car-oriented. In the debate between mobility and accessibility, the government has always pursued the mobility of the road, which practices the neglect of essentials. Some officials have argued that the fundamental goal of tackling urban traffic congestion is to guarantee the basic right of residents to travel conveniently, including the freedom to travel by car [33]. In many cases, urban decision-makers often verbally advertise "slow travel first and people-oriented" congestion control measures; however, the ultimate goal is to increase the speed of motor vehicles. This fact is based on the premise of "not harming the interests of car travel" as opposed to the premise of "slow driving and people-oriented" measures, which would be accused of increasing blockages [34]. This logic ignores the harsh reality that given the number of people and high densities of China's cities, the rapid growth of China's economy, and the shortage of oil resources, there is probably no solution that will ultimately satisfy the right of every Chinese residents to drive.

It should be recognized that a small number of people in cities travel purely for the enjoyment of transportation and that most people travel to attain social, recreational, educational, employment-related, and other opportunities and benefits from destinations [35]. Therefore, the government's focus should not be on keeping roads clear (increasing mobility), but on improving accessibility and providing the easiest and cheapest way for citizens to travel. Scientific urban planning and appropriate public policies can achieve twice the result with half the effort. This study found that the sparse block collocation policy is the most sustainable strategy, but did not analyze the strategy's implementation details. Future research should start with the concrete implementation details of the sparse block collocation policy.

Correspondence should be addressed to Wen Huo; huowen@stu.ahu.edu.cn

The steering gear device includes two parts, a steering gear control circuit and a transmission component. The transmission component includes a ball screw and a motor. During the operation of the steering gear, due to the presence of the steering gear ball screw motor and friction, a certain amount of heat will be generated, which will affect the steering gear control circuit in a confined space. At the same time, the steering gear is inevitable in the actual working process, and will experience a high temperature environment, which will increase the temperature of the internal structure of the steering gear, and due to the difference in thermal expansion coefficients between various materials, stress and strain will occur in the structure, which may cause mismatch or even cracks in the system structure, and the steering gear system cannot work normally. It is necessary to analyze the thermal characteristics of the overall steering gear under multiple factors. Based on this, this paper uses COMSOL three-dimensional simulation software to conduct thermal simulation analysis on the shell of the steering gear containing the control circuit board. The temperature distribution and stress-strain response law of the control circuit board in the box, and the influence of different materials and thickness of the box heat insulation layer on the thermal characteristics of the control circuit are discussed, and then a reasonable thickness and material of the heat insulation layer are obtained for the design of the rudder chassis for reference.

1. Introduction

Servo: It is a set of automatic control system composed of DC motor, transmission parts, sensors, and control circuits, which control the output angle of the rotating shaft by sending specific signals. The steering gear generally has a maximum rotation angle. With the progress of the times, electronic packaging devices have increasingly higher requirements for their performance. The substantial improvement in performance has caused a rapid increase in the internal temperature of the packaged devices. Therefore, the thermal, electrical, and mechanical performance requirements for the board-level solder joints in electronic products are also rising. According to Moore's Law proposed by Dr. Moore, every 18 months, the integration

density of semiconductor crystals on active integrated circuits doubles. The control circuit is the control core of the package structure. The dense integration of the control circuit greatly increases the heat generation per unit volume of the heating device such as the chip, and generates more heat. At the same time, the number of solder joints used for the connection of the chip and the circuit board is also increasing. The solder joints in electronic packaging devices are very important in the working circuit [1], and are mostly used for mechanical support and electrical connections. Moreover, studies have shown that the high reliability of the solder joints on the control circuit board usually determines the durability of electronic packaging devices and the working life of the equipment.

2. Related Work

Ye et al. [2] used the GaN (gallium nitride) power amplifier chip as the basic model to analyze the thermal resistance characteristics of its heat transfer path and studied the effects of box material, thermal insulation layer material, and chip size parameters on the heat transfer path. The influence of thermal resistance provides a feasible reference solution for the heat dissipation of power amplifier chips in the future. Once the thermal resistance of the heat transfer path is studied, a feasible reference scheme is given for the heat dissipation of future power amplifier chips. Zhong et al. [3] used high-sensitivity real-time Moiré interferometry to study the interface behavior of flip-chip structures under thermal test conditions. Su et al. [4] taking the chip packaging structure as a model, using infrared thermal imaging technology, studied the change law of the chip thermal stress with the change of current, and it is found that the chip thermal stress changes logarithmically with the change of the working current. At the same time, the relationship between chip thermal stress and operating current was simulated by finite element method to verify its experimental conclusions. The thermal characteristics analysis of the subrack-level electronic packaging structure has achieved certain results under the research of domestic and foreign scholars. Liu et al. [5] studied the structural characteristics, working principle, and heat transfer process of the railway passenger car water purification tank, and established the three-dimensional finite element model of the clean water tank, and its thermal insulation process and heating process are analyzed by transient thermal simulation. The response results are compared with the experimental data to verify the reliability of the model and the research process. Mei et al. [6] used a heavy-duty gearbox as a research model. Aiming at the thermal deformation caused by the thermal load, the thermal characteristics of the gearbox structure were simulated, and the steady-state temperature field distribution of the structure was obtained. The distribution is used as the thermal load, and the response results such as stress, strain, and thermal deformation under the combined action of the thermal load and the structural load are calculated. Qi et al. [7] carried out a three-dimensional finite element modeling of the gear box, combined with the basic theory of heat transfer and finite element analysis theory to conduct a thermal-structural coupling analysis of the gear box, and obtained the temperature field distribution and heat of the gear box. According to the response results, such as deformation, the locations of the maximum stress and the maximum displacement are determined, and the factors affecting the temperature field and the deformation field are analyzed. Xu et al. [8] established a three-dimensional finite element model of a new type of ATCA subrack, and studied the heat dissipation of ATCA chips by changing the structural parameters. On this basis, they studied the influence of air-cooled heat dissipation and fan type on the heat dissipation of the structural box. The finite element simulation of ATCA sub-box structure provides suggestions for the optimal design of the structure. Yoon et al. [9] carried out a three-dimensional finite element modeling of the box structure of a railway bridge, a three-dimensional solid element meshing of the overall structure of the box, and a thermodynamic simulation by applying boundary conditions. Yang et al. [10] used Pro/E three-dimensional software for solid modeling, combined with the basic theory of thermodynamics and finite element analysis methods, and performed thermal-mechanical simulation calculations through finite element software ANSYS, and analyzed the results of its thermal response. The weak links of the box body are removed, and then a theoretical basis is provided for the optimal design of the box body structure. Huo et al. [11] conducted a thermal simulation analysis on the overall structure of the reducer, obtained the overall temperature field distribution of the reducer, and then used the temperature field distribution as the combination of the external thermal load and the static load on the reducer box for thermal-mechanical simulation analysis, Get the stress, strain, and thermal deformation distribution. This paper establishes an overall three-dimensional finite element model that integrates the steering gear control circuit board and the ball screw of the transmission component in a box with a heat insulation layer, calculates the heat source heat of each part of the ball screw of the transmission component, and explores the effect of its heat on the steering gear. The influence of the control circuit, simulating the harsh environment in which the steering gear is in service, placing the two box models with or without heat insulation layer under gradual temperature load for simulation, and comparing and analyzing whether there is heat insulation layer respond in order to explore the effect of the thermal insulation layer on the protection of the internal control circuit of the box. Ming Che et al. [12] used finite element analysis software to simulate the influence of silicon gasket on the heat dissipation of the chip in the package structure. The analysis of the calculation results shows that the better the thermal conductivity of the silicon material gasket, the more heat is transferred, and the purpose of reducing the temperature of the package structure can be achieved. Shuai and Li [13] studied the factors that cause the chip to overheat and the commonly used heat dissipation methods. At the same time, the heating plate is used as a constant heat source to simulate the heating of the computer CPU. The heat dissipation effects of five different types of fans are compared under the various power conditions of the heating plate. Wang and Shen [14] used a multi-chip double-sided PCB board as a model, and carried out finite element simulation by changing the thickness of the PCB board substrate, the size parameters of the chip, and the value of chip power. The analysis found that the above factors all have a large effect on the temperature value.

3. Methods

In the text, the literature on the subject is comprehensively summarized by the method of literature research, and the key literature is refined and summarized, and then the simulation and reproduction of the same model and the same working conditions are carried out through COMSOL, and then the reproduced results are compared with the results in the literature. Carry out comparative analysis, such as simulation cloud map trends, numerical values, and curve changes. Through the comparison of the results, the error

difference is small, which verifies the feasibility of this correlation method. Then, this simulation analysis method is applied to the existing project. At the same time, some data of the existing project are compared and verified by simulation and numerical value to verify the correctness of the relevant numerical value and simulation results.

4. The Influence of the Ball Screw of the Steering Gear on the Thermal Characteristics of the Box-Level Control Circuit

When the steering gear ball screw is in operation, the power loss of its driving motor, the bearing, and a certain amount of heat are generated due to friction, and the heat generated will affect the steering gear control circuit in the sealed steering gear device. Therefore, it is necessary to study the thermal response of the heat generated by the ball screw under the control circuit, and analyze the thermal response of the steering gear control circuit alone to explain the magnitude of the heat effect of the ball screw. Figure 1 shows the three-dimensional structure of the ball screw.

4.1. Calculation of Heat Source of Steering Gear Ball Screw

4.1.1. Calculate the Heat Generated by the Motor. The motor and the lead screw are connected by a coupling, so the heat of the motor is transferred to the lead screw end by heat conduction. The heat is mainly related to the output torque of the motor and the mechanical efficiency of the motor. The heating of the motor is calculated by the following formula:

$$Q = \frac{M_T \cdot n_1}{9550(1 - \eta)},\tag{1}$$

formula: Q—heat dissipated, the unit is kW; M_T—the output torque of the motor, the unit is $N \cdot m$; n_1—motor speed, the unit is r/mim; η—mechanical efficiency of the motor, generally 0.85–0.9, here it is 0.9.

4.1.2. Calculation of Bearing Friction and Heat Generation.
The friction of rolling bearings is mainly due to the heat generated by the total resistance of the components inside the bearing to the movement when the inner and outer rings of the bearing rotate. Therefore, this part of the heat is not only related to the friction torque of the bearing but also proportional to the rotational speed of the ball screw. The heat can be calculated by the following formula:

$$Q = 1.047 \times 10^{-4} n_2 M,\tag{2}$$

formula: M—frictional moment of rolling bearing; n_2—screw speed.

The friction torque M of a rolling bearing is mainly composed of two parts, the torque M_0 related to the bearing speed, type, and lubricant properties, and the friction torque M_1 related to the bearing load, $M = M_0 + M_1$. M_0 is related to the bearing speed, type, and lubricant properties, and reflects the hydrodynamic loss of the lubricant.
FIGURE 1: Three-dimensional structure of ball screw.

4.1.3. Ball Screw Nut Pair Calorific Value Calculation. During the operation of the ball screw, the screw rotates and drives the balls to roll along the spiral raceway. At the same time, the balls themselves are also rotating. At this time, the friction between the ball screw and the nut is expected to produce friction between the balls. The heat is the heat generated by the ball screw nut.

The calculation expression of this part of the heat is similar to the friction heat of the rolling bearing, but the friction torque of the ball screw nut pair is composed of the driving torque M_D and the resistance M_P. The driving torque M_D of the screw refers to the driving torque that the screw drives the nut to do reciprocating motion against the axial load, Which is calculated as follows:

$$M_D = \frac{F_a P_h}{2\pi\eta},\tag{3}$$

formula: F_a—axial force of the screw; P_h—lead screw; η—the working efficiency of the screw nut transmission.

The resistance torque M_P of the ball screw refers to the preload of the screw nut pair, and the calculation formula is as follows:

$$M_p = \frac{F_p P_h * \left(1 - \eta^2\right)}{2\pi},\tag{4}$$

where F_P is the axial preload of the screw.

By querying the above parameter data and calculating by formula, it can be obtained that the heating power of the driving motor is 6.713 W, the friction heating power of the nut pair is 5.867 W, and the friction heating power of the bearing is 0.3995 W. According to the analysis of the actual situation, the heat generated by the friction of the nut pair and the bearing is mostly diffused by internal heat conduction loss, and the heat exchanged by convection through the air medium is very small, so the heat of the ball screw is equivalent to the heat of the driving motor.

4.2. Analysis of the Influence of the Ball Screw of the Steering Gear on the Thermal Simulation of the Control Circuit.
The working power of the heating source of the steering gear ball screw motor is 6.7 W, and the working model of the

driving motor and the steering gear control circuit are the same. The trend is shown in Figure 2, and the motor power value is 6.7 w.

The temperature trend is obtained by iteratively calculating the power load applied to the drive motor by finite element. Figure 3 shows the maximum temperature distribution trend chart of the drive motor after the end of the working cycle. The maximum temperature increases linearly during the working time and during the cooling time. Due to the large size of the motor, it is not enough to have a significant temperature change during the cooling time of this cycle. Therefore, the maximum temperature of the driving motor progresses with the cycle, and the maximum temperature shows a stepwise increase trend, and reaches the maximum temperature at the final time 20.522°C. The temperature rise rate is only 0.00348°C/s, so it is quantitatively considered that the heat source of the ball screw has little influence on the steering gear control circuit.

5. Establishment of a Three-Dimensional Finite Element Model of the Subrack-Level Steering Gear Control Circuit Board

5.1. Finite Element Model. The physical diagram of the steering gear device is shown in Figure 4. The control circuit and the ball screw are separated on both sides and fixed with the contact surface by bolts. Figure 5 shows the steering gear box with a 2 mm heat insulation layer designed according to the physical model. It fits seamlessly with all sides of the steering gear box to form a closed body. In order to improve the calculation efficiency, the steering gear control circuit model will be further simplified, and the SOP package with less impact on the overall body and other components far away from the heat source are ignored; in the previous section, by calculating and analyzing the heat generated by the motor, the frictional heat of the ball screw, and the heat generated by the nut pair, it is known that the frictional heat of the ball screw is mainly internal solid conduction. The influence of convection heat transfer on the control circuit is small, so in order to reduce the calculation load, the ball screw is ignored in the finite element simulation analysis model in this article. The final three-dimensional finite element model of the steering gear structure is shown in Figure 6.

5.2. Material Properties. In the simulation analysis of this article, the steering gear control circuit and the steering gear ball screw are assembled in the box as the research body. At the same time, the thermal characteristics of the steering gear control circuit are explored to identify whether there is a heat insulation layer and the influence of the parameters of the heat insulation layer on the thermal characteristics of the steering gear control circuit. Material is structural steel (steel structure), an epoxy material is an insulating layer, and each of the parameter values as detailed in Tables 1 and 2.

5.3. Meshing. The whole steering gear device is mainly divided into a free tetrahedron, and the parameters of each part are customized to achieve the purpose of optimal grid
Figure 2: Power cycle load.
Figure 3: Trend chart of maximum temperature distribution of drive motor.
Figure 4: The physical diagram of the control circuit of the box-level steering gear.

division. Set the minimum unit parameter of the important component QFP package, the value is 0.001 mm, the minimum unit parameter of the chip power inductor is set to
FIGURE 5: Steering gear box with heat insulation layer.
FIGURE 6: Simplified assembly drawing of the steering gear.

TABLE 1: Thermal simulation material properties.

Material	Thermal conductivity (W/(m K))	Density (kg/m³)	Specific heat capacity (J/(Kg K))
Structural steel	44.5	7859	475
Epoxy resin	0.1	980	1000

TABLE 2: Thermal-mechanical simulation material properties.

Material	Young's modulus (MPa)	Poisson's ratio	Thermal expansion coefficient [1/K]
Structural steel	2E5	0.3	$1.23E\text{-}5$
Epoxy resin	1.2E5	0.3	$6.71E\text{-}5$

0.01 mm, and the minimum unit parameters of the other PCB, steering gear, and heat insulation layer are set to the 0.1–5 mm range, the final overall meshing diagram is shown in Figure 7. Combined with the grid distribution diagram, it is found that the grid value around the important components is close to 1, and the quality is good. Therefore, it is believed that the grid division meets the accuracy requirements and can be used in finite element simulation calculations.

If the grid is further refined to make the grid quality reach about 0.85, the temperature inside the box is 70°C when it is stable, and the maximum temperature difference between the two is 1.4°C, it is considered that the difference is small. Within the acceptable range, it is quantitatively considered that the grid division with unit mass of 0.7955 has met the requirements of grid independence.

5.4. Boundary Conditions. The research and analysis process in the steering gear box is based on the working state of the rudder control circuit itself, so its boundary conditions are set as follows:

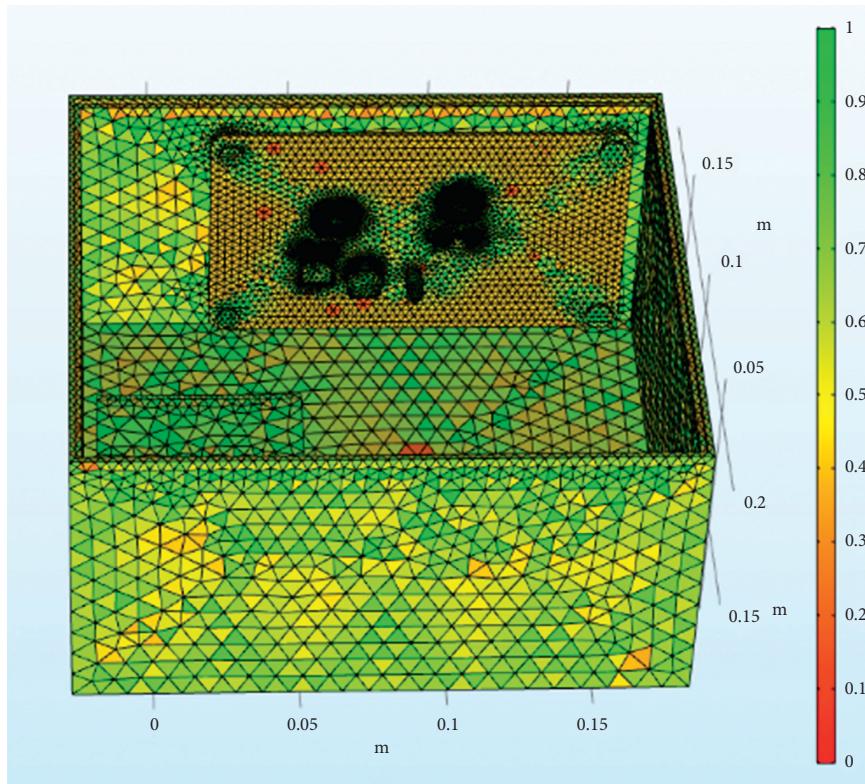
(1) Apply 1 W cyclic power to the heating source of the steering gear control circuit. Its changing trend is shown in Figure 2. In the power cycle load, the


FIGURE 7: Overall finite element mesh division of the steering gear.

ambient temperature is set to 20°C, the power is increased to the rated power after 0.1 s from the beginning of the cycle, and the duration is 5 s. After that, the power is reduced from the rated power to 0 after 0.1 s, and the cooling time of 20 s is a complete cycle. A full cycle time is 25 s with a 20% duty cycle. The chip loading power is 1 W. In this section, the cycle power is loaded for a total of 150 s;

(2) The ambient temperature of the working condition is set to 20°C.

(3) Fixing constraints are imposed on the lower surface of the steering gear box and the four bolts participating in the fastening connection, and the fixing constraints are shown in Figure 8.

(4) Set the convective heat transfer coefficient on the inner and outer surfaces of the box, and the coefficient is set to 10 W/(m²·K).

6. Analysis of the Thermal Characteristics of the Thermal Insulation Layer to the Plug-In Box Level Control Circuit

6.1. Temperature Response Analysis. In the process of service, the steering gear will usually experience a harsher natural environment, which will have a certain impact on its internal structure. In severe cases, it will cause the steering gear to malfunction. Therefore, the existence of a thermal insulation layer should be considered at the beginning of the steering gear design. Reduce the probability of failure of the steering gear.
FIGURE 8: Fixed constraint setting.

In the finite element simulation calculation, the environmental temperature change load is applied to the outer surface of the steering gear. The environmental temperature was raised from the initial temperature of 20°C to 90°C over 125 s, and was maintained until 250 s, with a temperature rise rate of 0.5°C. The case surface is in contact with the insulation layer. The external heat is transferred from the case to the insulation layer through heat conduction, and finally the temperature of the inner surface of the heat insulation layer is measured. As the air flow rate inside the steering gear box is extremely low, the inner surface of the heat insulation layer is considered to be equivalent to the temperature inside the steering gear box. The measured temperature inside the steering gear box is shown in

Figure 9. It shows that the temperature inside the box reaches a stable temperature of 68.6°C, and the heat insulation efficiency reaches 24%.

The external temperature-varying load is applied to the outer surface of the steering gear, and the measured time-varying temperature inside the steering gear is equivalent to the convective heat exchange external temperature, which is used to simulate the process of air transferring heat to the control circuit through convective heat exchange. After iterative calculation, the final temperature distribution of the steering gear under the action of the heat insulation layer is shown in Figure 10. The maximum temperature appears at the contact point between the lower surface of the control circuit and the heat insulation layer. The maximum temperature value is the ambient temperature of 90°C, and the minimum temperature value of 23.8°C appears on the drive motor. The drive motor is made of copper and has a large volume. At the final moment, there has not been a sufficiently high temperature rise, and the temperature value is low.

The steering gear control circuit is the core control component of the overall steering gear. Figure 11 is the cloud map of the temperature distribution of the PCB board at the final moment under the action of the thermal insulation layer. The main heat sources of the PCB include three parts: including the heat transferred through the convective heat transfer of the air medium. The bolt is in direct contact with the steering gear box and the control circuit through the heat transferred by heat conduction, and the heat generated by the intermittent operation of the heating source on the control circuit is transferred to the PCB through the pin solder foot heat. Therefore, it can be found in the figure that the maximum temperature of the control circuit appears at the bottom right corner where the lower surface is in contact with the heat insulation layer and reaches 65.7°C, and the minimum value appears on the upper surface of the control circuit, and its value is 50°C. The lower surface temperature of the control circuit is higher than the others. Components and the four bolt holes are relatively high due to the presence of heat conduction. The heat generated by the chip and the patch power inductor is relatively small compared to the outside temperature, so there will be no obvious temperature gradient near it.

Figure 12 shows a QFP package pin and a temperature change of the fillet. The curve is derived from the QFP package with increasing time. The temperature is gradually increased. At the time, the final temperature reached 51°C. At the same time, small periodic bulges will appear during the overall temperature rise of QFP package. This is because during this period of time the chip generates a certain amount of heat due to its own power, which causes a sudden temperature rise in the corresponding period of time, resulting in bumps. In addition, the heat generated by the power of the chip is transferred from the chip to the pins and then to the solder feet. The transfer process causes a certain temperature difference between the solder feet and the pins. Therefore, the temperature of the pins is slightly greater than the temperature of the solder feet during the relevant cycle period. Since the initial temperature value of QFP is low, the temperature rise rate is lower in the early stage of the environmental temperature effect, and the curve climbing trend is slower. In the later stage of the effect, the temperature rise rate is faster and the curve climbing trend is steeper.

6.2. Structural Response Analysis. Import the above temperature results into the structure module to calculate the structure results, as shown in Figure 13, which is a cloud diagram of the stress distribution of the steering gear at the final moment under the action of the heat insulation layer. Because the ambient temperature of the steering gear box and the steering gear itself has a larger temperature gradient, the wall of the steering gear produces a larger stress value, and the maximum stress value is at the edge position where the cover plate contacts the case body, which is a stress concentration phenomenon.

Since the overall stress gradient distribution of the steering gear is quite different, the PCB and the four bolts are separately analyzed for stress. As shown in Figure 14 is the stress distribution cloud diagram of the PCB board, the maximum stress appears on the surface of the bolt hole in the upper left corner, and the value is 75.3 MPa; Figure 15 is a cloud diagram of the stress distribution of four bolts. The maximum stress appears on the surface of the bolt at the lower right corner, and its value is 316 MPa. Query data learned by, the PCB yield strength of 350 MPa, yield limit of the steel of 454 MPa, the PCB and the bolt stress values are less than the corresponding yield limit.

Figure 16 shows the stress distribution trend diagram of the first group of pins and solder feet of the QFP package. The change trend is similar to the temperature change trend, and the stress value gradually increases with time. Among them, the copper pin stress change trend has obvious bump changes with the change of the chip power cycle, and the tin-lead soldering pin changes smoothly with the cycle. At the final moment, the stress value of the copper pin reached 90.7 MPa, and the stress value of the tin-lead solder pin reached 41 MPa.

Through the analysis of the stress value of PCB, four bolts and QFP pin solder foot, combined with the corresponding yield limit of each material and their respective common failure modes, it is conservatively considered that the common failure location of the steering gear control circuit is QFP under severe environmental conditions—the connection point between the pin and the solder foot.

7. Analysis of Thermal Characteristics of Sub-Box-Level Control Circuit with or without Heat Insulation Layer

In the previous section, the thermal response results of the steering gear box and the internal control circuit under the action of the heat insulation layer were elaborated. This section quantitatively analyzes the influence of thermal insulation by comparing the thermal characteristic response under the action of thermal insulation. The lower surface of the internal control circuit of the thermal insulation model is
FIGURE 9: Internal and external temperature curve of steering gear.
FIGURE 10: Cloud diagram of the temperature distribution of the steering gear at the final moment under the action of the heat insulation layer.

in contact with the thermal insulation, while the model without the thermal insulation is in contact with the surface of the box. In the finite element analysis and calculation, Figure 17 shows the internal temperature curve of the cabinet with or without the heat insulation layer. From the figure, it can be seen that the internal temperature value without the heat insulation layer is close to the external ambient temperature. When it reaches 89.8°C, the internal temperature value under the action of the heat insulation layer is 68.6°C. Only from the internal temperature performance analysis of the box, the thermal insulation

efficiency of the thermal insulation layer is 24%, and the thermal insulation effect is significant.

The external temperature change load is applied to the outer surface of the steering gear, and the measured time-varying temperature inside the steering gear is equivalent to the external temperature of convective heat transfer. Figure 18 shows the overall temperature distribution cloud diagram with or without heat insulation. In the figure, it can be seen that the overall temperature of the internal control circuit without the effect of the heat insulation layer is significantly higher than that of the internal control circuit
FIGURE 11: The temperature distribution cloud diagram of the PCB board at the final moment under the action of the heat insulation layer.
FIGURE 12: QFP package body pin and solder foot temperature change trend.

under the effect of the heat insulation layer. The two models have similar temperature distribution trends on the control circuit. The temperature of the four bolts is higher than that of other parts of the control circuit board, and the temperature of the middle position is lower. As shown in Figure 19, the temperature distribution of PCB with or without insulation layer is completely consistent. The maximum temperature of PCB without insulation layer is 90°C, and the minimum temperature is 68°C. The average temperature of the PCB board is 79°C; the highest temperature of the PCB board under the action of the heat insulation layer is 65.7°C, the minimum temperature value is 50 °C, and the average temperature of the PCB board is 57.4°C. The overall temperature of the two models is quite different.

Figure 20 shows the maximum temperature curve of the PCB board with or without the heat insulation layer. In the model without the heat insulation layer, since the lower surface of the control circuit and the bolt surface are directly

in contact with the steering gear box, the structural steel material has good thermal conductivity; therefore, the temperature rise rate of the PCB board is very fast, reaching the maximum value of 89.2 °C in a short time, and the temperature change curve is steep; in the insulation layer model, due to the existence of the insulation layer, the temperature that reaches the inside within the same time is much less than where there is no insulation layer. In the thermal layer model, the maximum temperature at the final moment is 65.7 °C, and from the figure, it can be concluded that the temperature growth trend of the PCB board is relatively flat.

Figure 21 shows the temperature curves of the three bolt faces with or without the heat insulation layer. The analysis shows that the temperature values of the left and right bolts on the lower surface are similar. Here, we only study the temperature of the three bolt faces. The analysis shows that there is no heat insulation. The bolt temperature value and the temperature rise rate in the layer model are greater than those in the insulation layer model. A comparative analysis
FIGURE 13: The stress distribution cloud diagram of the steering gear at the final moment under the action of the heat insulation layer.
FIGURE 14: The stress distribution cloud diagram of the PCB board.

of the maximum temperature changes of PCB boards and bolts in the model with or without the insulation layer is carried out. The temperature and rate of temperature rise of the insulation layer model are lower than those of the model without insulation layer, and the values are quite different.

Figure 22 shows the temperature curve of QFP pin solder fillet with and without thermal insulation layer. The temperature value of QFP pin solder pin under the thermal insulation layer model and the QFP pin solder pin under the model without thermal insulation layer are almost the same. At the same time, it can be found that the temperature values at the same location in the two models are quite different.

Figure 23 shows the overall stress cloud diagram with or without the thermal insulation layer. It can be concluded that stress concentration occurs in the overall stress distribution with or without the thermal insulation layer. Among them, the overall stress without the thermal insulation layer is greater than that with the thermal insulation layer. With the overall stress under the action, the maximum stress on the control circuit board inside the box still appears on the bolt surface.

The QFP pin soldering foot of the dangerous component on the control circuit is selected as the research object. Figure 24 shows the stress of the QFP pin soldering foot with or without the heat insulation layer. The final stress values of the pins without the heat insulation layer are 153 MPa and 90 MPa, respectively; the final stress values of the pins under the action of the heat insulation layer are 61 MPa and 41 MPa, respectively. The solder foot is made of tin-lead
FIGURE 15: Stress distribution cloud diagram of four bolts.
FIGURE 16: QFP package body lead and solder foot stress trend.

FIGURE 17: The internal temperature curve of the box with or without the heat insulation layer.

material, and the required stress value is 45 MPa. Therefore, the solder foot failure phenomenon may occur without the action of the heat insulation layer, which will cause the steering gear to fall into failure mode. By comparing the temperature and stress of the PCB board, bolts, and QFP pin solder feet under the action of the heat insulation layer, the values of the two are quite different, and the effect of the heat insulation layer is significant. Therefore, it is considered that heat insulation should be considered at the beginning of the design. Layers are necessary and indispensable.

Through comparative analysis of the temperature and stress response results of PCB board, bolts, and QFP pin solder feet under the action of the heat insulation layer, the response value under the action of the heat insulation layer is much smaller than the corresponding value under the action where there is no heat insulation layer In response to the

numerical value, the effect of the insulation layer is significant, so it is considered necessary to consider the insulation layer at the beginning of the design.

8. Comparative Analysis of Thermal Characteristics of Different Parameters of Insulation Layer

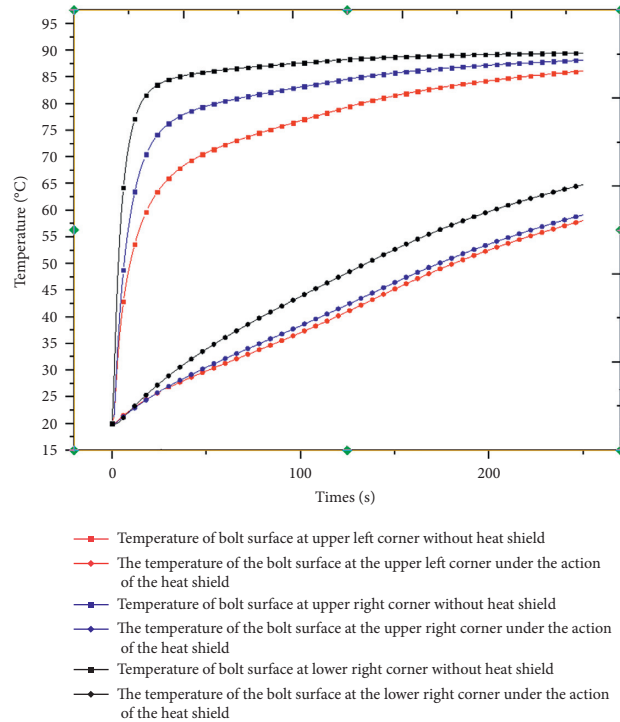
8.1. Comparative Analysis of Thermal Properties of Different Thermal Conductivities of Thermal Insulation Layers. The thermal insulation layer of different materials has different thermal conductivity, and the heat transfer from the external environment to the inside through the heat conduction method is different, which makes the temperature gradient generated by
FIGURE 18: Cloud diagram of overall temperature distribution with or without heat insulation layer. (a) Cloud diagram of overall temperature distribution without heat insulation layer. (b) Cloud map of the overall temperature distribution under the action of the thermal insulation layer.
FIGURE 19: PCB board temperature distribution with or without heat insulation layer. (a) PCB board temperature distribution without heat insulation layer. (b) PCB board temperature distribution under the action of the heat insulation layer.
FIGURE 20: PCB board temperature with or without the heat insulation layer.


Figure 21: Bolt surface temperature with or without the heat insulation layer.
Figure 22: QFP pin solder foot temperature with or without heat insulation layer.

the internal heat acting on the control circuit different. This section aims to study the thermal response of different materials and selects the one with better comprehensive performance of the selected materials by comparative analysis.

This section selects foamed polyurethane (EPU) materials with a thermal conductivity of 0.047 and asbestos materials with a thermal conductivity of 0.152, and comprehensively compares and analyzes the epoxy resin materials with a thermal conductivity of 0.1 studied in the previous section, from the aspects of thermal insulation effect and economic cost. Consider choosing a more suitable insulation material.

Figure 25 shows the internal surface temperature curve measured under the action of different insulation layers when the external environmental load is applied to the box body. The internal temperature reached is also different due to the different thermal conductivity of each material. Under the action of EPU, epoxy resin, and asbestos materials, the internal temperature reaches 58.8, 69.9, and 75.1, respectively. Due to the certain hysteresis of heat conduction, the time node when the internal temperature reaches stability under the action of the three thermal insulation materials is greater than the time node when the ambient temperature reaches stability.

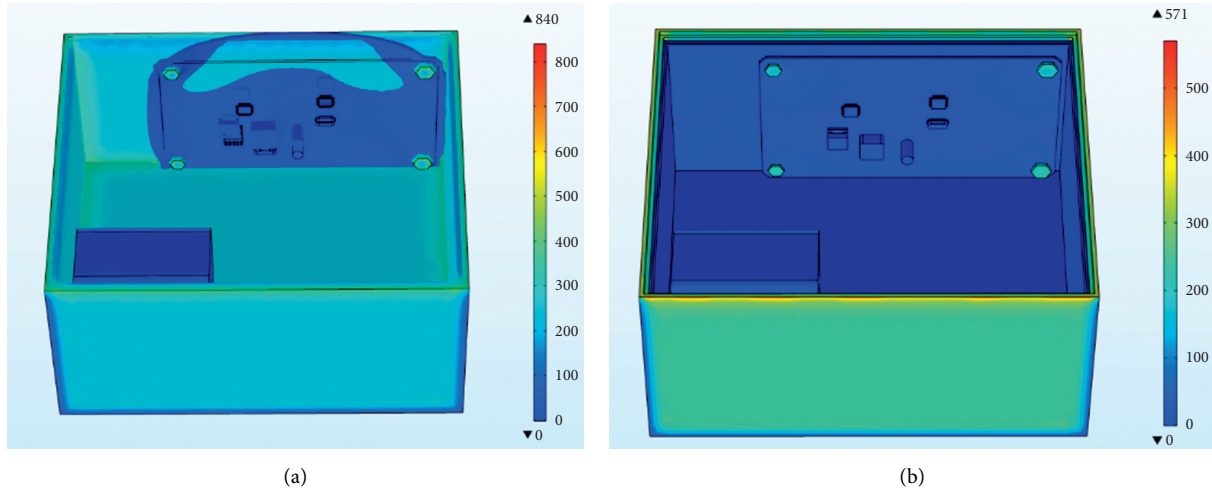
(a)   (b)


FIGURE 23: Overall, stress cloud diagram with or without heat insulation layer. (a) Overall stress cloud diagram without heat insulation layer. (b) The overall stress cloud diagram under the action of the insulation layer.
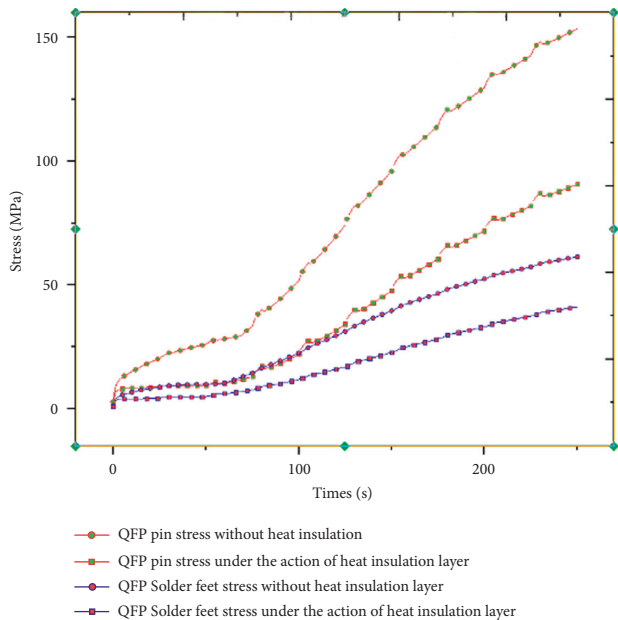

FIGURE 24: QFP pin solder foot stress with or without heat insulation layer.
FIGURE 25: The internal temperature of the box under different materials.

Figures 26(a)–26(c) are the overall temperature cloud diagrams under EPU, epoxy resin, and asbestos materials, respectively. It can be found from the figure that the overall temperature of the internal control circuit under the action of the EPU heat insulation layer material is the lowest, and in the asbestos the overall temperature of the internal control circuit under the action of the heat insulation layer material is the highest. With the increase of the thermal conductivity, the temperature of the internal control circuit increases. The temperature trend under the action of the three materials is the same, and the temperature value of the four bolts is higher than that of other positions of the PCB.

The control circuit is located in the steering gear and exchanges heat with internal heat through convection heat exchange. The temperature rise trend of different components on the control circuit is analyzed separately, and PCB and QFP solder feet are selected to study the temperature rise trend. Figure 27 shows the temperature rise curve of the PCB board under the action of three different heat insulation materials. The corresponding materials are EPU, epoxy resin, and asbestos. The maximum temperature of the PCB board at the final moment is 60.9°C, 65.6°C, and 72.7°C. The maximum temperature increase was 7.8% and 10.8% in sequence. Figure 28 shows the temperature rise curve of QFP soldering feet under the action of different insulation materials, corresponding to EPU, epoxy resin, and asbestos. The maximum temperature of QFP soldering feet at the final moment is 44.6°C, 51.7°C, and 56.2°C. The maximum temperature increase was 15.9% and 8.7% in sequence. The PCB board and QFP

(a)

(b)

(c)
FIGURE 26: Overall temperature cloud diagram under different materials. (a) Overall temperature cloud diagram under EPU material. (b) Overall temperature cloud diagram under epoxy resin material. (c) Overall temperature cloud diagram under asbestos material.
FIGURE 27: PCB board temperature under the action of different insulation materials.
Figure 28: Welding foot temperature under the action of different insulation materials.

comparative analysis of the temperature rise curve of the solder foot shows that the temperature rise curve rate of the PCB board is first large and then small, and the temperature rise rate of the QFP solder foot is first small and then large. The reason is that the temperature of the PCB increases through the heat conduction method. The main heat source of the QFP is Convection heat exchange with the internal air causing the temperature to rise.

Since the overall stress cloud chart trends under the action of different insulation materials are completely consistent, the QFP solder foot with obvious stress law is selected as the research object for stress analysis. Figure 29 shows the stress curve of QFP welding foot under the action of different insulation materials. For EPU, epoxy resin, and asbestos, the maximum stress value of QFP welding foot at the final moment is 32.6 MPa, 41.2 MPa, 46.6 MPa, respectively, and the maximum stress increase was 26.9% and 13.1% in sequence. The stress change curve of the welding foot under the action of different insulation layer materials is similar to the temperature change curve, but the stress change is more significant than the temperature change.

Through the temperature and stress comparison analysis of different components of the control circuit under the action of different insulation materials, it is found that the thermal conductivity of the EPU insulation material is the smallest compared with the other two materials, and the insulation effect is the best, but the EPU material is more expensive in the market. Under the action of asbestos as the insulating layer material, the stress value of the QFP soldering leg reaches 46.6MPa; at the final time, the soldering leg is made of tin-lead, and its allowable stress value is about 45MPa. The internal control circuit may fail under the action of the insulating layer material asbestos. Therefore, considering the heat insulation effect and economic cost, the epoxy resin material is selected as the heat insulation material for this product.

8.2. Comparative Analysis of Thermal Characteristics of Different Thickness Insulation Layers.

For certain insulation layer materials, different insulation layer thicknesses have different thermal resistances, so that the internal temperature under the action of insulation layers with different thicknesses is not nearly the same. This section studies the insulation layer under the condition that the insulation layer material has been determined for the influence of thickness; the optimal thickness of the thermal insulation layer is also selected from various factors such as thermal insulation effect and cost. This section selects the epoxy resin insulation material determined in the previous section to study the internal control circuit under the action of three different insulation layers of thickness 2 mm, 3 mm and 4 mm, and compares and analyzes the corresponding responses of their important components and comprehensively considers various aspects. Determine the appropriate insulation thickness.

Figure 30 shows the internal surface temperature curve measured under the action of different insulation layers when the external environmental load is applied to the outside of the box. As the thickness of the thermal insulation layer increases, the thermal resistance increases, and the temperature of the inner wall of the box decreases. The temperature of the inner wall of the thermal insulation layer with a thickness of 2 mm is $69.9°C$ at the final moment, and the temperature of the inner wall of the thermal insulation layer with a thickness of 3 mm is $63.6°C$ at the final moment. The inner wall temperature of the 4mm thickness insulation layer is $58.0°C$ at the final moment, and the inner wall temperature of the box decreases by about 9% for every 1mm increase in the thickness of the insulation layer.

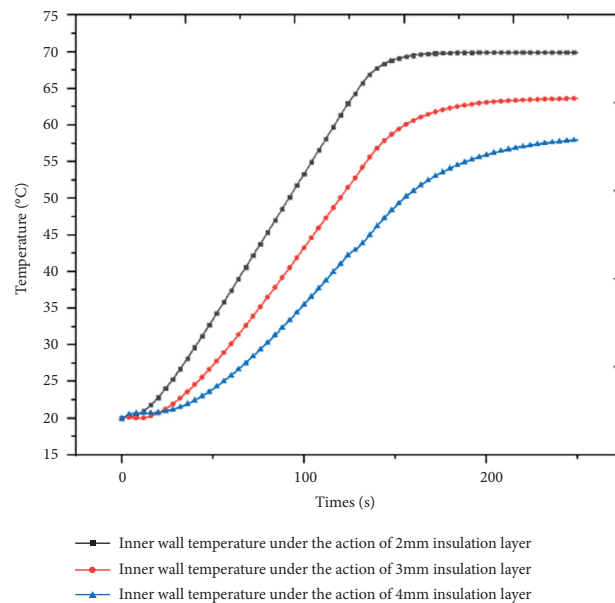
Figures 31(a)–31(c) are the overall temperature cloud diagrams under the action of 2 mm, 2 mm, and 4 mm insulation layers, respectively. As the thickness of the insulation layer increases, the temperature of the internal control circuit decreases. Increasing the thickness of the thermal insulation layer helps to reduce temperature of the control circuit and reduce the probability of failure.
FIGURE 29: QFP welding foot stress under different heat insulation materials.


FIGURE 30: Internal temperature under the action of different thicknesses of the heat insulation layer.

Figure 32 shows the temperature rise curve of the PCB board under the action of three different thicknesses of the heat insulation layer. Under the action of 2 mm heat insulation layer, 3 mm heat insulation layer, and 4 mm heat insulation layer, the maximum temperature value of the PCB board at the final moment is 65.6°C, 61.5°C, and 58.3°C, with the gradual increase of the thickness of the thermal insulation layer, and the maximum temperature drop ratios are 10.6% and 10.6% in turn. Figure 33 shows the temperature rise curve of QFP welding feet under the action of different thicknesses of heat insulation layers. Under the actions of 2 mm heat insulation layer, 3 mm heat insulation layer, and 4 mm heat insulation layer, the maximum temperature value of QFP solder feet at the final moment is 51.7°C, 46.2°C, 41.3°C, with the gradual

increase of the thickness of the thermal insulation layer, and the maximum temperature drop ratios are 6.3% and 5.2% in turn.

Figure 34 shows the stress curve of QFP welding foot under the action of different thicknesses of the heat insulation layer. Under the action of 2 mm heat insulation layer, 3 mm heat insulation layer, and 4 mm heat insulation layer, the maximum stress value of QFP solder foot at the final moment is 41.2 MPa, at 33.9 MPa, and 26.8 MPa, with the gradual increase of the thickness of the thermal insulation layer, and the maximum stress drop ratios are 17.7% and 20.9% in turn. The influence of stress changes under the action of different thickness insulation layers is greater.

Through the comparison of the overall temperature under the action of different thicknesses of the heat

(a)

(b)

(c)
FIGURE 31: Temperature cloud diagram under the action of insulation layers of different thicknesses. (a) Temperature cloud diagram under the action of 2 mm insulation layer. (b) Temperature cloud diagram under the action of 3 mm insulation layer. (c) Temperature cloud diagram under the action of 4 mm insulation layer.
FIGURE 32: PCB board temperature under the action of different thicknesses of the heat insulation layers.
FIGURE 33: QFP solder foot temperature under the different thicknesses of the heat insulation layers.
FIGURE 34: QFP welding foot stress under different thicknesses of the heat insulation layer.

insulation layer and the temperature of different components of the control circuit, it is known that as the thickness of the heat insulation layer increases, the internal temperature and heat act on the control circuit through convective heat transfer. The resulting temperature will decrease accordingly. By inquiring the electronic manual, the working permission temperature of related components on the steering gear was obtained. When the thickness of the heat insulation layer is determined to be 2 mm, the internal ambient temperature of the box has already met the working permission temperature.

Therefore, from the cost point of view, the thickness of the insulation layer of 2 mm thickness has met the working requirements; at the same time, it is known from the above analysis that the stress is more sensitive under the action of the insulation layer of different thickness, and the stress changes greatly. For high requirements, a 4-mm thick thermal insulation layer or even a larger thermal insulation layer can be used.

9. Conclusion

This paper establishes an overall three-dimensional finite element model that integrates the steering gear control circuit and the steering gear ball screw in the box, studies the influence of the internal ball screw heating source on the control circuit, and analyzes and calculates that the heat source of the ball screw is relatively high. The impact on the control circuit is small.

(1) In order to simulate the effect of the heat insulation layer of the steering gear box in the harsh natural environment during the service process, the case body is placed at a gradual temperature and finally kept at a constant high temperature environment, and a comparative analysis is made from the three perspectives of temperature and stress. Based on the finite element response of two models with and without the insulation layer, it is concluded that the effect of the insulation layer is significant, and the insulation layer is necessary in the process of design and use;

(2) Through the analysis of the thermal response of the steering gear under the conditions of different materials and different thicknesses of the heat insulation layer, the design of the heat insulation layer is further optimized and recommended.

Fatigue driving is one of the main reasons for the occurrence of traffic accidents. Brain-computer interface, as a human-computer interaction method based on EEG signals, can communicate with the outside world and move freely through brain signals without relying on the peripheral neuromuscular system. In this paper, a simulation driving platform composed of driving simulation equipment and driving simulation software is used to simulate the real driving process. The EEG signals of the subjects are collected through simulated driving, and the EEG of five subjects is selected as the training sample, and the remaining one is the subject. As a test sample, perform feature extraction and classification experiments, select any set of normal signals and fatigue signals recorded in the driving fatigue experiment for data analysis, and then study the classification of driver fatigue levels. Experiments have proved that the PSO-H-ELM algorithm has only about 4% advantage compared with the average accuracy of the KNN algorithm and the SVM algorithm. The gap is not as big as expected, but as a new algorithm, it is applied to the detection of fatigue EEG. The two traditional algorithms are indeed more suitable. It shows that the driver fatigue level can be judged by detecting EEG, which will provide a basis for the development of on-board, real-time driving fatigue alarm devices. It will lay the foundation for traffic management departments to intervene in driving fatigue reasonably and provide a reliable basis for minimizing traffic accidents.

1. Introduction

The fast-paced life of modern society not only promotes the rapid development of society, but also increases the work pressure of workers. Long-term high-intensity work can easily cause workers' mental fatigue. Mental fatigue will not only reduce work efficiency, but also be harmful to health and even cause accidents. In recent years, fatigue driving has become one of the main causes of traffic accidents. Truck drivers who travel long distances and drivers who work overtime are often prone to fatigue or drowsiness and some even fall asleep while driving. Therefore, fatigue detection has become an important topic in the field of driving safety. Scientists try to use this, to try to reduce the frequency and severity of traffic accidents, and formulate relevant regulations.

At present, there are still many problems in the research on driving fatigue detection technology. For example, the method of detecting the physical reaction of the driver has a high false alarm rate; the method of detecting vehicle parameters requires clear markings on the center line of the road and good light; and the method of measuring the pupil diameter is difficult to implement. In recent years, a large number of scientific researchers have invested in the research of noncontact collection of ECG and EEG and have made great breakthroughs, making the detection of fatigue through biological signals extremely attractive. It provides a basis for further research and development of on-board, real-time driving fatigue alarm devices, and provides a reliable basis for traffic management departments to scientifically and reasonably intervene in driving fatigue and minimize man-made traffic accidents.

At present, the mental fatigue detection at home and abroad mainly selects the following three characteristics:

(1) Behavioral characteristics: behavioral characteristics include changes in lateral lane positions and variability in vehicle heading differences, which are one of the commonly used driving indicators to identify fatigue through vehicle behavior. This method is easy to understand, but the standards for these features have not yet been formed, and it is not easy to achieve stable and effective recognition results.

(2) Facial expression characteristics: facial expression characteristics include the degree of eye closure and the frequency of nodding, etc.

Although this method is very convenient to use, the detection of these features is affected by various factors, such as image angle and image brightness. These limitations reduce the overall recognition accuracy of this method and limit its application scenarios.

(3) Physiological characteristics: physiological characteristics include ECG, heart rate, electromyogram, and EEG. Different from behavioral features and facial features, these features, as the mapping of the physiological changes of the human body, objectively reflect the current state and environment of the human body. Therefore, driving fatigue detection based on physiological features is a very popular application direction. And among these fatigue detection methods based on physiological features, detecting EEG signals is considered the most direct, effective, and promising method to detect driving fatigue.

Fatigue refers to a complex physiological phenomenon in which the physiological and psychological functions of the human body are out of balance due to continuous or high-intensity physical or mental work. Driving fatigue is the driver's excessive consumption of continuous driving or other physical labor for a long time, or lack of sleep, which leads to drowsiness, sluggishness, and weakness in the limbs. phenomenon of the situation. When a driver is fatigued, many features will change, including visible features such as driving posture, blink rate, eye closure time, nodding action, reaction speed, facial expressions, and invisible features such as EEG, ECG signal, EMG signal, skin temperature, skin resistance, respiratory rate, etc. The main manifestations are drowsiness and weakness of the driver, difficulty in eliminating drowsiness, decreased vision, gradually narrowing of the field of vision, inattention, decreased judgment, decreased thinking ability, weak limbs, decreased sensory organ function, unstable driving movements, delayed judgment, Rhythm disorders, knee fatigue, neck stiffness, backache and leg pain, loss of self-control, resulting in a series of uncomfortable symptoms such as being easily excited, irritable or driving fast.

When the driver is slightly fatigued, the shifting is not timely and accurate. In moderate fatigue, the operation is sluggish and sometimes even forgets to operate, In severe fatigue, often subconscious operation or short-term sleep phenomenon, loss of control over the vehicle.

In recent years, how to recognize the fatigue state of a driver has become a hot topic today. Chain R defines an EEG-based driver fatigue test method. The results show that the frequency characteristics of EEG can be well applied to driving fatigue testing, but the overall study lacks data support, and more data is needed to support its conclusions [1]. Yimyam W used 50 recorded EEGs to participate in driving simulation experiments, resulting in two fatigue states: alertness and drowsiness. The experimental results show that as the fatigue degree increases, the two complexity parameters are significantly reduced. The results show that these two nonlinear indicators can be used to characterize driver fatigue. However, the lack of experimental data in his research led to small differences in sample sets, resulting in inaccurate results [2]. Zeng studied the complex, unstable, and nonlinear characteristics of evaluating EEG signals. The results show that: this paper uses the combination of finite element features and AdaBoost classifier to detect driver fatigue based on EEG, ensuring the confidence to explore the internal physiological mechanism and wearable applications. The experiment did not take into account the deviation of the subject's gender and age parameters in the experiment [3].

This paper first extracts more representative EEG signal features by designing a more appropriate feature extraction method, and then selects a suitable classifier to perform optimized to achieve a better classification effect, and classify the signal features extracted by the new feature extraction method through the optimized classifier to achieve the optimal classification effect of the experiment. When studying driving fatigue, this article continuously analyzes the EEG data of driving for 2 hours, trying to find the time when the fatigue occurs. This is something that scholars who have studied driving fatigue have never done before. Most of them only select data from fatigue and normal states to analyze the differences.

2. EEG Signals and the Classification of Driver Fatigue

2.1. Composition and Classification of Brain-Computer Interface.
The exploration of the brain's operating mechanism is not only of great significance in medicine, but also of great help to the development of artificial intelligence. Brain-computer interface is a new technology developed for this purpose, and its application in scientific research is becoming increasingly extensive.

2.1.1. System Composition of Brain-Computer Interface.
The core of brain-computer interface (BCI) technology is to directly collect the EEG of the cerebral cortex through the electrodes and transmit it to the computer via the circuit for signal analysis, and then send the corresponding control commands to the external equipment to achieve a complete EEG control path, instead of passing through normal neuromuscular pathways such as peripheral nerves and

muscle tissues [4, 5]. The main working principle of the brain-computer interface system is: nerve cells generate local potentials when they are active. These potentials can be collected and analyzed in the cortex to analyze the changes in the brain's thinking activity at this time. These changes can be recorded and amplified by the electrode cap. After processing, the collected EEG extraction features are analyzed through information analysis, and the corresponding control instructions are made according to the features to complete the control of the external equipment. The pattern recognition part of BCI is mainly to send the EEG characteristic signal to the classifier and to distinguish the classification space to which the characteristic signal belongs by searching for a suitable decision plane. The result of the classifier is directly related to whether the feature is correctly identified, and therefore directly affects the effect and performance of the BCI. Different classifiers have different advantages in different application scenarios because of their different algorithm principles, so the choice of classifier is essential [6, 7].

A general brain-computer interface system consists of the following five main steps: EEG signal acquisition, signal preprocessing, feature extraction, pattern recognition, and sending external control commands.

The signal acquisition part of BCI is the connection between the system and the brain. This part mainly collects the electrical signals of the cerebral cortex through the electrode cap, then amplifies the electrical signals, and converts the amplified EEG signals into digital signals through A/D conversion. The signal acquisition part of BCI mainly involves the selection of signal types and the number of channels and positions. Since the collected EEG signals will be interfered by EEG, ECG, power, frequency interference, and some high-frequency noise signals, these signals will affect the follow-up, the reliability and accuracy of the processing part. Therefore, the preprocessing part of BCI will use denoising algorithm or filter to remove the noise signal doped in the signal and improve the signal-to-noise ratio of the EEG signal.

EEG signals are used by most BCI systems due to their high temporal resolution. BCI has a wide range of applications in the field of artificial intelligence because of its cheap equipment and no harm to the human body. The BCI system has a variety of classification methods from different perspectives:

Lossy and lossless BCI systems, the acquisition methods of the lossy BCI system can be divided into implantable and semi-implantable. The feature of the implantable BCI system is that the electrodes are implanted into the brain tissue in the cranial cavity, so that the collected brain signals are more accurate; the feature of the semi-implantable BCI system is that the electrodes are attached to the cerebral cortex in the cranial cavity, and the brain Cortical potential changes can be accurately recorded by the electrodes.

Induced and spontaneous BCI systems, the evoked BCI system has many kinds of elicitation methods, which can be divided into exogenous stimulation and endogenous stimulation according to the different stimulation sources. Potential changes induced by exogenous stimuli are called exogenous evoked potentials, including visual stimulus evoked potentials, auditory stimulus evoked potentials, and tactile stimulus evoked potentials. Endogenous stimuli are related to cognitive processes in the brain, and endogenous evoked potentials are brain potentials evoked by specific, multiple or diverse stimuli.

2.1.2. Application Fields of Brain-Computer System

(1) Rehabilitation Field. The BCI system has the most urgent needs in the field of rehabilitation. There are many patients with physical disabilities throughout the country. For them, the BCI system provides them with a new channel for communication with the outside world, which can significantly improve their quality of life and even live a normal life.

(2) Military Field. Although the current research on related technologies has not reached the stage of maturity in movies, the concept of using thinking activities in military operations is the consensus of all countries in the world, many countries have spent a lot in this field, and movies have also been realized.

(3) Leisure and Entertainment Field. Leisure and entertainment have always been an indispensable part of human life, so the research direction of brain-computer interface is also biased towards this [8]. Now, ordinary keyboard and mouse devices can no longer keep up with people's response speed and computer processing speed. People urgently need a new control method to control computers more conveniently for entertainment activities. Simple such as browsing the web, typing on the Internet, designing drawings, complex multiline operations, controlling games, These applications will greatly change the way of life and entertainment in the future, have large market potential, and attract countless teams to develop related technologies.

(4) The Field of Brain Science Research. The research of the BCI system originally originated from the study of brain cognitive science, such as the use of brain electricity to detect polygraphs, the study of mental activity based on brain electricity, and this article involved in driving fatigue detection based on BCI system [9]. The research of the BCI system is based on the research of brain science, and the research of the BCI system in turn provides help to the research of brain cognitive science.

2.2. EEG Signal.

Generally speaking, EEG refers to the electrophysiological phenomenon produced by the activity of brain nerve cells in the cerebral cortex, which is a kind of bioelectric signal. Since the human body is a complex system, the electrical signals collected through the scalp include not only EEG, but also physiological signals such as my electricity and ocular electrical signals, as well as noise interference such as instrument power frequency interference, so the effect of directly processing the collected EEG is not ideal. It is necessary to preprocess the EEG and then conduct research and analysis [10, 11].

People will experience various subjective feelings when driving fatigue, such as dizziness, blurred vision, difficulty concentrating, feeling irritable, feeling sleepy, muscle weakness, reference basis. When driving fatigue, the subjects will have many weakened functions controlled by the brain. Different parameters of the EEG signal represent different activities of the human brain and different mental states. However, the accurate extraction of these parameters requires good technical means suitable for EEG signals.

2.2.1. The Structure and Function of the Brain.
The brain is the most complex and mysterious organ in the human body, and there are many mysteries that have not yet been completely solved. The brain is divided into two parts: the left brain and the right brain. According to the existing medical data, the left and right hemispheres are responsible for different functions such as thinking and imagination, and are connected to each other through the corpus callosum. The left and right hemispheres are subdivided into four parts: frontal lobe, parietal lobe, temporal lobe, and occipital lobe. These areas control different functions. According to some latest brain science research data, the various functions of the brain are not only completed by the abovementioned parts alone, but are the result of the collaborative processing of various parts of the brain [12–14]. Even after some parts are damaged, the brain can coordinate the other parts to complete the functions of the damaged part of the brain. The cerebral cortex is the general term for the gray matter of the brain's surface layer, and its thickness is about 1.5–5.0 mm. The gray matter of the cerebral cortex in different regions corresponds to different functions, as shown in Figure 1.

According to scientific research data, at this stage, the cerebral cortex contains tens of billions of nerve cells. With this large group of nerve cells, the brain can achieve very complex functions. For driving fatigue detection based on EEG, it is first necessary to understand the relationship between mental fatigue and the state of different areas of the cerebral cortex and time, to accurately judge the state of mental fatigue.

2.2.2. The Generation Mechanism of EEG Signals.
Generally speaking, EEG refers to the local electrical signal produced by the activity of nerve cells in the cerebral cortex, which is produced by the electrophysiological activity of a large number of nerve cells in the relevant areas of the brain. According to the research data, the dendrites of nerve cells will generate an action potential after receiving stimulation. The potential will be transmitted along the axon to the axon terminal, and the potential will be transmitted to the next nerve cell through the axon terminal. The electrical signal generated by these large nerve cells transmitting potential is EEG [15, 16].

2.2.3. Characteristics and classification of EEG signals

(1) Randomness: because the cerebral cortex is not completely insulated, the electrical signals of different areas will influence and interfere with each other, sometimes accompanied by unconscious light discharge behaviors. Therefore, EEG has significant randomness, which humans cannot completely present. Analyzing the trend of EEG can only roughly analyze the characteristics of EEG.
(2) Nonstationary: the generation of brain signals is affected by many factors, so it has the characteristics of nonstationary. Using this feature of EEG, the amplitude and frequency of EEG can be compared to distinguish whether the brain is in a state of fatigue.

What we usually call an EEG refers to the brain scalp EEG, which is actually a graph of the relationship between the scalp potential difference and time. Brain waves are the comprehensive external manifestations of the overall activity of brain nerve cells, including ion exchange and metabolism. The EEG signal is an electrical phenomenon displayed on the surface of the cerebral cortex or scalp by the physiological activity of brain nerve cells. This electrical phenomenon accompanies a person's life from the beginning to end. Once a person dies, the electrical phenomenon disappears. Therefore, the EEG signal is a signal obtained by extracting the spontaneous and rhythmic physiological activity of the brain cell population on the surface of the scalp and amplifying it by a million times. EEG signals can be divided into spontaneous EEG and evoked EEG. Spontaneous EEG refers to changes in EEG without external stimulation. Induced EEG is a change in brain potential caused by artificially stimulating human sensory organs.

(3) Nonlinearity: the generation of EEG is based on the multiple coupling of human physiological state and life phenomena, so it has chaotic characteristics and nonlinearity. Simply using linear analysis of EEG cannot fully reflect the characteristics of EEG. It is necessary to use nonlinear analysis EEG to better analyze the internal information of EEG [17].

(4) Low amplitude, low frequency, and low signal-to-noise ratio: EEG signals have the characteristics of low amplitude, low frequency, and low signal-to-noise ratio. Since the EEG signal is the bioelectricity

Figure 1: Distribution map of cerebral cortex function.

generated by the activity of nerve cells, the amplitude of the EEG signal is relatively low only at the micro- and millivolt level, generally not exceeding $100\,\mu V$. The frequency of EEG signals is relatively low, generally between 0.5 and 100 Hz. It is precisely because of the characteristics of low amplitude and low frequency of EEG signals that it is easily interfered by other external signals and has the characteristics of low signal-to-noise ratio.

EEG signal is a manifestation of brain nerve activity and an important signal reflecting the state of brain activity. Its amplitude range is one and its frequency range is one. The rhythm of EEG signals changes with the change of a person's mental state and a series of transients such as sharp waves or spikes in epilepsy patients also appear. Usually, the collected EEG signals are very weak, and there is a lot of background noise and strong interference signals, such as power, frequency interference, ECG interference, breathing interference, swallowing, eye blinking, which increase the difficulty of analysis. However, because the method is a noninvasive method and contains a lot of physiological and pathological information, it still attracts the interest of many researchers. They focus on the time-varying nonstationary characteristics of EEG signals. It has continuously proposed analytical methods that can effectively characterize different physiological states of the brain [18, 19].

2.3. Feature Extraction Based on Frequency Band Power Spectrum.

When the human brain is active, it produces five frequency bands: alpha, gamma, theta, delta, and sigma. When the power spectrum peaks of the alpha wave and the beta wave are obvious, which are the main bands of the EEG, it indicates that the subject is awake; when the subject feels tired or even sleeps the peaks of theta wave and delta rise significantly [20, 21]. Using the STFT algorithm to extract the power spectrum is a power spectral density function (PSD) feature as follows:

$$STFT\{x[n]\}(m, w_k) = \sum_{n=1}^{N} x[n]w[n-m]e^{-jw_k n}, \quad (1)$$

where $w_k = (2\pi k/N)$, $k = 0, 1, \ldots, N-1$ is the angular frequency, m is discrete and ? is continuous, its mathematical expression is as follows:

$$w[n] = 0.5\left[1 - \cos\left(\frac{2\pi n}{(N-1)}\right)\right] = \sin^2\left(\frac{\pi n}{(N-1)}\right). \quad (2)$$

The energy spectrum at different frequencies of different EEG frequency bands is calculated as follows:

$$E(w_k) = X(m, w_k)X^*(m, w_k),$$

$$PSD(w_k) = \frac{1}{N}E(w_k), \quad k = 0, 1, \ldots, N-1. \quad (3)$$

The energy spectrum of each EEG band can then be defined as:

$$E(w) = \sum_{k=1}^{n} E(w_k), \quad (4)$$

where $x[n] = \{x_1, x_2, \ldots, x_n\}$ represents all frequencies in a frequency band.

2.4. Feature Extraction Method Based on EMD and Energy Spectrum

2.4.1. Empirical Mode Decomposition. Empirical Mode Decomposition (EMD) decomposes a given signal $x(t)$ into a series of Intrinsic Mode Function (IMF) components from high to low. EMD can be regarded as a type of wavelet decomposition. Its subbands are established according to the decomposition of each component of the signal. Each IMF component generated represents the details of the signal on a certain scale and frequency band [22, 23]. The steps of EMD decomposition are as follows:

(1) Identify all maximum points in the EEG and fit the upper envelope $e_{up}(t)$ of the signal, and identify all minimum points in the EEG and fit the lower envelope $e_{low}(t)$ of the signal.

(2) Calculate the average value $m_1(t)$ according to the synthesized upper and lower envelopes, the formula is

$$m_1(t) = \frac{e_{up}(t) + e_{low}(t)}{2}. \quad (5)$$

(3) Subtract $x(t)$ from $m_1(t)$ to obtain $h_1(t)$, and use the obtained $h_1(t)$ as the new EEG $x(t)$. Repeat step 1). After k screening, $h_1(t)$ at this time is the first IMF component of the signal, denoted as $c_1(t) = h_1(t)$.

(4) Repeat the above steps with the difference $r_1(t) = x(t) - c_1(t)$ between $c_1(t)$ and $x(t)$ as a new signal to obtain a series of IMF components. When the obtained IMF component or residual signal is less than a preset value, the empirical mode decomposition step is completed.

2.4.2. Principle of Energy Spectrum. Energy spectrum (Energy Spectral Density, ESD), arrangement of the harmonic energy contained in the signal, is called the energy spectrum, which describes the energy contained in each frequency component in the signal. The formula of the energy spectrum is as follows:

$$\Phi(w) = \left|\frac{1}{\sqrt{2\pi}} \sum_{n=-\infty}^{\infty} f_n e^{-jw_k n}\right|$$

$$= \frac{F(w)F^*(w)}{2\pi}. \quad (6)$$

In the formula, f_n is the signal sequence. Divide the observation data x(t) of length N into K segments of data of length M, that is, $N=KM$. Estimate the third moment of each piece of data $x_i(t)$ ($i = 1, 2, \ldots, k$):

$$\widehat{r}(i)(m,n) = \frac{1}{M} \sum_{k=s_1}^{s_2} x_i(t) x_i(t+m) x_i(t+n), \ i = 1, 2, \ldots, k. \quad (7)$$

Among them $S_1 = \max(1, 1-m, 1-n)$, $S_2 = \min(M, M-m, M-n)$. Find the overall average of the third-order moment estimates of these K segments of the data, and find the third-order cumulant estimate of x(t):

$$\widehat{r}(m,n) = \frac{1}{K} \sum_{i=1}^{k} \widehat{r}^{(i)}(m,n). \quad (8)$$

By estimating the third moment $\widehat{\beta}$ of the non-Gaussian white noise sequence w(k), the parameters of the AR model are obtained:

$$\widehat{r} \cdot a = \widehat{b},$$

$$\widehat{r} = \begin{bmatrix} \widehat{r}(0,0) & \widehat{r}(1,1) & \cdots & \widehat{r}(p,p) \\ \widehat{r}(-1,-1) & \widehat{r}(0,0) & \cdots & \widehat{r}(p-1,p-1) \\ \vdots & \vdots & \widehat{r}(0,0) & \vdots \\ \widehat{r}(-p,-p) & \widehat{r}(-p+1,-p+1) & \cdots & \widehat{r}(0,0) \end{bmatrix},$$

$$\widehat{b} = [\widehat{\beta}, 0, 0, \ldots, 0]^T. \quad (9)$$

A is the AR model parameter to be estimated for p. Use p model parameters to estimate the energy spectrum:

$$B(w_1, w_2) = \widehat{\beta}\widehat{I}(w_1)\widehat{I}(w_2)\widehat{I}^*(w_1 + w_2). \quad (10)$$

Among them,

$$\widehat{I}(w) = \left[1 + \sum_{n=1}^{p} a_n \exp(-jwn)\right]^{-1}, \ |w| \le \pi. \quad (11)$$

2.4.3. Feature Extraction Based on EMD and Energy Spectrum.

Traditional EMD-based feature extraction methods usually contain a large number of time-domain signals, which is very helpful for extracting the main components of the signal, but it is not ideal for the extraction of fatigue signals. The energy spectral density function can extract the frequency domain information of each IMF component and extract the time-frequency information of EEG by combining it with EMD decomposition. The flow chart of the algorithm is shown in Figure 2.

It can be seen from Figure 2 that after the original EEG has been preprocessed, the irrelevant noise signals have been roughly filtered out. The first three layers of IMF components are selected for processing, and after feature extraction, 96 energy spectrum features (32 channels × 3 layers of IMF) are obtained. Compared with the power spectrum feature extraction method, it has fewer features and requires less calculation and calculation time for classification.

3. Experimental Design of Driver Fatigue Classification Based on EEG Signal

3.1. Simulated Driving Experiment Design.
The EEG signals in this experiment are all collected by laboratory simulation driving. In this article, the real driving process is simulated by using a driving simulation platform composed of driving simulation equipment and driving simulation software. The driving simulator platform is an advanced simulator system that can simulate real driving conditions while providing dynamic displays of vehicles and surrounding traffic. The driving simulation platform itself consists of a fixed car, steering wheel, brake pedal, and accelerator pedal, a large screen, a high-performance computer, driving simulation software, and a multifunctional data acquisition board. The platform can dynamically record EEG during the mission and calculate the driving and running status of the vehicle.

The EEG acquisition equipment used in this experiment is an EEG signal acquisition and analysis system composed of Brain Amp, DC amplifier of German Brain Products, and corresponding software. The system includes E-Prime stimulation software, actiCAP electrode cap, Brain Amp amplifier, Brain Vision Recorder recording Software, and Brain Vision professional Analyzer analysis software, the physical object of the equipment is shown in Figure 3.

3.2. Experimental Objects and Methods.
In this experiment, the EEG data of 5 participants was selected as the training set, and the remaining 1 data was used as the test sample for feature extraction and classification experiments, pick out two sets of data from the data, one is normal signal data, and the other is fatigue signal data, and analyze them. We asked the participants to sleep only 4 hours as fatigue state data the night before data collection, and 8 hours sleep as waking state data, to obtain EEG data in the two states. The participants' simulated driving time was set at 8 pm the next day, during which EEG recording was started at 8:10, and signal recording was stopped at 8:30 pm.

The EEG acquisition experiment took 20 minutes. During the experiment, the subject was asked to sit on a chair and simulate the driving process on the driving simulation platform. During the experiment, the EEG was recorded and used with a 32-channel electrode cap according to the international 10–20 lead system. Brain Vision Recorder records EEG with a sampling rate of 1000 Hz. The temperature of the laboratory is maintained at 22°C, which provides the subjects with a comfortable and stable experimental environment. Figure 4 shows the actual scenario of the experiment.

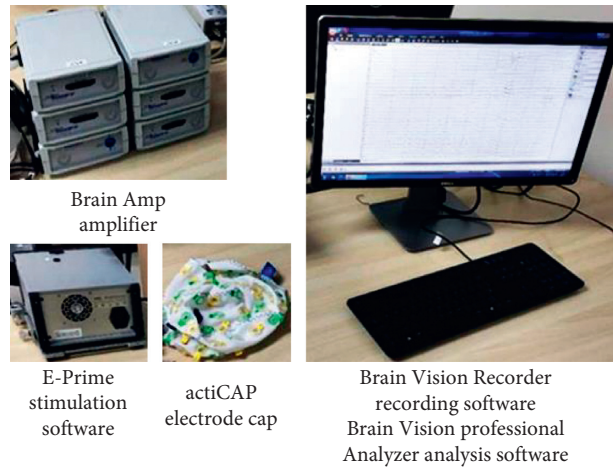
3.3. EEG Signal Collection.
Due to the different functional composition of various regions of the brain, the EEG signal bands appearing in different regions will also change. In addition, EEG signals have the characteristics of low amplitude and low frequency, which are easily disturbed by noise signals. Therefore, how to choose appropriate electrode selection location is essential. Using Brain Vision Recorder recording software to record the EEG during driving, it can be seen that most of the electrodes are in good contact with the scalp, and all signals meet the requirements of EEG collection. The EEG of fatigue and normal driving were collected, respectively. Each subject collected 20 minutes of normal signal and 20 minutes of fatigue
Figure 2: Flow chart of feature extraction algorithm.


Figure 3: EEG acquisition system(https://image.cnki.net/, author authorization is available).
Figure 4: Simulated driving experiment diagram. (https://image.cnki.net/, author authorization is available).

signals. The signals collected every 10 seconds were used as a sample to construct training samples and test samples. In this experiment, six subjects collected a total of 720 groups of normal EEG samples and 720 groups of fatigue EEG samples, and the collected 1440 groups of EEG data samples were subjected to subsequent analysis and processing.

3.4. Frequency Reduction and Filtering of EEG Signals. To study the driving fatigue EEG, it is necessary to analyze the five main EEG bands of alpha, beta, gamma, theta, and delta. The frequency bands of these five signals are roughly between 0.1 and 50 Hz, which belong to low-frequency signals, and the acquisition equipment, sampling frequency is 1000 Hz, which not only carries a large amount of irrelevant high-frequency noise and interferes with data processing, but also a large amount of data processing also causes a lot of burden on the processing and operation of the brain-computer interface device. Therefore, to better carry out the subsequent processing, the collected EEG is first subjected to frequency reduction processing, and the sampling frequency is reduced to 200 Hz, which greatly reduces the amount of data calculation and speeds up the data processing.

3.5. Denoising of EEG Signals

3.5.1. Hard Threshold and Soft Threshold Denoising. Noise shows strong randomness in the wavelet domain and can be considered as Gaussian noise. According to the characteristics of Gaussian distribution, most of the noise coefficients are in the interval $[-3\sigma, 3\sigma]$. Therefore, as long as the threshold is set to $\lambda = 3\sigma$, most of the noise can be removed. Among them, the hard threshold wavelet denoising formula is as follows:

$$\widetilde{d}_{j,k} = \begin{cases} d_{j,k}, & |d_{j,k}| \geq \lambda, \\ 0, & |d_{j,k}| < \lambda. \end{cases} \tag{12}$$

Among them, $d_{j,k}$ is the wavelet coefficient, $\widetilde{d}_{j,k}$ is the estimated value of the wavelet coefficient after hard threshold denoising, and λ is the threshold.

However, directly removing these wavelet coefficients will cause abrupt changes in the wavelet domain, resulting in local jitter in the denoised signal, which will affect the analysis and processing of the signal. Therefore, a soft threshold wavelet denoising method is proposed. Subtract 3σ from the coefficients greater than 3σ, and add 3σ to the coefficients less than -3σ. The formula of the soft threshold wavelet transform denoising method is as follows:

$$\widetilde{d}_{j,k} = \begin{cases} d_{j,k} - \lambda, & d_{j,k} \geq \lambda, \\ d_{j,k} + \lambda, & d_{j,k} \leq -\lambda, \\ 0, & |d_{j,k}| < \lambda. \end{cases} \tag{13}$$

After soft threshold processing, the signal after denoising is smoother than that after hard threshold denoising. At the same time, it will also cause partial loss of detail signal.

3.5.2. Improve Soft Threshold Denoising. The improved soft threshold method combines the advantages of soft and hard threshold methods and can effectively remove low-frequency noise. The formula is as follows:

$$\widetilde{d}_{j,k} = \begin{cases} a\lambda^2 - \lambda + d_{j,k}, & d_{j,k} \geq \lambda, \\ ad_{j,k}^2, & 0 < d_{j,k} < \lambda, \\ -a\lambda^2 + \lambda + d_{j,k}, & d_{j,k} \leq -\lambda, \\ -ad_{j,k}^2, & -\lambda < d_{j,k} < 0, \end{cases} \quad a < \frac{1}{\lambda}. \tag{14}$$

Among them, a is the shape coefficient. The value of a can control the shape of the function in the $d_{j,k} < \lambda$ area, that is, the degree of attenuation. When the value is 0, the formula for improving the soft threshold method is equivalent to the soft threshold method. The selection formula of the threshold is

$$\lambda_j = \frac{\sigma\sqrt{21g(N)}}{\lg(j+1)}, \tag{15}$$

where $b \geq 0$, j is the number of decomposed layers, N is the number of wavelet transform coefficients corresponding to the j layer, λ_j is the wavelet threshold, s is the variance of the noise, and in real life, the way the noise is generated is various, so the value of s is generally estimated according to the first-level wavelet packet decomposition coefficient, the estimation formula is as follows:

$$\widehat{\sigma} = \frac{\sum_{k=1}^{N} |d_{1k}|}{0.6745 * N}. \tag{16}$$

Among them, d_{1k} is the wavelet decomposition coefficient of the first wavelet decomposition layer, and 0.6745 is the adjustment coefficient of Gaussian white noise.

4. Experimental Driver Fatigue Classification Based on EEG Signal

4.1. Compare the Denoising Effects of Different Algorithms. We tested the effect of the improved method, the signal used is a piece of data from the Fp1 channel of subject No. 1. The sampling frequency after frequency reduction is 200 Hz, and it has passed the bandpass filter of [0.1 Hz, 50 Hz]. Processing. The wavelets in the experiment all decompose the original signal in three layers and extract coefficients. The shape coefficient of the soft threshold is 0.01 and the scaling factor is 0.5. The result is shown in Figure 5.

It can be seen from Figure 5 that there are many glitches in the signals of the hard threshold denoising and soft threshold denoising methods, therefore, the signal of the improved method is clearly better than the other three signals. Although the hard threshold denoising method and the soft threshold denoising method have certain effects, the signal effect after the improved soft threshold denoising processing is the best. This shows that the improved soft threshold denoising method can effectively combine the traditional hard threshold and soft threshold. Advantages of the method.
FIGURE 5: Experimental comparison of three wavelet threshold denoising methods.

Want to quantitatively analyze the pros and cons of the three wavelet threshold denoising methods, the signal-to-noise ratio (SNR), and root mean square error (RMSE) are again selected to judge the quality of the denoised EEG. The formula is as follows:

$$SNR = 10 * \log_{10}\left(\frac{\sum_{i=1}^{N} x^2(i)}{\sum_{i=1}^{N} \widetilde{x}^2(i)}\right),$$

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x(i) - \widetilde{x}(i))^2}.$$

(17)

Among them, N, $x(i)$, $\widetilde{x}(i)$ are the length of the EEG, the original EEG, and the EEG after noise reduction. Randomly select 100 groups of EEG and obtain the signal-to-noise ratio and the root mean square error, respectively, and calculate the average value after the denoising experiment. The experimental results are shown in Table 1.

It can be seen from Table 1 that the improved soft threshold denoising method has the largest SNR, while the RMSE is the smallest, and the denoising effect is the best.

4.2. EM and Energy Spectrum Feature Extraction Results. In this experiment, the EEG data of 5 subjects is selected as the training sample set, and the remaining 1 data is used for feature extraction and classification experiments as the

TABLE 1: SNR and RMSE results after denoising with different threshold methods.

Evaluation index	Threshold method		
	Hard threshold	Soft threshold	Improve soft threshold
SNR	14.49	14.36	18.42
RMSE	276.32	278.96	197.16

sample test. And any set of normal signals and fatigue signals recorded in the driving fatigue experiment were selected for data analysis. In the experiment, the preprocessed signal is selected for feature extraction. After EMD decomposition and energy spectrum feature extraction, the data is compressed to 84 feature points; after power spectrum feature extraction, the EEG data is compressed to 144 feature points. The preprocessed EEG is compared with the signal after the two feature extraction algorithms, and the results are shown in Figures 6–8.

It can be seen from Figure 6 that before the feature extraction, the signals of the normal signal and the fatigue signal are entangled, which is very difficult to judge. It can be seen from Figure 7 that after using the power spectrum to perform feature extraction on the signal, it can be seen that the low-frequency range of the EEG in the fatigue state fluctuates more, and it can be easily distinguished from the normal EEG. It can be seen from Figure 8 that after EMD decomposition combined with energy spectrum for feature
FIGURE 6: Original signal comparison.
FIGURE 7: Power spectrum signal feature extraction and comparison.

extraction, the energy difference feature in the low frequency range is more obvious than the power spectrum feature. Therefore, it can be assumed that the feature extraction method combined with EMD decomposition and energy spectrum is more suitable than the power spectrum. EEG recognition of driving fatigue.

Want to understand the pros and cons of the two feature extraction algorithms, and analyze the optimization effect of the PSO-H-ELM algorithm, so I select the EEG data of 5 participants as the training set, and the EEG data of the remaining participants as the test set. The experimental result is the operation of different subjects as the test set, as shown in Table 2.

It can be seen from Table 2 that although the test results of different subjects are biased, it can be found from the average accuracy rate that the features extracted using EMD decomposition combined with energy spectrum are using SVM, KNN and PSO-H-ELM three classifiers In the case, the classification effect is better than using the power spectrum feature extraction method. At the same time, the results show that the algorithm can achieve the best classification

effect after using the algorithm of EMD decomposition combined with energy spectrum for feature extraction.

4.3. Classification Performance of Different Algorithms.
Select 240 sample data of 1 participant as the test set, and 1200 sample data of the remaining 5 participants as the training set. The purpose of this arrangement is to avoid confusion between training and test data. The results are shown in Table 3.

It can be seen from Table 3 that the accuracy of 72.32%, 71.47%, 89.25%, 93.17%, 73.85%, and 70.79% were obtained by using KNN. The accuracy rates of support vector machines are 77.25%, 74.67%, 88.32%, 94.83%, 63.29%, and 73.33%, respectively. The accuracy rates of ELM are 70.85%, 66.83%, 86.25%, 88.77%, 58.25% and 67.75%, respectively. The accuracy rates of H-ELM are 78.17%, 81.08%, 89.24%, 89.38%, 71.78%, and 74.24%, respectively. Finally, the accuracy of 78.91%, 83.85%, 91.25%, 91.78%, 73.33%, and 76.75% were obtained using PSO–H-ELM. The accuracy of the algorithm changes greatly when different subjects are
FIGURE 8: EMD decomposition combined with energy spectrum feature extraction signal comparison.

TABLE 2: Different feature extraction algorithms using SVM, KNN, and PSO-H-ELM classifiers to classify the accuracy (%).

Feature extraction algorithm	Classification algorithm	1	2	3	4	5	6	Average accuracy
Power spectral density	SVM	81.43	83.59	94.38	89.76	70.79	74.13	83.33
	KNN	77.39	77.57	97.33	87.57	88.58	89.32	86.28
	PSO–H-ELM	81.43	80.76	97.73	97.06	85.75	85.26	88.83
EMD	SVM	90.75	85.38	88.25	100.00	97.29	95.67	93.62
	KNN	77.25	83.33	88.71	100.00	97.25	95.67	90.94
	PSO–H-ELM	89.60	88.85	94.25	69.57	99.85	98.23	94.24

TABLE 3: Classification accuracy using different training samples (%).

	Subject 1	Subject 2	Subject 3	Subject 4	Subject 5	Subject 6
KNN	72.32	71.47	89.25	93.17	73.85	70.79
SVM	77.25	74.67	88.32	94.83	63.29	73.33
ELM	70.85	66.83	86.25	88.77	58.25	67.75
HELM	78.17	81.08	89.24	89.38	71.78	74.24
PSO-HELM	78.91	83.85	91.25	91.78	73.33	76.75

used as training samples. Therefore, it is difficult to directly determine from Table 3 which classification algorithm has the best effect. To make the comparison of the experimental results more intuitive, the average classification accuracy rate of 5 classifiers is calculated, as shown in Table 4.

It can be seen from Table 4 that the average accuracy of the PSO–H-ELM algorithm is the highest, indicating that the proposed PSO–H-ELM algorithm is superior to other algorithms in driving fatigue detection. By comparing the performance of H-ELM and the proposed PSO–H-ELM in different situations, it can be found that the change of training data does not affect the optimization of the H-ELM algorithm by the PSO algorithm.

To confirm the results of the experiment, paired t-tests are used to test the accuracy of PSO-H-ELM to see if it has obvious advantages compared to other classifiers. The results of the statistical test are shown in Table 5.

It can be seen from Table 5 that the PSO–H-ELM algorithm has only about 4% advantage compared with the average accuracy of the KNN algorithm and the SVM algorithm. The gap is not as large as expected, but it is used as a

new algorithm for fatigue EEG. The detection is indeed more suitable compared to the two traditional algorithms. When comparing the PSO–H-ELM algorithm to the ELM algorithm and the H-ELM algorithm, it can be found that the advantages of the PSO–H-ELM algorithm are very obvious and stable. PSO–H-ELM is an optimized algorithm for H-ELM. The classification and recognition of EEG is much more accurate than that of H-ELM algorithm. Compared with traditional mainstream algorithms, the PSO–H-ELM algorithm is more suitable for the classification of driving fatigue EEG.

5. Discussion

(1) Living environment: the place of residence is too far from the work place; there are too many housework or the husband and wife are not in harmony; the mental burden is heavy; (2) Sleep quality: going to be too late, too little sleep time; poor sleep effect; noisy sleep environment cannot guarantee sleep quality. (3) In-car environment: poor air quality, poor ventilation; too high or too low temperature;

TABLE 4: The average classification accuracy of the algorithm (%).

bad noise and vibration; improper seat adjustment; tense relationship with fellow passengers. (4) Environment outside the car: driving in the afternoon, evening, early morning, and late at night; poor road conditions; good road conditions, single situation; driving in windy, rainy, foggy, snowy weather; poor traffic environment or crowded traffic conditions. (5) Operating conditions: long-term, long-distance driving; too fast or too slow; too limited time to reach the destination. (6) Physical condition: poor physical strength and endurance; decreased visual and hearing ability; weak physical strength or suffering from certain chronic diseases; taking drugs that are contraindicated in driving vehicles; special physiological periods for women (menstrual period, pregnancy). (7) Driving experience: low technical level and unfamiliar operation; short driving time and little experience; poor safety awareness.

Driving at high speed can easily make the driver nervous. Driving at a slightly lower speed than normal without affecting traffic can reduce mental stress and fatigue. At the same time, we try to reduce overtaking when driving, reduce emergency braking, and other actions, which can also reduce fatigue. When you feel sleepy during driving, you can also open the window to ventilate (to prevent endogenous oxygen deficiency), play different styles of music, chew gum, apply wind oil essence, and body spirit dew is more effective to prevent fatigue driving. A must-have, when you are sleepy, apply on the Renzhong acupoint, and take a deep breath to keep your brain awake and reduce fatigue. Under the premise of not affecting safety, you can stretch your fingers, shake your arms, twist your neck, and look as far away as possible. Always staring at the center line will cause visual fatigue.

If you drive a motor vehicle for more than 4 hours continuously, you should stop and rest, and the rest time should not be less than 20 minutes. Passenger vehicles, heavy-duty trucks, and semitrailer tractors used for highway operation shall install and use driving recorders that meet national standards. Traffic police can check the driving speed, continuous driving time, and other driving status information of the motor vehicle.

6. Conclusions

In daily life, the driver cannot always drive the vehicle in a stable state. When the driver finishes a day's work, his brain power becomes exhausted, and it is very easy to experience fatigue when driving a vehicle. To avoid the occurrence of fatigue driving, this article uses the stable and reliable characteristics of EEG, collects EEG through the brain-computer interface, and processes and analyzes it, to achieve the purpose of judging and early warning of fatigue driving. This paper implements a feature extraction method that combines empirical mode decomposition and energy spectrum: the data is decomposed into multiple IMF components through empirical mode decomposition, and then the energy spectrum is used to extract features for each IMF component, and these components are combined at the feature points to construct the feature vector of EEG. The experiment uses the new method and the power spectrum method to extract the features of EEG and uses a variety of classifiers for classification processing. Compare the classification experiment results of the two methods, and the better feature extraction effect of the new method is verified. This research still has certain limitations. For example, there are still some differences between simulated driving and actual driving, the simulated driving time is not long enough, the time when drivers of different physiques are fatigued under different road conditions, and the characteristics of fatigue will be different. There are still many problems in the development of driving fatigue research, such as real-time problems, contact problems, and cost-effectiveness of detection devices.

E-commerce product recommendation system can help users to find their own products quickly from a large number of products. To address the shortcomings of the current e-commerce product recommendation system, such as low efficiency and large recommendation errors, we designed an intelligent recommendation system based on social awareness and mobile computing. The behavioral characteristics of the current e-commerce product recommendation system are analyzed; the e-commerce product recommendation system is built according to the data processing technology of mobile computing, and the key technologies of the e-commerce product recommendation system are designed. The test results show that the proposed system overcomes the shortcomings of the traditional e-commerce product recommendation system, speeds up the speed of users to find the products they really need from a large number of products, improves the accuracy of e-commerce product recommendations, and the error of e-commerce product recommendations is much lower than that of the traditional, which has higher practical application value.

1. Introduction

With the continuous development of information technology, logistics technology, network technology, and intelligent technology, the number and variety of goods on the Internet has increased dramatically. Goods have been stored in huge quantities, and at the same time, people are trading goods on the Internet more and more frequently, and many types of e-commerce management systems have emerged [1–3]. Among the e-commerce management systems, the e-commerce product recommendation system is one of the most important subsystems, directly affecting whether users can efficiently search for the e-commerce products they want. Therefore, the design and research of recommendation systems have been an important research direction in the field of e-commerce applications [4–6]. The traditional e-commerce product recommendation system uses a single computer to manage all user requests and product data, but with the increasing number of users and product data, the shortcomings of the single-computer model have become

increasingly evident, mainly in the slow speed of the e-commerce product recommendation system, which makes it difficult to find the products that users really need within a short period of time [7–9].

The core task is to provide users with personalized product recommendation services by exploring the connection between users and products. Ultimately, achieving a win-win situation for both users and system owners [10, 11]. Large-scale e-commerce recommendation systems in the context of modern Internet applications are facing challenges in the following aspects: The data processing capacity of recommendation systems with a centralized architecture is limited. Stand-alone recommendation algorithms suffer from data processing scale limitations and processing efficiency problems [12]. In addition to the large number of users and products in large e-commerce systems, there are also many natural attributes of users and products, making it difficult to build accurate and effective models for high-dimensional users and products [13]. Business application requirements are often complex and variable, and user

concerns vary for different application scenarios, so recommendation systems based on fixed models and parameters often lack flexibility [14]. Recommendation models are often strongly correlated with data characteristics and application scenarios, which dictates that recommendation systems must integrate a variety of complementary recommendation technologies. Algorithms and models of existing solutions are relatively homogeneous, making it difficult to meet the mainstream needs of mainstream users while taking into account their individual needs [15].

In order to overcome the shortcomings of the stand-alone e-commerce product recommendation system, some scholars have designed a distributed processing technology-based e-commerce product recommendation system. The distributed processing system relies on the Internet to unify the management of multiple stand-alone machines, which significantly improves the efficiency of the e-commerce product recommendation system compared to the stand-alone working mode, but there are some shortcomings in the distributed e-commerce product recommendation system, such as the recommendation efficiency is still difficult to meet the user's requirements for a large quantity, and the e-commerce product recommendation error rate is high [5]. Mobile computing is a fast processing system based on a distributed system, with the advantages of parallelism, distribution, and robustness, and has been successfully applied in many big data processing fields [16].

2. Related Technical Analysis

2.1. Comparison of the Main Recommended Technologies.
The advantages and disadvantages of commonly used recommendation techniques, such as collaborative filtering, association rule mining, and knowledge-based empirical methods, are compared in Table 1.

2.2. Distributed Computing and Storage Technologies.
Google's papers on distributed infrastructure have had a huge impact on the industry, with ideas such as MapReduce [5] and GFS [17] providing key references for distributed computing and storage, of which Hadoop is an open-source implementation [18]. Hadoop avoids time-consuming data transfer problems when dealing with large-scale data by using mechanisms for distributed data storage and migrating code rather than migrating data; it allows the system to recover from node failures by using mechanisms for moderate data redundancy.

3. Dynamic Community Segmentation Based on Mobile Behavioral Similarity

Definition 1. : Mobile behavioral characteristics. Mobile behavior characteristics reflect the spatial and temporal distribution of users' movements in different spatial locations within a given time interval [19]. In this paper, we choose the spatial frequency and length of stay of users as the portrayal of mobile behavior characteristics, which can be expressed as

$$o\left(w_j, l_i\right) = \frac{f\left(w_j, l_i\right)}{f\left(w_j, l\right)} \times \frac{d\left(w_j, l_i\right)}{d\left(w_j, l\right)}, \tag{1}$$

where $o\left(w_j, l_i\right)$ represents the mobile behavioral characteristics of user w_j at a spatial location l_i, and $f\left(w_j, l\right)$ represents the frequency of visits by user w at f and at all spatial locations f, respectively, and $d\left(w_j, l_i\right)$ and $d\left(w_j, l\right)$ represent the length of stay of W, at l_i, and at all spatial locations z, respectively. The distribution of the characteristics of the movement behavior of user W, at all spatial locations, constitutes a q-dimensional vector (discrete spatial location-scale q) as

$$\mathbf{V}\left(w_j, l\right) = \left(o\left(w_j, l_1\right), o\left(w_j, l_2\right), \ldots, o\left(w_j, l_q\right)\right). \tag{2}$$

The distribution of mobile behavioral features used in mobile user community segmentation is a relative value calculation. In other words, the characteristic distribution portrays the user's "preference" for different spatial locations. In practice, the absolute values of the spatio-temporal distribution of different users in different spatial locations are different, i.e. $f\left(w_j, l_i\right)$ and $d\left(w_j, l_i\right)$ are significantly different, which is the basis for the concept of mobile activity of users within a community.

Definition 2. : Mobile activity. Mobile activity is relative to the distribution of mobile behavioral characteristics, which are essentially relative values, while mobile activity is an absolute value [20]. Mobile activity is defined as the product of the cumulative frequency of visits and length of stay of a user W, at different spatial locations, expressed as

$$a\left(w_j, l\right) = \sum_{i=1}^{q} f\left(w_j, l_i\right) \times \sum_{i=1}^{q} d\left(w_j, l_i\right). \tag{3}$$

Definition 3. : Mobile spatio-temporal communities. Given a discrete time interval c_i and a dataset of historical movement trajectories of a set of users w, the set of users is divided into a finite number of communities based on the calculation of the characteristics of the movement behavior of different users at different time intervals c_i and different spatial locations is expressed as follows:

$$P = \{p_1, p_1, p_2, \ldots, p_k\}, \tag{4}$$

where $p_i = (w_{i1}, w_{i2}, \ldots, w_{ix})$, w_{ij} corresponds to the ith segmented community, and users within the same community have similar mobile behavioral profile distribution, while users within different communities have different mobile behavioral profile distribution [21]. The following section describes the process of dividing mobile communities in detail. Using the mobile behavioral profile formula, the preference profile of each participating user for different spatial locations can be derived $o\left(w_j, l_i\right)$, for each user w, the profile is calculated at different spatial locations, and the resulting preference profile is expressed in the form of a matrix as follows:

TABLE 1: Comparison of the main recommended technologies.

	Advantage	Shortcoming
Collaborative filtering technology	Discover new and different interests and do not depend on domain knowledge. With the passage of time and the accumulation of data, the effect is getting better and better. The recommendation process has a high degree of personalization and automation and can deal with complex unstructured objects	There are typical problems such as scalability, sparsity and cold start, and the recommendation quality depends on the historical data set
Association rule mining	Can discover new and different points of interest, independent of domain knowledge	Rule extraction is difficult and time-consuming, and the degree of personalization is low
Knowledge experience-based approach	It can consider nonproduct attributes, reflect user needs, and make up for the lack of user knowledge and experience	Knowledge and experience are difficult to obtain, and recommendation is static

$$M = \begin{bmatrix} m_{11} & m_{12} & \cdots & m_{1q} \\ m_{21} & m_{22} & \cdots & m_{2q} \\ \vdots & \vdots & & \vdots \\ m_{n1} & m_{n2} & \cdots & m_{nq} \end{bmatrix}, \tag{5}$$

where $m_{j,i} = o(w_j, l_i)$, the cosine similarity is calculated for any 2-row vector of matrix M by the following formula:

$$\cos \theta_{j1,j2} = \frac{\sum_{i=1}^{n} \left(o(w_{j1}, l_i) \times o(w_{j2}, l_i) \right)}{\sqrt{\sum_{i=1}^{n} \left(o(w_{j1}, l_i)^2 \right)} \times \sqrt{\sum_{i=1}^{n} \left(o(w_{j2}, l_i)^2 \right)}}, \tag{6}$$

The similarity between users w_{j1} and w_{j2} in all spatial locations based on the distribution of their mobile behavioral characteristics is represented by $\cos \theta_{j1,j2}$. Based on this similarity, the k-means clustering algorithm is used to classify the n participating users into communities, resulting in seven different mobile communities. As mentioned above, the mobile activity calculation is used to identify a unique community organizer in each of the divided mobile communities m as the end-user super-user for task reception and data upload with the MCS platform, and as the task coordinator between different user subordinates within the community [22]. In order to indirectly group the spatial locations by communities, we use the average value of the spatial preference vector of all users in the community to represent the community's preference for spatial locations. If the community structure is $p_k = \{w_{i1}, w_{i2}, \ldots, w_{ip}\}$, then the community preference for spatial location $\mu(p_k, l)$ is expressed as

$$\mu(p_k, l) = \frac{1}{p} \sum_{x=i1}^{ip} V(w_x, l)$$

$$= \frac{1}{p} \sum_{x=i1}^{ip} [o(w_x, l_1), \ldots, o(w_x, l_n)]. \tag{7}$$

4. Merchandise Recommendations for Mobile Computing

The traditional e-commerce product recommendation system uses a single-computer model, where the user's e-commerce product tasks and related data are all stored on a single computer, and all work is completed on this computer, making the intelligent recommendation of e-commerce products quite time-consuming and unable to meet the current requirements of e-commerce product development [23]. Mobile computing introduces parallelism and task decomposition techniques on the basis of distributed processing systems, where a large-scale task is processed in pieces, resulting in many subtasks, each of which is carried out by one computer (node), so that the processing results of each subtask are obtained, and finally, the results of the subtasks are fused to obtain the final processing results, shown in Figure 1.

In an e-commerce product intelligent recommendation system, the recommendation algorithm is very critical, which directly affects the effect of e-commerce product intelligent recommendation. Therefore, this paper presents the specific design of the e-commerce product intelligent recommendation algorithm.

Let there be N users, which are denoted as User $= \{u_1, u_2, \ldots, u_j, \ldots, u_N\}$, and all e-commerce products are denoted as Item $= \{i_1, i_2, \ldots, i_j, \ldots, i_p\}$, and p denotes the total number of e-commerce products; there are M user tags, which can be denoted as Tag $= \{t_1, t_2, \ldots, t_j, \ldots, t_M\}$ so that the frequency of users clicking on e-commerce products and the corresponding tag values of e-commerce products describe the user characteristics, which are calculated as follows [24]:

$$V_{ut_l} = \mathrm{tf}_{\text{user rax}} \cdot \mathrm{idf}_{\text{user}_{\text{tus}}} \cdot \left\{ \frac{n_{ut_l}}{n_{ut}} \log\left(\frac{N}{N_{ul}}\right) \cdots \frac{n_{ut_i}}{n_{ut}} \log\left(\frac{N}{N_n}\right) \cdots \frac{n_{ul_N}}{n_{ut}} \log\left(\frac{N}{N_{ut_N}}\right) \right\}. \tag{8}$$
Figure 1: Working principle of e-commerce product recommendation system for mobile computing.

Let n_{ut_i} and n_{ut} be the number of times a user uses t_i and the total number of tags used by a user respectively, then the frequency of tags and the popularity of tags to users are calculated as follows:

$$\text{tf}_{\text{user}_l ag} = \frac{n_{ut_i}}{n_{ut}},$$

$$\text{idf}_{\text{user}_l ag} = \log\left(\frac{n}{n_{ut_N}}\right). \tag{9}$$

The feature vector describes the importance of e-commerce good and is calculated using the following metric:

$$V_{ut_j} = \text{tf}_{\text{item}_{ux}} \cdot \text{idf}_{\text{item}_{ta}} \cdot \left\{ \frac{n_{it_l}}{n_{it}} \log\left(\frac{P}{N_{it_i}}\right) \cdots \frac{n_{i_i}}{n_{it}} \log\left(\frac{P}{N_{i_j}}\right) \cdots \frac{n_{it_H}}{n_{it}} \log\left(\frac{P}{N_{it_N}}\right) \right\}. \tag{10}$$

where $\text{tf}_{\text{item}_{ux}}$ and $\text{idf}_{\text{item}_{ta}}$ denote the frequency and importance of the use of the e-commerce good, respectively; n_{it_l} is the number of times e-commerce good i is used for the jth time; n_{it} denotes the total number of uses of e-commerce good i.

The user preference matrix for e-commerce goods is calculated as follows:

$$\mathbf{V}_{uji_k} = \sum_{i=1}^{M} \mathbf{V}_{uj} \times \mathbf{V}_{i_k t} \tag{11}$$

In which $u_j \in U, j = 1, 2, \ldots, N; i_k \in I, k = 1, 2, \ldots, P$.

The e-commerce product preference characteristics of users u_j are

$$V_{u_j} = \left(V_{uj,i}, V_{uji}, \ldots, V_{uji_k}, \ldots, V_{u,i_i}\right), \tag{12}$$

where V_{uji_k} is the preference level of u_j for e-commerce products. Based on the user's preference vector for e-commerce products, the user e-commerce product preference matrix is established as

$$\mathbf{V}_{N \times P} = \begin{bmatrix} V_{u_1 i_1} & \cdots & V_{u_1 i_k} & \cdots & V_{u_1 i_p} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ V_{u_j i_1} & \cdots & V_{u_j i_k} & \cdots & V_{u_j i_p} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ V_{u_N i_1} & \cdots & V_{u_N i_k} & \cdots & V_{u_N i_p} \end{bmatrix}. \tag{13}$$

Similarity describes the degree of similarity between two e-commerce products, and intelligent recommendation algorithms obtain the similarity of e-commerce products based on cosine similarity [25]. The feature vector of an e-commerce product can be expressed as

$$\mathbf{I}_k = \left(n_{k1}, n_{k2}, \ldots, n_{ki}, \ldots, n_{kL}\right), \tag{14}$$

where n_{ki} is the value of the t_i-tagged e-commerce item i_k normalized. The full e-commerce product information can be described using the e-commerce product-specific vector matrix $\mathbf{I}_{k \times k}$ as

$$\mathbf{I}_{k \times k} = \begin{bmatrix} n_{11} & \cdots & n_{1k} \\ \vdots & \ddots & \vdots \\ n_{k1} & \cdots & n_{kk} \end{bmatrix}. \tag{15}$$

Cosine similarity between e-commerce products based on eigenvectors is expressed as follows:

$$\text{sim}\left(i_j, i_k\right) = \cos\left(\mathbf{I}_j, \mathbf{I}_k\right) = \frac{\mathbf{I}_j \cdot \mathbf{I}_k}{\left|\mathbf{I}_j\right| \times \left|\mathbf{I}_k\right|}. \tag{16}$$

(1) Let us divide an e-commerce product smart recommendation task and map each subtask to a corresponding mobile computation point via the map program [26]. (2) At each node, the user's preference matrix for the e-commerce product is calculated. (3) At each node, the similarity of e-commerce products is calculated and an e-commerce product similarity matrix is built. (4) Based on the user's historical search data for e-commerce products, each node searches the historical e-commerce products that user u has clicked on, and calculates the preference value between the user and the e-commerce product. (5) At each node, the preference values between users and e-commerce products are ranked, and the top N e-commerce products are selected as the intelligent recommendation results and the recommendation results of each node are obtained. (6) The recommendation results of each node are output to reduce, and the best N e-commerce products are finally recommended to the user through reduce fusion [27, 28].

The intelligent recommendation process of e-commerce products is shown in Figure 2.

5. Experimental Analysis and Testing

5.1. E-Commerce Product Datasets. To test the performance of the mobile computing-based e-commerce product recommendation system, an e-commerce management system with 50,000 e-commerce products and 2,000 users was selected as the test object. 80% of e-commerce product and user data were randomly selected as the training set, while the other data were used as the validation set. The performance of the e-commerce product intelligent recommendation system
Figure 2: Intelligent recommendation process for e-commerce products.

is evaluated by the accuracy and completeness rates, where the accuracy rate represents the accuracy of e-commerce product intelligent recommendation and the completeness rate represents the reliability of e-commerce product intelligent recommendation.

5.2. Comparison of Recommended Results. The accuracy and completeness rates of the e-commerce product intelligence recommendations are shown in Figures 3 and 4, respectively. It is clear from Figures 3 and 4 that the accuracy and completeness rates of the mobile computing-based e-commerce product intelligent recommendation are higher than those of the traditional e-commerce product intelligent recommendation. This is mainly because the e-commerce product intelligent recommendation algorithm in this paper takes into account users' preferences for e-commerce products, which improves the accuracy of the e-commerce product intelligent recommendation, and the reliability and stability of the e-commerce product recommendation are higher.

The recommendation time of the e-commerce product recommendation system is shown in Figure 5. As can be seen from Figure 5, the intelligent recommendation time for e-commerce products based on mobile computing has been significantly reduced, overcoming the shortcomings of the traditional e-commerce product intelligent recommendation system in terms of long recommendation times and low work efficiency, and helping users to find the e-commerce products they really need more quickly.

5.3. Social Perception Effect. This paper uses the WTD public dataset, which records approximately 11 weeks of communication data between 275 users with PDAs (personal digital assistants) and deployed APs on the UC San Diego campus, as experimental data. This dataset was used to validate the performance of the proposed group intelligence-aware social task distribution approach for mobile social networks. Due to the sparsity of different user data in the WTD dataset, 140 AP nodes are selected as spatial locations and 68 users are selected as participating users in this experiment. Distribution of mobile community behavioral features and the user connectivity network based on closeness is first tested.
Figure 3: Recall of e-commerce product intelligence recommendation system.
Figure 4: Completeness rate of intelligent recommendation systems for e-commerce products.

The task execution effect, the number of task distributions, and the energy consumption of task recovery were tested by randomly generating 100–400 mobile group intelligence-aware tasks, with the spatial location of the tasks randomly selected from 140 AP points and the time interval randomly selected from 0 : 00 to 24 : 00. The relevant parameters are set as follows: the user fails to perform the task with a probability of 0.3, the community organizer respects a new performer with a probability of 0.5, and the task is passed through the social network with a probability of 0.5; in the case of passing the task, the person to whom the task is passed performs or refuses to perform the task with a probability value of their closeness. The energy consumption coefficient for data transfer via direct networks is set to 1, and the energy consumption for data transfer via
Figure 5: Recommendation time of an intelligent recommendation system for e-commerce products.
Figure 7: MCS task distribution experiment I.
Figure 6: Social connection network based on intimacy.

Figure 8: MCS task distribution experiment II.

opportunistic networks is set to 0.4. The specific distribution of the socially connected network in terms of closeness is shown in Figure 6.

Figure 7 shows a comparison experiment between the random distribution strategy and the traditional sequential distribution strategy, as well as an experiment with different intervention strategies after task execution failure, where vs is the number of group wisdom-aware tasks and z is the task completion rate. In the comparison between the random distribution strategy and the traditional sequential distribution strategy, there is no replacement of users for the failed task, and if the selected user does not appear in the specified spatial area on the second day at the corresponding time interval, the task fails. It can be seen from the figure that the proposed random distribution strategy significantly outperforms the traditional sequential distribution strategy.

Figure 8 shows the distribution statistics of the tasks under the task execution failure intervention experiment and the results of the perceptual data recovery energy simulation experiment, where B is the number of task distributions, u is the energy consumption statistics, and IV is the number of tasks. The statistics of the number of task distributions under the failed intervention experiment show that the number of distributions is lowest for the community-based distribution and the social intimacy-based user delivery, followed by the community-based distribution and the replacement within the failed user community, and the traditional "platform one user" full user reselection. The reason for this is that user delivery and distribution based on social intimacy has a high rate of task acceptance and

execution. In addition to the above experiment, a questionnaire was conducted to simulate a real-life campus environment. This figure is generally consistent with the results of the WTD test. The reason for this is that the dynamic community segmentation based on spatio-temporal mobile behavior clusters users with similar mobile behavior so that suitable users can be searched for within a relatively small range of available users for replacement. The results of the perceived data recovery energy consumption simulation show that the optimal replacement strategy within the failed user community is, in order, social relationship-based intimate user delivery and distribution and the traditional "platform one user" full user reselection. The reason for this is that the optimal intracommunity replacement strategy maximizes the use of opportunistic mobile social networks for short-range communication and therefore consumes the least amount of energy, while the social relationship-based intimate user transfer and distribution comes second and the traditional "platform one user" full user reelection uses 3 G/4 G communication for data upload/download, which consumes the most energy. The energy consumption is the highest.

6. Conclusions

In order to overcome the shortcomings of the current e-commerce product recommendation system, this paper proposes a mobile computing-based e-commerce product recommendation system. Firstly, to address the shortcomings of the current e-commerce product recommendation system based on the stand-alone working mode, such as low efficiency and slow speed, the mobile computing working mode was introduced to decompose the e-commerce product recommendation task and carry out distributed and parallel processing; secondly, to address the problem of large recommendation errors in the e-commerce product recommendation system, the e-commerce product intelligent recommendation system integrates the user's preference for products. The results show that this paper's e-commerce product intelligent recommendation system works efficiently and has high accuracy in recommending e-commerce products, which can provide valuable reference advice for users when conducting e-commerce product transactions.

Data Availability

The datasets used during the current study are available from the corresponding author on reasonable request.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Intelligent Light Control System Based on Zigbee

Xinxin Wang and Lijun Wang [ID]

School of Mechanical Engineering, North China University of Water Resources and Electric Power, Zhengzhou, China

Correspondence should be addressed to Lijun Wang; wanglijun@ncwu.edu.cn

This system uses Freescale i.MX283 chip as the main control core of the control panel and LPC824 as the main control core of the light control point. ZigBee communication local area network is built. The ZigBee network is used to search all the nodes and display them on the control interface stably. The controller can selectively control the node and communicate with ZigBee. It supports simple and convenient human-computer interaction interface. The control panel can control RGB lamps of lamp control nodes as follows: control the light on and off, adjust the brightness of the light, toggle the color of the light, control the gradient of the light, control the flashing of RGB lamp, control timing switch of RGB lamp, realize the scene effect of the light, etc. After testing, the system is stable and applied to many lighting control occasions.

1. Introduction

With the rapid development of science and technology, the development trend of wireless communication combined with intelligent control systems is more and more obvious, such as smart homes and the Internet of things. They all take the system as a carrier and rely on a way of communication to control the state and exchange data. The control side controls the state (foreground effect), and the node changes its state (background effect). The system mainly processes and calculates various complex data and realizes the algorithm. Communication is mainly used for data transmission and the exchange of feedback. In this way, it can not only realize highly complex algorithm functions but also support a human-computer interaction interface which is convenient for users. The intelligent lighting control system based on ZigBee communication integrates computer technology, mechanical control theory, sensor technology, system engineering, and artificial intelligence technology. It has a wide range of applications and is the development trend of Internet of things communication in the future [1].

2. Overall Design Scheme

This design selects i.MX283 as the control interface; its core is an ARM9 processor. The processing speed is fast enough because it has enough RAM space; it can also run common operating systems such as UCOS, LINUX, and AWorks. It has its own ZigBee minimum system module supporting the ZigBee protocol. The LPC824 of Freescale is selected as the control node, and the processor is arm CortexM0+ which is a low-power controller with a processing speed of about 30 m. For the light control node, this speed is large enough, and it has its own ZigBee minimum system module that supports ZigBee protocol and can realize various state controls of RGB [2].

The software design is mainly divided into control panel and light control node. The control panel provides a simple human-computer interaction control interface for users who can click the interface control icon to send out the corresponding control signal according to the needs of their own functions. Then, the data layer will send the control signal to the light control node for execution through ZigBee protocol communication. The light control node continuously

queries and receives the control signal sent by the control panel and then analyzes the command and executes the corresponding control command to achieve the corresponding functions.

The control panel mainly involves five thread tasks [3]:

(1) GUI tasks: used to create and display function icons. When the user clicks the function icon, the callback function will be called to complete the corresponding function. For example, select and switch the target control node, send the control status command, receive the temperature and humidity data, mailbox data, and real-time display, receive the surrounding node information and display node-related information, and modify the display name of the node to facilitate memory.

(2) Temperature and humidity acquisition task of DHT11: mainly collect the current temperature and humidity, and send the data to the GUI interface through the temperature and humidity data mailbox.

(3) Receive control signal task of light control node: receive the control information data from the GUI task layer in real time, and then, the task is sent by ZigBee.

(4) ZigBee search task: search the surrounding node information, and send all node information to GUI.

(5) ZigBee sends control status task: sends control information data to the lamp control node.

(6) Light control node task: the light control node is equivalent to a state machine. ZigBee protocol is used to receive the control information from the control interface in real time and then analyze and execute the control information.

3. Software Design

The software development of intelligent lighting control system is based on eclipse software as the development environment, C language as the main programming language, and Freescale chip ARM9 and cortex M0+ as the core processor. The software module needs to use the task allocation, task scheduling, communication mechanism between tasks, GUI, GPIO port control, UART module, PWM module, and ZigBee communication protocol of real-time system AWorks.

3.1. ZigBee Networking and Communication Process. The coordinator can create a unique WLAN PANID. Routers and terminals can join a wireless LAN PANID, that is, network access. The PANID created by the coordinator and the PANID added by the router and terminal are preset in the program and are not automatically allocated by the module. Therefore, in the process of network creation and network addition, it is necessary to specify which LAN to create or need to join, so as to ensure the effectiveness of data transmission.

The coordinator module establishes the wireless local area network. This PANID is unique. When selecting the channel, select the channel without a local area network nearby (there are 16 channels in 2.4 G bandwidth to choose from 11 to 26) which can prevent competition and increase the stability of the signal [4].

When the coordinator creates a LAN and a module (router or terminal) joins the LAN, the node can communicate with the router. Terminals cannot communicate directly with each other and need to pass through routers to act as an intermediary. Sending data must comply with ZigBee protocol and can be developed using ZigBee protocol stack provided by ZigBee manufacturer. The protocol stack is like a development library written according to the provisions of the ZigBee protocol. Developers only need to develop through the API functions provided by the library functions so as to realize the sending and receiving of wireless data [5].

3.2. Interface Layer Design of the Control Panel

3.2.1. GUI Control Interface. emWin and ucGUI are the same; GUI graphics library is like a function encapsulation library which provides developers with various interfaces for drawing API. Understand API functions and precautions to carry out preliminary development, and emWin interface application structure is clear; each page is composed of three parts: (1) control structure array, (2) callback function, and (3) page creation function. Then, there is the window and control management which are mainly composed of (1) control handle, (2) control ID, and (3) message [6, 7].

(1) Control Array. View all the controls used in the current interface. The main function is to create and initialize the information of related controls such as the abscissa and ordinate of the control displayed in the current interface, the size, and name of the control.

(2) Callback Function.

```
static void _dialog(massge *p_msg) {
switch (p_msg-> id) {
case init://Reset control properties (size, color, etc.)
case parent://Operations trigger message processing such as clicking the//button, clicking the edit box
case timer://Timer trigger operation, timer will execute the program here
case paint://Window redraw message, display text in the window or draw lines,//rectangles, circles
}
}
Page creation function:
void task_ main(void)
{
gui_ Init();//initialization interface
create_ Win();//create interface
```

while (1) {delay (20); }//call GUI_ Delay function delay 20 ms

}

Each page has its own callback function which contains all the functions that the control needs to implement. Any operation of the interface will trigger and call this callback function and then process it in the program.

3.2.2. GUI Interface Design. The intelligent light control system based on ZigBee mainly includes the display and selection of node, the switch of node light, the color of light, the brightness of light, the flicker of light, the scene effect of light, the timing of light, and the gradient of light. The control selection mainly includes button control, checkbox control, slider control, and text control [8, 9].

(1) Creation and Start of Interface.

```
void gui_task(void * p_arg)/* GUI task function
entry */
{
WM_HWIN Win;
GUI_Init();/* Initialization interface */
Win = CreateSmsrt_Control(WM_HBKWIN);/*
Create interface */
while(1) {
GUI_Delay(20);/* Waiting for task scheduling */
}
}
```

Button control is used for the selection of light color. When user presses button control, GUI task will call callback function to create a color selection interface.

The program framework of button control is as follows:

```
static void dialog(massge * p_msg) {/* GUI task
callback function */
switch (p_msg ->msg_id) {/* Type judgment of
callback */
case notify_parent:/* The callback type is operation
trigger message */
id = get_id(p_msg ->win_src);/* Get interface con-
trol type */
ncode = p_msg -> data.v;/* Operational data */
switch(id) {/* Control type selection */
case botton_0:/* botton_0 Control type */
switch(ncode) {
case click:
break;
case reaessed;/* Click operation */
create_colo_win();/* Create a color selection interface
*/
break;
}
break;
```

}}}

(2) Checkbox Control. Switch for light, scene effect, timing function, and gradient function. It is equivalent to a check box. Open a function (such as scene effect function); click the scene effect option box to check it. Then, the GUI task will call the callback function to execute the selected condition options of the checkbox control, and the LED status data mailbox will be sent out to control the lighting effect of the light control node [10, 11].

The program framework of the checkbox control is as follows:

```
static void dialog(massge * p_msg) {/* GUI task
callback function */
switch (p_msg ->msg_id) {/* Type judgment of
callback */
case notify_parent:/* The callback type is operation
trigger message */
id = get_id(p_msg->win_src);/* Get interface control
type */
ncode = p_msg -> data.v;/* Operational data */
switch(Id) {/* Control type selection */
case check_1:/* check_ 1 control type */
switch (ncode) {
case click:
break;
case reaessed:{/* With ID_ CHECKBOX_ 1 click
operation */
send_mailbox(mail_type,&data, wait_time);/* Send
various data messages */
break;
}
break;
}} }
```

(3) Slider Control. Used for brightness adjustment of light and flicker frequency adjustment of light. It is like people seeing progress bars, but it has its own length range and size. It is like a ruler; drag it randomly, and the current dimension value will be represented at the last stop. Then, the size returned by the ruler can be used to adjust the intensity and flicker frequency of the RGB lamp which is proportional to the length of the size [12, 13].

The framework of the glider control is as follows:

```
static void dialog(massge * p_msg) {/* GUI task
callback function */
switch (p_msg ->msg_id) {/* Type judgment of
callback */
case notify_parent:/* The callback type is operation
trigger message */
id = get_id(p_msg->win_src);/* Get interface control
type */
```

ncode = p_msg - > data.v;/ ∗ Operational data ∗ /

switch(id) {/ ∗ Control type selection ∗ /

case slider_1:/ ∗ SLIDER _ 1 control type ∗ /

switch (ncode) {

case clicked:

break;

case released:/ ∗ SLIDER _ 1 click operation ∗ /

hItem = get_dialog_item(p_msg- > win, slider_1); / ∗ Get handle ∗ /

slider_set_width (hitem,15);/ ∗ Sets the size of the slider ∗ /

slider_set_range(hitem,0,9);/ ∗ Set the scale range of slider ∗ /

val = slider_get_value(hitem);/ ∗ Gets the current size value ∗ /

send_mailbox(mail_type,&data, wait_time);/ ∗ Send data message ∗ /

break;

}

break;

}}}

(4) Timer Mechanism of GUI. GUI handles corresponding events through the callback function. When time is up, it will execute an option callback function of the timer, and the timer will be set once. When the timer is used again, the timer count must be enabled again. This design mainly has two timers: one is responsible for the timing, receiving temperature and humidity data information every 2 seconds, and displaying it on the interface. The other is responsible for receiving the number of surrounding nodes every 3 seconds, dynamically increasing and deleting the number of nearby nodes, and displaying them on the interface [14].

Timer program framework is as follows:

static void dialog(massge ∗ p_msg) {/ ∗ GUI task callback function ∗ /

switch (p_msg - > msg_id) {/ ∗ Type judgment of callback ∗ /

case timer:/ ∗ The callback type is timer ∗ /

if (get_timer_id(p_msg - > data.v) = = 0) {/ ∗ TIMER0 ∗ /

receive_mailbox(mail_type, p_data,wait_time);/ ∗ Receive temperature and humidity data mailbox ∗ /

restart_timer(p_msg - > data.v, 2000);/ ∗ Restart the timing for 2 seconds ∗ /

}

if (get_timer_id(p_msg - > data.v) = = 1) {/ ∗ TIMER 1 ∗ /

receive_mailbox(mail_type, p_data,wait_time);/ ∗ Receive data mailbox of surrounding nodes ∗ /

3.3. Design of Data Layer of the Control Panel.

This system needs frequent data transmission and data transmission between tasks. So the data processing layer is designed. All data will be collected, sent, or accepted directly or indirectly through the data layer. The main data involved are temperature and humidity data, status command data of light control node, number of surrounding nodes, control information data sent by ZigBee, search node queue data, current node information list, and modified name node information list. The main tasks involved are as follows: ZigBee searches the information of nearby nodes, sends the control data to the light control node, receives the light control node data from the interface layer, and collects the temperature and humidity in real time and sends it to the interface layer and interface touch screen [15, 16]. The overall structure of the control panel is shown in Figure 1.

3.3.1. Realization of Touch Screen Tasks.

It mainly completes the initialization and calibration of LCD and monitors whether there are touch screen operations in real time. When there are touch screen operations, it will call the interface callback function to perform the corresponding functions. Its task level of 2 is the highest so as to successfully monitor all touch screen operations [17]. The flow chart of touch screen detection is shown in Figure 2.

3.3.2. Realization of Temperature and Humidity Real-Time Acquisition.

According to the protocol specification of DHT11, read the measured temperature and humidity and then send the data to the interface layer display by e-mail through intertask communication. Mission priority is 7. The driving steps of the DHT11 temperature and humidity sensor are as follows:

(1) After the DHT11 module is powered on, wait for a second before sending the instruction to the module and set the data pin of DHT11 to the input state to detect the external signal.

(2) The controller sends out a start signal (low level) and then waits for the temperature and humidity module to respond to the controller [18].

(3) After the temperature and humidity module generates the response signal, the high level of 80 microseconds is output to tell the controller to prepare the data to receive.

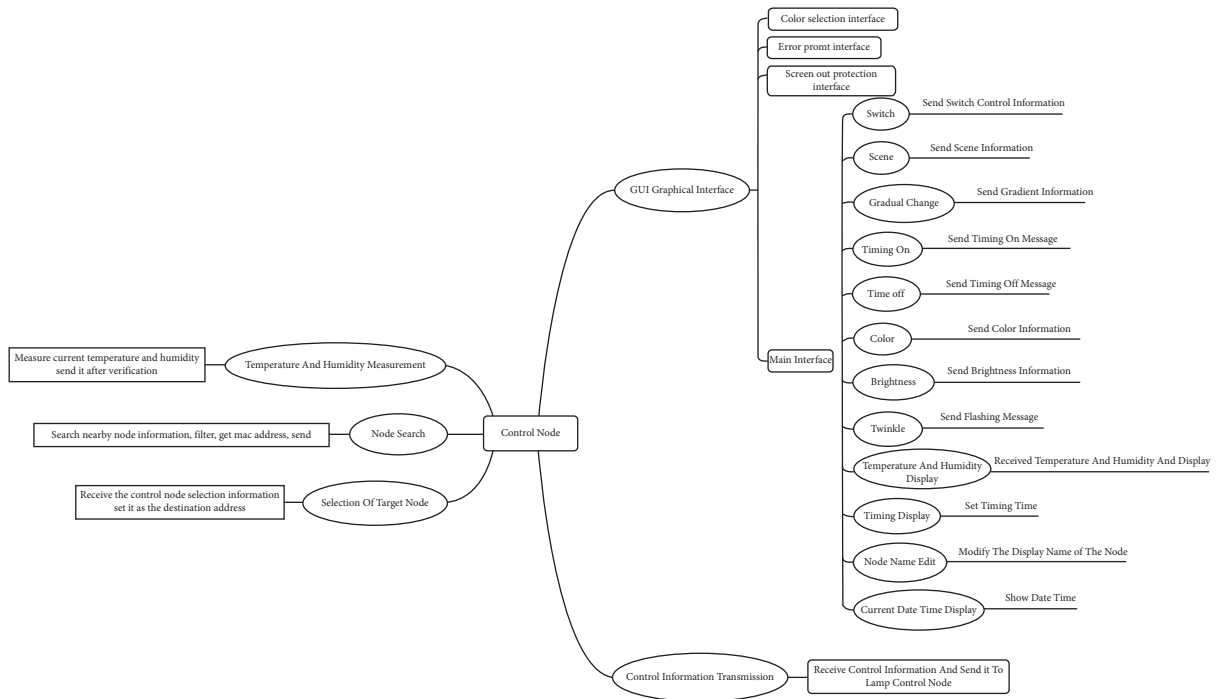
(4) After the preparatory work is completed, DHT11 starts to send data to the controller; the controller only needs to receive it. The data output by DHT11 has 40 bits including 16 bits of temperature data, 16 bits of humidity data, and 8 bits of calibration data.


Figure 1: General structure of the control panel.
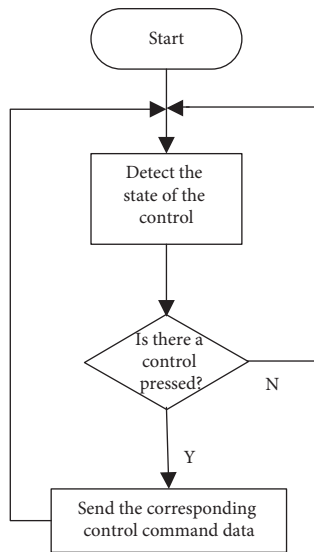

Figure 2: Flow chart of touch screen detection.

(1) Data Format. Because DHT11 adopts single bus communication, it can only transmit data in one direction at the same time. It transmits bit by bit (generally used to transmit digital data). Because data are transmitted through high and low levels, it is necessary to specify the form of data. The format of data "0" is 50 ms low level + 28 ms high level and the format of data "1" is 50 ms low level + 70 ms high level.

(2) Controller Parsing Data. The data received by the controller is continuous level, so developers need to convert the level into effective data. According to the data format, there are many kinds of parsing methods. The method used in this design is as follows: first, wait for the low level to pass, that is, wait for the data line to pull high, then delay for 60 us, because 60 us is greater than 28 us and less than 70 us, and then detect whether the data line is high at this time. If it is high, the data is determined as 1; otherwise, it is 0 [19, 20].

(3) Precautions. There will be a lot of delay waiting in the process of starting the temperature and humidity sensor and reading the data. Active delay in the operating system causes the operating system to perform other tasks with high priority. If the temperature and humidity measurement task is delayed, but the operation system does not return (because there are high priority tasks to be processed), the temperature and humidity data read will be incorrect, and the verification will not be successful in the final data verification. There are two solutions. Method 1: when entering the task of measuring temperature and humidity, the priority of this task is set to the highest; then, it will be lowered back to the original priority after measurement is completed. Method 2: when entering the task of temperature and humidity measurement, pause the task switching, then turn on the task switch after the measurement is completed. Of course, they will have a certain impact on the whole system. The most obvious consequence is that users will obviously feel that the response of the system is not timely. Finally, combined with their advantages and disadvantages, this system did not use these two methods, because the indoor temperature will not change very fast, and it only needs another 30 seconds to have a successful test to meet the actual needs [21]. The flow chart of temperature and humidity measurement and display is shown in Figure 3.

3.3.3. Realization of ZigBee Search Nearby Node Information Task. When users want to control a node, they first need to retrieve the existence of the node nearby. Before ZigBee search nodes, some parameters of ZigBee need to be set such as channel of the network, PANid of the network, and the source address of target address. The design sets 2.4 G of network channel, 11 network channels, 1010 network IDs, and 2020 source addresses, in which the target address can be dynamically switched according to the control target. After configuring the basic information, search constantly the number of nearby nodes and their address information in the task and then send the received number of nodes and node address information to the interface layer for processing. It is worth noting that ZigBee is also a peripheral resource. When a task is using ZigBee to send messages, the ZigBee module needs to be protected. At this time, another task can no longer search the information of nearby nodes through the ZigBee module. So it is generally to add a lock to lock to the ZigBee module and prevent other tasks from accessing it to prevent competition. The flow of search for nearby node information is shown in Figure 4.

3.3.4. Realization of Node Information Display Task. After searching the nearby nodes, it needs to be displayed on the control interface to control them. According to the row comparison between the node currently searched and the node last displayed, if there is a node in the last display list but not in the current search, it will be deleted from the display list. If there is no node in the last display list but there is a node in the current search, it will be added to the display list for display [22]. It is displayed in a list box control of emWin. The flow of showing current node information is shown in Figure 5.

3.3.5. Receive Interface Layer Sends Out the Control Status Task of Light Control Node. The purpose of this task is to receive the light control status information sent by the interface layer in real time. Concentrate the control status here and prepare to send it to the light control node, for example, switch, node selection, light brightness, light intensity, and so on. The priority is high, and the task level is 4. The receiving of light control status information is mainly in the form of a mailbox. First, create a mailbox data type that controls the status information type and set the number of mail. Finally, initialize and allocate memory space. It should be noted whether the sender has blocked sending, that is, whether he has been waiting for the successful sending and has been received by the receiver, or just send without waiting. The receiver is similar. This design uses sender blocking, receiver not blocking, and receiver real-time view receiving mailbox, if there is a mailbox to receive, not ready to receive the next time. The flow of receive control command and send to node is shown in Figure 6.

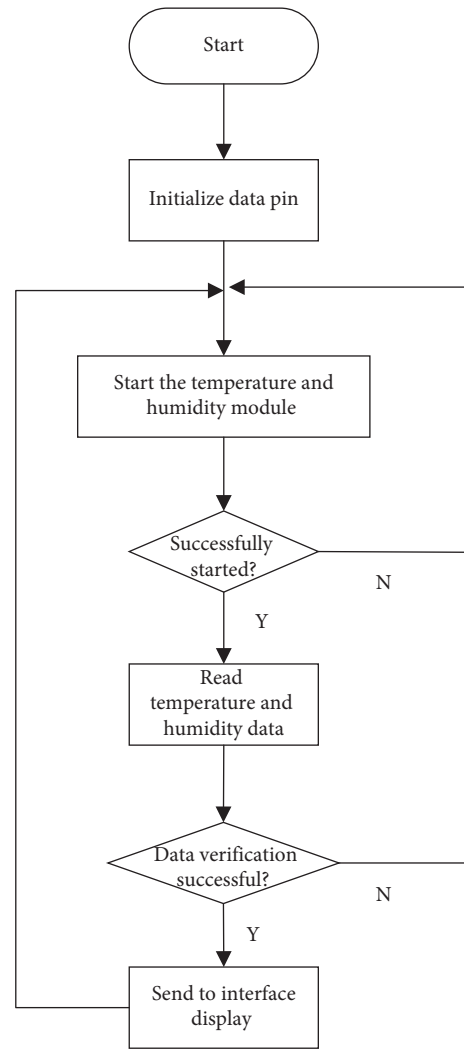
3.3.6. Modifying Node Name Task. Because the node is displayed in the control panel in the form of the network address of the node, and the network address is in the form


Figure 3: Flow chart of temperature and humidity measurement and display.
Figure 4: Flow of searching for nearby node information.

of a 16-byte number, the node that may be seen on the interface is displayed in the form of a hexadecimal byte similar to 02030507, which will be very inconvenient for
Figure 5: Flow of showing current node information.
Figure 6: Flow of receive control command and send to node.

customers to use. Do not recognize where this node is or what special function it has from its name. In order to facilitate the use, set the name of the node that users can understand such as the living room and bedroom so that you easily identify and distinguish nodes. The flow of renaming node names is shown in Figure 7.

3.4. Data Layer Design of Light Control Node

3.4.1. Function Overview. The light control node is the controlled terminal equipment which is placed in any room or outdoor and controlled through the control panel to achieve the corresponding functions. The main functions are light on and off, light gradient, adjustable frequency flicker of light, timing switch, scene effect, brightness adjustment of light, and the color setting of light. The light control node structure is shown in Figure 8.
Figure 7: Flow of renaming node names.

3.4.2. Function Realization of Light Control Node. The software design of the light control node is like an infinite cycle state machine. Although it does not have the support of the operating system, it can continuously use the ZigBee module to receive the control signals from the control panel. Then, the control signal is parsed into the corresponding control command, entering the status query. Then execute the corresponding state function, that is, each function module that the light control node can achieve. These functions are to be debugged separately and sorted and packaged after debugging [23]. State machine implementation block diagram of light control node is shown in Figure 9.

4. System Debugging and Optimization

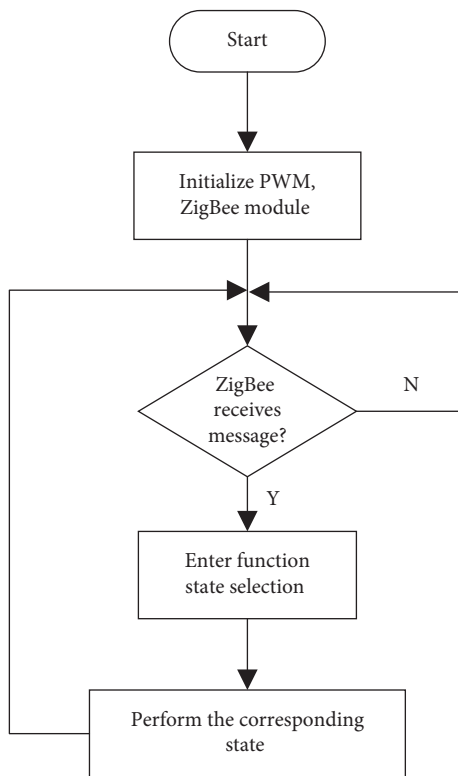
4.1. Communication Debugging between Multitasks. When programming in a system without an operating system, two different functions also need to be exchanged generally through the way of global variables to exchange data. Generally, data exchange is carried out through global variables. When ZigBee searches the current number of surrounding nodes and information, it needs to send the information to the interface task for display. Before sending, the data will be printed out by serial port printing. After receiving the data, the interface will print out the data which is always 0. The problem is that the memory here is cleared after sending which causes the received data to be always 0. Finally, the memory space will be cleared after receiving the data.
Figure 8: Light control node structure.


Figure 9: Light control node state machine.

In the process of multitasking, when different tasks use the same hardware device at the same time, it needs to be protected artificially. The most common method is to lock the module or memory and unlock it after accessing it. When the ZigBee module searches for nearby nodes, due to the scheduling of tasks, it is possible to send ZigBee information. At this time, there will be two tasks accessing the ZigBee module at the same time which will seriously lead to the death of the task and slightly lead to errors in the search

or the sending of information which can not achieve the expected effect of the program. This module needs to be protected. When task A accesses this module, it will lock this module. At this time, if task A is scheduled to execute another task B, it will wait until task A's access ends when it also needs to access this module. After task A is unlocked, Task B can have the opportunity to access this module which avoids the problem of multiple tasks accessing the same module at the same time. During debugging, it is found that ZigBee sending task is not executed.

In the process of node display and name change debugging, two identical nodes will be displayed. Sometimes, when the node name is changed, it still displays the previous node name. The solution is to create two linked lists. Linked list A records the node information currently displayed; linked list B records which node names have been changed. First, the node searched is compared with list B. The name of the node is changed. The node searched is compared with list B and updated displayed. When the node name is modified, the information and name of the node are added to list B, and then the node in list A is deleted.

Because ZigBee belongs to wireless communication, there is instability. When the number of surrounding nodes remains unchanged, the result of the last search may be different from that of the next time. The interface will flash especially unstable in this way. This requires filtering. The first filtering scheme: search five times each time, and it is determined to exist if two or more times are found; otherwise, it is determined to not exist so that the nodes displayed on the interface are stable. But there is a problem; that is, the task has been searching, occupying ZigBee module resources; other tasks have to wait until the end of the search task to access which is not real-time enough. The second filtering scheme is to establish a queue, put the searched node at the end of the queue each time, delete the node information at the head, and move the queue members next time, that is, move the first one to the position of the second

queue member and do it in turn. The number of member nodes of the queue is four and remains unchanged. As long as there are two or more members with this node, it will be judged that this node exists. In this way, each search can make it displayed on the interface, the number of searches is reduced, and the time of occupying the ZigBee module is four times less than the previous scheme. There are more opportunities for other tasks to not only occupy the ZigBee module but also improve the real-time performance of the task, but the disadvantage is that it takes about 3 seconds to remove a node. But this has little influence and the second design scheme is finally selected based on the practice.

In order to ensure the correctness of multitask execution, the function of real-time temperature and humidity detection is added. It only needs to ensure that the temperature and humidity verification is successful once in one minute. Otherwise, it takes 40 times to read the temperature and humidity data, and the reading of each bit of the data needs to delay to judge whether it is high level or low level. When this delay occurs, the CPU will switch to other tasks to improve its utilization, but when the delay time expires, due to the priority of the task, the task did not switch back on time which finally led to the unsuccessful verification of the measured data.

4.2. Debug of Light Control Node

4.2.1. Dimming with PWM Wave.
Pulse width modulation (PWM) is the time of high level output in a cycle. The adjustment of the duty cycle is the modulation of the pulse width. The color brightness of different RGB of duty cycles is different. Different colors can be modulated by outputting different PWM waves to the three channels of red green blue. The PWM module is like a timer built in. First, a count upper limit value (cycle) is set; then, a time t is set. When the counter is less than t, it controls the output low level of IO port. When the time is higher than t, the output of IO port is controlled as high level. When the counter reaches the upper limit, it will time again. So repeatedly, IO port outputs rectangular waveform [24].

4.2.2. Light State Adjustment.
The adjustment of color is mainly realized through the three primary colors of red, green, and blue. The RGB lamp can be configured with 256 different colors which depend on the adjustment of three PWM waves that control red, green, and blue. When the user sends the color switching command on the color selection panel of the control panel, the lamp control node will realize the color preparation by controlling three PWM waves of red, green, and blue.

Brightness adjustment: only change the brightness of the light, and keep the original color unchanged. The duty cycle of red, green, and blue PWM is equal to the increase or decrease of the column.

The flashing frequency of light can be controlled by a software program. The principle of flicker is to continuously control the light on and off showing certain regularity. The delay time between on and off is different with different flashing frequencies.

The gradient effect is realized by sending corresponding instructions from the controller. The lamp control node will make the lamp produce the effect of breathing lamp, slowly turn on, and then slowly turn off, and so on when the controller sends the gradient command.

Scene Effects: three different scene effect modes. Scene Effect 1: red, green, and blue lights turn on and off alternately, and with the passage of time, the speed of alternation is faster and faster. Scene Effect 2: use a random generating function to configure the color to be random and change once per second. Scene Effect 3: the breathing effect of red, green, and blue lights. The scene effect of each scene control signal is changed once.

Timing switch: the timing control lamp is on and off and is timed by the control end. When the preset time is over, the controller sends the control information of the timing switch.

4.3. Optimization of Light Control Node Real-Time State Switching.
When debugging the light control node, the control panel keeps sending control commands, but the light control node does not switch state in real time. Instead, when one state is executed, it will receive another information and then execute it. When a sent state is executed for a long time (scene effect), if the control interface sends another state (color switching) during execution, but the light control interface does not execute the latest sent state (color switching), it will continue to wait until the last state (scene effect) is executed. This will make people feel as if the command sent by the user has not been executed. Because the ZigBee module does not support interrupt, it can only use software to improve the real-time performance of the execution state. When executing a task (Scene Effect 1, red green blue cycle switch), the red light is on, keep the current execution state, exit this state, and go back to see if there is a control command received; if not, continue to execute the previous state and then switch the light to green. At this time, if the new control information is received, the control will be executed. This greatly increases the real-time performance of task switching and can interrupt the current task state to execute another state.

5. Summary

This design mainly involves ZigBee wireless communication technology, task allocation, and management of the operating system, resource management, and communication between multiple tasks, emWin interface design, PWM wave control of RGB lamp status, serial port debugging, and j-link debugging skills. The system supports ZigBee protocol communication, supports the human-computer interface, controls the light on and off, and controls the light brightness and color, gradient, flashing frequency; supports timing switch, and scene mode. It supports the automatic addition and deletion of lamp control nodes, can display indoor temperature data in real time, can stably display node

information, can freely modify the name of node display, and identify nodes with the same network address. The design has a wide range of applications. It provides technical support for the application of ZigBee technology in the field of light control.

One of a very significant computer vision task in many real-world applications is traffic sign recognition. With the development of deep neural networks, state-of-art performance traffic sign recognition has been provided in recent five years. Getting very high accuracy in object classification is not a dream any more. However, one of the key challenges is becoming making the deep neural network suitable for an embedded system. As a result, a small neural network with as less parameters as possible and high accuracy needs to be explored. In this paper, the MicronNet which is a small but powerful convolutional neural network is improved by batch normalization and factorization, and the proposed MicronNet-BN-Factorization (MicronNet-BF) takes advantages about reducing parameters and improving accuracy. The effect of image brightness is reduced for feature recognition by the elimination of mean and variance of each input layer in MicronNet via BN. A lower number of parameters are realized with the replacement of convolutional layers in MicronNet, which is the inspiration of factorization. In addition, data augmentation is also been changed to get higher accuracy. Most important, the experiment shows that the accuracy of MicronNet-BF is 99.383% on German traffic sign recognition benchmark (GTSRB) which is much higher than the original MicronNet (98.9%), and the most influence factor is batch normalization after the confirmation of orthogonal experimental. Furthermore, the handsome training efficiency and generality of MicronNet-BF indicate the wide application in embedded scenarios.

1. Introduction

Traffic signs, usually erected at the side of roads, use texts or symbols to provide road information for vehicle divers and pedestrians (see Figure 1). Traffic sign recognition is essential in advanced driver assistance systems (ADASs) and autonomous vehicles [1]. In the real cases, camera installed on the vehicle takes photos of roads. The information processing system processes the image and detect and classify the traffic sign according to its characters. The classification result provides road information for drivers or adjusts the motion state of an autonomous vehicle. Because the captured images are affected by brightness and weather conditions, traffic sign classification has high requirement in accuracy and robustness.

For the sufficient research of traffic sign recognition, researchers established a multitraffic sign recognition dataset such as German Traffic Sign Recognition Benchmark

(GTSRB) [2], Belgium Traffic Sign Classification Benchmark (BelgiumTSC) [3], and Tsinghua-Tencent 100K dataset [4]. GTSRB dataset provides 51,840 colorful images of German road signs in 43 classes. This dataset also provides cropped images for accurate classification. Most of images are clear, but part of them is blurred and darkness used to test the algorithm's robustness. It not only allows researchers to test the accuracy of their algorithm and to compare it with human performance but also to be transformed by the histogram of the oriented gradient algorithm to prevent projection distortion [5] or denoised to promise the quality of dataset [6].

In recent years, convolution neural networks (CNNs) show high performance in the GTSRB dataset [7–9]. CNNs, inspired from human's visual perception mechanism, are applied broadly in computer vision [10]. As a deep learning network, it has many layers to simulate neurons to learn the characters of images. It has showed high performance in

FIGURE 1: Various categories of traffic signs under different weather and brightness in GTSRB.

many datasets such as CIFAR [11] and ImageNet [12], so people consider applying the enhanced CNN (e.g., LeNet-5 [13], Caps Net [5], PFANet [14], differential evolution evolved RBFNN [15], etc.) in traffic classification. However, application in vehicles has its restriction. The network requires high response speed under the limited storage space. The hardware installed on the vehicle does not have enough computation ability, which causes the scale of the network limited [16]. As such, some famous mature deep networks such as GoogLeNet [17] and VGG [18] are too deep or huge to be applied in vehicles directly. However, small networks are feasible. Zhang et al. [1] proposed two light weight CNN simple student network and deep teacher network and assisted the training of the student model to achieve high accuracy in traffic sign classification. Arman et al. [19] proposed a novel thin yet deep convolutional neural network for a light weight architecture. Cao et al. [20] used HSV color space preprocess images and applied improved LeNet-5 CNN model with a small number of parameters in traffic sign classification. Although the research studies above have slimmed the networks to adapt the embedded system, the recognition of brightness and blur pictures of traffic sign is still an arduous challenge. Wong et al. [21] proposed MicronNet and trained it with the augmented (e.g., HSV augmentation, Gaussian blur, motion blur, etc.) traffic sign photos. However, the augmented dataset in [21] have no emphasis, causing information redundancy. There are still a number of optimizations in the structure of MicronNet and the augmentation of traffic sign dataset, and it is essential to find a proper balance between the processing of a traffic sign

dataset and the light weight structure of the convolutional neural network.

Inspired from the above network, we proposed a CNN based on MicronNet, a small network and overcomes drawbacks of the original network. In this study, we mainly focus on MicronNet-BN-Factorization (MicronNet-BF) which fused the superiority of MicronNet, batch normalization, and factorization. In addition, the appropriate augmentation methods of insufficient illumination traffic signs are selected for a better training performance.

The main contributions of this paper can be summarized as follows:

> The complicated data augmentation methods (including shift, flip, mirror, HSV, blur, and rotation) are simplified into shift, scale, and the V channel of HSV, avoiding that too much data augmentation may introduce some useless or even false characters of traffic sign and reduce the accuracy of the neural network.

> Two channels are additionally supplemented to the first layer, 1-by-1 convolution, to enhance the learning of image features from the dataset. 5-by-5 convolutional layer is replaced by two sequential 3-by-3 convolutional layers, reducing parameters and extracting more meticulous characteristics to increase the accuracy.

> Batch normalization can learn and fix the input means and variances of each layer. For the traffic sign recognition, the adverse effect of brightness is effectively reduced, improving the classification accuracy of insufficient lighting images.

2. Related Work

MicronNet [21], a small deep convolutional neural network, is proposed to achieve real-time embedded traffic sign classification. The network structure is optimized from a large network by repeating omitting parameters and testing network to maintain high accuracy with the least number of useful parameters. The final optimized network reaches 98.9% accuracy only containing 0.51 M parameters and which is competitively with the deep inception-based CNN [22] with 10.5 M or single CNN with 3 STNs [23] with 14 M, etc. Furthermore, a few logical operations are required for MicronNet to perform inferences and short computation time meanwhile. However, the network cannot deal with dark and blurred images well (see Figure 2). Based on the MicronNet, we adjust data augmentation and modify parts of the network to make it suitable to both common images and dark images.

Ioffe and Szegedy [24] proposed batch normalization (BN) to improve classification accuracy and training rate. Because of internal covariate shift, the changed parameters of the previous layers causing each layer inputs changed after every training epoque, and traditional network training chooses a low learning rate. Batch normalization normalize every layer's input for each training minibatch. We introduce batch normalization to MicronNet to improve its learning rate and accuracy.

Szegedy et al. [25] based on GoogLeNet [17] presented the inception V2 network. In this paper, Szegedy presented a theory that two sequential small convolutional filters can replace a large convolutional filter to improve the learning rate and reduce parameter number and achieve similar accuracy because the receptive field of two methods are the same. The factorizing mentality is fused in MicronNet either.

3. Proposed Methods

3.1. Data Augmentation. The uneven distribution of data will be decreasing the accuracy of classification. Researchers use a various of data augmentation techniques to balance the number of samples [21, 26]. However, on the one hand, the data that can be augmented based on one sample is limited and cannot be increased indefinitely due to the distortion of the characteristics of sample in the process of augmentation. On the other hand, the ministructure of the neural network cannot effectively learn too much characteristics. As a result, the proposed data augmentation is simplified to three ways: (i) shifting, (ii) brightness, and (iii) scale. The properties of choosing these three ways can be described as follows: (1) Shifting can help to deal with the partially covered traffic signs. (2) Brightness can help to learn the traffic signs under different light conditions. (3) Scale can help to handle various sizes of traffic signs. The examples can be seen in Figure 3.

3.2. MicronNet-BF. MicronNet is a compact deep neural network proposed for traffic sign classification on embedded devices [21]. It has struck a relative balance between the

augmentation of a traffic sign dataset and the simplifying of the network architecture, but the main problem in the example of misclassified traffic images is either heavily motion blurred (left), partially occluded (middle), or exhibit poor illumination (right). Based on the MicronNet and inspired from the network architecture of inception V2 [21, 25], an improved network architecture MicronNet-BN-factorization (MicronNet-BF) is proposed in this paper. MicronNet-BF is taken to (1) improve the total accuracy on traffic sign recognition problems, (2) keep the same model size or achieve a smaller model size for embedded devices, (3) achieve better performance on classification accuracy of a special class (low brightness images).

Figure 4 shows the overall network architecture of MicronNet-BF, and Table 1 prints the details of parameters. In this architecture, it mainly has 5 convolutional layers, 2 fully-connected layers, and a SoftMax layer. All the activation functions in this network are chosen to be rectified linear unit (ReLU) for the reducing of computational complexity. In this network, the 1-by-1 convolutional layer in the original MicronNet is extended to have 3 output channels, and the 5-by-5 convolutional is replaced by two of the 3-by-3 layers. Furthermore, batch normalization layers are added into the proposed network to deal with the brightness difference in the input images and improve training speed.

The batch normalization layer in a network learns the mean and variance of dataset, and fixes the input means and variances of each layer. In the application of traffic sign classification, the brightness of each input image is closely related to the mean and variance value of the image. By normalization of the mean and variance of each image, the batch normalization layer turns all the images in the dataset to have a similar brightness, which improves the classification accuracy of the low brightness traffic sign images.

On the one hand, inspired by the idea of "factorization" into smaller convolutions in inception V2 [25], the 5-by-5 convolutional layer is replaced by two of the 3-by-3 convolutional layers, as shown in Table 1. The 3-by-3 convolutional layer used in this replacement enables the network to learn some smaller scaled feature from the input images and share the features among the following up 3-by-3 convolutional layer. Furthermore, the spatial coverage of the original 5-by-5 layer is maintained by the overlap of two 3-by-3 convolutional layers. In this way, this improvement results in a slight deeper network with the ability of learning smaller scaled details from the traffic signs, which significantly improved the overall classification accuracy.

On the other hand, traffic signs are normally designed with colors of high contrast, including black, white, red, yellow, and blue. In order to use the color information in the traffic sign classification, the 1-by-1 convolutional layer is extended to have 3 output channels. In the traditional network, the 1-by-1 convolutional layer combines the RGB color of the input image to 1 value on each pixel location, which can be considered as a RGB to gray conversion. After extending the output channel to 3, the 1-by-1 convolutional layer becomes a color extraction layer, which provides 3 different color combinations for the following up layers.

4. Experimental Evaluation

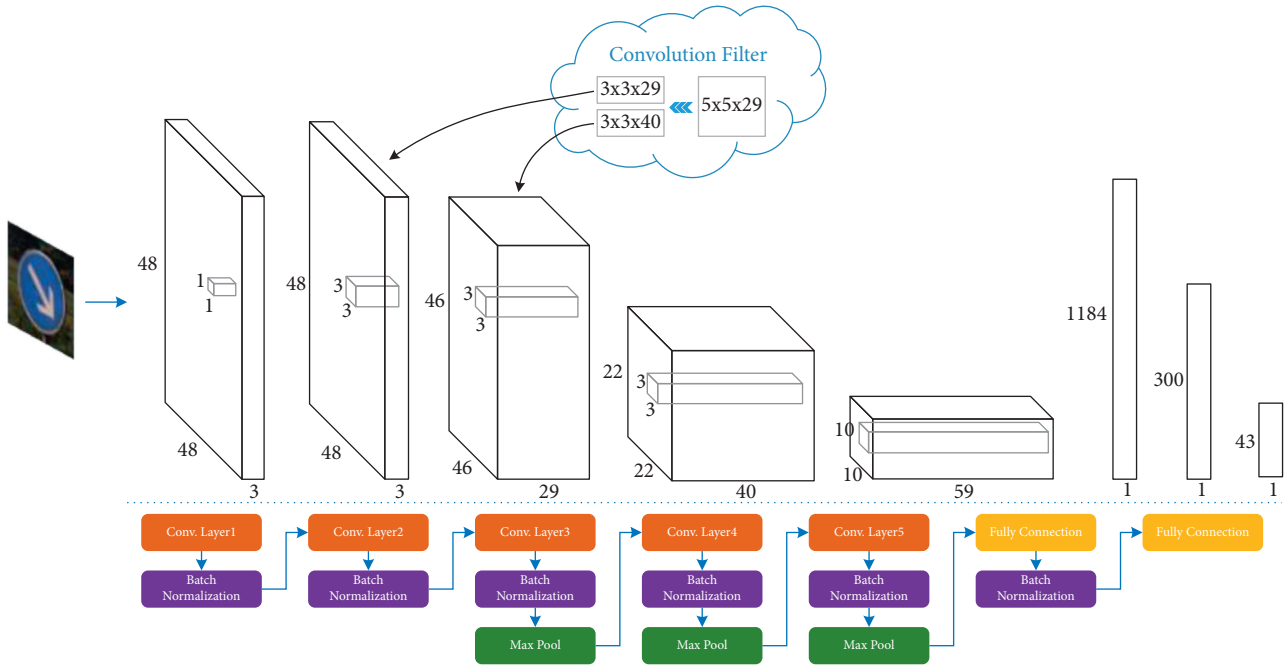
4.1. Implementation Details. For a fair comparison, both methods and algorithm architectures take similar learning hyperparameters. A learning rate of 0.007 is used for MicronNet and MicronNet-BF in most scenes. The hyperparameters of comparison methods are taken as the default of the corresponding cite paper. Meanwhile, the same experiment platform is used in all experiment and is a Linux Ubuntu20.4 operating system with PyTorch. The GPU is GTX1080ti of NVIDIA. As an evaluation index, the accuracy rate refers to the percentage of the number of correctly recognized in the test dataset to the whole number of test dataset, and time refers to the sum of training time of 100


FIGURE 4: Brief structure diagram of MicronNet-BF. The sizes of convolution filters and convolution layer's inputs are expressed on the upper diagram, and the brief description of MicronNet-BF's complete layer structure on the below.

TABLE 2: Abbreviations of networks.

Abbreviation	Network
MicN	MicronNet (self-trained)
MicN-B	MicronNet + BN
MicN-O	MicronNet + 1-by-1 × 3 outputs
MicN-3	MicronNet + 2 × 3-by-3
MicN-L	MicronNet + insufficient lighting
MicN-BF	MicronNet-BN-factorization (the fusion of all above)
FIGURE 5: Testing set brightness distribution. The samples with brightness lower than 40 are constituted to the brightness insufficient dataset.

samples in each epoch. Additionally, some abbreviations for networks have been adopted for briefly expression, as shown in Table 2.

For the comparing of the recognition of networks on dark images, the insufficient brightness images of traffic sign are extracted from the testing dataset to combine a new challenging dataset. After ordering the brightness of the whole testing dataset, the first 20.57% samples (the number of 2599) were used as the new insufficient illuminated traffic sign dataset; that is, the average brightness of each sample in the new dataset was lower than 40. The quantity distribution of the testing dataset is shown in Figure 5. The samples with

red are constructed to a harder dataset, and the rest samples are used for testing.

4.2. MicronNet-BF Evaluation with GTSRB.

For the comparing with MicronNet [21], the proposed MicronNet-BF is evaluated on German traffic sign recognition benchmark (GTSRB) [27] firstly. The GTSRB dataset contains color traffic sign images from 43 classes and intends for recognition. On the one hand, the evaluation with the overall accuracy on GTSRB is taken normally. For further challenges, the recognition of lower brightness images from the GTSRB testing set is processed meanwhile. On the other hand, during the training of the network, rotation, shifting, and scaling are used as data argumentation strategies to improve the generality of the resulting network, especially for the testing images with partly visible sign.

Figure 6 shows the testing accuracy and training time of the proposed network MicronNet and the comparison networks based on GTSRB dataset. Comparing with the MicronNet, the batch normalization layer added into it improves the classification accuracy from 97.686% to 98.74%. Furthermore, the extending of output channels on 1-by-1 layer improves the accuracy to 97.561%, and the replacement of two 3-by-3 layers improves the overall accuracy to 98.777%. Thus, the overall accuracy with 99.383% of the MicronNet-BF is improved by the three strategies proposed in this project, respectively. What is more, the comparison of MicN-BF × L with 99.448% and MicN-L with 98.147% indicates the great recognition performance of MicronNet-BF under insufficient brightness.

4.3. Validation of MicronNet-BF Influence Factors.

In the front section experiment, it was proved that batch normalization, extending of output channels on 1-by-1 layer, and factorization were successfully integrated into MicronNet, but the effect and influence processes of each factor need further experimental verification. The Taguchi orthogonal array experimental method can greatly reduce the number of experiments than grid searching experiment and inference of the optimal parameter combination by the orthogonal method [28, 29]. The Taguchi orthogonal array experimental method is used to obtain the optimal values and evaluate the influence of factors [30, 31].

There are three factors in MicronNet-BF that need to be focused on. In addition, the interaction between factors should also be considered, including dataset with insufficient illumination. For a summary, there are seven factors (including MicN-B, MicN-O, MicN-3, MicN-L, MicN-B × O, MicN-B × 3, and MicN-O × 3) and two levels (including N (NULL) and A (APPLY)) in the experiment. With respect to selected factors, $L_8(2^7)$ orthogonal array was designed for the validation experiments, and the experimental design and the results are shown in Table 3.

For an immediate point of view, the best accuracy with 99.448% is taken with the network of MicronNet-BF under the insufficient brightness testing dataset; it is consistent with the conclusion of the previous subsection. In Table 3, I_{A1} denotes the summary of accuracy under the first level of the factors, and I_{A2} for the second level, R_A represents the absolute value of the difference of I_{A1} and I_{A2}. The meaning of I_{T1}, I_{T2}, and R_T is similar with the third before but for time. From the row of R_A, the biggest difference is the factor of MicN-B and the smallest is MicN-O, and it indicates that the factor MicN-B has the most influence of the recognition accuracy of traffic signs, and the factor MicN-O has the lowest influence. The result in the row of RT shows that the factor MicN-B has the most influence of the training time too, but the factor MicN-B X O has the lowest. According to the difference value of interaction factor, there is only a tiny effect about accuracy and time. Therefore, the ranking of effects can be sorted as MicN-B > MicN-3 > MicN-L > MicN-B × 3 > MicN-O × 3 > MicN-B X O > MicN-O.

For the insufficient brightness traffic sign dataset, the recognition accuracy is shown in Figure 7. The best accuracy with 99.448% is taken by MicronNet-BF, and the accuracies of MicN-B × L with 98.936% and MicN-3 × L with 99.079% are better than MicronNet significantly. The recognition ability of batch normalization and factorization for traffic signs with insufficient brightness is proved. Although the accuracy of MicN-O × L with 97.96% is no better than others, this tendency can be seen in Table 4 with the R_A of MicN-O. On the one hand, it is indicated that extending the output of the 1 by 1 layer to three channels cannot enhance the recognition performance of traffic signs with insufficient brightness, but MicN-O can improve the classification performance of traffic signs with normal illumination and rich colors to a certain extent, and hardly increase the extra training time meanwhile. Therefore, the MicN-O is also effective.

On the other hand, the fluctuation of loss value and accuracy rate in the process of iteration can also reflect the role of various factors. As Figure 8 shows, networks present various fluctuation trends in the training process. MicN fluctuated widely in the first 10 iterations and remained fairly flat thereafter. The loss value of MicN-B dropped quickly, but the subsequent fluctuations lasted for a long time. The loss value of MicN-O dropped faster than MicN and have a bit fluctuation later. MicN-3 get the best performance in the process of iteration, dropped fastest, and more flatted. Finally, under the balance of various factors, MicN-BF loss value decreases rapidly with few fluctuations so as to achieve the best classification performance quickly and maintain stability.

4.4. Comparison Evaluation.

With the discussion in the previous subsections, the test of MicronNet-BF on GTSRB dataset is quite complete. In order to further verify the recognition performance of MicronNet-BF on addition traffic sign dataset and different types of datasets, some representative datasets were selected. The properties of several dataset and the evaluation performance are listed in Table 4.

The Belgium Traffic Signs Classification dataset has 62 categories, 4,591 samples for training and 2498 for testing. The results show that the recognition performance of MicronNet-BF with 82.122% is better than MicronNet with
FIGURE 6: Accuracies and time of networks based on GTSRB. The best accuracy with 99.448% is taken with MicronNet-BF under the insufficient brightness dataset.

FIGURE 8: The accuracies and losses of networks. Obviously, the loss value of MicN-B is more volatile.

TABLE 5: Classification accuracies of GTSRB and parameter number of algorithms.

Network	Parameter (M)	Accuracy (%)
Deep inception-based CNN [24]	10.5	99.81
Single CNN with 3 STNs [30]	14	99.71
HLSGD [33]	23.2	99.65
Student network [1]	0.73	99.61
MCDNN [16]	38.5	99.46
MicronNet-BF	**0.44**	**99.38**
MicronNet [21]	0.55	98.9
DNN [16]	1.54	98.52

The bold characters and numbers represent the proposed algorithm and its parameters, respectively.

80.388%. It indicated that with the training of a small number of traffic signs, the classification performance of MicronNet-BF decreased, but it was still higher than MicronNet. On the one hand, the generalization of MicronNet-BF and MicronNet has been verified with the accuracies of 99.58% and 99.49% on the dataset of MNIST. In the more challenging number classification dataset of SVHN, MicronNet-BF maintained a slight advantage, indicating that the structural superiority is not limited to the recognition of traffic signs. In the case of more complex dataset Cifar10 and Cifar100, MicronNet-BF is unable to learn deeper features as to its lightweight structure, and the

recognition accuracy is only 78.67% and 49.93%, respectively, but it still far exceeds MicronNet with 34.83% and 10.33%.

On the other hand, the MicronNet-BF is mainly used in embedded devices. By comparing the difference of structure between MicronNet-BF and MicronNet, replacing a 5-by-5 convolution filter with two 3-by-3 convolution filters has the greatest impact on the number of variables, and the number of variables is reduced to 0.44 M. As listed in Table 5, compared with the state-of-art networks, with the minimum number of variables of 0.44 M, MicronNet-BF has achieved excellent results with a difference of no more than 0.4% compared with the larger networks.

5. Conclusions

In order to improve the recognition performance of traffic signs further, the MicronNet-BF which is fused by MicronNet, batch normalization, and factorization is proposed. The addition of batch normalization enhances the recognition performance to 98.74%, which is 1.05% higher than the performance of MicronNet. The application of factorization improves the accuracy to 98.77%. The MicronNet-BF which is combined by multifactors listed above has a recognition performance with 99.383% which has a great improvement than MicronNet. On the one hand, the batch

normalization and factorization do enhance the ability of recognizing the traffic signs with insufficient brightness after the experiment evaluation. On the other hand, the most influence factor is batch normalization after the confirmation of orthogonal experimental. In the end, the performance of MicronNet-BF used in BTSC, Cifar10, and Cifar100 is better than MicronNet.

Although the algorithm is applied in the embedded system, the less parameters are not better, and striking a balance between the number of parameters and the size of storage space needs further study.

Data Availability

All the dataset could be found in https://paperswithcode.com/datasets, including GTSRB, BTSC, Mnist, SVHN, Cifar10, and Cifar100.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

This paper provides an in-depth study and analysis of data transmission in key aspects of the enterprise using internet of things (IoT) technology. IoT technology can provide an effective solution to the integration of enterprise resources and efficiency improvement. If it can be properly introduced into the enterprise, it not only can effectively integrate the enterprise resources in the management but also can significantly improve the efficiency and thus further reduce its operating cost. This paper explores the management application strategy of IoT in the key aspects of digital transmission in enterprises. It can also increase productivity to address labour shortages. Most importantly, because of the internet of things technology, many emerging industries have been derived. In order to achieve this research objective, firstly, based on the in-depth study of the problems of digital transmission of key aspects of the enterprise, this paper evaluates and summarizes the supply chain, safety, efficiency, and quality problems that often occur in the past operation and management of the case enterprise and analyses the main reasons for the formation of the problems and then recognizes the necessity and feasibility of introducing IoT technology and management; secondly, based on the kernel of IoT and industrial IoT technology combined with the main modules of enterprise operation management, using the 5S field management method, we try to build a three-dimensional all-round electrical equipment enterprise IoT management application scheme design system; and finally according to the planning and design rules and management process, we focus on implementing digital transmission network application projects from the enterprise level combining key links of technology and management. This paper studies not only technical innovation but also a revolution in management. The research in this paper will provide a more feasible technical and management design scheme for the application of IoT in enterprises for industry reference.

1. Introduction

The role played by the new generation of technology products in human life is irreplaceable, and the former science fiction movie scenarios are being used in modern life one by one [1, 2]. According to a study by the Internet Data Center (IDC), by 2020, there will be 29.5 billion connected devices worldwide, creating an IoT market of $1.7 trillion. According to a study by McKinsey & Company, a world-class consultancy, the economic impact of the IoT will be worth $11.1 trillion to $13.9 trillion per year by 2025, with industrial applications worth $1.2 trillion to $3.7 trillion, making it the largest economic application of all [3]. Many countries have included IoT as an economic development priority in their national strategies. This shows that IoT is the

future technology trend in human development, and its application not only can improve the quality of products and services and increase the source of customers but also can increase productivity to solve the labour shortage. Most importantly, many new industries have emerged because of IoT technology [4].

In recent years, the emergence of IoT technology has improved people's quality of life, and many countries have incorporated IoT into their national strategies for economic development, especially in manufacturing, which is predicted to be the largest economic application area in the future [5]. In the decade since its emergence to the present day, blockchain technology has grown rapidly into mature and practical information technology [6]. Blockchain can be thought of as a distributed ledger that is monitored and

maintained by all participants through the network, thus ensuring the authenticity and immutability of information. At the same time, blockchain, as a "decentralized trust network," can maximize the elimination of human intervention, and each node in the network does not need to know who the other is if it conforms to the consensus encryption mechanism to complete the operation and achieve distributed storage [7]. Blockchain's decentralization, immutability, openness, and transparency provide a new path for the development of digital transmission of key aspects of enterprises.

With IoT technology as the core, embedded development technology, wireless sensor network technology, and fault diagnosis technology are applied to realize the wireless monitoring and evaluation system of the pump group based on IoT [8]. The sensor is used to monitor the running state of the centrifugal pump set, and the running data of the centrifugal pump in the current state are collected and uploaded. The cloud server performs health assessment, fault diagnosis, and fault prediction on the current state of the centrifugal pump and gives corresponding treatment measures and treatment suggestions according to the system's evaluation of the current state of the centrifugal pump. This is conducive to the timely detection and troubleshooting of faults by the staff and prolongs the service life of the equipment.

2. Related Works

The industrial internet of things (IoT) is an information technology based on the Internet, which integrates various sensors, intelligent terminals, and other advanced devices by various means to achieve the interconnection of everything [9]. As shown in Figure 1, the industrial IoT architecture can be roughly divided into three layers: the sensing layer, the network layer, and the application layer. The perception layer of industrial IoT consists of many sensors and controllers, mainly including various types of sensors such as vibration, pressure, temperature and humidity, RFID tags, QR codes, and various intelligent devices. The main task of the sensing layer is to realize the collection of data from various devices and transmit the collected data to the network layer, receive and execute the commands from the network layer, realize intelligent control, and realize a wireless monitoring and evaluation system for pump groups based on the internet of things. The sensing layer of industrial IoT consists of many sensors and controllers, mainly including various types of sensors such as vibration, pressure, temperature and humidity, RFID tags, QR codes, and various smart devices [10]. The main task of the sensing layer is to realize the collection of data from various devices, transmit the collected data to the network layer, and be able to receive and execute commands from the network layer and realize intelligent control. It is mainly responsible for the transmission of various types of information and is the link for the transmission of information throughout the industrial internet of things [11]. The application layer is mainly responsible for data storage, data processing, analysis and decision-making, and so on. It controls the perception layer

to carry out corresponding actions and realize remote monitoring and control of industrial equipment to achieve the purpose of human-computer interaction in IoT.

From the perspective of the internet of things technology, its origin, development, and popularization in foreign countries started early, so the overall system technology supported by the internet of things technology applied in different directions and fields is also completer and more comprehensive. It is of great significance to give corresponding treatment measures and treatment suggestions, which will help staff find and eliminate faults in a timely manner, prolong the service life of equipment, and reduce the number of equipment downtimes. Internet of things technology is a multi-disciplinary, comprehensive technology system. It involves computers, with wireless communication, multinetwork interconnection, sensor collection, and integration technology [12]. Foreign scholars and even development teams belonging to companies have invested a lot in hardware technology support or software application and correlational and collaborative research, and some technologies are even in a forward-looking position in the world. This network is usually part of an ecosystem (ecosystem) that includes connectivity between things, applications, and data analysis. Although networks are not a prerequisite for internet systems, the value of the internet of things being realized has the potential to create a huge and global impact [13].

Concerning the impact of IoT on business operation and management, industrial IoT has indeed developed rapidly and vigorously in recent years, and production automation and process automation have improved quality and efficiency for many enterprises, in addition to which the return on investment has also been quickly obtained [14]. In this paper, we propose and study an enterprise key link digital transmission system based on the internet of things, which is supported by the three-layer structure of the internet of things as a big framework, involving node data collection, RFID access technology, data transmission module, and so on. The main components of the data are equipment status information, node water pressure at the collection end, and hardware control information; the system is intended to complete accurate data collection and smooth transmission at the same time to data information for additional processing, so that it can provide decision support for the overall system and the construction of the ontology-based monitoring and early warning system model. In terms of the data visualization user side based on the cloud data transit, a friendly interface, humanized interactive, and easy-to-operate program are developed for the web application side of the manager [15].

3. Enterprise Critical Link Digital Transmission System Model Setup

3.1. Mathematical Modelling. The overall supply chain traceability system architecture can be divided into three layers, mainly including the data access layer that obtains product data and status information and uploads them through the interface program; the data core layer that
Figure 1: Simple architecture of industrial IoT.

invokes smart contracts to complete the supply chain business logic and conducts blockchain data storage according to the received data information; and the application representation layer that includes the traceability query web page and WeChat traceability query applet [16]. It involves node data collection, RFID access technology, data transmission module, and so on. The main components of the data are equipment status information, collecting end node water pressure, and hardware control information. The system aims to complete accurate data collection and smooth transmission. Information undergoes additional processing so that it can provide decision support for the overall system.

The data access layer consists of various sensors, 4G modules for data upload, and the data upload app, which mainly completes the task of acquiring product data information and uploading it to the core layer. The ways to obtain the product data information include various types of sensor acquisition and scanning the product QR code using the data upload app, which has a unique QR code number, which is the unique identity of each food product, and the QR code number is generated by 32 bit MD5 encryption algorithm; the food product is photographed using the data upload app to obtain the actual photo. The type of data information acquired mainly includes the production or growth environment information collected by sensors, the product status information acquired by scanning the QR code, and the physical photos acquired by taking photos.

The main body of the data core layer is the blockchain network, aided by a generalized interface program and smart contracts, and the entire blockchain network consists of many blockchain nodes. The full-node server that fetches the uploaded information from the data access layer calls the storage function in the smart contract through the interface program to populate the information into the transaction data and encrypt the transaction data; then the transaction is published and broadcasted in the whole network; and then the transaction is packaged into a block and broadcasted to the whole blockchain network by the consensus algorithm verification of other nodes, and the block is added to the blockchain as the latest block after the completion of the verification. Figure 2 represents the data storage process using the smart contract approach.

The user is registered through the user management module at the end of the web page and must fill in the required fields; the whole process is monitored by the administrator; the administrator account is assigned by the senior level of the system and does not have to be registered; and the new user information generated by the module will be stored to the cloud centre data [17].

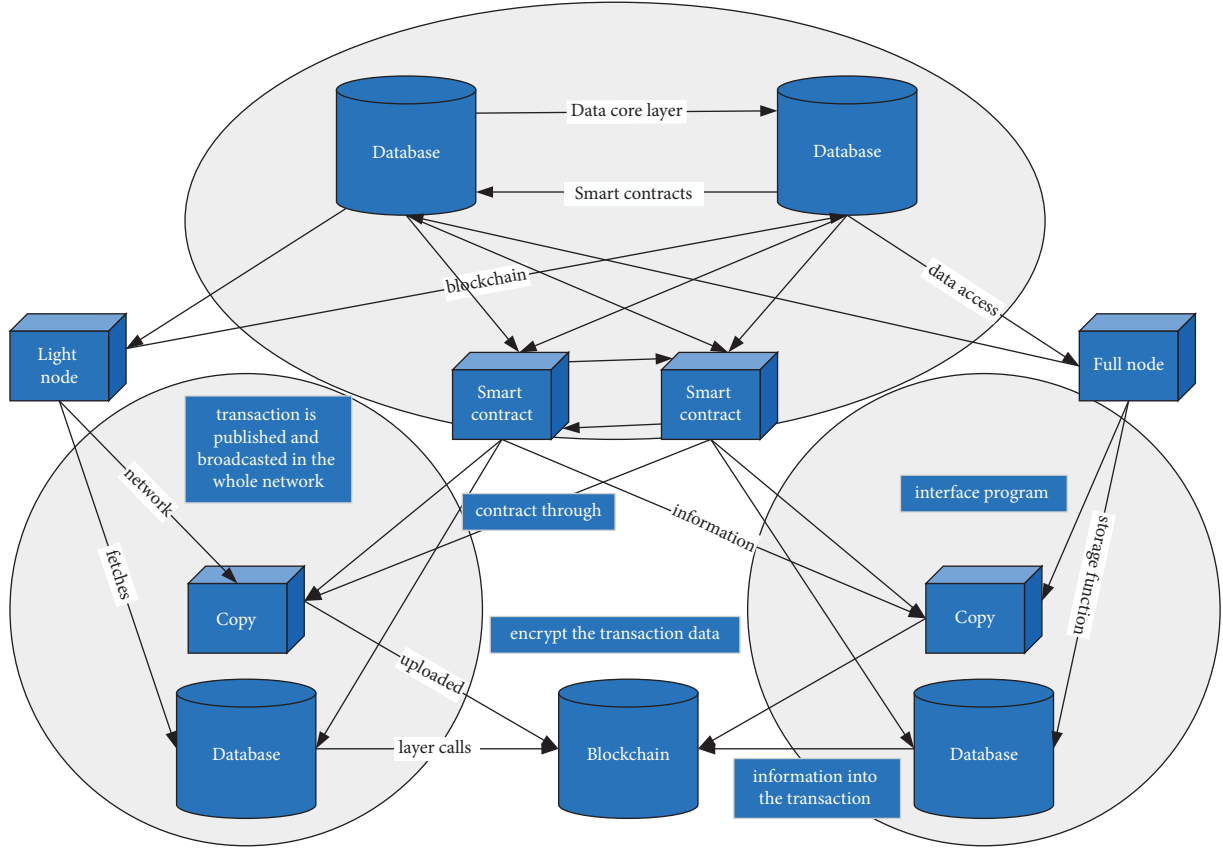
Administrator users can obtain information through two-way data transmission with the database, then monitor different types and locations of node equipment, alarm equipment, and so on, and can view the status of the equipment and the adjustment of operable nodes. When a device fails, the device administrator can view the failed


FIGURE 2: Data core layer architecture topology.

device without showing the cause of the device failure to the field and then request maintenance on the failed device. It mainly includes the data access layer that obtains product data and status information and uploads it through the interface program; the data core layer invokes smart contracts to complete the supply chain business logic, stores blockchain data according to the received data information, and includes the traceability query web page and the application presentation layer of the WeChat traceability query applet. After the approval is completed, the system will feed back the approval result. After the approval, the relevant technicians will be arranged to carry out maintenance and repair and upload the data records to the database for viewing after completion.

$$PR_T - W + C + R_D > 0. \qquad (1)$$

This paper will be based on the modern production management concept and adopt the basic idea of joint optimization of management tools and technology, based on the characteristics of motor production in the information technology environment, for the current production operation of the Shanghai Electric Machinery Factory to carry out an in-depth study of the existing problems, based on which an improvement program is proposed: The design focus of this Internet of Things application scheme is the combination of production management methods and Internet of Things technology; this theoretical framework helps promote the deeper application of traditional

production management methods and the mechanism of reuse in the introduction of IoT. The overall idea is to combine the theories of IoT and production management with the main problems of production management and operation management of Shanghai Electric Factory. The solution starts from the needs of the production operation of the enterprise, and then the architecture of the system is carried out.

Another constraint on efficiency is site management, and 5S is a powerful tool. Companies can improve efficiency in the production process while employees can work safely, healthily, and comfortably, and at the same time, companies want to reduce costs; they must start with manufacturing costs that have a high-cost structure. The product cost of the company accounts for 80% of the total cost of the company, while the manufacturing cost (direct labour and equipment improvement) accounts for about 20%, so this study will focus on the improvement of productivity through 5S to do research. In the combination with the internet of things (IoT), the main performance is that it can be supplemented with 5S management while using IoT. The full-node server that gets the information uploaded by the data access layer calls the storage function in the smart contract through the interface program to fill the information into the transaction data and encrypt the transaction data and then broadcast the transaction in the entire network, and then pass the data of other nodes. After the consensus algorithm is verified and the transaction is

packaged into blocks, it is broadcasted to the entire blockchain network. In the process of 5S management, IoT technology is actively used, such as through the completion of RFID reading and writing method tests, business process combing, and so on, to provide technical means for on-site management. Simple simulation once, the fluctuation of the adaptive alarm valve is shown in Figure 3.

Finally, through all the data collection devices on-site, the production quantity, yield rate, work-in-process distribution, equipment operation, personnel efficiency, equipment efficiency, and quality inspection results, and other real-time on-site consultation is fed back to the ERP system. Therefore, to grasp the production status of the manufacturing site, information collectors, such as handheld barcode machines or fixed barcode machines, are usually installed at each production line input station to collect various production information, operation status, environmental data, quality data, and so on through these barcode machines and then store this information in the database of the MES system. You can view device status and adjust operational nodes. When a device fails, the device administrator can view the faulty device without showing the cause of the device failure to the site and then apply for maintenance of the faulty device.

$$C = \frac{E_{\min}|x(t)|}{\sum_{t=1}^{\sqrt{n^3}} x(t^2)}. \tag{2}$$

3.2. Design of Digital Transmission Systems for Key Aspects of the Enterprise.
The cost and energy consumption of LoRa wireless communication technology are lower than those of NB-IoT wireless communication technology, and in the actual industrial application, the branch units are often located in remote places, so the NB-IoT technology may not be covered by the operator, so LoRa technology is used as the communication method for wireless monitoring in this paper [18].

$$\delta = \frac{g}{d},$$

$$d = \sum_{i,j=1}^{N} \max d_{ij}. \tag{3}$$

In MATLAB 2015a software, consider a random deployment of 50 sensor nodes in a fixed square area with a side length of 100 m. These nodes are static and do not have information about their location. A mobile NB-IoT node joins this cluster and is first at position 1 (0, 0), then moves to position 2 (33, 0), position 3 (67, 0), position 4 (100, 0), position 5 (100, 33), position 6 (100, 67), position 7 (100, 100), position 8 (67, 100), position 9 (33, 100), position 10 (0, 100), position 11 (0, 67), and position 12 (0, 33). The single- or multi-hop information from all nodes in the region is received at each location stop, and this one with the smallest value of node hops passed from each node is recorded and noted as the shortest path. The node distribution is shown in Figure 4.
FIGURE 3: Fluctuation of the adaptive alarm valve.
FIGURE 4: Distribution of nodes.

In Figure 4, it is the location of the mobile cluster head localization stay of NB-IoT, and ○ is the node whose location is unknown and needs to perform the localization calculation. The minimum value of the two-two combined hop count sum between any node to the 12 anchor locations is used as the shortest path between the two locations by 12 times measured hop count calculation. The application scheme of the internet of things is proposed, which is composed of multiple modules. The solution starts from the needs of the production and operation of the enterprise and then carries out the architecture of the system. An estimated jump distance value is then calculated by equation. After calculation, the node positioning error accuracy is 32.81% on average for 20 times, which achieves the position positioning function of the unknown node, but the error degree is still high. Through the analysis of the influence of related factors and parameters on the accuracy, a better combination of

positioning-related parameters is obtained for more accurate positioning.

The importance of smart contract security is increasingly recognized with the occurrence of well-known blockchain projects such as the DAO and Parity multi-signature wallets whose market capitalization evaporated overnight due to contract vulnerabilities that were attacked and caused huge losses. Formal verification is a security audit method for testing the security of smart contracts [19, 20]. Formal verification is a method that uses mathematical models to logically test hardware or software and predict results. For smart contracts, performing formal verification provides good assurance that the problems described in the previous section will not occur during the execution of the smart contract code, maximizing the security and reliability of the entire system.

4. Results and Analysis

4.1. Mathematical Model Results. In recent years, with the continuous development of Internet of Things technology, automatic sensing technology for tank level monitoring has achieved comprehensive development. After prudent research, it is believed that such aspects as an automatic level metering system, oil leakage and oil shortage real-time monitoring system, and so on can be effectively integrated with the help of intelligent internet of things platform while realizing the real-time transmission of oil tank information to enhance the overall monitoring and management of the equipment CNC bus level: (1) system advantages: each external site storage tank area has a wide range of distribution space, monitoring points, wiring complex, and other objective disadvantages and (2) real-time management: for enterprise decision-making, IoT technology allows more real-time correct management can be achieved; site managers can view real-time production progress, equipment status, material inventory status, and other information through the central monitoring platform to make appropriate decisions and arrangements to improve production efficiency. At the same time, through automated data collection, production data can be collected more completely, and through statistical analysis, abnormal quality conditions can be detected early, and product yields can be improved, and costs reduced. For workers, IoT technology replaces tedious and labour-intensive actions, such as meter reading and routine inspection—allowing more time for higher-value work, such as production data analysis, production efficiency improvement, equipment maintenance, and so on and allowing their expertise to be utilized.

$$P[X(t_n) = X(t_{n+1})]. \tag{4}$$

If $P_r + W - C + R_D - L > 0$, then $x = 1$ is the intelligent in WSNs the unique evolutionary stable state ESS of the node evolutionary game. In this communication setting, we set the value P to a constant. By increasing P_r or W or decreasing C, R_D, or L in equation, we can satisfy the condition that will force nodes to avoid choosing the no-forwarding strategy. As the value W increases (regardless of which policy the node chooses in the initial state), all nodes will eventually choose the forwarding policy, and the system will reach a steady state. Under normal circumstances, the transmission rate can only reach about 37.5 kbps, so LoRa communication technology is suitable for wireless monitoring occasions with many centrifugal pumps and a wide distribution range that do not require high communication speed.

When a node is in a busy (backlogged) communication environment and the node selects the forwarding policy too often, it wastes the node's time and effort. Therefore, in this case, it is more beneficial to choose the no-forwarding policy. We give the incentive r for nodes choosing the no-forwarding policy. R is the average probability of packet forwarding, $R = 1 - \beta$. If α or $1 - \beta$ decreases, R increases, and the positive correlation between α, $1 + \beta$, and R varies as shown in Figure 5.

There are various ways to increase the probability of packet forwarding in smart nodes in WSNs, such as increasing the bandwidth or frequency, improving hardware or transmission protocol algorithms, and so on. By increasing the R-value, $P_r + W - C + R_D - L$ tends to 0; then, nodes will increasingly choose the forwarding policy and the WSNs will reach the steady-state faster. In this case, if we increase P, it will not affect the final evolutionary steady state but will increase the speed of convergence to the evolutionary steady state. Conversely, if the value of P increases, it is difficult to satisfy the condition of Theorem 3 that $P_r + W - C + R_D - L < 0$, and then the WSNs will slowly reach the steady state. In this case, if we increase r, it will not affect the final evolutionary steady state but will reduce the speed of convergence to the evolutionary steady state. The company's product cost accounts for 80% of the company's total cost, while the manufacturing cost (direct labour and equipment improvement) accounts for about 20%, so this research will focus on improving production efficiency through 5S.

We set the parameters to satisfy the conditions of the theorem, as shown in Table 1. The experimental results are shown in Figures 4 and 5, from which we can observe the trend of the evolution curve of the node states in the smart nodes in WSNs.

There are various ways to combine NB-IoT technology with WSNs; one of the options is to use NB-IoT nodes and WSNs nodes in a hybrid network according to their characteristics, playing the characteristics of traditional WSNs nodes such as random deployment, flexible networking, and low price and NB-IoT's wireless wide-area access, low efficacy and long life, and strong penetration capability. NB-IoT and WSNs hybrid network with aggregation/cluster head nodes and common sensing nodes. Common sensing nodes are the common number of sensor nodes that are randomly distributed within the monitoring area. We do not have high requirements for the data processing capability, storage capability, and communication capability of such nodes, and they are often composed of inexpensive miniature sensors whose function is to be responsible for data collection and data transmission. Aggregation/cluster head nodes for data aggregation, which are much more capable than ordinary sensor nodes, and their impact on the
Figure 5: Plot of the variation between α, $1 + \beta$, and R.

Table 1: Experimental data.

Group	P	R_T	R_D	C	L	W
1	0.424	0.81	0.905	0.693	0.959	0.783
2	0.639	0.611	0.751	0.567	0.479	0.647
3	0.966	0.701	0.568	0.679	0.414	0.849
4	0.889	0.485	0.916	0.755	0.941	0.848
5	0.982	0.745	0.629	0.623	0.748	0.476

functional implementation of the overall WSNs is also significant. The sensor nodes send the collected data to the near-neighbour sensors, using a multi-hop transmission, and the data is finally aggregated to the aggregation node.

Wireless sensor nodes in different hierarchical positions and serving different functions have different node degrees. Sensor nodes with smaller node degrees have a single function, simple security mechanisms associated with them, and a higher probability of being controlled by viral malicious programs. Through the handheld barcode machine or fixed barcode machine, the production data, operating status, environmental data, quality data, and so on are collected, and then these data are stored in the database of the MES system. In contrast, sensor nodes with larger node degrees are fully considered in the network planning and design to be configured with system access rights restrictions, security firewalls, and other mechanisms so that their ability to cope with the prevention of attacks against cracking is enhanced, and the probability of being breached is reduced.

$$\xi(K) = \frac{m}{d(\kappa)}. \tag{5}$$

4.2. Enterprise Key Link Digital Transmission System Model Simulation Experiments. To deploy a computer as a blockchain node, we need to install node.js, the Ethereum client, the git distributed version control system, and also the Truffle compiler for smart contract writing, including Solidity, Web3.js, and Solidity development framework.

Environment variables are configured after installing Node.js, and the rest of the environment variables will be configured automatically after the software is installed. In a Linux environment, use apt-get and nm. Command in a terminal window to download and install the above software to complete the preparation work before setting up the environment.

Since EtherChannel is based on accounts to complete operations, after opening a blockchain node, the first step is to create a new account and enter personal. Click on the new account on the command line to create a new account, while EtherChannel will prompt to set a password. At this point, the account is locked and will fail when deploying and invoking smart contracts, so you need to use it personally. Since the recap set up when opening the blockchain allows access to the personal family of functions, the account can be automatically unlocked by writing this function to the Node.js interface. Before a smart contract can be called using the interface program, it needs to be compiled and deployed on the blockchain. The deployment of a smart contract on the Ethereum blockchain is done in the form of a published transaction, which is stored in the data field of the transaction. All blockchain nodes receive the transaction and perform signature verification and consensus algorithm to reach an agreement and achieve the storage of the contract on the chain. When a failure occurs in one part of the system, the system reacts and records it first, and the detailed test results of one cycle are shown in Figure 6.

By chance, we came across an AR game for preschoolers: the mobile app software scans a card with an animal pattern on it, and a three-dimensional image of the animal on the card appears on the phone with animal sounds, which helps children learn. This game uses card patterns as a medium to enhance human understanding and memory with three-dimensional images and sounds. This game has inspired us. Instead of card pattern information, QR code information or RFID information can be used in the workshop; three-dimensional images of animals can be replaced with various three-dimensional images of parts; and sound information can be presented in the form of explanations in drawings. The 2D code or RFID on-site can record various information such as the model number of the parts, their location, and their position in the finished product. The transmission distance of the signal in the open area can reach 10 km; the transmission distance in the town can reach 1~2 km; and the maximum transmission rate can reach 250 Kbps. Because there are more young workers in the workshop, most of them like to play games; the way of learning through mobile phones is easily accepted; and the three-dimensional model pattern display is far easier to be understood than explaining with drawings. Through the mobile phone can also make the content of AR learning competition software to enhance learning initiative; in addition, through the two-dimensional code mark or RFID each work step into the system, you can trace the completed work and incomplete work, to achieve the guidance function of the work task, through the mandatory process of the production process and process control, to avoid errors in the work.
FIGURE 6: Fault time-domain data waveform.
FIGURE 7: Schematic diagram of the evolution of packet forwarding curve denoted by W.

When the rate at which nodes choose a forwarding strategy in the initial state is 1%, reaching the stabilization point $\chi2^* = 1$ requires about 110 games, but if $W = 4$, reaching the same stabilization point requires only about 40 games. Satisfying the conditions of the theorem, the larger the cooperative incentive, the faster the intelligent nodes in WSNs reach the equilibrium point. When the rate of nodes choosing the forwarding strategy in the initial state is 99%, it takes more than 100 games to reach the stabilization point $\chi1^* = 0$ if $W = 3$, but only more than 80 games to reach the same stabilization point if $W = 4$. Under the condition that the theorem is satisfied, the gain of nodes that choose the forwarding strategy is smaller than the gain of nodes that do

not choose the forwarding strategy. However, the cooperation incentive promotes cooperation among nodes to forward packets to each other, thus reducing the rate at which nodes reach the evolutionary steady state of intelligent nodes in WSNs, and the dynamic trend is shown in Figure 7.

ESP-12F has three working modes: STA, AP, and STA + AP hybrid mode. From the viewpoint of the usage requirements of this system, since the monitored temperature and humidity data, voltage, and related information need to be transmitted to the cloud platform, the system must be able to connect with the router connected to the external network to realize data exchange, so the main working mode should be set in STA mode to access the Wi-

Fi network established by the hotspot already connected to the external network to realize the functions such as data upload.

The platform needs to be modularized to facilitate future expansion. Because the functions developed so far are only a very small part of the functions that the IoT can achieve and because the IoT technology is developing rapidly, it is very difficult to expand the platform later if it is not designed in a modular way, so it must be developed using a modular design. The platform must be a data presentation centre. As a platform software for industrial IoT, data presentation is the most basic function. After the data read from the sensing end are transmitted to the data collection end through the network bus, a large amount of data will be deposited in the storage; the platform needs to display two aspects of data; on the one hand, the currently collected data is displayed instantly so that employees can be informed of the current working status of the equipment; and on the other hand, historical data should also be displayed so that it can be compared with the best working status.

5. Conclusion

With the gradual launch of the 5G network, the new generation of the mobile communication network has more support and more openness for the connection of things, and the mobile communication network will play a greater role in promoting the development of IoT technology. The integration and development of IoT in various industries face a broader application prospect. Information technology, including the internet of things, is a technology for electrical equipment companies to connect customers, suppliers, and production processes; to overcome the information and communication between production equipment, so that production equipment can pass information to each other; to establish a key link between customers and suppliers through the internet of things; through the introduction of smart equipment and careful calculation of customer requirements, the production process is simplified and costs are reduced; the calculated information will be passed to production equipment and suppliers by introducing intelligent devices. We can finely calculate customer requirements; transfer the calculated information to production equipment and suppliers; achieve precise production; collect data affecting the production process; analyse, evaluate, and mine the data; and then establish a prediction model to make production equipment self-aware, self-memory, self-cognition, self-decision, and self-reconstruction. In the future, companies can use this model to produce different customized products and the lowest production cost.

SDN Control Strategy and QoS Optimization Simulation Performance Based on Improved Algorithm

Bin Zhang ⓘ and Xin Liu

School of Information Engineering, Shandong Youth University of Political Science, Jinan, Shandong 250103, China

Correspondence should be addressed to Bin Zhang; 140011@sdyu.edu.cn

In the past few years, the Internet has become more and more popular, and more and more people use the Internet. A lot of new software has been developed on the Internet, so the network traffic has increased rapidly. A company once clearly stated that, in the future, the network volume in our country will reach nearly 5 zb. In addition, the network is comprehensively unified, and the learning of the Internet is strengthened by the way of suggesting errors. It is also necessary to learn from the external environment to make the finite value of the network as good as possible. Reinforcement learning is about solving many difficult problems. Use reinforcement learning to promote and change this state, so that the advantages of the network can be fully developed. Regarding the environment and actions at the time as the basic mapping requirements, and the network technology strategy can be best developed. In order to solve the QoS optimization scheme of the current mainstream heuristic algorithm in the software-defined network scene, the software-defined network QoS optimization algorithm is proposed. First, the network resources and status information are unified into the network model, and then, the long- and short-term memory network is used to improve the algorithm's flow perception ability. Finally, based on the deep reinforcement learning algorithm, a dynamic traffic scheduling strategy that satisfies the QoS objective is constructed. Among them, QoS refers to the main functions of the entire network system, especially for some new users, but for many old users, this system can represent a certain application, for example, whether a certain software can get timely, whether it can work smoothly when processing videos, and whether it can be interrupted when making a voice call for improvement.

1. Introduction

In the upcoming 2022, the total amount of China's network will reach 5zb. This number represents that the Internet is being widely used, and basically the Chinese are using the Internet from door to door [1]. It also proves that the number of people using the Internet is innumerable. Faced with the rapid development of the Internet, on the premise that many large companies and consumers use the Internet at the same time, Internet companies are also undergoing an unprecedented huge test [2]. This is because when many consumers use the same network at the same time, problems such as freezes, unclear videos, and unusable traffic will occur [3]. At present, the basic meaning of software-defined networking is to accept the major changes of the newly developed network [4]. Because the original network also

has some problems, we have to find many new ways to solve these original problems. The basic purpose of the software is to unbind the initial network control, separate it from the original, and then use the control panel to perform a comprehensive search, so that our program will not be stuck or unclear status [5]. This program was then sent to the company above, in order to unify the network in an all-round way, so as to facilitate the management of the staff and make the network develop in an orderly manner [6]. The main reason is to make network management simple because many people still do not know how to use the network [7]. If it is too difficult, they will face many problems. After solving the difficult problems, the cost must be minimized, so that our costs are reduced, and the highest benefits can be obtained, and consumers can use it with confidence [8]. We must also greatly support the advantages of network

innovation and then find out many shortcomings and solve them one by one [9]. There are many large and well-known Internet companies that are also applying this feature to give full play to their advantages, learn from each other's strengths, and maximize the interests of consumers [10]. This can also dig out potential functions on the largest scale and achieve utilization. The biggest is to change some of the functions of the network and to properly solve the previous bad aspects, so that we can use it comfortably. The goal is to make the network more meaningful, and the meaning of the network itself lies in letting consumers solve problems, make their lives more convenient, and meet the interests of consumers [11]. Only when the Internet is done can our lives become more colorful and beautiful.

2. Related Work

Literature [12] proposes that there is a lot of false information on the Internet, because the Internet itself is virtual, and many things you see may not necessarily mean that it is real, because some consumers do not understand this aspect. At the same time, many criminals have processed network information, so that many consumers have been deceived by false information on the Internet. To solve this difficult problem, the relevant departments have come up with a solution. This method is used to connect the Internet and resources. The hub of the Internet is to solve the virtual existence of the Internet, help consumers not be deceived, and strengthen online learning. Literature [13] concisely put forward some problems existing in the network and based on these existing problems came up with a solution and then constructed a model, which is called a mathematical model. Literature [14] provides a mechanism that can manage and solve this problem well. In Literature [15], it is pointed out that because the user's choice is different, each solution is different, and the strategy is also different. Literature [16] has good control ability and good calculation ability, so the content designed according to its characteristics is different, and the network path and change system are also different. Literature [17] chose to introduce a new type of technology, which can change the original resource and network allocation. In the literature [18], there is a model that proves that the use of management methods can solve the problems well. Literature [19] uses it to link with broadband in a wireless network. With broadband, half of the problem can be solved in this way. Literature [20] pointed out that there are many places where the network is used, and many places have problems that are difficult to solve. Aiming at this series of problems, an organization can solve the current problems, and its name is called the regional network. Because each piece of network is divided into different regions, each region has its own network, which solves some of them well. And because the network sometimes has disconnection problems, problems like freezing of videos occur. Literature [21] proposed software that can use algorithms to control the virtuality of the network and the allocation of resources and the network. The ultimate goal is to solve the problem of insufficient allocation. Literature [22] applies governance technology to the network and proposes two solutions. Literature [23] pointed out that the use of open data to manage

the traffic required in the network will solve the problem of unclear video network stalls. It also proposed a document mechanism to further ensure the high quality of the video and a better quality of the traffic network in the increasing number of traffic videos and the most basic difference, so as to meet the needs of consumers to a greater extent. A good network and network companies are also improving, and our lives are also progressing and will become better.

3. SDN Network Analysis Based on Deep Reinforcement Learning

3.1. SDN Control Strategy Based on Deep Reinforcement Learning. Reinforcement learning is to use an intelligent method to learn, using the environment as a guide for the next step, and its ultimate goal is to better reflect the intelligence and maximize the benefits. Through reinforcement learning, many ways to solve the problem have been discovered. One of them is because there is little information obtained through the external environment, and it must rely on its own experience and original materials to learn, and it has obtained it in the subsequent environment. Reinforcement learning can obtain a lot of information from the environment, so as to analyze and change the current environment. There is an algorithm that can be used as a major point of solving the problem, and that is to calculate the resource allocation in the wireless network. This calculation should be solved first. In the algorithm, we have to make analogies and assumptions and then calculate the number of calculations. The results are calculated, and the $\triangle$ is the most important core. Observe and get rewards or punishments. The following are rewards or punishments:

$$R_t = \sum_{i=t}^{T} \gamma^{(t'-t)} \cdot \gamma_i. \tag{1}$$

Among them, y belongs to a factor, and R is calculated from beginning to end and includes the sum of rewards and the sum of punishments. In addition, t means time and q is defined as a special dynamic variable in mathematics. The core of an algorithm is to use formulas for algebra. Use this method to learn and use simpler methods to calculate dynamic variables:

$$\begin{cases} Q_{k+1}s_t, \alpha_t = Q_k s_t, \alpha_t + \alpha_k \cdot \delta_k, \\ \delta_k = \gamma_{t+1} + \gamma \cdot \max Q_k s_{t+1}, a' - Q_k s_t, \alpha_t \, (a' \in A). \end{cases} \tag{2}$$

In the formula, α represents the time and rate of learning. In addition, s and a, respectively, represent the distance and a certain state of the action, which is the difference in time, and α represents the state and distance of the execution n times. In addition, in order to realize the algorithm of formula two, the conditions must be met:

$$\begin{cases} \sum_k a_k^2 < +\infty \, , \quad \sum_k \alpha_k = +\infty, \\ \lim_{k \to \infty} Q_k = Q^*. \end{cases} \tag{3}$$

According to the process described above, we can know that in a certain state, and we can choose the best method by ourselves; that is, choose the best expected value to analyze a specific function:

$$Q^* s, a = E_{s'-\xi} (r + \gamma \cdot max) Q^* (s', a'|s, a). \tag{4}$$

In the general environment, various states will exist. s is regarded as a certain state after performing an action, and α is a combination of one state and another state and executed.

3.1.1. Constructing Special Value Functions.
By strengthening the learning of the special value function in the network, taking this function as the core problem in transforming it into another function, it can be expressed as

$$\hat{Q} s_{sys}, a; \Theta \approx Q^\pi (s_{sys}, a). \tag{5}$$

In a more in-depth research algorithm, if you want to calculate a certain function, you can rely on a model. This model can update itself and then calculate it. The special value function in the Q-Learning algorithm can be rewritten as

$$Q^* s_{sys}, a = Q s_{sys}, a + a \left[R_{once} + \gamma max Q s_{sys}, a' - Q(s_{sys}, a) \right]. \tag{6}$$

Among them, a is a learning factor, and a is a learning factor in another state and a certain action in another state.

A certain kind of table cannot store every state of the system, so we have to change this kind of table and solve the solution in this article, which is to let the functions replace each other and express them by approximate functions.

3.1.2. Constructing Loss Function under Dual Network Architecture.
To make the results calculated by this algorithm more specific, two very similar network mechanisms must be constructed. One of the mechanisms is relatively stable and does not change frequently. We call it the destination network and use a letter to value it. Another mechanism is called the core network. Determine a certain function by strengthening the computing power, and its loss function expression is

$$\lim_{k \longrightarrow \infty} Q_k = \Theta_*. \tag{7}$$

A function gradient can be obtained by calculating through listing:

$$\frac{dL\Theta}{d\Theta} = E \left[Q_{target} - (s_{sys}, a; \Theta) \frac{dQ(s_{sys}, a; \Theta)}{d\theta} \right]. \tag{8}$$

Use the previously mentioned formula to calculate the function gradient for a lot of training and finally get the most accurate function value, and the purpose is to achieve the goal of special points. There is a special derivative:

$$\nabla_{\Theta_k} L_k \Theta_k = E \left[\left(R_{once} + \gamma max Q_{main} s_{sys}', a' ; \Theta_{k-1} - Q_{main} s_{sys}, a; \Theta_k \right) \nabla_{\Theta_k} Q s_{sys}, a; \Theta_k \right]. \tag{9}$$

Among them, the value of one parameter is fixed.

3.1.3. Experience Playback.

$$Q s_{sys}, a; \Theta_k \overset{modification}{\longrightarrow} Q(\psi s_{sys}, a, \theta'). \tag{10}$$

In addition, an input state in the ΦBei network system is also a combination of two parameters including neural network and destination network. The corresponding mechanism can be modified to

$$\begin{cases} D \overset{modification}{\longrightarrow} \overline{D} = [\overline{e_1}, \overline{e_2}, \dots \overline{e_l}], \\ \overline{e_i} = (\psi s_{sys,i}, a_{net,i}, r_{once,i}, \psi s_{sys,i+1}). \end{cases} \tag{11}$$

3.2. Analysis of SDN Framework Modules

3.2.1. QoS Routing. Topology Management Module.
There is a module that uses an automatic check for network problems to identify the connection between the controller and the noncontroller switch and the switch and automatically write down the Internet address, IP address, and open data and other information, and check information: save, delete, update and change regularly.

Network Monitoring Module. One reaction in the network is to block the network traffic. The more serious the blockage is, the stall will occur. Use (12) to calculate the link congestion rate:

$$g_{link} = \frac{C}{B}. \tag{12}$$

In Table 1, B represents the amount of stutter in the video, C represents the amount of bandwidth in the link, and g represents the sum between the two quantities. Therefore, if we want to calculate this number, we must find the calculation number in it. The China map finds that it can be represented by the amount of special points and the amount of broadband at special points. The acquisition of the open protocol is simple, and it can be obtained by receiving and sending through the port. If you want to obtain the flow table, you must also use the calculation shown in Table 1.

When performing statistics, you can only select the port and number of special points, the number of bytes, and the time included. At t_1, the transmission of a special point is represented by a letter, and the number of bytes received is R. At time t_2, the transmission of a special point is represented by another letter, which represents a received time, and finally find the corresponding result. The finally

structofp_port_stats{	
uint16_tport_no;	/ ∗ The port number ∗ /
uint64_trx_packets;	/ ∗ Number of received messages ∗ /
uint64_trx_packets;	/ ∗ Number of sent messages ∗ /
uint64_trx_bytes;	/ ∗ Number of bytes received ∗ /
uint64_trx_bytes;	/ ∗ Send bytes ∗ /
uint64_trx_bytes;	/ ∗ Duration ∗ /
};	

obtained network monitoring data can be expressed by Equation (16):

$$B = \frac{Tx_2 - Tx_1}{t_2 - t_1} + \frac{Rx_2 - Rx_1}{t_2 - t_1}. \tag{13}$$

We can also calculate the result we want using formulas (15) and (16).

The open protocol does not have a way to directly detect the network delay, so it is not a good method to use the open protocol to calculate the delay.

Path Calculation Module. Use the methods passed through to calculate the comprehensive network information and use the data provided by the network monitoring module. Relatively speaking, the highest-level data is used for statistics, and other low-level data should be used with the least. The path is calculated at the cost.

Routing Management Module. By controlling the router to calculate the number we want and send it to the company for the company to carry out the next exchange, the switch can carry out the next business forwarding. It mainly contains the following functions:

This module can identify different businesses differently. After identifying the highest and best data, it will be sent to other companies and the results will be calculated. Compared with other levels of data, the results will be sent out. The best result can be calculated at the cost of the shortest path.

3.2.2. Queue Scheduling Management

Queue Agent Module. In a modular display controller, if we want to open the company to exchange and communicate commands, this is what we want.

Traffic Management Module. The flow module is used for management in the open switch, so that the rapid channel and the template in the controller can be integrated with each other. The related queue scheduling and simple algorithm become very simple, and the management strategy can be analyzed and answered later.

3.3. Analysis and Design of Lagrangian Relaxation Routing Algorithm

3.3.1. Delay-Constrained Minimum Cost Path Problem.
There are definitely the most advanced and advanced ones in the network, and there are also some problems with delay

and congestion in the network. If you want to find this value, you want to minimize link congestion. Then, we have to figure out a way to solve it.

$$cp = \sum_{u,v \in p} c_{uv}$$
$$dp = \sum_{u,v \in p} d_{uv} \tag{14}$$
$$p^* = \min\left\{cp|dp \le \Delta_{delay} , p \in P_{st}\right\}.$$

3.3.2. Using Lagrange's Median Theorem for Algebraic Algorithms.
In real life, there are good ways to solve this problem, but it is impossible to find a theory to replace this algorithm. It is necessary to use Lagrange's median value theorem to approximate this value, so that this problem can be solved.

LARAC is implemented by an aggregate cost function, which is shown in formulas (15) and (16).

$$c_{uv}\lambda = c_{uv} + \lambda \times d_{uv}, \tag{15}$$

$$c_\lambda p = \sum_{u,v \in p} c_{uv}\lambda. \tag{16}$$

Use a letter to represent Lagrange's median theorem, and c represents a level of aggregate cost function.

Use Lagrange's median theorem to calculate link congestion rate and weighted rate; see equation (18).

$$c_{uv} = ag_{uv} + 1 - a \times 1, 0 \le a \le 1 , \forall u, v \in E, \tag{17}$$

$$\lambda = \frac{c(p_c) - c(p_d)}{d(p_d) - d(p_c)}. \tag{18}$$

If d(pr)≤Δdelay, then a new way must be found; otherwise, the solution cannot be solved by using that way.

3.4. PDW Queue Scheduling Management Algorithm.
According to a technique for randomly detecting queues, this technique can be divided into two algorithms: one algorithm is to calculate the average queue length, and the other algorithm is to calculate the probability. The detailed calculation formula is shown as follows:

$$q_{ave}t_n = wq_{ave}t_{n-1} + (1 - w)qt_n. \tag{19}$$

The probability of packet discarding is related to the minimum value min, maximum value max, and the reference probability p. The calculation formula for the discarding probability p is shown as follows:

$$p = p_b \times \frac{q_{ave}t_n - q_{th\_min})}{q_{th\_max} - q_{th\_min}}. \tag{20}$$

This algorithm is the biggest change to the previous algorithm, and it can judge the level of scheduling management and carry out the congestion processing rate. And

its change is to add a level-related processing on the original basis. And through this kind of relevant processing, it is very good to improve the service quality of the network.

4. Software-Defined Network QoS Optimization and Implementation

4.1. QoS Control Framework and Route Optimization. The router involves four modules: network management module, network monitoring module, network path calculation module, and routing management module, as shown in Figure 1.

4.1.1. Topology Management Module. As soon as the open protocol enters a certain network mechanism, the controller will respond quickly and discover the protocol and periodically control the machine and switch to exchange information with the switch and then change and update these links. The last step is that the exchange events of these links are recorded in the list.

This kind of controller uses the shortest path for calculation, and its disadvantage is that it cannot make advanced distinctions based on the shape of the network. It can also protect all kinds of information on the network from being infringed. It can also use a certain method to exchange and protect the mapping information of the node based on the comprehensive mapping information provided by the network monitoring module. The purpose of this method is to map the switch node to other switch nodes. This method is also the realization of the algorithm. After the switches are exchanged, two methods can be obtained to obtain the minimum path between the switches.

This kind of management system will make periodic changes, change the information according to this periodic change, and then perform different corresponding processing based on this information. The purpose is to protect the stability of this network. This kind of management system also has very important components such as top management. With this component, the shortest path and minimum cost between special points can be calculated. The relationship between related classes and interfaces of topology management module is shown in Figure 2.

4.1.2. Network Monitoring Module. The network monitoring module can obtain comprehensive data and network congestion rate periodically and orderly and calculate the path to maximize the processing of this information. Among the other two modules, the two network monitoring modules are also a good choice to calculate data in an orderly manner.

Module management should be performed on the link, and the controller should be used to expand the module, and the control module should be used as the most basic management module. Let other modules forward and discard the processing separately. The most important module is processing. After processing, it can be forwarded according to the path. Table 2 contains the main methods.

4.2. Experimental Network Test Platform

4.2.1. Experimental Network. The software and hardware configuration of each node in the network is shown in Table 3. In the table, DPID/IP represents the switch network identification number or the terminal host IP address.

4.2.2. Business Priority Mark. To distinguish different services differently, it is necessary to carry out a special mark for each type of service. From the following table, we can know that there are many special values for the business priority level of the business type, as shown in Table 4.

4.2.3. Experimental Testing Tools. Iperf is a network performance testing tool that can test the network data reception rate and packet loss rate. Use this software to send and receive data, and test the data receiving rate and packet loss rate.

4.3. QoS Optimization Function Test and Result Analysis

4.3.1. Experiment 1: QoS Path Calculation Validity Test

   (i) Experimental purpose
   (ii) Under the premise of network congestion, the calculation method is used to find the result with a small path cost.
   (iii) Experimental scenarios and steps
   (iv) Use the HTB queue in LinuxTC to limit the maximum sending rate of the switch port to 5 Mbps. Since the network mainly transmits UDP packets, the transmission volume of other types of packets is small, so the maximum transmission rate of the switch port is used as the bandwidth of the link connecting the port.
   (v) Experimental results and analysis

According to Table 5, we can know that if the congestion rate is different, its result will be different.

From Table 5, we can see how fast the router is, its congestion rate, its cost, and some important information. Its supply chain is shown in Figure 3. It can be seen that the data in parentheses can reflect the price of the cost, which can be obtained by calculation. So this router is composed of OVS4 and OVS1, so that the cost can be lower.

4.3.2. Experiment 2: Dynamic Rerouting Effectiveness Test

   ① Experimental purpose
   (i) When the network QoS path is congested, the path can no longer meet the QoS requirements of the highest priority service data flow. It is necessary to test whether the highest priority service data flow can be rerouted to the new QoS path when the QoS path is congested.
   ② Experimental scenarios and steps
FIGURE 1: Prioritized QoS control is implemented in Floodlight.

TABLE 4: Business priority mapping.

Business type	Business priority value	Transport layer source port number	Ds domain value	Tos field value
Conversational business	4	25554	4	16
Streaming business	3	25553	3	12
Interactive business	2	25552	2	8
Background business	1	25551	1	4

TABLE 5: Network link congestion rate and delay information.

Link	Congestion rate	Cost price	Time delay (ms)
E1(OVS3- > OVS1)	0.1727	26	20
E2(OVS2- > OVS1)	0.4096	46	60
E3(OVS4- > OVS1)	0.8259	84	145
E4(OVS2- > OVS3)	0.3254	39	28
E5(OVS4- > OVS2)	0.1067	19	15
FIGURE 3: QoS routing topology.

(ii) In experiment 1, the QoS transmission path is OVS4- > OVS2- > OVS3- > OVS1, and the Floodlight controller will store this QoS path in the path set cache. After experiment one, continue with this experiment. The experimental steps are as follows:

(1) On the switch side, use the flow table delete command to delete the flow table entries in the switch.

(2) Add static flow entries in OVS4, OVS2, and OVS1, so that HOST5 sends background UDP packets with the transport layer source port number of 25551 to HOST6 through these three switches in turn.

(3) HOST5 sends UDP messages with source port numbers of 25554 and 25551 to HOST6, and the messages are sent for 30 minutes. Since the Floodlight controller path set caches the session message QoS path, the session message transmission path is OVS4- > OVS2- > OVS3- > OVS1, and the background message transmission path is OVS4- > OVS2- > OVS1.

(4) Read Floodlight log, obtain network link parameters and update QoS path.

③ Experimental results and analysis

Looking at Table 3, we can see that Floodlight calculates the QoS path as OVS4- > OVS1.

From the data in Table 6, it can reflect some accidents, costs, and important information encountered when the router is in use. When we are using the LARAC algorithm, we can calculate the final result. The information we get from now is the speed of the router, how much it costs, and how long it takes to get the network link without crowding it. It has the best service, that is, it can pass QoS, so that we can know whether the path will be updated by comparing the old and new data.

4.4. QoS Optimization Performance Test and Result Analysis

4.4.1. Experiment 3: Dispatching and Managing the Network and Inspecting Its Performance.

The higher the level, the faster the speed; the QoS performance will be best protected, which can explain the importance of performance and speed, as shown in Figures 4-5.

TABLE 6: Update the link congestion rate and delay information before the QoS path.

Link	Congestion rate	Cost price	Time delay (ms)
E1(OVS3->OVS1)	0.7145	74	146
E2(OVS2->OVS1)	0.9925	99	892
E3(OVS4->OVS1)	0.2317	31	40
E4(OVS2->OVS3)	0.9252	93	738
E5(OVS4->OVS2)	0.9999	100	1276
FIGURE 4: PDW policy classification service receiving rate.
FIGURE 5: PDW strategy classification business submission rate.

The higher the level, the better the effect, and the performance of QoS can be protected in advance. This explains the requirement that the PDW policy distinguishes performance and protects different levels of performance.

4.4.2. Experiment 5: Control Frame Level and Performance Test

(i) ① Experimental purpose

In this experiment, we can obtain important information about the speed of reception and transmission. Only after this operation can we detect the benefits of framework performance.

② Experimental scenarios and steps

We can understand from the figure, the importance of broadband transmission speed. The broadband performance is good, the speed is fast, the control frame level is higher, and at the same time, a high-performance processor is required to operate, so that there will be no delay.

When we look at Figures 6 and 7, we can see at a glance the usage of the sending rate and the importance of the framework.
FIGURE 6: QoS control framework receiving speed of different priority packets.
FIGURE 7: QoS control framework different priority message delivery rate.

Figure 7 shows how fast the best sending rate is, and the most advanced receiving speed can better stabilize this program. When the sending rate reaches 2 times, the data transfer speed will be very fast, and the program can be stabilized without the best telegram. Then, its stability needs a best suit to complete, making it more advanced. From this point of view, the higher the QoS framework, the better, and the QoS control framework also achieves better stability, improves network utilization, increases the amount of data transmission, and improves usage efficiency, so it can be used better.

5. Conclusion

We all know that, in today's networks, the speed of the network is fast or slow; some are very fast, and some are very slow, and even disconnected and stuck. And the quality is good or bad. Some networks are of good quality and very efficient, and some of them are not satisfactory, so we need to strengthen network learning. The speed of the network speed and the quality of the network are important factors that

affect the network, and the most advanced transmission and reception are guaranteed, and other services have received the best service from then on. This is the network we need most. In the network, we also need to study the priority levels of different services. For the most advanced clients, we must ensure timely solutions. For some low-level services, we must perform module partition processing. Research the QoS of different priority services in the SDN network, provide end-to-end delay guarantee for the highest priority services, and provide differentiated QoS services for other services. By introducing the concept of QoS, two traditional network models that can improve QoS are explained, and the characteristics of the models are analyzed. The four types of services transmitted in the network are differentiated and set according to their QoS requirements. In order to ensure the QoS of different services, a QoS control framework in the SDN network is proposed. The various functional modules in the QoS control framework are implemented in Flood-light and OpenvSwitch soft switches. From the previously mentioned situation, the QoS framework has important functions and advantages. It can make the speed faster, the

quality better, and it also promotes better service. It has been welcomed by the public, so the development of routers is a good prospect. There will be better development in the future, which can help people observe and receive information anytime and anywhere, but also the utilization rate has been well developed, without polluting the environment, and expanding the transmission volume. At the same time, it is also necessary to know how to develop a better framework and exchange tests based on this original QoS control framework, as well as the control of the control framework by the switches in the network. The switch plays a very important role in the network because it can make the best use of the various functions in the framework and finally become a reality, so that some false things in the network no longer exist and the network can function as a router. Performing a perfect test to maximize the benefits of the network is the best result we need.

Data Availability

The data used to support the findings of this study are included within the article.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

In underwater acoustic sensor networks (UASNs), the reliable transfer of data from the source nodes located underwater to the destination nodes at the surface through the network of intermediate nodes is a significant challenge due to various unique characteristics of UASN such as continuous mobility of sensor nodes, increased propagation delay, restriction in energy, and heightened interference. Recently, the location-based opportunistic routing protocols seem to show potential by providing commendable quality of service (QoS) in the underwater environment. This study initially reviews all the latest location-based opportunistic routing protocols proposed for UASNs and discusses its possible limitations and challenges. Most of the existing works focus either on improving the QoS or on energy efficiency, and the few hybrid protocols that focus on both parameters are too complex with increased overhead and lack techniques to overcome communication voids. Further, this study proposes and discusses an easy-to-implement energy-efficient location-based opportunistic routing protocol (EELORP) that can work efficiently for various applications of UASN-assisted Internet of Underwater Things (IoUTs) platforms with reduced delay. We simulate the protocol in Aqua-Sim, and the results obtained show better performance than existing protocols in terms of QoS and energy efficiency.

1. Introduction

The genesis of life on Earth had its inception on water, from which it went on to conquer varied frontiers. With the advent of the latest technologies, today's world is more connected than ever before, but ironically the blue planet still lacks efficient underwater connectivity. Underwater acoustic sensor networks (UASNs) [1–3] made their way into the limelight of research quite recently; its pivot objectives deal with an array of versatile interests from oceanographic studies dealing with marine geology, marine ecology, and physical and chemical oceanography. Another significant application is resource extraction, which mainly concerns harnessing abundant rare-earth minerals, petroleum, and natural gas under the sea bed, calamity prevention, deep-sea climate monitoring, and protection, surveillance, and reconnaissance of strategic waters by naval forces around the globe. Conventional methods used for undertaking these tasks mentioned above require humans to physically dive into the ocean's depths or rely on remotely operated underwater vehicles (ROUVs). After the data collection process gets over, these units resurface to provide

the output. The data acquired always fell short of fulfilling its objectives as there were problems like the lack of accurate real-time data, stringent storage constraints, inability in handling mobility, and capability to withstand underwater pressure.

UASNs have cell-powered sensor nodes deployed throughout the ocean bed that interact with each other and with the sonobuoys located at the surface to suffice these objectives. Their presence ensures effective communication with the sensor nodes (real time), and they are also the first responders to notify the base station if any nodes fail. Besides all these conspicuous merits, they have been used in underwater acoustic research and antisubmarine warfare for a long time, reflecting its practicality as the UASN's function under tight frequency limitations. Numerous unique features of the underwater environment make the deployment and use of UASN quite a challenging task [4–7]. Underwater conditions are different from the situations on land where the communication takes place with radio frequency (RF) aid. Unfortunately, the underwater environment consumes the energy of the RF waves and renders itself impractical. The mobility of underwater sensors with the ocean currents is another major challenge. To get better off from the challenging underwater situations, UASNs communicate using acoustic waves [8–10]. Underwater acoustic waves typically operate in the frequency range of 10 Hz to 1 MHz. The delay of propagation accompanies this slender range, but it seems to be the only viable choice forward on modicum energy store. UASNs make another edge by facilitating interfaces to communicate with autonomous underwater vehicles (AUVs) remotely. This feature will exponentially increase the range of AUV control, and this merit will also help us perceive the underwater world for research with an added advantage of burgeoning the amount of ocean monitored by human beings, which currently accounts for only 5%. Routing of data packets right from the sensor nodes to the sonobuoys and to surface stations is one of the most challenging issues faced in UASNs, primarily due to the rapid energy drainage, limited bandwidth, significantly high latency, and reduced reliability [11–17]. Figure 1 presents a sample application scenario of UASNs.

Terrestrial wireless sensor networks (TWSNs) have a conventional set of routing protocols that ensure good network performance. TWSNs at no point of operation face interruptions similar to ocean currents. Doppler spreading, interim path loss, and link quality loss create numerous challenges for routing in underwater environments. In a nutshell, the quality of service (QoS) and energy constraints of UASNs inextricably impede it from resorting to routing protocols of TWSNs. Majority of all the routing protocols proposed for TWSNs, thus proving to be powerless when it comes to UASNs. Numerous unconventional routing protocols were put forth in recent years for UASNs, and each focused-on energy efficiency, thus improving various QoS parameters like throughput, latency, load balancing, and robustness. Some of these protocols have already been tested for research, military applications, and catastrophe prediction. The selection of an appropriate routing protocol is significant as it is answerable for the reliable deliverance of data packets to the destination.

Table 1 presents the variations between the terrestrial wireless sensor networks (TWSNs) and underwater acoustic sensor networks (UASNs). Routing protocols in UASN face numerous design challenges. The weightage given to path selection accounts for the various problems that have to be confronted in the underwater environment, such as marine aquatic life, acoustic disturbances, propagation delay, and seismic shadow zones. Many new routing protocols are proposed to tackle these dilemmas; however, most of them lack the description of appropriate routing strategies. Routing strategies advocate the parameters, which will be extensively useful for researchers and other professionals to calibrate the effectiveness of algorithms used in UASNs to develop a strategy to tackle limitations like high propagation delay and energy usage. Picking the suitable scheme ensures engineers achieve desired productivity in applications. The routing protocols for UAWNs are mainly classified into location-based protocols and location-free protocols. The location-based protocols instrument the use of the information contained in the sensor nodes that are mostly two/three-dimensional position coordinates. In contrast, location-free/depth-based protocols depend mainly on pressure information present in sensor nodes. Most of the earlier conventional protocols proposed for UASNs selects the best path for sending data beforehand without considering the dynamic nature of the network environment. This negligence of the traditional routing protocols tends to compromise the use of the widespread resources in the network and can also pave the way to network failure. When setbacks like these started to portray, routing in UAWNs seems like an insurmountable dilemma, and the concept of opportunistic routing protocol (ORP) was then proposed [18–20]. This traction appeared due to various contributing factors like the increased need for extended capacity and expectation of top-notch QoS. The basic idea behind ORP turns the table on the demerit of unreliable transmission, that is, the undesired broadcast nature exhibited by the unreliable transmission is exploited here instead of selecting the nodes beforehand. The selection of nodes in ORP happens on the go. Numerous neighboring nodes (candidate set) receive the broadcasted message. The candidates belonging to the candidate set are sorted according to the metrics and prioritized based on the probability of becoming the next-hop forwarder. The candidate with the highest priority is given the ability to forward the data packets while others discard the packets. This is known as candidate coordination. Opportunistic routing protocols have proved their robustness and adaptability to uncertain conditions by showing their significant presence in many essential fields like oil/gas pipelines, power grids, and management of metro/railroads. Currently, the advancements closely related to ORP have not yet reached their pinnacle as many problems are yet to be solved. However, the prime intention that sleeps behind it is being the ability to make a set of independently weak nodes emerge together as a virtually robust set of links. Thus, ensuring reliability which in turn plummets the retransmission rates and chop down the energy consumption of UAWNs. All of these pros and cons will be thoroughly surveyed in this study.
FIGURE 1: Underwater acoustic sensor networks (UASNs).

TABLE 1: Differences between the TWSN and UASN.

	TWSN	UASN
Mobility	Low/medium	High
Reliability	High	Low
Data rate	High	Low
Bandwidth	High	Low
Interference	Low	High
Propagation delay	Low	High
Energy usage	Low	High

The major contributions of the work are highlighted as follows:

(i) We review all the major location-based opportunistic protocols proposed for routing data packets in underwater acoustic sensor networks over these years. Numerous energy-based, QoS-based, and hybrid location-based opportunistic routing protocols have been proposed in 2019, 2020, and 2021, and they promise to provide much better performance to various real-time applications deployed in UASNs. Very few works have provided reviews on these latest protocols, and we initially tried to address this research gap. We analyze and present a brief description of their working mechanism and highlight their issues and challenges. These issues can be taken up in the future for further improvement in the design of routing protocols in UASN.

(ii) From the review of the latest protocols, it is observed that increased delay and energy drainage are the two significant areas of concern that need further solutions. We then tried to model an easy-to-implement routing protocol that can guarantee energy efficiency with reduced delay to various applications deployed in UASNs.

The rest of the study is organized as follows: in Section 2, various applications using underwater acoustic sensor networks are discussed. The fundamental principles of opportunistic routing are explained in Section 3. Energy-based, QoS-based, and hybrid location-based protocols are discussed in Section 4. The proposed energy-efficient and delay optimized protocol is discussed in detail in Section 5. The future research directions are discussed in Section 6, and the study concludes in the next section.

2. Underwater Acoustic Sensor Networks

The planet we dwell upon is covered approximately with 71% of water. Under this blue element, lies countless untapped resources that will enable human society to advance in countless ways. In order to consolidate this final frontier, underwater wireless sensor networks prove to be the need of the hour. The underwater wireless sensor network (UASN) is the collection of self-driven sensor nodes and autonomous vehicles connected underwater to perform different collective tasks based on user applications. The sensor nodes can occupy different depth locations that will permit us to spread our reach even to the ocean's deepest places. The self-driven sensor nodes will collect and transfer the sensed data to the target destination using acoustic signals. The attractive applications of UASNs comprise real-time surveillance, disaster prevention, navigation assistance, water quality determination, industrial organization, fish tillage, underwater exploration, and pollution tracking. Almost each of these applications of UASN demands sensor nodes to transfer sensed data timely and precisely through the source node present underwater towards the destination node on

the surface with the help of intermediate nodes in the network. However, due to the dynamic nature of UASNs, continuous node mobility, communication voids, and limited battery storage often lead to degraded network performance. In this complicated underwater environment, how to route data packets promptly and effectively even with the presence of a communication void is the most challenging research question.

2.1. Challenges in UASNs. This section presents an overview of various challenges in underwater acoustic sensor networks.

2.1.1. Acoustic Communication. The terrestrial networks depend on RF waves to execute communication. Whereas the underwater environment is highly unpredictable, and RF waves are unfortunately absorbed. Additionally, a high amount of attenuation paves the way to energy loss; hence, RF waves are not an option to be considered. Optical waves cannot be regarded as a choice because the mobility of the nodes is unable to guarantee accuracy. The only viable option in this scenario is acoustic waves. Many other flaws are associated with the usage, but a suitable routing protocol is expected to sort out the dilemma.

2.1.2. High Mobility. The underwater sensor nodes are constantly on the move. These movements are caused by ocean currents which arise due to wind, breaking waves, temperature, and salinity variations. For efficient data gathering, the movement of these nodes is vital and indispensable. However, in reality, this high mobility induces the formation of curves to the acoustic waves, which triggers the emergence of zones that makes some of the sensor nodes in the network unable to participate in data transfer, which brings forth performance issues to the network.

2.1.3. Underwater Noise and Interference. The ocean is packed with a lot of noises and interferences that arise from varied sources. Some of the underwater noises are caused by breaking waves, rain, and marine life. However, various sources are man-made like, shipping, military sonars, fishing, and research activities. These disturbances affect the quality of data packet delivery in the underwater environment.

2.1.4. Low Bandwidth. The operational frequency range of the underwater sensor nodes is primarily restricted due to the usage of acoustic waves as the medium of transmission. The bandwidth is a meager spectrum that lies between 1 kHz and 50 kHz. This poses a significant problem for routing protocols as it requires an enormous amount of data exchange at various stages like discovery and maintenance. Tight bandwidth constraints put challenging design constraints on acoustic systems. In order to perform communication with AUVs, it is more important to have a wider bandwidth rather than a rate. Moreover, the routing

protocols are forced to choose routing paths from this small frequency range for data delivery. However, due to the dynamic nature of UASNs, continuous node mobility, communication voids, and limited battery storage often lead to degraded network performance. In this complicated underwater environment, how to route data packets promptly and effectively even with the presence of a communication void is the most challenging research question.

2.1.5. Low Data Rate. Speed is a crucial factor when it comes to information exchange. The faster the data reaches the destination, the better. Unlike its counterpart (terrestrial environment), the speed at which data is transmitted in the underwater environment is influenced by numerous factors. Firstly, the propagation speed of acoustic waves is inferior to RF waves by many folds that create room for propagation delay. Secondly, there are various persuasive components like depth, temperature, and the degree of salinity of the water. The data rate is meager and accounts for approximately 100 kbps or occasionally a bit more.

2.1.6. Transmission Loss. The hurdles when it comes to underwater sensor network implementation are numerous. Acoustic waves do not guarantee any reliability for the network. On top of that, path loss, Doppler spreading, and high latency will provide a clear picture that there is a considerable amount of packet loss. Transmission loss in any network is not a desirable outcome. Interference is one of the main reasons for packet loss to occur. When the same nodes participate in data transmission continuously for an extended period, the battery can run out, resulting in a communication blackout, and the node will no longer be able to transfer data collected from some places in the network. The acoustic signals have open channels, which are more likely to be utilized by an attacker or malware and to wreak havoc in critical services like routing, localization, and synchronization. Delay variance and bit error are two constituents that can lead to a high amount of packet loss and bit error rates.

2.1.7. Error Prone. The underwater sensor nodes, unlike their conventional counterparts, are not reliable. The environment in which it has been implemented does not support its operation. The mobility, high latency, delay in propagation, high interference, noise, etc., make them highly susceptible to errors. The changes that manifest due to the variation in salinity, depth, and acoustic speed have an implicit effect on making the data transmission process error prone.

2.1.8. High Energy Consumption. Energy drainage is a significant problem in UASNs. Communication between various nodes in a network rudimentarily requires the acknowledgment of its position. The nodes are constantly swaying in harmony with the ocean currents, and it is essential to update their position consistently with their neighbors for effective participation in the data transmission

process. Ironically, this position-update process drains quite some energy from these sensor nodes. Another avenue wherein the power consumption rates rocket is when packets have to be retransmitted due to high interference. The data load bestowed on end nodes that connects to the surface stations rapidly depletes the battery power, resulting in the termination of connection with the rest of the nodes in the underwater network. The consumption rates vary with the depth in which it is implemented; the battery is expected to operate well in shallow and deep-water conditions.

2.1.9. Channel Attenuation. Channel attenuation is another dilemma that underwater sensor nodes have to confront. The implementation of sensor nodes in the ocean bed is beneficial only if it can collect and transfer data, but due to channel attenuation, the data collected cannot be efficiently extracted from the received signal.

2.1.10. Short Network Lifetime. The pivot grounds for the short lifetime of underwater sensor nodes are due to its source of energy, the battery storage. The nodes extensively consume energy while localization, routing, and data transfer. The hostile underwater condition makes the replacement of cells regularly a challenging task. Therefore, an efficient routing protocol has to consider energy consumption while making decisions on routing path selection. Furthermore, if the nodes run out of energy, it will result in the formation of dead nodes that can affect the network performance and data transmission to the surface stations.

2.1.11. Security and Privacy Issues. UAWNs are made and deployed to monitor places consistently that are far from the shoreline. There is a high chance that the nodes are deployed in strategic waters for specific applications. Attackers can easily manipulate UASNs to inject malicious attacks upon the network. They can also be physically destroyed by enemy divers/AUVs. In the worst-case scenario, attackers can inject fake nodes into the network to provide misguided information and use compromised nodes to extract exclusive data from the network.

2.1.12. Physical Challenges. The sensor nodes have to be fabricated so that they are compact, rigid, and waterproof and should also be able to withstand the pressure of water. Marine life is the next physical challenge that these sensor nodes have to face. In reality, it is physically impossible to protect every one of the nodes in the network.

2.2. Applications of UASNs. This section presents an overview of the major applications that use UASNs.

2.2.1. Military Applications. The military applications of UWSNs can cover a wide range of requirements from monitoring to reconnaissance. In 1982, the United Nations Convention On the Law of the Sea allowed countries to exercise jurisdiction on territorial waters up to 200 nautical miles along the baseline. The naval force guards the coastline against invaders, but the underwater regions in strategically important areas are vulnerable. This vulnerability can be defeated with the help of UASNs. It will enable the militaries to detect enemy divers, submarines, torpedoes, AUVs, and naval mines. The ability to get real-time data will enhance strategic decision-making.

2.2.2. Oceanography. Oceanography is the study of physical and biological aspects of the ocean. Oceanographic studies and researches will provide humans with the capability to understand the various phenomena that take place in the ocean and also be able to predict or artificially simulate similar conditions that will benefit human society. Oceanography can provide efficient analysis if it can collect real-time data. UASNs can be utilized to perform experiments to unravel the mysteries of the underwater world consistently, which will indirectly help us to obtain solutions to various problems oceanographic problems.

2.2.3. Coral Conservation. Corals are one of the most beautiful living things on the planet. It takes millions of years to form barrier reefs. The Great Barrier Reef in Australia is the most extensive collection of corals on the phase of the Earth. However, it is dying due to coral bleaching due to the shift in climatic conditions throughout the world. Coral reefs around the globe are on the verge of extinction, and nations are trying to change the situation. Human interference has the likeliness to accelerate the degradation process, but data collection is seemingly impossible without human interference. UASNs are a profound solution that can provide real-time data to conservationists by limiting human interference.

2.2.4. Resource Tapping. The Earth has resources that are tucked away in the depth of the ocean. UASNs provide a way to get the know-how of these varied resources. UASNs will enable us to find out the location, approximate quantity, and dispersion pattern of resources present in the ocean bed. Petroleum and natural gases are an inevitable part of our civilization, which are unfortunately limited. New potential sources can be located for extraction using UASNs.

2.2.5. Fishing, Farming, and Recreation. The fishing industry will benefit from the use of UASNs as they will help locate groups of fish. Underwater farming has been used to cultivate seaweed, lettuce, basil, etc., in countries like Japan and Italy. Knowing the nature of the ocean is an integral part of taking out cruises for recreation purposes deep into the ocean. UASNs can tell leisure seekers about the risks of a tsunami or hurricane before they embark on a cruise.

2.2.6. Disaster Prevention/Prediction. The implementation of UASNs will enable us to detect in advance any underwater earthquakes and volcanic eruptions, which will help us prevent or predict disasters. Many aircraft have gone missing

over these years in oceans, and no data about their disappearance was harnessed. One of such shocking incidents is that of Malaysia Airlines 370. UASNs, provided it is implemented correctly, will enhance us to chart the ocean, and it is possible to derive a pinpoint location of any possible crash site.

2.2.7. Climate Change. The rising sea levels and warmth have grabbed international attention. The polar ice caps are at the risk of meltdown. Accurate screening and reports of the polar meltdown can be undertaken with the help of UASNs, which will help researchers and environmentalists to find solutions to these baffling dilemmas.

3. Opportunistic Routing in UASNs

The uncertainty of the underwater environment poses many underlying threats to establishing efficient communication strategies. The constraints on power and the constant movement of nodes due to tides make opportunistic routing (OR) a viable solution. The opportunistic routing owns different modus operandi. On receiving a data packet, the host node takes into consideration a set of eligible neighboring nodes and prioritizes them based on various parameters. These parameters are different facets like the node closest to the destination and least power draining. A suitable packet forwarder gets opted from the candidate set based on priority and availability. Thus, in the case of unreliable underwater communication, OR proves to be promising as it provides extended reliability, robustness, and QoS than other legacy routing methods.

The principle of opportunistic routing idea was initially developed in ExOR [19] in 2005. The notable advantage of this protocol is that this protocol exploits the multiplex communication opportunities in which the broadcast character belonging to the wireless network develops. The fundamental working of opportunistic routing can be implemented in this protocol, and the three main steps include the following: Initially, the sender node can broadcast the message data. Secondly, upon receiving that data, one relay node is selected as the best forwarder node. After that, the selected best relay node transports the message transmission to the next best relay, and so on. The method is continued until the data reaches the target position. Compared to traditional routing methods, the next-hop relay is selected only after it has received the data, thereby reducing the number of data retransmissions.

The UASN's operation using acoustic channels for communication has many downfalls as there is a prevalence of solid attenuation, time-varying multipath, ambient noise, and modicum propagation speed. All of these contribute to increased delay, error, limited bandwidth, high energy consumption, communication cost, and at times temporary loss of connectivity among nodes of the network. The profound influence of channel fading is crucial to confront as it can directly impact declining routing performance. The scope of application of OR is of paramount importance because it has significantly low retransmission rates, in turn

reducing the power consumption. Assured packet delivery facilitation by opportunistic routing ensures no wastage of network resources. It also reduces the chance of system collapse and diminishes retransmission costs. Additionally, opportunistic routing is a versatile choice as it applies to a variety of networks.

Opportunistic routing facilitates a dynamic and instant multiple-path routing technique through opportunistic relay selection, unlike the traditional routing method. Instead of a single precomputed relay, opportunistic routing initially broadcasts a data message to a set of forwarder relay nodes. Fundamentally, these forwarders are organized according to a particular unit. The idea of this method is to select the best forwarder relay among all the nodes. This selected relay manages the process of forwarding the packets. These steps are recursively executed until the packet is transmitted to the target destination. The rudimentary opportunistic routing mechanism consists of the following four steps:

(i) Forwarder relay set choosing

(ii) Broadcasting of data to forwarder nodes

(iii) Coordination scheme is used for best relay selection

(iv) Forwarding of data by the best relay

Each node in opportunistic routing broadcasts a data packet to various adjacent hops periodically. Hence, if communication to one neighbor crashes, another nearby node that has received the data packet can transmit it. OR defines a group of various next hops as the best forwarder relay collection and indicates it as a forwarder relay set (FRS). When a message gets transmitted to FRS, numerous forwarders can obtain a similar message packet. We can avoid duplicate transmission by selecting a single candidate as the best relay. Each node in the FRS is allocated a priority that is calculated based on a predefined variable. Suppose the node with the most significant priority present in the FRS favorably acquires the message, it transmits that to the target. Otherwise, the node that has the next most significant priority transmits the data packet, and so forth. The leftover candidates will discard this data packet. The FRS selection is divided into three main components as follows: (a) forwarder relay discovery, (b) prioritization variable calculation, and (c) forwarder relays selection, prioritization, and filtering.

To find out the neighbor node, periodic or nonperiodic packets are broadcasted. This neighbor node depends on the link quality, which is changeable as well as dynamic. Hence, this phase is given the charge of computing the stability and quality of the links to reach the neighborhood. Based on these values, a group of nodes is determined. Initially, every node located in the vicinity of the sender node is added to the FRS. Then, the forwarders are taken and sorted based on the chosen variable. After an FRS is elected, priorities are given to forwarder relays based on a specific value. So, the variable selection affects the network throughput significantly. The priority variable election depends on the routing application needs and targets. For some applications, such as emergency recovery, the position data is essential. Consequently, the relay nodes must know their location, and routing can be

executed by selecting the relay that is locationally nearest to the target node. Controlling the number of forwarder relays can reduce the overhead and duplicate data transmissions. Moreover, since the size of FRS grows, the number of forwarders who cannot listen to one another also increases. This leads to duplicate packet transmissions. Hence, it is suitable to avoid some forwarder candidates from the FRS. This approach is termed candidate filtering or forwarder. The conventionally used filtering method avoids the forwarders, which are not suited instead of the source. But somehow, this policy cannot guarantee efficient network performance. Another method of FRS creation is discussed in some previous works. The technique is based on implementing an algorithm that can optimize correctly and compute the optimal forwarder relays set for every node, such as forwarder relay sets that are created by Dijkstra's algorithm. However, these methods do not solve the issues of duplicate data transmission.

The optimal relay selection that uses a coordination scheme is used for the coordination of packet forwarding operation between next near nodes. This scheme is responsible for selecting the most suitable forwarder relay to push forward the data packet. Coordination methods need signaling between forwarders. The basic coordination schemes are generally classified into a timer-based, contention-based method, and token-based coordination scheme. In a contention-based method, the main principle is that forwarder relays contend to transmit the data packet with the help of control messages. For example, if a sender node transmits a forward request, its near hop nodes have to compete with themselves to come to a consensus on the forwarding of the data packets. In the timer coordination method, the forwarder relays are supposed to be ranked according to a specific priority value. This rank is commonly added with the message header, which is consistent with the hierarchy in which potential forwarders are permitted to respond. Thus, the largest priority node is allowed to respond to the first slot. The next priority node responds to the upcoming time slot, etc. However, this method is straightforward and easy to carry out, timer-based coordination that incurs some delay, affecting network performance. Another method is the token-based coordination scheme, in which the transferring of data packets is only possible through a token holder. In this scheme, the duplicate message transmission is completely prevented, but it faces increased overhead control. A forwarder (relay) node contains the overhead data packets that are being sent when a token arrives. Tokens travel with connected forwarders because more miniature priority forwarder relays can listen to large priority nodes. If no token arrives, the candidates may be moved into an idle state, slowing down the network.

4. Location-Based Opportunistic Routing Protocols in UWSNs

All routing protocols for UAWNs can be classified as location-based protocols and location-free protocols. The location-based protocols instruments data contained within sensor nodes that are mainly two/three-dimensional position coordinates. At the same time, the location-free protocols/depth-based protocols depend on the information related to pressure on sensor nodes. The focus of this study lies in location-based protocols as they provide better performance than location-free protocols. Vector-based forwarding (VBF) [21] was one of the earliest protocols proposed in this category. This protocol can fabricate some virtual vector pipe that exists between the source and the destination. Only the nodes in the vicinity of the "vector" right through the source and destination will have the ability to do message forwarding. Hence, routing involves only a tiny group of nodes.

Similarly, numerous location-based protocols were proposed for UASNs. Some of the protocols focused on improving energy efficiency, while others focused on improving QoS parameters like delay and delivery ratio. Recently, many hybrid protocols also have been proposed which consider both energy efficiency and QoS. This section presents a comprehensive discussion on all the latest location-based protocols proposed for UASNs.

VBF makes use of the node location information to make the routing decisions. The knowledge of the position of nodes encourages it to be faster, reliable, and scalable. With the protocol, a virtualized pipe is created from source to destination, and those nodes in the pipe possess a higher probability of becoming the forwarder nodes, while the nodes outside are disregarded. Sink-initiated query and source-initiated query are the two main ways in which VBF addresses routes to different queries. Conceptually, all nodes inside the virtual pipe have the eligibility to forward the packets, but due to limitations like energy, mobility, and propagation delay of acoustic waves, a self-adaptation algorithm was suggested. Another protocol, directional flooding-based routing (DFR) [22] defines a forwarding method formulated by the angle among the center and intermediate nodes. The nodes are responsible for forwarding the data packets through a flooding method. It also considers the quality of the link between the sender and the destination node. A significant concern with this protocol is redundant data transmission and increased energy consumption. The information-carrying routing protocol (ICRP) [23] is an influential conservative, continuous, and versatile directing protocol. The sender hub checks the current location to the final destination when it owns the data to be sent. If there is no current course or path, it starts a path development process by communicating with the information packet, conveying the route disclosure message. Every node present on the network communicates to maintain the reverse route with the information path.

Hop-by-hop vector-based forwarding (HH-VBF) [24] is another variation of VBF where each forwarder resorts to a different routing vector. HH-VBF rudimentarily is just a version of the vector-based forwarding protocol. HH-VBF is a viable option compared to VBF as it can work well with sparse networks and is not liable to the routing pipe radius threshold. However, there is an increase in the computational delay, which in turn degrades the network performance. Reliable and energy balanced routing (REBAR) protocol [25] is a routing protocol that is energy efficient that

helps in varying the broadcast domain. REBAR has good reliability and increased lifespan of the network. To balance the energy consumption in the network, a flexible scheme is developed to establish the data propagation range. Here, the nodes near the destination have a modicum radius. However, the increased node movements may expend an excessive amount of energy, resulting in degradation of performance. Vector-based void avoidance (VBVA) [26] protocol is simply an extension of the VBF protocol and focuses on addressing the void problem and energy efficiency in UASNs. The protocol works similarly to VBF when there is no void but uses a revised strategy when voids appear in the network. This helps the protocol to maintain better energy efficiency even with voids in the network.

The energy-efficient and collision aware (EECA) [27] multiple-path routing methods are founded on computing two different collision-free paths using restricted-energy modified flooding. It is one of the earliest protocols that gave equal importance to the betterment of QoS and energy efficiency in the network. Here, multipath power-control transmission (MPT) allows packet data transfer within limited end-to-end data error value and reduced power of transmission. The reliable energy-efficient routing protocol [28] functions on the foundation of link quality, physical data distance, and energy available in the UASN. These three values are calculated and shared with all nodes in the network. The protocol uses a local flooding mechanism with an adaptive selection and gives good reliability and energy efficiency performance.

Location-aware routing protocol (LARP) [29], the GPS is used to identify the exact area of the sink nodes. The sink nodes then broadcast the location information in the network. At the least three sink nodes are used for reference, other nodes in the network calculate their position. The sender can locate the next hop by broadcasting two things as follows: (1) location of the destination node and (2) moving direction of the packet. Packets are forwarded if the receiving node discovers that it is moving in a similar direction. The quality-of-service aware directional flooding-based routing (QoSDFR) [30] extends the DFR protocol. In this routing strategy, the sink node is responsible for sending feedback to various other nodes in the network about the channel condition, and based on the feedback, the optimal forwarder is selected. Protocol results in high throughput because of the limited energy consumption and varying channel conditions.

Scalable and efficient data gathering (SEDG) [31] protocol tries to increase the delivery ratio of the packet and also saves the modicum energy by feasible assignment of the member nodes and gateway node (GN). Here, an autonomous underwater vehicle (AUV) goes through the network area with a precomputed elliptical route and collects data from the gateway node (GN). AUV-aided efficient data gathering (AEDG) routing protocol [32] employs an AUV to gather information from gateways or intermediate nodes and use the shortest path tree (SPT) algorithm to balance the energy consumption. Besides that, AEGD designs a model that improves the result and saves energy by reducing the node members. Furthermore, the nodes live for an extended

time to transfer data, thereby increasing delivery chances. The delay-aware energy-efficient routing protocol (DEEP) [33] is a delay-aware routing protocol dependent on collision rate and energy. DEEP makes use of an adaptable node aimed to minimize the collision rate. All the intermediate nodes are elected by virtue of delivery ratio and link quality. In the channel aware routing protocol (CARP) [34], the next-hop transmitter node is elected due to its distance from the previous intermediate node and available energy. Here, every intermediate node is familiar with its neighborhood between the destination node and the next hop. Sender then broadcasts a PING message to the network to compute the next forwarder. Considering a case where the hop value of a sink is lower than the sender node, it replies a PONG data. CARP uses an efficient relay selection method, which doubles the packet delivery ratio.

The novel efficiency forwarding protocol (NEFP) [35] is a proactive anycast routing protocol proposed for UWSNs. It promotes three different approaches. One defines a routing method that avoids unnecessary forwarding of packets where the collision dilemma is averted using a timer. Moreover, finally, the design uses Markov chains to calculate the probability of forwarding the data packets that encourages adaptability to constantly changing network topology. Nevertheless, the performance of the suggested protocol is decreased in the sparse region and as a result, reduces the number of forwards in the phases. Geographic and opportunistic routing protocol with depth adjustment (GEDAR) [36] is a geo-opportunistic routing protocol proposed for a minute-monitoring task. It utilizes a greedy forwarding method to advance the message towards the next hop. The source node chooses the best candidate from the forwarding set. The opportunistic routing in GEDAR reduces the number of retransmissions. GEDAR uses a recovery mode that helps to avoid the void areas. If a node is present in the void area, it will adjust its depth to overcome the void, and new messages will be queued. The greedy strategy will reschedule the node later. Markov model-based routing (MMVR) [37] selects its route from the lower surface to the top level based on changing data traffic. The routes are stable and adaptable, with fewer hops from the sender node and destination. In a localization-based dynamic routing protocol (LBDR) [38], the network is split into smaller layers, and a virtual routing vector is made within the sub-layers. Nodes will move in and out of the virtual vector based on the water current, resulting in high throughput. Void handling geo-opportunistic routing (VHGOR) [39] protocol focuses more on efficiently handling the communication holes in the network. Here, a quick hull algorithm is used to avoid a convex hull. When the node or hub reaches a convex region, rebuilding the convex void helps check an alternate and different way to resume the greedy transmission. VHGOR improves the network performance in networks with voids compared to other routing protocols.

Geographic and opportunistic routing (GOR) [40] protocol shows efficient multi-hop data transmission in UWSNs with an upgraded strategy compared to previous protocols. Sometimes, this method gives room for the

formation of the void region, and GOR tackles this issue using some void-handling algorithms. The framework considers network density, traffic load, and energy control features to bypass the empty region. The range-based low overhead localization technique (LOTUS) [41] significantly improves on earlier versions of the localization protocols. The protocol can estimate locations based on only two references, enabling this technique to work in networks with fewer nodes. The geographical duplicate reduction flooding (GDflood) [42] considers the location data regarding sensor nodes and joins it with network coding. Energy-efficient grid routing based on 3D cubes (EGRCs) [43] employs a 3D cube network that is subdivided into small cubic clusters. The cluster head is determined based on the remaining energy and position of the intermediate node. All the cluster heads then compute their intermediate node based upon the delay and location. EGRCs reduce energy consumption and end-to-end delay and increase the network performance.

Mobile energy-efficient square routing (MEES) [44] is a routing protocol focusing on energy efficiency in underwater sensor networks. The method uses a division of the network field into dense and sparse regions. A major advantage of this method is that, the mobile sink shifts in a clockwise direction that ensures the highest coverage of nodes in the network which will, in turn, result in high throughput and energy consumption. Topology control vector-based forwarding (TC-VBF) [45] is a revamped version of VBF, which tries to address the limitation of VBF in light conditions. Another protocol energy-efficient multipath grid-based geographic routing protocol (EMGGR) [46] fragments the network into 3D grids. The routing is executed in a grid-by-grid fashion with the help of gateway nodes. Disjoint paths result in high energy efficiency and a good packet delivery ratio. Balanced multiobjective optimized opportunistic routing (BMOOR) protocol [47] uses a strategy where the data from the lower surface takes the best route through the intermediate nodes to the top-level sink. Here, the nodes are located as per dynamic assessment with regards to optimal energy forwarders. The BMOOR protocol needs no spatial data, which is costly in UWSN. The protocol is developed using a generation-based bio-inspired, meta-heuristic algorithm. This helps in delay depreciation and maximization of delivery ratio, and thereby the network lifetime is enhanced. Another proposed protocol for UWSN is energy-efficient interference aware routing (EEIAR) [48] that opts for the best forwarder following the shortest distance. The shortest distance determination decreases the propagation delay. The power control-based sharp directing routing (PCR) [49] selects the most optimal transmission power level available at each submerged sensor node, which helps improve the packet delivery conveyance at each round. Also, it condemns the usage of high-power transmission and the uncontrolled consideration of neighboring hubs in the following hop candidate set, which would end up being the root cause for building the energy utilization on the network. The simulation outcomes depict that PCR diminishes the energy expenditure by adjusting the transmission power and electing the best candidates. The stateless opportunistic routing protocol (SORP) [50] uses a novel method to employ a variable forwarding area that can be reshaped and replaced according to the regional density and placement of the potential forwarding nodes to improve the energy and reliability. The protocol gives good performance compared to the previous protocols. Glider-assisted link disruption restoration mechanism (GALDRM) [51] uses a link disordering recognition with a related link rebuilding method. In the connection acknowledgment system, the group nodes gather the link data. The cluster heads gather the disruption data in link disruption and then schedules gliders as relay nodes to revive the link. Utility capacity is built up by limiting the channel. A multiplier technique illuminates the ideal area of a lightweight flyer. The simulation outputs exhibit a glider-assisted reconditioning procedure that helps to reduce energy consumption. The energy-aware void-avoidable routing protocol (EAVARP) [52] expands the network lifetime and packet delivery rate in underwater sensor networks. EAVARP includes layering and data collection phase with the help of directional forwarding strategy and uses residual energy and data transmission to avoid cyclic transmission and flooding. Fuzzy logic-based VBF protocol (FVBF) [53] improves VBF protocol. It focuses more on the selection of a single forwarder node in VBF. FVBF is the fuzzy logic-based VBF protocol. The best forwarding node is chosen according to the angle of projection distance and the battery level. The smallest distance shows that the node is in the vicinity of the target node. The projection angle allows it to be selected onto the virtual routing vector pipe. The best advantage of this protocol is that it achieves better energy and throughput. However, nodes in the selected vector terminate on dealing with a high load of the message, which is similar to the conditions in VBF.

Mobility-assisted geo-opportunistic routing (MSAGOR) [54] protocol is mainly based on interference avoidance. Here, the network region is fragmented into compact cubes to diminish the interference, which helps to make additional well-informed routing strategies for better energy utilization. Moreover, an optimal number of transmitting nodes are selected from each cube based on its distance to the destination. This proximity will help to avoid void nodes. The extensive simulation results reveal that this protocol will maximize the delivery ratio and network lifetime. Totally, opportunistic routing algorithm (TORA) [55] is an anycast, geographic opportunistic routing protocol proposed for UWSN. The protocol is implemented to avert parallel transmission, bring down end-to-end delay in the network, tame the dilemma of void regions, and enhance network throughput. TORA uses time on arrival and its range-based equation to localize nodes. The energy-aware opportunistic routing (EnOR) [56] is an energy-aware opportunistic routing (EnOR) protocol that can adjust the priority level of forwarding between candidate nodes. This leads to steady energy utilization and increased network lifetime. By using the residual energy, link reliability, packet advancement ratio, and EnOR change the priority of transmission level. Adaptive hop-by-hop cone vector-based forwarding protocol [57] tries to improve the reliability of data transmissions in the sparse sensor regions by making some modifications to the base angle of the cone as per the

network structure. These protocols improve the network performance by reducing the number of duplicate packets and also enable a better selection of the potential forwarder node.

Authors in reference [58] discuss implementing a modified strategy for depth-based routing that can transfer the data reliably to the surface sonobuoy. The technique mainly uses the 2-hop neighbor technique and tries to improve the delivery ratio of packets in the network. Authors in reference [59] proposed a technique combining the ant colony optimization algorithm, artificial fish swarm algorithm, and dynamic coded cooperation to improve efficiency by reducing energy consumption. Improving the flexibility of the protocol with the network was one of the major tasks of the proposed algorithm, along with finding the most optimal route. In reference [60], authors presented a Q-learning-based multi-hop cooperative routing protocol for underwater networks. Using this algorithm, the nodes with maximum Q-value were selected as the next forwarders in the network to transfer data from the source to the destination. A coding-aware strategy was proposed for efficient routing in networks with the sparse deployment of nodes [61]. The topological information was used to expand the candidate set using the protocol. An interesting approach that utilizes AUVs to carry sensor nodes to repair the routing voids when foreseeing the occurrence of voids was proposed in reference [62]. The protocol initially predicted the location for repair and then directed the AUVs to the particular location to carry out the repair process. Most of the proposed protocols are complex and incur high overhead, which degrades the performance of the network. Although many of the current protocols improve the data delivery ratio significantly, it comes at the cost of increased energy consumption. It is vital to develop a simple to implement a protocol that can take care of energy efficiency in the network while ensuring reduced delay in the network.

5. Energy-Efficient Location-Based Opportunistic Routing Protocol (EELORP)

In this section, we present the discussion on the proposed energy-efficient location-based opportunistic routing protocol (EELORP) that is designed to provide better energy efficiency and data delivery with minimum delay.

5.1. Theoretical Analysis. Initially, we try to provide a theoretical analysis to the proposed protocol. The focus is mainly on the delay of transmissions that can be reduced further to enhance the performance of the system. In the underwater network, a delay occurs within two different links, the wireless sensor to the wireless controller and wireless controller to the actuators. The delays are denoted by $T_{w(s-c)}$ and $T_{w(c-a)}$. Assuming the controller to be time invariant, the delays due to two sources are combined together to get total wireless sensor network delay as follows:

$$\text{Twt} = \text{Tw}(s-c) + \text{Tw}(c-a). \tag{1}$$

The computation delay of the controller can also be included in the total wireless sensor network delay. As the assumption in the wireless controller is time invariant, the decision of controller $d_{(t)}$ is independent of the time it receives the sample $S((\gamma b)$. So, the total wireless sensor network delay is only important for us. The analysis of UWSN stability is carried out by assuming two different scenarios as follows: (a) the continuous UWSN network delay system is considered by determining UWSN stability with constant network delay and (b) the discrete UWSN network delay system is considered by determining UWSN stability with time-varying networking delay.

For a continuous UWSN network-delayed system, the UWSN having total network delay as T_{WT} at the time $t = \gamma b$ is considered. The assumption is extended by making $T_{wt} < b$ for all values of "γ" belonging to "S" with $\gamma \in s$. The system is modeled mathematically as follows:

$$\frac{\partial}{\partial t}l(t) = Pl(t) + Qd(t - T_{WT}), \tag{2}$$

where "t" belongs to $[\gamma b, \gamma b + b]$. Also with P, Q, R, and S as known matrices, we have the following relation:

$$M(t) = R\gamma(t) + Sd(t). \tag{3}$$

$d(t)$ is the received signal with no delay and $d(t - T_{WT})$ is the received signal with delay. In the case of $d(t)$, that is, received signal with no delay $d(t) = d(\gamma b)$ for $t \in [\gamma b, (\gamma b + b)]$.

Proposition 1. *The UWSN with the delay mentioned above validates the below-mentioned difference equations. The derived equation is as follows:*

$$l(\gamma b + b) = \tau l(\gamma b) + \varepsilon_0(T_{WT})d(\gamma b) + \varepsilon_1(T_{WT})(d(\gamma b - b)). \tag{4}$$

For $\tau = \int_0^b e^{Pb}$, we obtain the following equation:

$$\varepsilon_0(T_{WT}) = \int_0^{b-T_{WT}} e^{Pb}d\gamma\varphi,$$

$$\varepsilon_1(T_{WT}) = \int_{b-T_{WT}}^{b} e^{Pb}d\gamma\varphi. \tag{5}$$

Now, we have the following equation:

$$l(t) = e^{P(t)} + \int_0^t P(t-r)\varphi d(\gamma)d\gamma. \tag{6}$$

If the delay $t_0 > 0$, then the above equation is rewritten as follows:

$$l(t) = e^{P(t-t_0)}l(t_0) + \int_{t_0}^t P(t-r)\varphi d(\gamma)d\gamma. \tag{7}$$

For for $t > t_0$, we have the following equation:

$$l(\gamma b + b) = \tau l(\gamma b) + \in d(\gamma b), \tag{8}$$

where $\tau = e^{Pb}$ and. $\varepsilon = \int_0^b e^{Pr}d\gamma\,\varphi$.
Applying equation (7) to (4), we obtain the following equation:

$$l((\gamma b + b)) = e^{Pb}l(\gamma b) + \int_{\gamma b}^{\gamma b + b} e^{P(\gamma b + b - \gamma)} d\gamma \varphi d(rb - T_{WT}) d\gamma,$$

$$= \tau l(\gamma b) + \int_{\gamma b}^{\gamma b + T_{WT}} e^{P(\gamma b + b - \gamma)} d\gamma \varphi d(rb - b) + \int_{\gamma b + T_{WT}}^{\gamma b + b} e^{P(\gamma b + b - \gamma)} d\gamma \varphi d(rb),$$

$$\gamma^1 = (\gamma b + b - \gamma), \tag{9}$$

$$\tau l(\gamma b) - \int_{b}^{b + T_{WT}} e^{P\gamma^1} d\gamma^1 \varphi d(\gamma b - b) - \int_{b - T_{WT}}^{0} e^{P\gamma^1} d\gamma^1 \varphi d(\gamma^1 b),$$

$$= \tau l(\gamma b) + \varepsilon_0 (T_{WT} d(rb)) + \varepsilon_1 (T_{WT} d(rb - b)).$$

In other scenarios, multiple copies of the signal are transmitted in the time interval and they take different routes while travelling corresponding to the direct path and scattered path. The spread in the delay indicated as σ_τ of 1 to 3 .... $h(\tau)$ is the delay profile. Taking the Fourier transform, we obtain $H(f) = \int_0^\infty h(\tau)e^{-J2\pi f\tau} d\tau$. The coherence bandwidth at which the delay profile response is almost flat, if the signal bandwidth $\beta_s < \beta_c$ is less than coherence of $\beta_c = 1/2\sigma_\tau$.

Figure 2 shows the signal for $\sigma_\tau \ll T_s$ or $\sigma_\tau \gg T_{signals}$. So, the sound signal interferes each other significantly and so on as delay spread increases to $\sigma_\tau > T_{signals}$ and $1/T_{signals} > 1/\sigma_\tau$, which implies to $\beta_s > 2\beta_c$ obtained as the interference. The T_x is stable and R_x is moving towards T_x, indicating the change in the frequency of sound varying due to relative motion between the T_x and R_x.

5.2. Simulation Results. In this section, we discuss the performance comparison of the proposed EELORP protocol by conducting simulations in Aqua-Sim [63–66]. Aqua-Sim is an extended version of NS-2 and offers easy implementation of underwater network scenarios. The parameters used for setting up the network are given in Table 2.

Using the simulations, we measure the energy consumption in nodes and the delay that occurred in the transmission of data in the UWSN. We also compare the results obtained by our proposed work with vector-based forwarding (VBF). Figure 3 shows the energy consumption by nodes in the network. From the results obtained, we can see that the nodes consume less energy using the proposed EELORP protocol compared to VBF protocol. Initially, the nodes have the same level of energy consumption with both the protocols, but as the number of nodes increases, the energy consumption using VBF becomes more compared to the proposed scheme. This signifies the better energy efficiency offered by the proposed protocol.

Figure 4 shows the delay incurred in transmission of the data packets using the protocols in the UWSN. From the results, we can see that using the proposed method EELORP and VBF, the delay incurred remains almost similar when the number of nodes is less. But as the number of nodes increases, the EELORP has less delay compared to VBF in the network. Thus, our results show that the proposed protocol can be used efficiently for numerous possibilities in underwater acoustic sensor networks with reduced delay.

6. Future Research Directions

6.1. Energy Efficiency. This has emerged as one of the major research areas for opportunistic routing protocols in underwater acoustic sensor networks. With restrictions and various limitations in recharging the sensor nodes, it is very important for any routing protocol to minimize the energy usage in the nodes while ensuring that the data gets delivered to the destination. Numerous protocols have tried to improve the energy efficiency in the network, but as UASN has an unpredictable nature, we should for further improvement in this research direction.

6.2. Channel Utilization. The unique features of UASNs like high propagation delay, constant mobility of sensor nodes, high error rate, and interference lead to a major challenge in ensuring the efficient utilization of the channel. Most of the existing protocols have various limitations in channel utilization and this area would be a major area of focus.

6.3. Communication Holes. Dealing with communication holes is a major challenge in UASNs, especially in networks with sparse deployment. Frequent movement of the sensor nodes due to currents and other reasons and failure of sensor nodes due to energy drainage or damage create void areas in the network. Thus, nodes will be unable to find suitable neighbor nodes to forward the data packet to the destination.

6.4. Security. Security of the data transmitted has become one of the major requirements of the applications deploying UASNs. It is therefore vital for all the routing protocols to include a security mechanism that can secure the data from any attackers.

6.5. Reliable Delivery. Reliable delivery of data packet at the destination is a major challenge in UASNs with a dynamic environment. Due to multiple reasons like damage of nodes, lack of energy, voids, etc., the data packet might get lost in the network. It is very important for any protocol to have strategies to manage any data loss and to make sure that the data reaches the destination, also keeping the number of retransmissions to a minimum to save the energy of nodes.

TABLE 2: Simulation specifications.

Parameter name	Values
Simulator name	NS 2.35 with aqua-sim
Dimension of topology	$1500 \times 1500 \times 1500$ m
Transmission range	250 m
Antenna type	Omni-directional
Data rate	50 kbps
Packet size	25 to 125 bytes
Number of nodes	100 to 300
Simulation time	200 s
Number of simulation runs	10
Protocols	EELOP, VBF
FIGURE 3: Normalized energy consumption versus the number of nodes.
FIGURE 4: Delay versus number of nodes.

7. Conclusion

This study presented a systematic survey on the location-based opportunistic routing protocols in underwater acoustic sensor networks. The study initially discussed the working of underwater sensor networks, the challenges and issues, the latest applications using UASNs, and the working of opportunistic routing in underwater acoustic sensor networks. A detailed discussion on all recently proposed location-based opportunistic routing protocols was presented with a focus on their design and working. A discussion on the design and working of an easy-to-implement energy-efficient location-based opportunistic routing protocol (EELORP) that can be used efficiently for numerous possibilities in underwater acoustic sensor networks with reduced delay was presented. A discussion on results obtained with simulations was then presented along with comparisons with existing protocols. Finally, a brief discussion on the future research directions was presented.

In this study, a wavelet recurrent fuzzy neural network is used to conduct in-depth research and analysis on the real-time regulation of physical training intensity. Firstly, an inter-process control technique is proposed to solve the problem of incomplete control flow graph construction caused by the inability to effectively collect all program control flow information in the process of static analysis, in preparation for the research of fuzzy testing technique. Next, a wavelet recursive fuzzy neural network-guided fuzzy testing technique is proposed to solve the problem of fuzzy tests falling into invalid variation due to the lack of directionality in the fuzzy testing process. Each neuron in the feedforward network is divided into different groups according to the order of receiving information. Each group can be regarded as a neural layer. The neurons in each layer receive the output of the neurons in the previous layer and output to the neurons in the next layer. The empirical data show that injury-preventive fitness training can effectively improve all physical qualities in the first phase of preparation and can effectively maintain the physical state and effectively contribute to their abilities during the competition period, and its injury-preventive fitness training interventions were verified by statistical analysis to have a dangerous main effect on their pre and post-test performance. Therefore, it is still not possible to determine its correlation with the coordination and improvement of the athletes' physical fitness, and the integration of the basic physical training and rehabilitation physical training systems, making this theory a new special training theory.

1. Introduction

Physical fitness is based on the energy metabolic activities of the three major energy supply systems of the human body and is an important component of athletes' competitive ability, as expressed through the skeletal muscle system. Physical fitness training is one of the main ways to improve the athletes' special athletic ability and special performance. With the continuous updating of world records in competitive sports, the important role of physical training is becoming increasingly significant. Based on the data model of each training stage, the stage goal is set and the training goal is "digitized." The data analysis and feedback method is then used to represent and evaluate the achievement of the athletes' goals at each stage of training, and if the desired numerical goals are not achieved, the reasons for this are sought and adjustments are made until the goals are achieved [1]. Sports injuries are a topic that every athlete faces and are the most likely to occur during training and competition. The factors that occur are related to the athlete's type of sport, technique, and tactics, basic physical athletic ability, training and game facility environment, and psychological factors. Basketball is also one of the sports with a high injury rate due to high-intensity confrontation and high-speed rushing, under excessive use of joints muscles and ligaments [2]. Modern basketball is very powerful in terms of physical collision and confrontation, so the risk of injury to athletes during training and competition increases. The nuisance of injuries throughout different intensity levels of basketball has been a pressing issue. It is the only interface between genetic algorithm and specific application problems and is the only basis for natural selection. The genetic operations that change the internal structure of the population are all controlled by the evaluation function. Many types of

evaluation functions can be used in genetic algorithms, but they should satisfy the following condition: the function values are partially ordered. From studies and reports, it has been found that common acute injuries among basketball players include bruises, contusions, fractures, joint sprains, and muscle strains. The incidence of sports injuries is as high as 71.1%. Sports injuries not only hurt the physical and mental health of individual athletes but also affect their competitive level and restrict the development of the whole team, forming a vicious circle [3].

Injury prevention physical training is a combination of rehabilitation physical training, basic physical training, special physical training, and special technical and tactical needs together to form ways and methods, applied to athletes in different special physical training sports, injury, and functional state supervision to reduce the risk of damage and injury of athletes in the competitive state. It combines the functions of physical training and rehabilitation training [4]. Physical training as an intervention is supported by knowledge of rehabilitation medicine to ensure physical fitness for daily training. The main purpose is to improve and develop the quality of training by providing a basis for recovery training after an athlete's injury and by combining it with an injury prevention-based training philosophy.

Therefore, the inter-test path feedback is needed to use the insert pile technique to use the algorithm to guide the sample variation at the right time to achieve the predefined fuzzy test effect. The stubbing technique is carried out by adding a portion of code to the front of each basic block of the program, which gets executed during the execution of the program [5]. The purpose of this study is to investigate the digital control of physical training of athletes. By creating a relevant physical training monitoring and evaluation system, thus representing the entire training process of the athlete with data. This includes the development of the plan, the statistics of the training data, the evaluation of the stage training effect, and the feedback of the stage training effect. During training, the activation function saturates due to the excessive adjustment of the weights, so that the adjustment of the network weights almost stagnates. To avoid this situation, one is to choose a smaller initial weight, and the other is to use a smaller learning rate. The BP algorithm can make the network weights converge to a final solution, but it cannot guarantee the global optimal solution of the error hyperplane, or it may be a local minimum. The digital control is truly achieved so that the athletes' fitness level develops in the expected direction, which in turn provides a digital basis for athletes' fitness training and makes a slight contribution to promoting the development of the sport.

In the second part of this study, the existing research is analysed and explained and the shortcomings of the existing research are presented. In the third part of this study, we focus on the design of wavelet recursive fuzzy neural network algorithm and the real-time regulation system of physical training intensity. In the fourth part, we provide a detailed analysis of the neural network algorithm and the performance results of the system. In the last part of this study, we summarize and explain the results of this study.

2. Related Works

The influencing factors and implementation effects are comprehensively analyzed. The training process is arranged in slightly different proportions, with the barbell training method as the main body and comprehensive equipment as the auxiliary training. The method of administration required for basketball-specific strength is experimentally corrected, verified that a variety of combined training methods can reduce the excessive fatigue and sports injuries of basketball players [6]. It was pointed out that their characteristics and the choice of basketball training intensity methods must be compatible with each other. The development of basic and special strength training is directed towards training in centrifugal and centripetal, positive, and negative forces, static to dynamic balance, power chains, and responsiveness, and the generation of power differs from the traditional speed and explosive power in muscle power, which is produced by neuromodulation of attack energy [7]. It introduces the concept of strength quality, illustration of body strength training in different parts, classification and description of characteristics according to body position and movement characteristics, intensity division, and flexibility training principles and methods to develop a good basis for training methods and overall training rules, which can be used as a basis and direction for the promotion of special strength of each sport; there are overall strength training methods according to the body power chain and training patterns [8]. With the rehabilitation and injury prevention training, we hope to prevent the incidence of sports injuries and have the effect of postinjury rehabilitation [9].

Athletic training is a scientific and theoretical system of great complexity consisting of multiple disciplines and the cross-organization of multiple training theories and training methods guided by the corresponding theories [10]. This object maintains the trend of motion in its direction of motion. The mechanical motion of the object does not occur in isolation, it interacts with the surrounding objects, and this interaction is manifested as the mechanical motion of the moving object and the surrounding objects in the transfer process. Momentum is a physical quantity that measures mechanical motion from the perspective of mechanical motion transmission. The overall system of physical training must analyse evaluating the actual situation. The overall planning, implementation, operation of the training cycle, body load monitoring, nutrition and rehabilitation, injury prevention and fatigue recovery, and evaluation and monitoring of training are composed of seven components, which are different subsystems [11]. The assessment of explosive power and speed qualities refers to the ability of the athlete to reach the fastest speed shown in the shortest possible time with and without changing the direction of travel, and the athlete is tested based on maximum heart rate and respiratory rate for an appropriate period; the assessment of agility qualities refers to the athlete's ability to decelerate to 0 and accelerate again during a change in direction of travel [12].

The motion of a sliding mode variable structure control can be divided into two processes, namely, converging mode

and sliding mode. First, the control force will make the system state converge to the sliding mode surface motion before the system does not move to the sliding mode surface, and when the system reaches the sliding mode surface, the control law on the sliding mode surface is determined by the selected sliding mode surface and is no longer affected by external disturbances, which can ensure the stable operation of the system [13].

2.1. Wavelet Recursive Fuzzy Neural Network Physical Training Intensity Real-Time Modulation Analysis

2.1.1. Wavelet Recursive Fuzzy Neural Network Algorithm Design. Neural network control is an artificial intelligence system that emulates the human thought process; however, the initial neurons in neural networks had only two states, on and off, which could not reflect the highly nonlinear characteristics of the actual neurons [14]. As researchers in various fields at home and abroad successively invested in research, it created the rise of artificial intelligence control methods.

The input signal $x_1, x_2, \ldots, x_n$ to the basic structure of a neuron is the input signal from other neurons to this neuron. The signal path is like that of the input nerve on the actual neuron structure, that is, the dendrites, which transmit and receive information from other nerve cells. The input signal to the artificial neuron is adjusted by connection weights $w_1, w_2, \ldots, w_n$, which can be positive or negative, with positive connection weights indicating growth and negative connection weights indicating negative inhibition. Aiming at this problem, a method is proposed to minimize the conflict between the convergence speed and the steady-state error by introducing the momentum term and optimizing the momentum factor. The algorithm reduces the cost function of nonlinear principal component analysis the fastest through the optimized momentum term, so that the convergence speed of the algorithm is accelerated. After the input signals weighted by the connection weights are all summer, the excitation function on the artificial neuron is nonlinearly transformed to obtain a new output signal, which is then communicated to the other neurons of the system, and its function is equivalent to the nucleus of a nerve cell on the actual neuron structure:

$$\text{net}_j = \sum_{i=1}^{n} \left(w_{ji}^2 x_i \right) + b_{ij},$$
$$y_j = f\left(\text{net}_j\right) + b_j, \tag{1}$$

where w_{ji}^2 shows the value of the connection weight of the i-th input to the j-th neuron, b_j denotes the bias of the j-th neuron, $f(\text{net}_j)$ is the nonlinear excitation function of the neuron and converts the sum of the product weights at the input to the value at the output. A single neuron can process and learn data if multiple artificial neurons can be combined into a complete neural network after some proper arrangement. The number of layers of the designed neural

network can be decided according to the complexity of the problem to be solved, the classification of neural networks in terms of the number of layers can be broadly classified as single-layer neural networks and multi-layer neural networks, and its structure is shown in Figure 1.

As the neural network can learn online, the fuzzy system has the characteristics of logical description and judgment, wavelet processing can analyse time-varying signals, and the recursive structure gives the system better dynamic characteristics [15]. The recursive wavelet fuzzy neural network is structurally divided into a total of five layers, with three implicit layers, namely, the affiliation function layer, the rule layer, and the recursive wavelet function layer. The neural network controller combines the neural network with fuzzy logic, wavelet processing, and recursive structure to improve its processing capability and accuracy and to solve the shortcomings of static mapping. The transfer relationship between each layer will be explained next.

Both neuron nodes in this layer are input nodes, which are equivalent to the input variables. The error of the H-type motion platform includes the position synchronization error of the two axes and the speed synchronization error of the two axes. The linear transformation relationship between the input and output of the neurons in this layer can be expressed as follows:

$$\text{net}_j^1 (N) = x_i^2,$$
$$y_j^1 (N) = \text{net}_j^1 (N), \quad j = 1, 2, \tag{2}$$

where x_i^2 is the input signal of the input layer, and the input variables are the position synchronization error and velocity synchronization error $x_1^1 = e_{y_1} + e_{y_2}$, e_{y_1} and the e_{y_2} position tracking error of the Y_1 and Y_2 linear motors, respectively; $y^1 (N)$ is the output signal of the input layer; N is the number of samples.

$$y_j^2 (N) = f_j^2 \left(exp \, \text{net}_j^2 (N) N \right), \quad j = 1, 2, \ldots, 6. \tag{3}$$

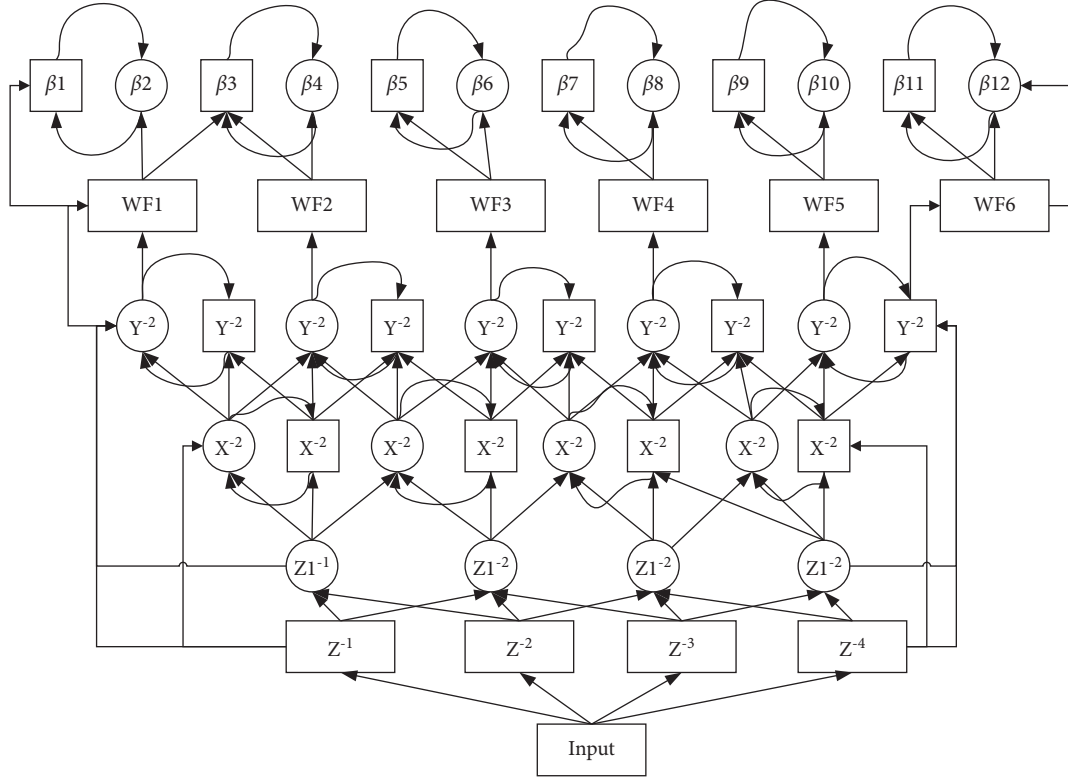
The output of each neuron in the input layer corresponds to 3 neurons in the affiliation function layer, the nonlinear transformation in the affiliation function layer uses Gaussian function, and this transformation method incorporates the fuzzy logic inference method so that the inductive performance of the network is improved. The mutation direction is provided for the sample mutation; then the neural network is used to build a program flow flattening model, the branch logic of the program is simulated smoothly, and a more effective mutation position is obtained through gradient calculation. Here, $x_i^2 (N) = y_i^2 (N)$ is the output of the input layer; m_j is the mean of the Gaussian function of the affiliation function layer; σ_j is the standard deviation of the Gaussian function of the affiliation function layer; $y_i^2 (N)$ is the output of the neurons of the affiliation function layer. This layer contains wavelet function operations, recursive operations, and the posterior part of fuzzy logic rules. The output of the wavelet function is ψ_k, denoted as follows:


FIGURE 1: Wavelet recurrent type neural network.

$$\phi_{ik}\left(x_i^1\right) = \frac{1}{\sqrt{|b_{ik}|}}\left[1 + \frac{\left(x_i^1 - a_{ik}^2\right)}{b_{ik}^2}\right]\exp\left[1 - \frac{\left(x_i^1 - a_{ik}^2\right)^2}{2b_{ik}^2}\right],$$
(4)

$$\psi_k = \sum_i w_{ik}^2 \phi_{ik}\left(x_i^1\right).$$

where is the i-th wavelet function in the k-th neuron of ϕ_{ik} this layer; ψ_k is the output of the k-th wavelet function; x_i^1 is the connection weight of the wavelet function; a_{ik} and b_{ik} are the translation factor and scaling factor of the wavelet function, respectively. From Figure 2, we can see the relationship between different translation factors and scaling factors on the input and output of wavelet functions.

The gradient descent method, also known as the error backpropagation algorithm, is a basic learning algorithm in the regulation process of neural network systems. The computational process of the gradient descent method is to solve for the minimum value along the direction of the decreasing gradient or the maximum value along the direction of the increasing gradient and to adjust the parameters in the neural network in a feedback manner so that the system error gradually approaches the minimum value. The energy function V is first defined as follows:

$$V = \frac{1}{4}e^2.$$
(5)

The recursive wavelet fuzzy neural network with parameter learning updates the iterative algorithm in the output layer with the error term, as shown in the following equation:
FIGURE 2: Schematic diagram of the wavelet function.

$$\delta_o^5 = \frac{\partial V}{\partial e}\frac{\partial e}{\partial y_o^5}.$$
(6)

The algorithm first establishes the most ideal access network and the least ideal access network. The attribute parameters of the most ideal access network are relatively good, and a positive ideal solution can be obtained by normalizing the attribute parameters of the most ideal

access network. However, the attribute parameters of the least ideal access network are relatively poor, and a negative ideal solution can be obtained by normalizing the attribute parameters of the least ideal access network. By calculating the geometric distance between each candidate network and the positive and negative ideal solutions, the proximity of each candidate network to the positive and negative ideal solutions is obtained. These closenesses are then sorted. The closest network is the one closest to the ideal solution [16].

The fourth layer of the fuzzy neural network model is the fuzzy inference layer. Since each alternative network score corresponds to three layers (L, M, and H), there are a total of 3 M nodes in this layer. The input and output of performing the operation at the fourth layer node yield are expressed as

$$I_i^4 = \sum_{j \in G_i} x_{ij}^4,$$
$$O_i^4 = \max\left(1, I_i^4\right), \tag{7}$$

The first part fuzzifies the input alternative network parameters, establishes fuzzy rules, outputs the scores of the alternative networks, and relies on the adaptive learning capability of the neural network for error backpropagation in the process of network selection to adaptively adjust the affiliation function parameters, which in turn enables the fuzzy neural network to be trained. After the scores of each alternative network are obtained through training, the scores of each alternative network are weighted according to the degree of preference of different business users for each alternative network, and the alternative network with the highest weighted score is selected to serve the users. The reason is found in time and the corresponding adjustments are made until the goal is achieved. Sports injury is a topic that every athlete will face, and it is the most likely to occur in training and competition. The main part of the second part is to use the dragonfly algorithm to find the optimal initial parameters of the Gaussian affiliation function of the fuzzy neural network when no fuzzy neural network training is performed until the end of the iteration, and the food location found by the dragonfly population is the optimal initial parameter of the Gaussian affiliation function.

2.1.2. Physical Training Intensity Real-Time Regulation System Design. The motion data acquisition side consists of a motion acquisition module and an adjustable weighted dumbbell. The motion acquisition module is placed in a 3D printed circular housing with dimensions of 104 mm outer diameter, 20 mm inner diameter, and 20 mm thickness, which is fixed directly on the threaded rod. The motion acquisition module mainly includes a microprocessor module, a power supply module, and a sensor module. Among them, the microprocessor module uses an ESP8266 microcontroller with a built-in Wi-Fi module, the sensor module uses a JY901 motion sensor,

and the power supply module uses a lithium polymer battery and charging circuit [17]. The microprocessor module is the core of the system, and the ESP8266 developed by Loxin is used in this system, which provides a highly integrated Wi-Fi SoC solution with low power consumption, compact design, and high stability to meet the requirements of the system.

The ESP8266 has a built-in ultra-low-power Ten silica L106 32 bit RISC processor with a CPU clock speed of up to 160 MHz and supports real-time operating systems (RTOSs) and Wi-Fi protocol stacks, leaving up to 80% of the processing power for application programming and development. Its high level of integration, with standard digital peripheral interfaces, antenna switches, RF, power amplifiers, low-noise amplifiers, filters, and power management modules, allows it to be significantly reduced in size. At the same time, the ESP8266 features low power consumption and is designed for mobile devices, wearable electronics, and IoT applications, while having ultra-low power consumption. The functional principle of the ESP8266 is shown in Figure 3.

After powering up the data acquisition module, the program first initializes the MCU and the sensor module, searches for a Wi-Fi network, and joins it to establish a secondary peer-to-peer network. At this point, the MCU starts collecting data from the sensor module. A brief description of the process of the distribution network follows. There are two cases in which the ESP8266 needs to be wired to connect to a specified Wi-Fi network. The first is when the ESP8266 is first powered up, and the second is when the user has changed the network environment. The traditional method of network pairing is to write the wireless network to be connected into the ESP8266 program, and when the module is powered on, it automatically searches for the specified wireless network and connects to it. This pairing method is easy and fast but has the drawback that it cannot be changed when the wireless network environment changes or when the user needs to reconnect to another wireless network. Therefore, there is a need to improve the network allocation procedure to be able to achieve more flexible network allocation.

In the data layer, the server receives the data information from the collector and the client and then needs to store the data on the server and perform some related data processing. Therefore, a database of user information and user workout information needs to be created for easy management. The server uses an SQLite database, and the established database contains the following data tables as listed in Table 1.

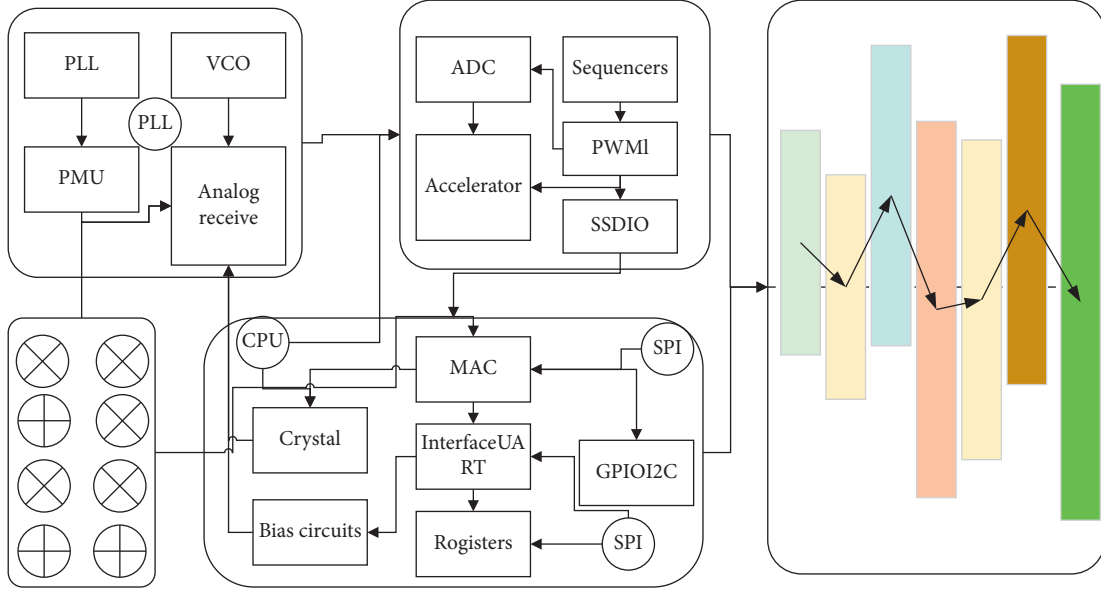
The collected acceleration signal line is analysed to determine whether the signal needs low-pass or high-pass filtering processing. After a lot of experiments, it was found that the average time to do a dumbbell movement is about 3 s, which corresponds to a frequency of 1/3 Hz, which belongs to the low-frequency part of the signal [18]. It is used under the supervision of athletes in different special physical training sports, injuries, and functional states to reduce the risk of injury and injury of athletes in


FIGURE 3: Functional schematic.

yPalstance	double	Y-axis angle

competitive conditions. It combines the functions of physical training and rehabilitation training. The acceleration signal changes to a certain extent to reflect the changes of the human dumbbell exercise, so the main frequency range of the acceleration signal is mainly distributed in the range of 0–10 Hz. FFT transformation is performed on the collected acceleration signal and its spectrum is viewed, as shown in Figure 4. It can be found that the main frequency components are within 5 Hz, and the amplitude of the signal above 5 Hz is almost negligible. The acceleration signal is low-pass filtered to retain the signal components from 0 to 10 Hz and remove the effect of high-frequency noise.

In this study, second-order low pass filtering will be used to filter the signal. The expression of the second-order filter transfer function is given by the following equation:

$$d \cdot \frac{d^2 y(t)}{dt^2} - e \cdot \frac{dy(t)}{dt} - c_2 y(t) = a \cdot \frac{d^2 x(t)}{dt^2} - b \cdot \frac{dx(t)}{dt} - c_1 x(t). \tag{8}$$

$y(t)$ is the output signal, and $x(t)$ is the input signal. For a dumbbell movement that rotates around an axis, such as a bending movement, the curve with the largest variance among the three-axis angular velocity curves
FIGURE 4: Acceleration signal spectrum.

collected at the acquisition end is selected as the judgment curve of the movement endpoint. The over-zero point of the curve is the highest or lowest point of a single dumbbell action, and the curve between the two zero points is a cycle curve of the dumbbell action. Since the collected data are discrete points and not a continuous curve, and these discrete data cannot be well fitted using a sine function, it is not possible to directly find out the over-zero point of the angle curve. In this study, a moving average filter and an energy threshold judgment are introduced to find the valid angle curve over zero points. The period of a single dumbbell action is about 3 seconds and the sampling frequency is 100 Hz, we can know that there are about 300 discrete points in the angle curve for each dumbbell action.

2.1.3. Experimental Design for Physical Training Moderation.

Evaluation is the key link of the digital control process, the setting, and modification, and improvement of training objectives, the formulation, implementation, and regulation of training plan, the evaluation, identification, and feedback of training results all need the participation of evaluation system. Making full use of the guidance, identification, feedback, and motivation of evaluation indexes, a complete set of special physical quality evaluation systems for javelin throwers is established to evaluate the physical fitness level of athletes, such as avoiding the one-sidedness caused by the evaluation of individual physical quality indexes and comparing the gap between the strong and weak items of individual physical quality [19]. According to the average price result, we can carry out targeted training to improve the athletes' physical fitness level. Physical fitness evaluation is "the assessment of the real state of the athlete's physical movement ability."

The comprehensive level of physical fitness in this study refers to the average level of 10 physical fitness indicators of athletes. As the athletes' fitness level improves, the growth rate of each physical quality gradually decreases and the athletes' pursuit of physical quality gradually fades. Long-term accumulation may lead to athletes' shortcomings in physical fitness and gradually widen the distance between them and excellent athletes, which is not conducive to athletes' long-term development. The sample mutation is guided by the timely use of the algorithm to achieve the purpose of the present fuzzing test effect. In response to the above situation, the comprehensive evaluation standard of physical fitness applied to evaluate athletes comprehensively, so that the overall physical fitness level of athletes can be steadily improved and the concept of reflecting the overall level by single quality is rejected, as listed in Table 2.

The specificity of basketball sports is the need for athletes to have the strong physical strength to accomplish the embodiment of technical movements. In the study, no significant variability was found in the relative peak rotational torque of hip and knee flexors and extensors on both sides in our male basketball players. The results showed that knee strength and knee joint strength were more balanced, and there was no significant difference between the left and right-side surfaces [20].

The second phase is the competition period. It can be observed that in the second phase, with the intervention of this training method, the player's basic strength does not decline, but still maintains a small growth, but not as much as in the first phase, which can be observed by the T-value less than -10. The goal of Phase II is to maintain the player's base strength capacity so that it does not decrease due to the high level of competition and exertion during the competition, allowing the player to maintain peak physical condition for the entire season.

3. Results and Analysis

3.1. Performance Results of Wavelet Recursive Fuzzy Neural Network Algorithm.

The two-axis position synchronization error when using a global sliding mode control method

combined with a recursive wavelet fuzzy neural network synchronization compensator. Compared with the cross-coupled controller, the maximum value of the dual-axis position synchronization error is reduced from $16.78\,\mu m$ to $1.02\,\mu m$, and the maximum magnitude during regulation is $15.63\,\mu m$. Using the recursive wavelet fuzzy neural network synchronization compensator designed in this chapter between the two axes can effectively improve the anti-interference performance of the platform compared to the cross-coupled control compensator.

To facilitate the extraction of feature values, 50,000 sets of seems signals collected from the plate support exercise were analysed by grouping every 200 data points into one group, with a total of 250 sets of data, using the first 80% sets of data for network training and the last 20% sets of data for prediction. The prediction results are shown below, where the x-axis represents the data groups and the y-axis represents the frequency values of MF (MPF). The data fitting curve is shown in Figure 5.

The recursive wavelet fuzzy neural network synchronization compensator designed in this study improves the synchronization performance of the dual axes in the Y direction compared with the cross-coupling control compensator, and it can instantly adjust the compensation signal of the dual axes under the change of the beam load, improve the tracking accuracy of the system in the single axis, suppress the influence of the sudden added load on the system, and make the system have a better antidisturbance performance, including plan formulation, training data statistics, stage training effect evaluation, and stage training effect feedback.

If adaptive adjustment of the size of the parameters ensures that the sum of squares of the network errors is minimized, network training can greatly improve the generalization ability of the network by effectively controlling the complexity of the network. During the neural network training, a correction function for the performance function is introduced based on the conventional mean square error performance function. The performance of the neural network is analysed by comparing the mean square error MSE before and after optimization, and the results are shown in Figure 6.

The network performance indexes obtained by LM and SCG optimization methods are better than the original
FIGURE 5: Neural network prediction curve fit for MPF values.

FIGURE 6: Mean square error MSE of MF before and after optimization for each channel.

indexes, in which the LM algorithm is the best, it is known from the quantitative data that the application of the LM optimization algorithm has a great improvement in the accuracy of the designed BP network, and it is also more accurate for the prediction effect, which reduces the prediction error and achieves the purpose of optimization.

FIGURE 7: Experimental results.

The simulation results show that the recursive wavelet fuzzy neural network compensation controller can dynamically compensate the single-axis tracking error and the inter-axis synchronization error of the system so that the tracking error and synchronization error of the system are effectively reduced and the influence of the load change and uncertain disturbance terms on the control process of the system is reduced, thus improving the control accuracy and robustness of the H-type motion platform.

3.2. Experimental Results of Real-Time Modulation of Physical Training Intensity. When designing a training program, the formulation of phased training objectives and the evaluation of training results are of great importance. The development of training objectives is the premise and basis for the entire training process, and the evaluation of training results is a key step in testing the training program. The combination of these two can be used to test the effectiveness of the current phase of training and to further grasp the overall situation of each athlete's training effectiveness throughout the year.

Compare the "actual training results" with the "expected target results," if there is no significant difference between the two, then the original training plan is continued to implement; if the difference between the two is more obvious, then the reasons for the deviation are analysed, timely adjustment of the training plan is carried out, and different feedback means are taken. In the following section, we will analyse the completion of the target in the preparation period, the first competition period, and the second competition period, as well as the reasons for the deviation, and point out the adjustment measures to "correct the deviation," as shown in Figure 7.

If all the training data of the athlete is normal, and the training intensity and training volume meet the training

requirements, but the deviation still exists and is outside the error allowance, the reason is most likely that the goal is set too high. The second is that the athlete fails to maintain a good view of training. This is manifested by the abnormal training data of a certain athlete, where the load intensity, load volume, and target completion rate are significantly lower than those of other athletes. Negative ones indicate reverse inhibition. The connection weight is like the ganglion in the actual neuron structure, which is used to indicate the connection strength between two nerve cells. After continuous learning and adjustment, the output of the neuron can gradually approach the required expected value.

Coaches should look at the athletes' strengths and weaknesses from a "developmental" perspective and combine "multi-year training goals," "annual training goals," "large cycle training goals," and so on. The coach should design a long-term training plan, continue to develop the athlete's physical strengths, and gradually adjust the athlete's shortcomings. Physical training needs to be a combination of work and rest, and a good balance between training and recovery time.

4. Conclusion

In the past, sports medicine has focused on physiologically based recovery and rehabilitation but has neglected to focus on rehabilitation physical training and injury prevention physical training. This has led to repeated injuries and long recovery times for basketball players, as well as an increased risk of injury unknowingly because of injury and lack of indepth knowledge of physical training. There are major shortcomings in fitness testing, program development, training arrangements, training methods, training monitoring, and effect evaluation, which are the main reasons for the high incidence of sports injuries. Through the assessment and diagnosis of athletes' physical fitness status and real-time monitoring, the training quality and training load control of physical training can be ensured to effectively reduce the risk of sports injuries. In addition, through the eight basic injury prevention tests, athletes can be targeted to improve their ability to prevent sports injuries and to maintain their athletic performance through functional training and sports medicine treatment programs after suffering a sports injury, and to recover their original athletic performance in a short period and then to improve it. Extracting and analysing the eigenvalues in the time and frequency domains, a multilayer algorithm incorporating decision trees were designed to successfully identify 8 movements. The experimental results show that the algorithm achieves a combined recognition rate of 96.3%.

Cardiovascular disease (CVD) poses a serious threat to urban health with the development of urbanization. There are multifaceted and comprehensive influencing factors for CVD, so clarifying the spatial distribution characteristics of CVD and multiple environmental influencing factors is conducive to improving the active health intervention of urban environment and promoting the sustainable development of cities The spatial distribution characteristics of CVD deaths in a certain district, Bengbu City, Huaihe River Basin, China, in 2019 were explored, and the correlation between multiple environmental factors and CVD mortality was investigated in this study, to reveal the action mechanism of multiple environmental factors affecting the risk of mortality. Relevant studies have shown that (1) CVD deaths are characterized as follows: male deaths are more than females; the mortality is higher in those of higher age; most of them are unemployed; cardiocerebral infarction is the main cause of death; and the deaths are mainly distributed in the central city and near the old urban area. (2) The increased CVD mortality can be attributed to the increased density of restaurants and cigarette and wine shops around the residential area, the increased traffic volume, the dense residential and spatial forms, the low green space coverage, and the distance from rivers. Therefore, appropriate urban planning and policies can improve the active health interventions in cities and reduce CVD mortality.

1. Introduction

A great number of studies have demonstrated the high mortality and disability rate of cardiovascular disease (CVD) [1] and the resulting global burden of diseases [2]. The traditional risk factors for CVD include hypertension, diabetes, dyslipidemia, obesity, smoking, alcohol consumption, and lack of physical exercise. However, under the biological-psychosocial medical model, the influencing factors on health are multifaceted and comprehensive, including environmental factors. Previous studies have shown that the urban population is more likely to suffer from cardiovascular diseases than the rural population in some developing countries [3]. Industrialization, urbanization, aging, and constant changes in the ecological environment and lifestyle have brought challenges to people's health in the rapid urban development. A lot of cities are experiencing a major shift in the disease spectrum from infectious diseases to chronic noncommunicable diseases. Therefore, it is conducive to improving active health interventions in urban environment and promoting sustainable urban development in the future to identify the mortality distribution characteristics of CVD and environmental influencing factors.

Previous studies have shown that unreasonable diet, excessive oil, and salt intake will increase the pressure of human circulatory system [4], thereby leading to CVD morbidity and mortality. The increase in the amount of physical activity, such as work, commuting, and leisure, will appropriately reduce the risk of CVD-related death [5], and the accessibility of sports and leisure activity facilities and open space will also have an influence on the level of physical activity of residents [6]. Residents will tend to commute by non-motor vehicles and increase daily activities provided that the urban road slow traffic system is perfect and the bus

stops are dense [7]. In addition, residents engaged in manual work will have increased daily activities [8], thus reducing the risk of death. Air pollution [9–11] and noise pollution [12] constitute the important risk factors for CVD, of which long-term air pollution has a greater impact on CVD than short-term one [13]. The closer distance to the pollution source or the greater density of the surrounding pollution sources will increase the possibility of exposure to pollutants [14, 15], including a large number of industrial pollutants [16], the cooking fumes from [17], the exhaust gas emissions of motor vehicles, and urban transportation facilities, such as railways, subway lines, and airports [18]. Roads and restaurants produce noise pollution while causing air pollution, thereby leading to the occurrence of cardiovascular diseases [19]. The nearer distance from rivers and the higher green space coverage can effectively reduce the concentration of particulate matter (Douglas, W., and [20–22]) and lower CVD mortality. Cold weather and sudden temperature drop in winter are prone to causing overreaction of human function, resulting in death from acute CVD [23, 24]. The difference in temperature in different urban regions will lead to the difference in mortality.

In general, current studies focus on the macro-level of county [25], prefecture [26], and state [25], but neglect the small scales, such as communities and streets; meanwhile, the consideration of environmental factors is relatively simple, and the influence of aging population and old urban areas is relatively ignored. A large number of people in the Huaihe River Basin in Central China died of chronic diseases caused by the environment many years ago [27]. The urban environmental pollution is relatively serious now, seriously endangering the physical and mental health of residents. In view of this, the distribution characteristics of CVD deaths were analyzed, and the influences of multiple environmental factors on CVD were systematically investigated in this study with the old urban area in Bengbu City of Huaihe River Basin as the subject, to reduce CVD mortality by proper urban planning and policies, and provide certain research ideas for healthy city construction in other areas of Huaihe River Basin.

2. Materials and Methods

2.1. Study Area.
Bengbu City, located in the south of Huaihe River Basin, China, is characterized by high population density and rapid urbanization [28]. Bengbu was an important industrial city and traffic hub in China before, where a large number of chemical, pharmaceutical, and building materials enterprises and the heavy traffic pressure have produced a large amount of pollution in Bengbu, seriously affecting the physical and mental health of residents. A certain district is located in the Western old urban area of Bengbu City, adjacent to the commercial and cultural center of the city in the east and the Huaihe River (one of the seven major rivers in China) in the north, and it is also the administrative area with the largest population in Bengbu City, so it is suitable for the research on urban environment and population health. The study area consisted of 12 blocks numbered YH01-YH12 in a certain district, which were divided into 2,744 spatial units by 100 m grid (Figure 1). The study area is located in the mid-latitude region, where northeasterly wind is the most prevalent throughout the year, the average temperature in January is 1°C, and it is susceptible to cold waves in winter.

2.2. Data Sources

2.2.1. Sources of Data Related to CVD.
The data of cardiovascular disease (CVD) mortality were collected from the population whose cause of death was cardiovascular disease (ICD-10 code I00-I99) determined by Bengbu Health Commission in 2019, including detailed address, age, gender, and occupation before death. Inpatients whose home addresses and affiliations were not within the study area were excluded, so the final number was 469 in total. The number of resident population in a certain district in 2019 was derived from the official bulletin of Bengbu National Bureau of Statistics.

2.2.2. Environmental Data Sources.
The land use data and built environment data in environmental data were obtained from the Anhui Urban & Rural Planning and Design Institute, and the data contained the main uses of each land in a certain district in 2019, as shown in Figure 2(a), which included roads, green space and river, residential land, industrial land according to urban land classification, and the base area and floor number of each building. Commercial and bus stops are derived from open-source point-of-interest (POI) data, which are characterized by large sample size, wide coverage, and detailed spatial resolution, making spatial analysis more comprehensive, objective, and in-depth, as shown in Figure 2(b). Data of environmental pollution indexes were obtained from the Bengbu Bureau of Ecology and Environment, and the pollution values of each spatial unit were obtained by the interpolation method for the pollution monitoring point data. Data of land surface temperature and vegetation coverage were derived from Landsat 8 remote sensing data in January 2019 provided by USGS and coded LC81210372019023LGN00.

2.3. Influencing Factor Index System.
To explore the distribution characteristics of cardiovascular disease (CVD) and environmental influencing factors in urban residents, the basic characteristics and spatial distribution characteristics of CVD deaths were analyzed, and the correlation between various environmental influencing factors and CVD mortality was explored (Figure 3). Environmental influencing factors included land use, road traffic, spatial form, and natural environment, with their potential impacts on CVD shown in Table 1. The calculation formula for CVD mortality is as follows:

$$\text{Mortality} = \frac{\text{Nc}}{\text{Np}} \times 100\%, \tag{1}$$

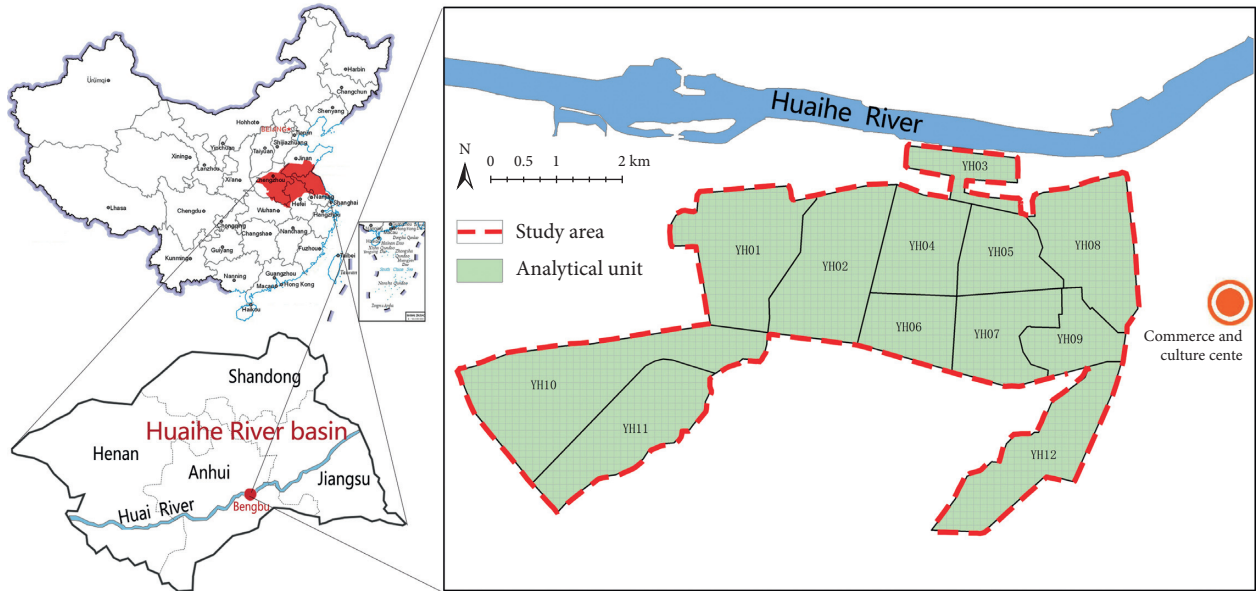
where Nc is the number of deaths due to CVD in a unit and Np is the total population in a unit.


Figure 1: Area bitmap.

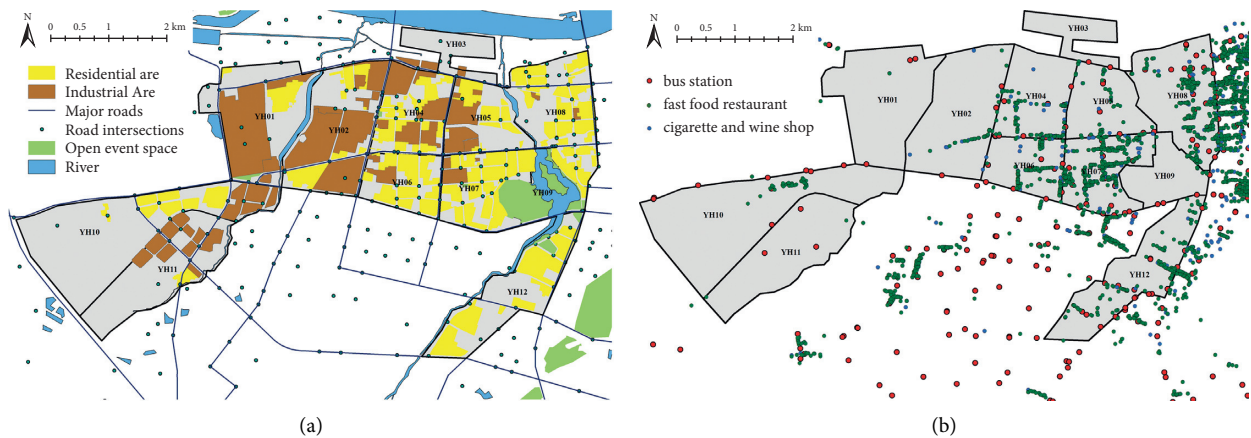
(a)   (b)


Figure 2: Present distribution.
Figure 3: Conceptual framework.

2.4. Study Methods

2.4.1. Spatial Autocorrelation Assessment. Global spatial autocorrelation [29] is usually measured by Moran's I, and

the aggregation of subregional geospatial CVD deaths is judged according to the spatial distribution pattern of the whole region. Moran's I range is $[-1, 1]$, and the larger value indicates the more obvious spatial correlation, and the

TABLE 1: Environmental influencing factors.

Category	Subcategory	Variable	Unit	Definition	Potential impact of hypothesis
Land use	Live	Residential density	%	Living area/total land area	Cause pollution and physical and mental stress
	Industry	Distance from the nearest industry	m	Distance from the nearest industry	The closer you are to industry, the more pollution you get
	Business	Fast-food restaurant density	Pcs/ha	Number of fast-food restaurants in 500 m buffer zone/buffer zone area	Intake relatively high salt and oil
		Tobacco and liquor shop density	Pcs/ha	Number of tobacco and liquor stores in 500 m buffer zone/buffer zone area	Increase the risk of alcohol and smoking
	Open the activity space	Distance from the nearest open space	m	Distance from the nearest open space	It is more convenient to exercise and relax
	Vegetation cover	Normalized difference vegetation index (NDVI)	—	NDVI in 2019	Vegetation coverage can reduce air pollution, increase green vision rate, and delight body and mind
Road transport	Traffic	Road network density	m/ha	Road length/total land area	Increase air and noise pollution
	Road intersection	Road intersection density	Pcs/ha	Number of road intersections in 500 m buffer zone/buffer zone area	More air and noise pollution
	Bus stop	Bus stop density	Pcs/ha	Number of bus stops in 500 m buffer zone/buffer zone area	It is more convenient to travel and increase the amount of activities
Spatial form	Building density	Building coverage	%	Total area of building basement/total area of land	High density reduces the wind speed, which increases the concentration of air pollutants and makes people depressed
	Volume fraction	Volume fraction	—	Total construction area/total land area	High density reduces the wind speed, which increases the concentration of air pollutants and makes people depressed
Natural environment	River	Distance from the nearest river	m	Distance from the nearest river	Adsorption of air particles by water body
	Particulate matter (PM) (Ground) surface temperature	Mean PM$_{2.5}$	Ug/m^3	Average PM$_{2.5}$ in 2019	Increase air pollution
		Mean PM$_{10}$	Ug/m^3	Average PM$_{10}$ in 2019	Increase air pollution
		Mean surface temperature	°C	Surface temperature in January 2019	Cold winter temperatures increase the risk of death

smaller value indicates the greater spatial difference, with the specific calculation formula as follows:

$$\text{Moran's } I = \frac{n \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} (x_i - \overline{x})(x_j - \overline{x})}{\sum_{i=1}^{n} w_{ij} \sum_{j=1}^{n} \sum_{i=1}^{n} (x_i - \overline{x})^2} \ (i \neq j), \qquad (2)$$

where n is the number of study units; x_i and x_j represent the CVD mortality in area i and area j, respectively. $\overline{x}$ represents the average CVD mortality; W_{ij} represents the spatial weight matrix.

Local spatial autocorrelation [30] can reveal the heterogeneity of local space, make up for the atypical characteristics of local areas in the whole region, and fully reflect the variation trend of local geospatial epidemic risk. The spatial difference in CVD mortality was measured by local indicators of spatial association (LISA) in this study, with the calculation formula shown as follows:

$$\text{LISA}_i = z_i \sum_j w_{ij} z_j, \qquad (3)$$

where z_i and z_j represent the standardized values of CVD mortality in area i and area j, respectively. W_{ij} represents the

spatial weight matrix. In the LISA of local spatial autocorrelation, CVD mortality can be divided into four categories: high-high clustering (H-H), high-value clustering; low-low clustering (L-L), low-value clustering; high-low clustering (H-L), outliers with high values mainly surrounded by low values; and low-high clustering (L-H), outliers with low values mainly surrounded by high values.

2.4.2. Spearman's Rank Correlation. To investigate the relationship between CVD and environmental factors, the correlation between the mortality rate of CVD (dependent variable) and the values of various environmental factors (independent variables) was comprehensively measured by Spearman's rank correlation [31], with the specific formula referred to formula (3). Compared with Pearson's correlation, Spearman's rank correlation can make up for the fact that the correlation of environmental factor values may not be linear and are interfered with detection error and other factors, thus making the correlation more significant [32]. CVD mortality and environmental factor values were subject

to normalized processing (value range of [0, 1]), which was used to balance the dimensional gap of data and enable different data to be counted under the same conditions.

$$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}, \quad (4)$$

where ρ is Spearman's correlation coefficient, with the value range of [−1, 1], and the larger absolute value indicates the stronger correlation. n represents the number of areas of CVD mortality, and d_i represents the rank difference between dependent variable (CVD mortality) and independent variable (environmental influencing factor values).

3. Results

3.1. Basic Characteristics of CVD Deaths. A total of 469 people died of cardiovascular disease (CVD) in the study area in 2019 according to the statistics of collected death data, with the basic characteristics of death population, such as gender, age, occupation, death season, and specific diseases leading to death, shown in Table 2.

The analysis results showed that the mortality among male CVD patients was significantly higher than female patients, with a ratio of about 1.18 : 1. The elderly over 80 years accounted for 54.15% of CVD deaths, and those under 60 years only accounted for about 10%, indicating that the higher the age, the higher the mortality. Winter (December to February of the following year) and autumn (September to November) were the most frequent periods of CVD deaths, accounting for 27.93% and 27.72% of the total number of deaths, respectively, and the mortality in autumn and winter was 1.25 times higher than that in spring and summer. The largest number of CVD deaths was among the unemployed (26.01%), followed by workers (6.61%), freelancers (5.54%), and farmers (2.56%). Among the specific diseases causing death, cerebral infarction and myocardial infarction accounted for 24.09% and 19.62%, followed by coronary heart disease (17.70%).

3.2. Spatial Distribution of CVD Deaths. In 2019, there was a significant difference in the number of CVD deaths among different units in the study area. YH07 and YH08 accounted for 73.56% in terms of deaths, of which YH08 had the largest number of CVD deaths, namely 180, followed by 165 deaths in YH07 and no deaths in YH10 and YH11. The kernel density analysis of CVD deaths was conducted with ArcGIS software (Figure 4), and unit density of CVD deaths in the study area could be calculated, which could intuitively reflect the distribution of CVD deaths in a continuous area [33]. The analysis results suggested that CVD deaths were mainly distributed in the vicinity of Unit YH09 in Zhanggongshan Park and the north of Unit YH08 near the Huaihe River. The area near YH09 was an old urban area of Bengbu, characterized by high population density and serious aging. A total of 365 people died within the 1 km buffer zone of

Zhanggongshan Park, accounting for 77.82% of the total deaths; moreover, the density of deaths was lower in the area farther away from Zhanggongshan Park. The north of YH08 is also a large population gathering area, close to the central city of Bengbu and Huaihe River in the east.

Among 2,744 study units, 1,053 units containing residential land (i.e., unit population greater than 0) were taken as the research samples after the outlier samples were excluded. The normalized mean value of the calculated CVD mortality values of all study units was normalized to be 0.008, with the standard deviation of 0.055, indicating that there were significant spatial differences in the CVD mortality. Global Moran's I index analysis showed that the spatial distribution of normalized mortality index was of spatial autocorrelation (Moran's $I > 0$, $Z = 2.192$, $P < 0.05$), indicating that there was a significant spatial aggregation phenomenon in the distribution of CVD deaths. In addition, there was a local spatial autocorrelation in the normalized mortality index according to the spatial distribution of LISA clustering (Figure 5), in which H-H clustering (22) was mainly distributed in the middle of YH08, forming a significant H-H clustering of CVD mortality. L-L clusters (121) were mainly distributed in YH05, YH10, and YH12, with a few scattered clusters in other units, showing more L-L clusters in the CVD mortality.

3.3. Relationship between Environmental Factors and CVD Mortality. The results of Spearman's rank correlation analysis are shown in Table 3. Among land use, road traffic, spatial form, and natural environment, there are 14 environmental factors showing significant correlation and statistical significance with CVD mortality ($P < 0.05$). There was no correlation between industry and CVD mortality ($P > 0.05$). The spatial distribution of environmental influencing factors is shown in Figure 6.

3.3.1. Land Use. The model showed that the residential density was positively correlated with the CVD mortality ($\rho = 0.127$), indicating that the higher the residential density, the higher the CVD mortality. The density of fast-food restaurants and the density of cigarette and wine shops showed a significant positive correlation with the CVD mortality in the 500 m buffer zone ($\rho = 0.287$, $\rho = 0.286$), indicating that the higher the density of fast-food restaurants and cigarette and wine shops, the higher the mortality. There was a significant negative correlation between the nearest distance to the open space and the CVD mortality ($\rho = -0.189$), indicating that the farther from the park, the lower the CVD mortality. The normalized difference vegetation index (NDVI) in January showed a significant negative correlation with CVD mortality ($\rho = -0.179$), indicating that the higher the vegetation coverage, the lower the CVD mortality.

3.3.2. Road Traffic. The model showed that the road network density and the intersections within the 500 m buffer zone were significantly positively correlated with the CVD

TABLE 2: Statistics of CVD death population.

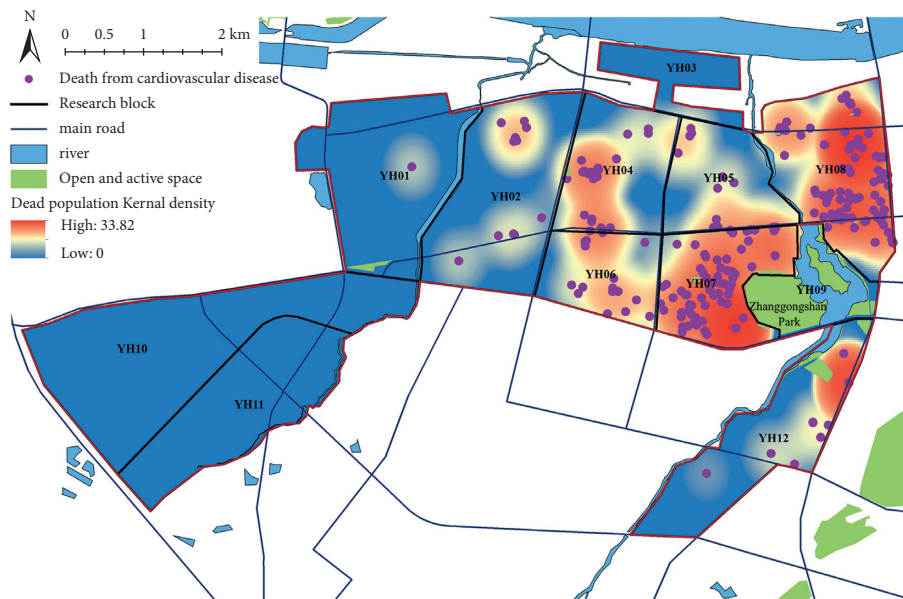
Category	Classify	Death toll	Proportion of deaths (%)
Gender	Man	254	54.16
	Woman	215	45.84
Age	≥80 years old	254	54.15
	70–79 years old	109	23.24
	60–69 years	58	12.37
	<60 years old	48	10.23
Occupation	Unemployed	122	26.01
	Worker	31	6.61
	Individual operator	26	5.54
	Farmer	12	2.56
	Other	278	59.27
Dead season	Spring (March–May)	110	23.45
	Summer (June–August)	98	20.90
	Autumn (September–November)	130	27.72
	Winter (December–February of the following year)	131	27.93
Specific diseases leading to death	Cerebral infarction	113	24.09
	Cardiac infarction	92	19.62
	Coronary heart disease	83	17.70
	Encephalorrhagia	55	11.73
	Pulmonary heart disease	43	9.17
	Other	83	17.70


FIGURE 4: Distribution map of CVD death population.

mortality ($\rho = 0.138$, $\rho = 0.220$), indicating that the greater the traffic volume, the higher the CVD mortality. Meanwhile, there was a significant positive correlation between the density of bus stops and the CVD mortality within the 500 m buffer zone ($\rho = 0.238$), indicating that there was a lower risk of death among the people living in the area with sparse bus stops.

3.3.3. Spatial Form. The model showed that building density and floor area ratio were significantly positively correlated with CVD mortality, with the correlation coefficients of 0.104 and 0.115, indicating that high-density space would increase the CVD mortality.

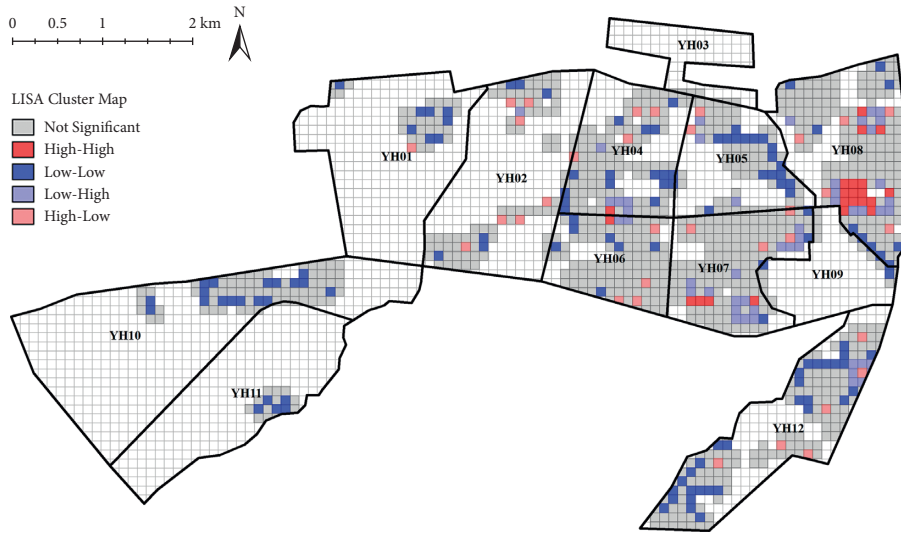
3.3.4. Natural Environment. There was a significant positive correlation between the distance to the nearest river and the CVD mortality ($\rho = 0.121$), indicating that the closer to the river, the lower the CVD mortality. The average annual $PM_{2.5}$ and PM_{10} were significantly positively correlated with the CVD mortality, with the correlation coefficients of 0.088 and 0.072, indicating that the higher the average annual particulate matter (PM) concentration, the higher the CVD


FIGURE 5: Spatial autocorrelation distribution of CVD normalized mortality index.

TABLE 3: Correlation between environmental factors and CVD mortality.

Category	Subcategory	Variable	P (correlation coefficient)	P value (double side)
	Live	Residential density	0.127*	0.000
	Business	Density of fast-food restaurants in 500 m buffer zone	0.287**	0.000
		Density of tobacco and liquor stores in 500 m buffer zone	0.286**	0.000

	River	Distance from the nearest river	0.121**	0.000
Natural environment	Particulate matter (pm)	Average annual $pm_{2.5}$	0.088**	0.004
		Average annual pm_{10}	0.072*	0.020
	(Ground) surface temperature	Surface temperature in January 2019	−0.135*	0.000

* $P < 0.05$, ** $P < 0.01$.

mortality. The average temperature was negatively correlated with the CVD mortality, with a correlation coefficient of -0.135, indicating that the lower the temperature in winter would contribute to the increase in the CVD mortality.

4. Discussion

(1) The characteristics of CVD deaths were significant and of spatial clustering.

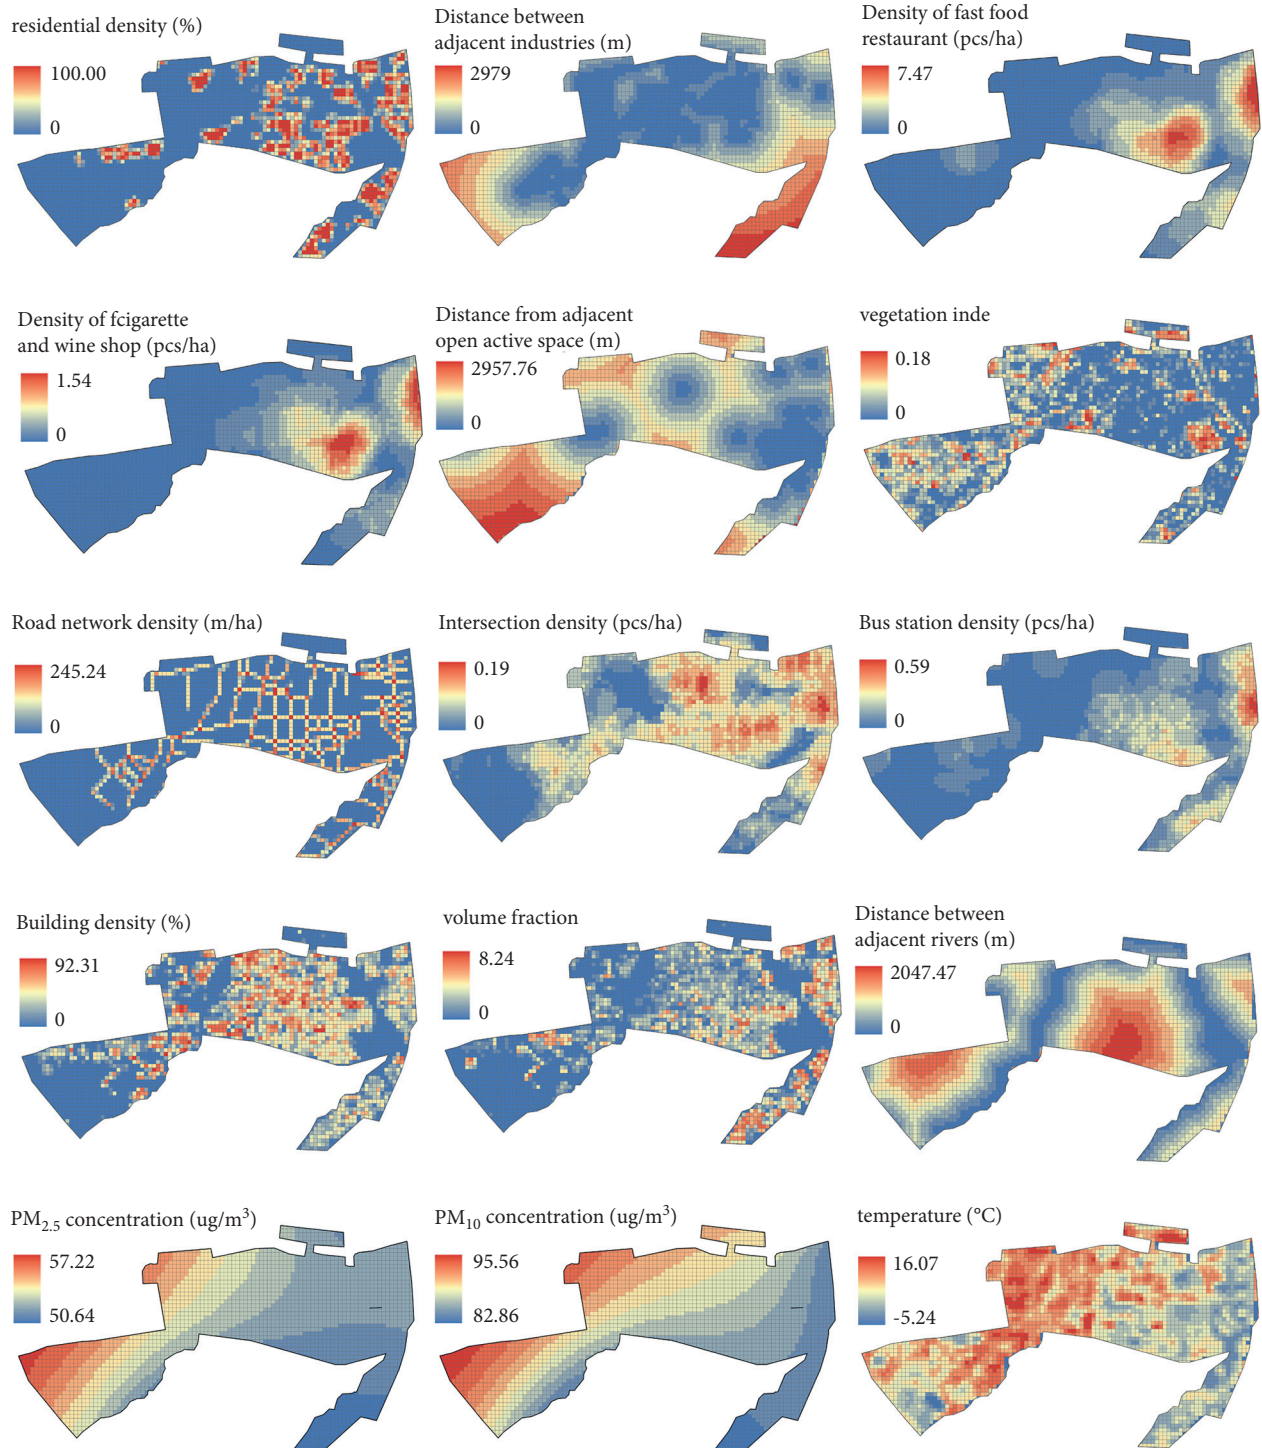
Consistent with the conclusions of previous international statistical studies, the CVD deaths were characterized as follows: male deaths were more than females; the mortality is higher in those of higher age; most of them are unemployed; and cardiocerebral infarction was the main cause of death. In addition, the deaths were mainly distributed in the old urban area, and there was a significant spatial clustering phenomenon [34]. Previous studies have shown that alcohol abuse [35] and smoking [36] can affect the cardiovascular system, and males are more likely to do alcohol abuse and smoking than females, causing the difference in mortality. The risk of cardiac arteriosclerosis will increase with age; that is, the mortality is higher in those of higher age [37]. Working can reduce the risk of CVD [8], and the risk of CVD is lower in residents engaged in manual work, but higher in those unemployed. Low temperature and sudden drop in air temperature will


FIGURE 6: Spatial distribution of environmental influencing factors.

cause vasoconstriction and elevated blood pressure of human body, increasing the risk of sudden myocardial infarction [23, 24]; therefore, autumn and winter are the seasons of high incidence of CVD, and the mortality is higher in the urban areas with lower urban temperature [38].

(2) The higher density of restaurants and cigarette and wine shops will increase the CVD mortality.

It has been further confirmed in this study that the density of restaurants and smoking restaurants around the residential area showed a significant positive correlation with the CVD mortality. The daily activity distance that can meet the basic material and life needs of residents by 10-min walking is 500 m [39]. Handy et al. [40] found that the frequency of walking to businesses was positively

correlated with the number of businesses within the service radius; therefore, people in the areas with highly dense restaurants and cigarette and wine shop will have higher probability of dining out and buying cigarettes and wines. In the study area, located in northern Anhui, the restaurant diet contains high fat and salt, and the dense dining facilities will bring more cooking fumes, sewage, and other environmental pollution, in which a lot of fat and cholesterol oxide [17] will lead to hypertension, hyperlipidemia, and other metabolic disorder CVD, and the increased probability of buying alcohol and tobacco will raise the risk of alcoholism, thereby causing sudden death [17].

(3) The influence of environmental factors related to particulate matter concentration on the CVD mortality.

Consistent with the conclusion of previous studies abroad, long-term exposure to high levels of pollutants will affect the human circulatory system [41], thereby inducing CVD mortality. According to the data of disease burden from Barcelona, Spain, it was estimated that 849 cases of CVD could be prevented each year if the exposure level of air pollution could be reduced to the WHO recommended level [42]. There is a higher risk of death for residents in areas with high concentrations of particulate matter. The finding is further confirmed in this study: the increased traffic volume [43], dense bus stops [44], and dense residential and spatial forms [45, 46], low green space coverage [47], and longer distance from rivers [47] can increase the CVD mortality, of which the possible reason may be associated with the increased concentration of local particulate matter and other noise pollution and psychological harm.

(4) Discussion on the correlation between industrial and open activity space and CVD mortality.

Different from general studies, it is found that there is no significant relationship between CVD mortality and industry in this study, for which reason may lie in that northeasterly wind is the most prevalent in the study area throughout the year, and there are few residential areas located downwind of industry, only accounting for less than 10% of the study units; therefore, the influence of industry on the study unit is not significant. Meanwhile, this study also reveals that CVD mortality is lower in the areas farther from open space area, and the possible reason is that the study area is an old urban area that lacks green space, there are only 3 parks with the area of more than 1 ha within or 500 m from the study area (aggregated distribution), and there is relatively little activity space, which also is the common fault of an old urban area. The elderly are at high risk of dying from CVD, and they will deliberately choose the area around the open activity space when choosing housing, which will have a certain impact on the conclusion.

5. Conclusions and Prospects

To explore the distribution characteristics of cardiovascular disease (CVD) in urban residents and the environmental influencing factors, this study analyzed the basic characteristics and spatial distribution characteristics of CVD death population, explored the correlation between multiple environmental factors and CVD mortality, and revealed the factors affecting the risk of death and its mechanism, with the main conclusions as follows:

(1) The correlation study conducted in this study is of good scientific nature and research significance, and the conclusions are consistent with international studies. Therefore, the study methods can provide some research ideas for the construction of healthy cities in the Huaihe River Basin or other regions.

(2) With obvious characteristics, CVD deaths are mainly distributed in the vicinity of Unit YH09 in Zhanggongshan Park and the north of Unit YH08 near the Huaihe River. Therefore, attention should be paid to the key areas with the maximum number of CVD deaths and the population at high risk, and medical input should be increased to reduce the death risk.

(3) Because long-term exposure to high pollutants in the environment will cause CVD death, the following measures can be taken to reduce the CVD mortality in the construction of healthy cities in the future: increase traffic arterial roads around residential areas to reduce the traffic volume and vehicle exhaust emissions in residential areas; increase open space to reduce living and spatial density; plant more plants and building more rivers to reduce the local air pollution; and make dispersed layout of commercial facilities, such as restaurants and cigarette and wine shops, around residential areas to effectively reduce the risk of CVD death. Meanwhile, attention should also be paid to the influence of the areas with a higher density of the elderly on the analysis results.

Appropriate urban planning and policies can improve the active health interventions in cities and reduce the CVD mortality. To a certain extent, it can also provide more research perspectives for the construction of healthy cities in the future, and promote the development of healthy cities. In addition, this study is based on panel data, and little consideration is given to the changes of built environment and CVD mortality caused by time changes, so time series related research will be carried out in the future. At the same time, different lifestyles will affect CVD mortality, so further research on the correlation between residents' lifestyles and CVD mortality will be conducted in the future.

Minimally invasive surgery (MIS) has already had a significant impact on surgical treatment (spine). Because they are less invasive, minimally invasive treatments are often preferred over open spine surgery. MIS and open spine surgery in terms of posterior lumbar fusion (PLF), lumbar disc herniation (LDH), and cervical disc herniation (CDH) were all observational studies based on randomized controlled trials. Seventeen RCTs and six observational studies were conducted. Chemotherapy had no effect on the long-term alleviation of the neck or arm pain in patients with CDH. In LDH, MIS was superior in terms of pain relief, rehospitalization rates, and improvement in quality of life. At the expense of increased perioperative endoscopic, readmission, and revision rates, MIS achieved a significant reduction in 2-year expenditures, fewer medical problems, and improved Oswestry score ratings. There is no evidence to support the use of MIS over open surgery for lumbar or cervical process disc herniation. In comparison, MIS-TLIF has several advantages, in addition to lower revision/readmission rates. However, MIS significantly increases the surgeon's radiation exposure, regardless of the patient's sign. However, the effect on patients is unknown. These findings could help patients make better decisions when comparing open spine surgery to minimally invasive spine surgery, especially given how much advertising is out there for MIS.

1. Introduction

Historically, "open surgery" has been the method of choice for spine surgery. A lengthy incision must be made in the area to be operated on for the surgeon to be able to examine and analyze the anatomical structures. More back and neck disorders may now be treated with minimally invasive surgery thanks to recent technical advances. Because MISS does not require a long incision, it reduces the risk of substantial damage to the muscles around the spine. Pain and recovery time are reduced. The indications for minimally invasive spine surgery are similar to those for open surgery. Spine surgery is usually shown only after nonsurgical treatments like drugs and physical therapy have failed to relieve severe symptoms. Also, surgery is only shown if your doctor has discovered the specific cause of your pain, such as a herniated disc or spinal stenosis. There are a variety

of minimally invasive techniques available. Every one of them has one thing in common: reduced muscle injury and smaller incision size. Using minimally invasive procedures to undertake common operations such as lumbar decompression and spinal fusion, which are both effective, decompression lowers pressure on the spinal nerves by removing bone fragments or a herniated disc. This procedure is used to correct problems with the spine's small bones (vertebrae). The goal is to heal the painful vertebrae and then fuse them together to form a single strong bone structure. The goal of this article is to explore spinal decompression and fusion techniques that are minimally invasive. MISS (minimally invasive spine surgery) is another term for this procedure. Using specialized tools, surgeons can reach the spine through small incisions during these operations. During open surgery, the doctor makes a six-inch incision or less and then moves the muscles to the side to see the spine.

The surgeon can now reach the spine and remove sick or injured bone or intervertebral discs using the side muscles. Additionally, the surgeon can see right away where cages, bone grafts, and screws are needed to supply support and ease healing of the spinal bones throughout the procedure. Open surgery may cause a significant level of criticality because of the possibility of the muscle being harmed during the tugging or "retraction" procedure. While muscle retraction is designed to aid the surgeon in finding the location of the problem, it often affects anatomy more than the surgeon needs. Therefore, muscle injury is more likely to occur because of this, and patients may feel postoperative pain that is distinct from the back discomfort they were experiencing before the surgery. It is possible that this will result in an extended recovery time. Added complications may include higher blood loss and infection risk because of the larger incision and harm to soft tissues. This technique was created to treat spinal illnesses while minimizing injury to muscles and other natural spine systems. Additionally, it allows the surgeon to see only the part of the spine that is affected by the problem (the problem area). In addition, MIS offers the advantage of requiring fewer incisions, resulting in less bleeding and requiring fewer hospital stays. The most common technique is the tubular retractor. A tiny incision is made and a tubular retractor is inserted into the spinal column through the skin and soft tissues. This builds a tunnel to the affected area of the spine. The tubular retractor keeps the muscles relaxed throughout the process. The surgeon gets access to the spine using small devices that are integrated into the tubular retractor's central core. To install fusion devices such as screws or rods, the retractor must first be removed from the area of the injured bone or disc. For some surgeries, many retractors or incisions may be needed.

The surgeon uses fluoroscopy to guide him through the process of creating the incision and inserting the retractor. During the surgery, a screen shows the surgeon real-time X-ray pictures of the patient's spine. During surgery, the surgeon will typically use a microscope to examine the spine's key components, such as the discs and joints. After surgery, the tubular retractor is withdrawn and the muscles are allowed to heal. The likelihood of muscular injury is more common with open surgery; in the spine surgery sector, new minimally invasive procedures are constantly being developed. An endoscope, for example, is currently being used by some spine surgeons to gain access to a problem site in the spine. Anesthesia for MISS is most administered as either general anesthesia (during which you stay unconscious) or regional anesthesia (during which you are awake during the procedure).

1.1. Overview of the Manuscript. In this manuscript, the meta-analysis of the clinical effect of MIS-TLIF surgery in the treatment of minimally invasive surgery of the orthopaedic spine and the common comparison between the MIS and the TFIL are discussed in the following section, which is followed by the literature survey. Participation in the research is subject to certain requirements. Extraction of information, the quality of the research, and analytical statistics are used to analyze data. Evidence levels are used to categorize the effects of research investigations, and patients and the process of choosing the method are discussed as follows.

2. Minimally Invasive Spine Surgery Is a Common Surgery

The compression of a nerve by a herniated disc in the lower back can cause severe leg discomfort, numbness, and even paralysis in certain cases. To ease these symptoms, the disc is surgically removed. A diskectomy is the medical term for this procedure.

To remove the herniated disc, the patient is turned face down and a tiny incision is made. During the surgery, a small part of the lamina bone is removed. This gives a better view and an idea for the surgeon to visualize the spinal nerve and the disc. A surgeon (doctor) delicately retracts the nerve and removes only the affected disc, leaving the rest of the nerve intact. It is also possible to employ this minimally invasive method to repair herniated cervical discs in the neck. The technique is known as MIS posterior cervical foraminotomy/discectomy.

Open lumbar fusions may be done via the back, belly button, or side. Lumbar fusions may also be performed minimally invasively. The surgeon can approach the spine from the side, reducing the amount of spinal nerve displaced during the surgery enabled by the transforaminal lumbar interbody fusion (TLIF). After the patient is placed face down during a MIS-TLIF, the surgeon installs one retractor on each side of the spine, completing the procedure. This avoids rupturing the midline ligaments and bone. The surgeon removes the lamina and disc, then places the bone transplant into the disc region, fastening it with screws or rods as needed. To boost the likelihood of healing, the surgeon may choose to use a bone transplant in addition to the patient's own bone on occasion. Aside from being performed minimally invasively from the side, spinal fusions are also performed regularly. The side approach is enabled by the Direct Lateral Interbody Fusion (DLIF) and Extreme Lateral Interbody Fusion (XLIF). They are superior to conventional spinal fusion procedures in that they do not injure the back muscles or strain or pull on the spinal canal nerves.

An oblique lateral interbody fusion is a more contemporary variation of this surgery that is performed on the left side of the body (OLIF). OLIF, like XLIF and DLIF, needs the use of a side incision. Instead, OLIF enters an oblique position, avoiding the psoas muscle (the muscle on the side of the spine). All three of these lateral strategies produce outcomes that are comparable. MISS, like any other operation, entails some inherent hazards that must be understood and accepted. Some studies show that MISS has similar issues to those associated with open spinal fusion surgery, but some studies show that MISS has a lower infection rate than open spinal fusion surgery. Before surgery, your doctor will go over each risk with you in detail, and they will take specific precautions to help avoid any negative outcomes.

3. The Following Issues May Arise Because of MISS

Antibiotics are given to the patient before, during, and often after the surgery to lower the risk of developing an infection. It is normal to experience some bleeding after surgery, but it is usually not significant. There is a pain in the area where the graft was placed. Occasionally, a small number of people have persistent discomfort at the location of their bone transplant. Some symptoms can recur on a regular basis. Some people may revert to their first symptoms. Pseudarthrosis, insufficient bone growth, causes incomplete spinal fusion healing. If this happens, further surgery may be necessary to produce a solid bone union. Pseudarthrosis is more frequent among smokers, who are more susceptible. Nerve injury is a big issue. These operations may injure nerves or blood vessels. These kinds of ramifications are quite uncommon. Blood clots are formed. It is also possible that blood clots will form in the legs because of surgery, which is unusual. If they shatter and travel to the lungs, they are a major hazard to the patient's health. Minimally invasive procedures can result in shorter hospital stays since they are less intrusive. MISS patients typically return home on the same day or within one to two days of being admitted to the hospital. The exact length of their hospital stay varies depending on their condition and therapy. Most patients who undergo conventional surgery are admitted to the hospital for three to five days after the procedure.

Because minimally invasive therapies do not damage muscles or soft tissues, postoperative discomfort is believed to be less severe than that experienced following traditional open procedures in most cases. While you can expect some discomfort, current advances in pain management help your doctor manage and treat your pain. Physical therapy may be recommended by your doctor to aid you in regaining strength and speeding up your rehabilitation. Depending on the procedure and your overall health, this will vary. Specific workouts might aid you in regaining the strength you need to return to work and your normal activities after an injury. It might take months for the bone to harden after a fusion. On the other hand, your degree of comfort will often improve far more quickly. For the fused spine to heal properly, it is vital that it keeps proper alignment throughout the healing process. On the job, you will learn to move appropriately, reposition, sit, stand, and walk. The amount of time it will take you to return to your typical activities after a MISS varies based on your unique operation and condition. In the days after surgery, your doctor will check on you to ensure you are recovering well.

Medical and surgical therapies are evaluated objectively through research. The quality of evidence decides how much research impacts management. Class I data from prospective randomized controlled trials (RCTs) are the most persuasive in showing a treatment's effectiveness. In this research, the following conditions are analyzed, such as [1]. Five studies comparing MIS with open surgery for CDH were chosen as Class I trials. Four RCTs and systematic analysis were included. The RCTs included 200+ MIS patients and 150+ open surgery patients, following them for more than 100 weeks (about 2 years) [2]. Only one of the four RCTs (8 percent) used a discectomy without fusion on 19 of 200+ open surgery participants. The remaining 150+ patients had anterior cervical discectomy. Only 37 out of 200+ MIS patients (15%) had fusion, while 100 out of 150+ had posterior foraminotomy. A posterior cervical discectomy was performed on 60 individuals, and an amniotomy or discectomy was performed on 18 patients (specific procedure per patient not reported). In RCTs, only 95 of 200+ MIS patients (42%) employed an anterior approach, compared to 190 of 200+ conventional open patients (88%) [3, 4].

This review shows that MIS did not enhance neck pain and arm discomfort, compared to TLIF for CDH. While MIS helped relieve temporary neck discomfort, when lumbar patients were included in the pooled estimate analysis, this improvement was not statistically significant. Minimally invasive vs. open surgery Twelve trials comparing MIS with treatment of LDH produced Class I evidence. It includes ten RCTs and two systematic reviews. In the 10 RCTs, 489 individuals receiving MIS and 500+ patients with traditional open surgery were recruited in the 10 RCTs. Both groups did not obtain fusion. Out of 500+ open patients, 500+ got discectomy, and 19 had percutaneous nucleosome, with the follow-up durations of 50–100 weeks (about 2 years) [4–6].

On average, MIS is inferior to open LDH surgery for leg discomfort, less back pain, lifestyle and quality of life, and rehospitalization. Conversely, MIS was linked to a decreased risk of infection and a reduced hospitalized duration. Postoperative Oswestry Disability Index (ODI) scores were not altered. The authors suggest that any alleged decreased infection incidence is linked with MIS. When compared to open surgery, MIS exposed the surgeon's thyroid and eye more than tenfold, his chest 14-fold, and his hand 20-twofold. Surgery with a minimum of invasiveness against surgery with a maximum of invasiveness: disc herniation is a condition in which the disc protrudes from its normal location (cervical or lumbar) [5, 6]. Data from 14 RCTs on CDH and LDH were combined to form a single comprehensive assessment. When compared to traditional open surgery, the study discovered that minimally invasive surgery (MIS) decreased infection rates while increasing nerve root damage, durotomy, and reoperation rates. However, none of these changes were statistically significant. At the rear of the neck, the lumbar spine is fused [7].

4. Literature Survey

Lumbar fusion surgery treats spinal instability, stenosis, spondylolisthesis, and degenerative disc disease symptoms, normalizing motion and stability while keeping load-bearing ability and aligning the system. Lumbar fusion operations

have grown in popularity in the US during the last several decades [8].

Transitioning from traditional open surgery to less invasive approaches is the method of choice for many surgical procedures. According to postoperative histology and imaging examinations, standard open procedures leave traces of scar during tissue development, muscle retraction, and stripping, all of which have a negative impact on outcomes and increase the likelihood of reoperation. To help maintain paraspinal muscular anatomy and bone architecture, minimally invasive treatments employ a muscle-dilating approach. These treatments have been proven to reduce the incidence of iatrogenic soft-tissue injuries [9] [6–8]. Reduced postoperative discomfort, decreased intraoperative blood loss, a shorter postoperative staying in hospital, fast recovery to normal activities, and a lower reoperation rate are just a few of the reasons that minimally invasive spine (MIS) therapies are becoming increasingly popular. Due to the lack of long-term data on patients receiving minimally invasive spinal fusion for severe back pain, the use of these procedures instead of standard open fusion methods continues to be controversial in the medical community. We want to add to the data in this discussion by supplying long-term, prospectively recorded results from one of the biggest presently known series of MIS-TLIF by following patients up to 28 months (about 2 and a half years) [10]. According to our findings, MIS-TLIF beat open TLIF in all domains, except for the fusion rate. As reported in the meta-analysis, the MIS-TLIF procedure had an identical fusion rate as the open TLIF procedure but with a shorter hospital stay, faster ambulation, and less blood loss [11]. Staying in the hospital for less time also reduces medical expenditures because MIS-TLIF enhances ambulation speed [12]. The MIS group's postoperative VAS and ODI scores were lower than the open groups. Although the preoperative clinical and functional baseline measures were equal across the groups, the open group's postoperative ratings were lower than those of the MIS groups. So, MIS-TLIF improved outcomes while reducing trauma [13].

In recent years, TLIF has gained widespread acceptance and recognition as a surgical method that significantly reduces the likelihood of relative nervous system disorders, despite the advancement of fusion technology. However, the open TLIF technique requires paraspinal muscle splitting to be successful. It does not hurt, but it ruptures a large piece of the posterior compartment, causing muscle stiffness and low back discomfort. As a result of its advantages over standard open surgery, such as less harm to spinal soft tissues and paravertebral muscles, it has gained popularity in recent years. The advantages of MIS-TLIF can be linked to the fact that less paravertebral muscle dissection and retraction occur throughout the procedure [14].

According to the study, it is found that the MIS-TLIF and open TLIF have no difference in the surgery time, complication rates, or reoperation rates. Despite this, the compilation and reoperation rates for the MIS are better than the open TLIF process. One of the most persuasive arguments is that the learning curve for minimally invasive surgical abilities is steep, requiring added years of experience

to perfect the necessary skills [15]. The advancement of surgical devices and technology may pave the way for realizing the other critical goals. Our meta-analysis has several flaws that need to be addressed. Because we only looked at prospective and retrospective research, issues including data bias, nonblinding or improper, inadequate baseline comparisons, and data collection must be addressed. For the second time, the current study relied on a small number of outcome indicators; clinical outcomes should be assessed by a variety of alternative aims or subjective characteristics. In addition, there were inconsistencies in the definition and assessment of fusion during the study. A further point to mention is that many of the investigations were completed in a short or medium amount of time. More long-term follow-up studies must be reviewed to analyze the evaluation process for the effectiveness of these measures. Finally, an inherent bias was added to the data by combining them all together [16]. Data collection and inappropriate or nonblinding were challenges that arose due to solely looking at prospective and retrospective studies. The use of MIS-TLIF is also not related to an increase in complications or reoperations. Comparing open surgery and MIS, there are fewer lesions, better outcomes, and the same fusion rate. Surprisingly, MIS-TLIF has been linked to fewer complications and reoperations. This may be due to increased acceptability of MIS-TLIF, familiarity with the surgery, ability in MIS abilities, and development of proper surgical instructions and instruments. Added high-quality research is needed to confirm and compare these findings [15, 16]. We searched the CNKI, Wanfang, and VIP databases for relevant information using the keywords "MIS" and "TLIF". Many researchers recommend restricting the search to English-language articles. The retrieval period ran from the database's creation until January of the current year. It was also searched for articles related to the original research and review papers in the reference lists of those articles. Two reviewers independently reviewed all publications based on their titles, abstracts, or full texts. The two reviewers assigned to them knew the writers and their journals [17]. On a particular research project, diverse viewpoints were heatedly debated until an agreement was set up.

4.1. Participation in the Research Is Subject to Certain Requirements.
The criteria for consideration were as follows: (3) at least one clinic result or perioperative data were presented in the article; (4) the patients had degenerative disc disorders (disc herniation, canal stenosis, or spondylolisthesis); this study excludes the patient who underwent open TLIF or MIS-TLIF for other illnesses. These patients were likewise eliminated from the study [18, 19].

4.2. Extraction of Information.
From the research that was included, we were able to extract information for the categories listed as follows: (1) the names of the authors and the year of publication; (2) the study strategy; (3) the type of evidence; (4) the total number of patients recruited, as well as the number of patients in each group (MIS-TLIF versus open TLIF); (5) the average amount of time spent following

up; (6) the average follow-up time and rate (in percentage points); (7) the patients' average age; (8) the proportion of patients who are male and female; (9) predictive diseases (like degenerative disc disease, spondylolisthesis, and others are classified into three categories); (10) clinical outcomes; (11) perioperative data points; (12) inclusion/exclusion criteria; (13) information about the postoperative period; (14) the total number of lumbar segments treated; (15) the definition of fusion and the assessment of the measure; (16) the types and quantity of grafts used; (17) the number and type of cages used; (18) the screw fixation technique and the number of issues met; (19) the number of complications met. We had not predicted any problems ahead of time. Moreover, the total number of challenges was tallied up for analysis [19, 20].

4.3. The Quality of the Research. Levels of Evidence (2009) Class I claims were supported by high-quality randomized controlled studies (RCTs). Class II evidence includes RCTs of moderate to inferior quality and correct cohort studies. Class III evidence includes cohort and case-control studies of moderate or inferior quality. The Case Series Study was in Class IV Evidence. Two reviewers separately evaluated the publications, and disagreements were discussed until a consensus was reached [21, 22].

4.4. Analytical Statistics Are a Type of Statistics That Is Used to Analyze Data. WMDs were used to measure the ODI, average blood loss, hospitalized duration, time taken for the surgery, and VAS. The relative risk (RR) measure and 95% confidence interval were used for dichotomous data. Each study has its own unique set of criteria for evaluating the efficacy of the fusion procedure. Consequently, the total number of studies within each category was not equal. In this research, a random-effects model was preferred over a fixed-effects model because it supports a distribution that the fixed-effects model does not. All tests required a p-value of 0.05 or less. The publication bias was investigated using funnel plots. Asymmetry suggests a publication's prejudice, while symmetry implies no bias. We could conduct added database analysis using Review Manager [5].

4.5. Evidence Levels Are Used to Categorize the Effects of Research Investigations. Randomized double-blind placebo-controlled trials are appointed as Class 1 trials (randomized outcome measures) [23]. Experiments were conducted without a randomization procedure (Class II). Unlike Class I, this group is not random. Case-control, cohort, and interrupted time studies processed with controls are all examples of Class III Observational Studies. Observational studies without controls are Class IV (Class III, without controls) and Ability (Class V) (invited only can comment).

5. Patients and the Process of Choosing the Method

Between 2003 and 2010, 318 MITLIF surgeries, as shown in Table 1, were conducted on 304 consecutive patients, all of whom were treated using a paramedian muscle-sparing technique. During the operation, 120 men and 184 women were included in the research. The mean age (range, 19–93) and gender (male) at surgery were 62.4 and 19.4, respectively. The senior author performed all 318 MITLIF surgeries on all 318 patients from an outpatient neurosurgery spine clinic. Following a thorough clinical history, physical exam, and lumbar spine radiological study, the diagnosis was made. When spondylolisthesis and retrolisthesis were diagnosed, they were classified according to the Meyerding classification (I–IV). All the patients were examined outside of a hospital environment.

Complicating matters, the patient also has several medical conditions, which are listed in the table. Spondylolisthesis (66%) was the most common clinical condition, followed by central spinal stenosis (47%) and foraminal stenosis (34%). The most common clinical findings were persistent severe low back pain, neurogenic claudication, and radiculopathy-related symptoms [5]. Patients experienced symptoms for an average of 68.6 months (about 5 and a half years) before surgery. Previously, 70 individuals had lumbar surgical operations performed on them (23%). When clinical and imaging data agreed, as well as symptoms that had lasted for more than six months and had not responded to nonoperative treatment, patients were considered candidates. The table shows patients who had conservative nonoperative therapy. If a neurological impairment was deteriorating or if the patient presented with considerable, incapacitating pain and a good correlation between clinical and radiographic data, surgical therapy was started no sooner than 6 months. If nonoperative treatment fails, surgical intervention is recommended as the last resort for patients who were physically unsuited for surgery, patients who had a recent bleeding diathesis, patients who were infected, patients who had incongruent clinical and radiographic data, and patients who were infected [5, 22, 23].

In the field of outcome measurement, outcome measures are a type of outcome measurement. Low back pain, back-related functional disability, and physical and mental quality of life were all improved when the visual analogue scale (VAS), the ODI, and the Short-Form 30+ were used to assess patients' reported results (SF-36). During the recruitment process, patients were requested to complete these validated questionnaires, and they were also asked to complete them again at various stages throughout the postoperative period. The presurgery scores, all later follow-up, and change scores were all analyzed for significance. A secondary outcome measure was the rate of fusion, the rate of reoperation, the amount of intraoperative blood loss, and the length of time spent in the hospital following the procedure. To assess fusion, radiologists separately and blindly reviewed radiological images taken from the lumbar anterior-posterior and lateral flexion/extension views during the postoperative phase. We considered fusion effective when there was no considerable motion or angulation at the fused level, no implant latency, no hardware loosening or breakage, and bridging bone growth.

TABLE 1: Recommendation for patient population.

Recommendation	Population of the patient
As compared to open surgery conducted normally, MIS	
1. It has no effect on short-term functional outcomes.	
2. It does not have a negative impact on long-term performance.	
3. It does not alleviate acute arm discomfort.	Cervical disc
4. It does not supply relief from persistent arm discomfort.	herniation
5. It supplies immediate relief from severe neck aches.	
6. Does not supply relief from chronic neck pain.	
When compared to conventional open surgery, MIS	
1. It does not improve function in the short term.	
2. It does not have a negative impact on long-term performance.	
3. It does not supply enough relief for leg pain.	
4. Low back pain is not well relieved by this medication.	
5. It has a greater likelihood of requiring rehospitalization.	
6. The quality of life is negatively affected by the procedure.	
7. The chance of surgical site and infection issues is reduced.	Lumbar disc
8. It is possible that it is associated with a shorter period of hospital stay.	herniation
9. It does not show Oswestry Disability Index scores after at least six months after surgery interns of statistically significant difference.	
10. In addition, it exposes the surgeon to more than ten times the amount of radiation that would otherwise be supplied to the thyroid or the eyes.	
11. Exposure to more than 14 times the quantity of radiation supplied to the chest is imposed on the surgeon.	
12. Subjects the surgeon's hand to more than 22 times the amount of radiation received by the patient.	
According to the existing practice of open surgery, as compared to open surgery as it is now practiced,	
1. The incidence of nerve root damage is growing.	
2. The incidence of nerve root injuries is decreasing.	
3. A rise in the number of inadvertent durotomies that occur	Disc herniation
4. Increased reoperation rates are becoming more common as a trend.	
5. Infection-prevention trends in the United States	
When comparing MIS with TLIF and open TLIF	
1. leads to much less blood loss than the latter.	
2. It leads to a considerable reduction in back pain on the second postoperative day after surgery.	
3. It involves much greater amounts of intraoperative radiation time.	
4. It does not need a major increase in overall operating time.	
5. Despite considerable improvement in the ODI over a brief period, there is no statistically meaningful difference in terms of long-term clinical outcome.	
6. There is no statistically significant difference in the radiographic outcome.	Posterior lumbar fusion
7. It has led to reducing the number of hospitalizations of the patients	
8. It has reduced the amount of time necessary to a normal life routine.	
9. It has reduced indirect expenses.	
10. During a two-year period, he has cut social expenses.	
11. It has resulted in increased narcotic independence	
When compared to open TLIF/PLIF, MIS-TLIF/PLIF has the following benefits over the former:	
1. A faster rate of revision.	
2. A higher risk of hospital readmission.	Posterior lumbar fusion
3. There has been no change in the incidence of surgical complications since the study began.	
4. A reduction in the number of medical problems	

The most persuasive evidence supporting MIS compared to open spine surgery in the patient group suffering from CDH, LDH, and PLF is reviewed.

6. Data Analysis Using Statistical Methods: Analyzing the Information

To compare the ODI, SF-36, and VAS values for each time, Student's t-test was used. Consideration is decided based on the p-values, i.e., p-values <0.05 are noted as significant and p-values >0.05 are noted as highly significant.

On the other hand, three RCTs compared MIS-TLIF and open TLIF. Both open surgery and MIS were inspected for an average of 25 months (about 2 years). On postoperative day 2, blood loss and back pain were much lower in individuals receiving minimally invasive surgery (MIS), although it took significantly longer to supply intraoperative radiotherapy. Because all patients underwent open lumbar spine surgery prior to being randomly distributed to a group, the research had significant limitations. There was no difference in operating time, blood loss, or postoperative hospitalization between minimally invasive and open surgery. MIS needed less postoperative drainage and recovery time (40 days (about 1 and a half months) vs. 76 days (about 2 and a half months), but more time for intraoperative fluoroscopy. The VAS evaluations did not vary between the

two groups at 3, 6, 12, and 24 months (about 2 years) postoperatively, but the ODI did. Four years after surgery, a study of 41 patients (21 with MIS and 20 with open TLIF) found no clinically significant differences between the open TLIF and MIS groups. In terms of narcotic independence, two-year social cost, and return to work, numerous non-randomized prospective studies have set up that MIS-TLIF is better. MIS was comparable to open TLIF in terms of operating time, complication rate, and reoperation rate but with reduced blood loss and reduced hospital stay. In the second meta-analysis of 20+ trials, the surgical team received higher radiation. In a recent PLIF trial, it was found that MIS and open fusions have no differences. MIS had a higher revision and readmission rates than those in open TLIF and PLIF.

7. Conclusion

The strongest evidence does not confirm that the MIS process is better than open surgery for cervical or lumbar disc herniation. On the other hand, increased revision, readmission rates, reduced hospitalization, cost of treatment, and time to reach the normal life are disadvantages of MIS-TLIF fusion. No RCT comparing MIS-TLIF only to open PLIF has been conducted, which would supply valuable information. Any surgery involving MIS exposes the surgeon to much higher radiation. This is especially true for lumbar spine surgery, which is quite common. Whether this exposure had any effect on the patients is unknown at this time, and more research is needed. Patients must be informed of the most recent results to choose between MIS and open spine surgery or TLIF. This is critical given the current medical advertising climate that heavily promotes MIS.

The increasing maturity of Internet information technology has led to the rapid rise of blockchain technology. In essence, a blockchain is a shared database. In recent years, blockchain technology has attracted the attention of the public and society. With the continuous development of the market economy, many domestic enterprises have grown in size. At the same time, companies are also faced with various risks, and business risks will have a great impact on the company's production. This article aims to prevent the business risk of Internet information security platform enterprises based on blockchain technology. Through the PoS algorithm, PoW algorithm, secure hash algorithm, and the principle of direct trust, the Internet information security platform is designed. Firstly, the platform is used for a business risk test with a small company, and the platform satisfaction survey is conducted on the employees of the company. The test results show that the subplatform design reduces the business risk of the company by 5%–10%, and employee satisfaction is high. The signature simulation of this algorithm under the same conditions as the SMRA and RSAR methods is also carried out. The results show that the performance of this algorithm is better. This study opens up a new path for small and medium-sized enterprises to prevent business risks.

1. Introduction

Due to the complexity of current market issues and fraud, some companies do not understand preventive measures and have little understanding of legal issues in their business, making them unable to effectively avoid operating risks. Blockchain is an important concept of bitcoin. In essence, it is a decentralized database [1]. In a narrow sense, blockchain is a chained data structure that combines data blocks in chronological order, and a distributed ledger that cannot be tampered with and forged in a cryptographic way [2]. Broadly speaking, blockchain technology is a new distributed infrastructure and computing method that uses blockchain data structures to verify and store data, uses distributed node consensus algorithms to generate and update data, uses cryptography to ensure the security of data transmission and access, and uses intelligent contracts composed of automatic script code to program and operate data.

The essence of blockchain technology is a decentralized database, and its main feature is to provide digital trust.

Information on the Internet is transparent and anonymous. It is this characteristic that makes information extremely insecure, and information loss, theft, and forgery are very common, which makes the Internet have some information security risks. If this problem cannot be resolved in time, it will seriously affect people's trust in the Internet and drive people away from the Internet. Only by comprehensively preventing the Internet information security platform from corporate management risks can we effectively guarantee Internet information security and reduce corporate operating risks. Improve the company's information risk management capabilities and raise the company's management level to the international advanced level, which provides a strong guarantee for the company's international development and cooperation. This paper aims to propose an effective business prevention scheme for the Internet platform based on blockchain technology to ensure the information security and transaction security of enterprises.

Technical personnel such as Viana E. proposed an Android-based solution for smartphones to identify and

report potentially unsafe settings and developed an application that can check smartphones to search for unsafe user configurations based on a predefined list. It reduces the attack of netizens by malicious users [3]. But at that time, they did not use the blockchain technology that has been particularly popular in recent years to reduce the risk of such Internet security information leakage. Researchers such as Bendul J C identified corporate risk culture and product vulnerability as the main factors influencing the implementation of preventive activities during transportation. Regression analysis illustrates the relationship between risk and quality-related influencing factors and the shipper's ability to perform risk prevention activities [4]. But they only studied the corporate risk culture and did not conduct in-depth research on the prevention of corporate operating risks. Scientists such as JJ Sikorski emphasized cryptocurrency mankind's research and practice potential in relation to the 4th industrial revolution. They came to the conclusion that bitcoin has the possibility to be underutilized in addition to supporting and boosting the industrial rebellion's efficiency, and they have defined the subject of future work [5]. However, they did not apply blockchain technology to Internet information security management and risk prevention in business operations. The above research contents are scientific and technological research on risk prevention, which can provide some references and ideas for this research. However, some research schemes do not use cutting-edge blockchain technology or do not protect the core content of enterprise risk. These are the key points of this research.

Protecting the security of information on the Internet, when using traditional information protection mechanisms, is difficult to ensure security. In order to better maintain the security of the network environment, the use of blockchain technology can enhance the protection effect, including user information, transaction activities, electronic communications, infrastructure, etc., which can be protected accordingly. A new blockchain-based Internet information security platform will improve information control capabilities and allow users to safely use online information. The experimental part of this paper not only pays attention to the maturity of technology but also has more humanistic characteristics, referring to the user's satisfaction with the platform.

2. Blockchain Security Algorithm

2.1. Direct Trust Mechanism.
The trust mechanism refers to the various parts of the company's system that constitute and influence the mutual trust relationship and the relationship management mechanism between them. Assuming that the lending decision of lender B is not affected by factors such as income and environment, but only depends on the credibility of the borrower, then, when the credibility is $P (0 \leq P \leq 1)$, the business operation risk rate is P.B. The basis for judging the credibility of the borrower's future performance of the contract is the borrower's credit information, where the information set displayed by the borrower W on the platform is $W = \{W_1, W_2, W_3, \ldots, W_i\}$. In actual

situations, W may deliberately conceal unfavorable information or exaggerate certain pieces of information, and its true information set is $W' = \{W'_1, W'_2, W'_3, \ldots, W'_i\}$. However, B can only see the set W, so the direct trust expectation made is

$$W = c_1 U_1 + c_2 U_2 + c_3 U_3 + \cdots + c_m U_n. \tag{1}$$

C_i $(i = 1, 2, \ldots)$ is the expected influence coefficient of each information factor on the credibility obtained by B through subjective judgment. The true value of direct trust is

$$W' = c'_1 U'_1 + c'_2 U'_2 + c'_3 U'_3 + \cdots + c'_m U'_n. \tag{2}$$

From the above two formulas, it can be concluded that the enterprise operating risk rate is

$$P(W > W' | j = k) = \frac{1 - \left(\sum_{j=0}^{k} \left(C_k^j \right)^2 / 4^j \right)}{2}. \tag{3}$$

2.2. PoW Algorithm.
PoW proves that a certain amount of work has been completed at the end of the work. The PoW algorithm has three main components: the work function proof, the retardation and difficulty values, and how to calculate the work function proof. And then use the PoW algorithm to block the input data. The most difficult part of PoW is the amount of calculation. The work end needs to do some difficult work to get a result, but the verifier can easily check whether the work end has done the corresponding work through the result. The benefits of the PoW algorithm include complete decentralization, free entry and exit of nodes, simple algorithms and simple implementations to reach consensus between nodes without exchanging other information [6, 7]. This algorithm is highly secure and requires a lot of damage to the system funds and allow 50% of the nodes in the entire network to fail. The PoW algorithm also has many shortcomings. For starters, it necessitates a significant amount of computational power, is susceptible to less supervision, and poses security hazards. Simultaneously, the introduction of huge mining tanks has brought attention to the issue of computational capacity, namely the potential of a "51 percent attack." The performance is low, but whenever a resolution is formed, the entire network is required to join in the computation. Reaching an agreement is impossible, disagreements are prone to occur, and a large number of confirmations must be waited for. The following are the specifications for the structure of chunk H said by a node in PoW: B is a particular hash technique, where T is a set quantity in $H(A)$target. That is, the hash value in its entirety. The chunk must be less than the stated amount and include a specific number of locations. The block is a lawful block such that if it fits this criterion, other nodes will accept it. If the node finds such a lawful zone, it will compensate the mines excavated with particular digital money. It also overcomes the problem of several distributed nodes causing problems with judgment. The overall chance P of discovering a valid chunk within every test, provided the greatest checksum is H, is

$$P = \frac{T_{\text{target}}}{H_{\text{max}}}. \tag{4}$$

Clinched alongside Bitcoin, the worth of t is balanced each 2016 obstructs (two weeks), which may be balanced toward the taking after formula

$$T_{(\text{new})} = \frac{T_{2016}}{2W} \cdot T_{\text{tar}}. \tag{5}$$

Around them, T_{2016} speaks to the duration of the time expended should produce the past 2016 territory squares. At those duration of the time expended may be shorter, those last focus quality will be Additionally more modest. Those challenge esteem of the created piece might make acquired toward recipe 3:

$$D_{(\text{difficulty})} = \frac{T_1}{T_{\text{current}}}. \tag{6}$$

2.3. PoS Algorithm. The PoW (proof of work) is the proof of workload, also known as mining. Most public chains or virtual currencies, such as bitcoin and Ethereum, are based on the PoW algorithm to realize their consensus mechanism. That is, the distribution of money is determined according to the effective work of the mining contribution. Compared with PoW, the PoS algorithm avoids a large amount of waste of resources caused by mining, reduces the consensus time between different nodes in a good low-level network environment, reaches the millisecond level, and has a large number of advantages. A PoS is a method of obtaining accounting rights based on decentralized computing competition. The supervisory ability is weak and has the same fault tolerance as PoW. It can be found in many different PoS applications that this is a hybrid way of using account balance custom mining (where b represents the account balance and t is a timestamp)

$$H(B, t) \le b * T_{(\text{target})}. \tag{7}$$

2.4. Blockchain Data Security Design. Blockchain is an important concept of bitcoin. In essence, it is a decentralized database. At the same time, as the underlying technology of bitcoin, it is a series of data blocks associated with cryptographic methods. Each data block contains a batch of information about bitcoin network transactions, used to verify the validity of its information (anticounterfeiting) and generate the next block. This article aims to improve the security and anonymity of blockchain transactions. For the signing algorithm of blockchain transactions, which cannot resist quantum computing attacks and the security problem of user identity privacy leakage, the research on key technologies for transaction security and privacy protection of blockchain has been carried out. The main research results of this paper are as follows:

Generation of key: randomly select two large prime numbers p and q to calculate: $n = pq$, $Q(n) = (p-1)(q-1)$, then select either positive integer e and calculate d so that

$de = 1 \bmod Q(n)$, where e is the public key and d is the private key.

The clear text encryption formula for the encryption process is

$$C = M^e \bmod n. \tag{8}$$

The ciphertext decryption formula for the decryption process is

$$M = C^d \bmod n. \tag{9}$$

The user uses the public key set L and his private key SK to generate a signature (r, s) as follows:

$$s = \left((1 + SK)^{-1} (k - rd) \right) \bmod n. \tag{10}$$

Using the sender node i message content and the public key as input to obtain the message verification code using formula (11), we get

$$\text{HMAC}(PK_i, S_i) = H(PK_i | S_i), \tag{11}$$

where PK is the public key of i, S is the message content, and H is the hash function. Blockchain users in this distributed network, the signature is verified in the following way, and the miner verifies the transaction through the following two formulas:

$$e \le 2s\sqrt{m}, \quad e \ne 0,$$
$$pk_a e = \sum_{i=1}^{d} (-1)^{M[i]} C_i. \tag{12}$$

The lattice signature algorithm used in transactions in the quantum blockchain scheme after this chapter satisfies the correctness requirement. The protocol process knows the tail signature $e = e' - u$. Thus, the following inequality can be obtained:

$$e \le e' + a \le 2s\sqrt{m}. \tag{13}$$

Since $A_1(e' - a) = (A_1 e' - A_1 a)$, we can output

$$e' \leftarrow \text{Sample Pre}(A_1, S_{ms}, b, s). \tag{14}$$

The signature satisfies $A_1 e' = b$. We get

$$\begin{aligned} A_1 e &= A_1(e' - a) \\ &= b - A_1 a \\ &= \sum_{i=1}^{d} (-1)^{M[i]} C_i + A_1 a. \end{aligned} \tag{15}$$

Through the analysis of equations (13) and (14), it is proved that the lattice signature algorithm used in the proposed postquantum blockchain scheme transaction satisfies the correctness.

ECC (error checking and correction) is error detection and correction algorithm for NAND. For the same key length, the key length of the ECC algorithm grows slowly, while the key length of the RSA algorithm grows exponentially, as shown in Table 1.

Table 1: Comparison of ECC and RSA key lengths.

Symmetric key length (bit)	RSA key length (bit)	ECC key length (bit)
86	1024	32
68	2048	16
16	3074	64
64	7660	4
54	14230	256

3. Design and Innovation of Internet Information Security Platform Based on Blockchain Technology

3.1. Blockchain Technology to Build a Distributed Model of Internet Information Security Platform. Blockchain technology creates a distributed model for specific applications. The distributed model places the data that different users need to access different parts on different servers to realize horizontal expansion. All users participate in the maintenance of the database. Use encryption technology to create data blocks and interconnect the data blocks [8, 9]. These interconnected data blocks are called blocks, and the data blocks are connected in chronological order to form a blockchain. Each block contains a time period, and the content in the block is the new information generated during the time period, and which covers the anticounterfeiting mark used to verify the information. During the information submission process, the information can only be retained in the database with the approval of the developer and cannot be deleted or changed at will. In terms of architectural design, the architecture of an Internet information security platform based on blockchain technology is shown in Figure 1.

3.2. Core Technology of Enterprise Operation Risk Prevention Based on Blockchain. The secure hash algorithm is an encryption technology [10]. It is to transform the input of any length into an output of a fixed length through a hash algorithm, and the output is the hash value. This transformation is a compression mapping; that is, the space of the hash value is usually much smaller than that of the input, and different inputs may be hashed into the same output. In short, it is a function that compresses messages of any length into a message digest of a fixed length. In the data calculation process, if the corresponding hash value is calculated in the forward direction, the calculation process is easy. When the hash value is used, the calculation of the corresponding data is an inverse calculation, and it can be known that this calculation is somewhat difficult. Blockchain networks use hash trees to perform calculations, which are used to construct a Merkle tree whose nodes are hash values. This method can verify the authenticity of a large amount of data. For example, in the security verification process, if a transaction is executed on the double flower subchain, the hacker will find a strong block in the network environment and create a weaker block with a higher cost before that. Judging from the displayed results, if the confirmation time

is 1 minute (in 1 MB blocks), a double-spending attack is required. Hackers may occupy 20% of the computing power of the entire network, and the hacking fee will reach 0.8 US dollars. If the block is 4 MB, the double-spending attack will need to pay a high transaction fee of more than $40. This type of security level is relatively low, and its security is similar to that of Bitcoin. Tables 2 and 3 show the transaction security of the security confirmation [11,12].

Analysis of the data in Tables 2 and 3 shows that as the information in the random block changes, its own Merkle hash also changes, and the information contained in the next block also changes. If hackers forge information, their computing power does not support false blocks, and the speed of false blocks exceeds the growth rate of the blockchain and is discarded [13, 14]. The information in each block is not only text information, but also data information, including nonlinear information (such as video information, image information, and various structured messages). The information stored in all blocks will be permanently protected and cannot be maliciously modified. Therefore, blockchain information is relatively safe [15–17].

4. Prevention of Business Risks of Internet Information Security Platform Enterprises

4.1. Necessity of Building an Internet Information Security Platform. Because this article uses the Fabric blockchain platform, it provides pluggable module configuration and management, by writing-related programs to implement the group signature scheme, and then using the RPC protocol in the blockchain network to remotely call the scheme of this article by controlling the upstream and downstream of the swarm nodes. We verify that our improved scheme can implement dynamic join and exit of nodes, as shown in Table 4.

After designing a blockchain-based Internet information security platform, we applied this platform to a small company to conduct a one-month business risk test. The test results are shown in Figure 2.

It can be seen from Figure 2 that in the first ten days of the year, the Internet information security platform was still in the debugging stage, and information security leaks were more serious. In particular, hackers attacked the system and employee login accounts were stolen. Vulnerability repairs have reduced the probability of various information security incidents by more than half in just over 10 days from early to late. This also proves that the Internet security platform can greatly reduce business risks, and the construction of an Internet information security platform is effective for the company. It is urgent to say [3, 18].

4.2. Corporate Employees' Satisfaction Survey on Internet Information Security Platforms. The data structure of blocks in a blockchain-based supply chain management system is shown in Figure 3.

The dotted box in Figure 3 corresponds to the data layer, the categorical Merkel tree layer, the classification Merkel

FIGURE 4: Blockchain-based virtual link network of information of a business entity in the supply chain.

tree root layer, the directory layer, and the block header layer in the block data structure, respectively.

For the supply chain with a production enterprise as the core, the operation process is described according to the order of business operation, so the process of generating the corresponding information for a certain business entity is also carried out according to the supply chain operation business process. The network of virtual links between a business principal's information in a blockchain-based supply chain is shown in Figure 4.

After a one-month risk test, we conducted a questionnaire survey on the company's employees of different age groups on their satisfaction with the platform design. We distributed 110 questionnaires and recovered 110, of which 2 were invalid questionnaires and the rest. There are 108 valid questionnaires in total, and the statistical results are shown in Figure 5.

It can be seen from Figure 5 that more than 50% of employees are very satisfied with the design of this security information platform. They believe that this platform can greatly reduce business risks and increase the company's net income. Less than 10% of employees are dissatisfied with the platform and think. This platform still has a lot of shortcomings, such as the design page is too simple, the system functions are not rich enough, etc.

4.3. Confidentiality Measures for Blockchain Electronic Signatures. For ring signatures, it has the following characteristics: *Correctness.* If the user can sign the signed message according to the correct signing steps and it has not been tampered with, then during the verification phase, the resulting ring signature must meet the ring signature verification formula. *Unconditional anonymity.* It is almost

Figure 5: Enterprise employee satisfaction survey.

impossible to determine the true identity of the signer. Assuming that there are n members participating in the ring signature, even if the attacker steals the private keys of all voters by some means, the chances of him being able to successfully identify the true signer of a signature will be less than $1/n$. *Unforgotten.* It is difficult to successfully forge a legitimate signature. In the whole process of ring signing, the verification process of each ring member is different, and the signature result is the same. In this case, it is difficult to counterfeit.

Blockchain technology is a decentralized distributed database technology with the characteristics of trustlessness, transparent transaction openness, and immutable data, which can effectively reduce data management costs, improve work efficiency, and protect data security. However, with the development of quantum computing, quantum computing attacks with strong computing power can crack classical cryptographic algorithms, which poses a huge threat to transaction security that relies on elliptic curve digital signature algorithms to ensure the transaction security of the blockchain. At the same time, due to the transparency of transaction information on the blockchain, relevant research has proved that there is also a risk of user identity privacy leakage [19]. Therefore, research on blockchain transaction security and privacy protection has become an important topic in the current blockchain security field.

Since the concept of electronic voting was first proposed in 1981, its basic model can be summarized as shown in Figure 6.

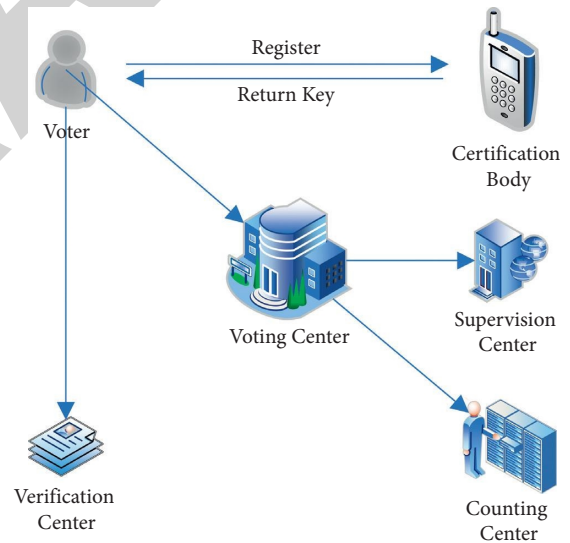
This paper designs an experiment to compare and analyze the signature generation times of the SMRA algorithm and the RSA-based signature algorithm RSAS, and the experimental data is shown in Table 5.


Figure 6: Diagram of the basic model of electronic voting.

The above data shows that in the case of an equal number of ring members, the signature generation time of the SMRA algorithm is less than that of the RSAS algorithm, and the signature efficiency is higher. Based on the above data, this article draws a simulation diagram as shown in Figure 7.

Through simulation experiments, the performance efficiency of the protocols is compared. The public key length, private key length, and signature length of the scheme in this section and the SMRA and RSAS methods are tested respectively, and $q = 2^{10}$, $d = 64$, and $m = 6n\log q$ are set under reasonable parameters according to the actual requirements in the lattice cryptographic algorithm, we set the security

TABLE 5: SMRA and RSAS signature time comparison analysis.

Number of ring members SMRA	Signature generation time (ms)	RSAS signature generation time (ms)
1	16.54	21.57
5	17.92	23.54
10	19.72	25.03
20	20.81	26.9
50	22.72	28.79
80	24.03	30.34
100	25.9	31.46
150	27.35	33.2

parameter n range from 10 to 160 increments, in turn, 16 tests. The experimental test results of public key length, private key length, and signature length for each scenario are shown in Figures 8–10, respectively.

Simulation test results show that with the continuous increase of the security parameter n, the public key, private key, and signature length of this section scheme are shorter than other schemes. In summary, the proposed signature algorithm has a relatively short one.

5. Conclusion

Internet information security issues are diverse, which means that Internet companies and users should have a sense of prevention when using the Internet and actively use new technologies to build an information security fortress on the Internet so as to reduce business risks. The development of blockchain technology provides a new model for Internet information security that is completely different from traditional forms of security prevention. The use of blockchain to develop Internet information security platforms can effectively protect the information security of enterprises. For example, a user's basic information, transaction information, and contact information can be guaranteed, thus greatly reducing the risks of business operations. But it should also be pointed out that any technology is a double-edged sword, with opportunities and challenges. The development of new technologies inevitably faces risks, and the blockchain is the same. Therefore, in the process of applying blockchain technology, we should think carefully, study carefully, make full use of the benefits of blockchain technology, and create an excellent new information security platform on the Internet that contributes to the prevention of business risks.

Motion Fatigue State Detection Based on Neural Networks

Hu Li ⓘ, Yabo Wang, and Yao Nan

Lanzhou City College Sports Institute, Lanzhou 730070, China

Correspondence should be addressed to Hu Li; 201872397@yangtzeu.edu.cn

Aiming at the problem of fatigue state detection at the back of sports, a cascade deep learning detection system structure is designed, and a convolutional neural network fatigue state detection model based on multiscale pooling is proposed. Firstly, face detection is carried out by a deep learning model MTCNN to extract eye and mouth regions. Aiming at the problem of eye and mouth state representation and recognition, a multiscale pooling model (MSP) based on RESNET is proposed to train the eye and mouth state. In real-time detection, the state of the eye and mouth region is recognized through the trained convolution neural network model. Finally, the athlete's fatigue is determined based on PERCLOS and the proposed mouth opening and closing frequency (FOM). The experimental results show that in the training process, we set the batch_size = 100 and the initial learning rate = 0.01. When the evaluation index is no longer improved, the learning rate is reduced by 10 times to 0.001, and a total of 50 epochs are trained. The precision and recall of the system are high. Compared with the infrared image simulating the night state, the RGB image taken by the ordinary camera in the daytime has higher precision and recall. It is proven that the neural network has high detection accuracy, meets the real-time requirements, and has high robustness in complex environments.

1. Introduction

As shown in Figure 1, machine learning is the general name of a class of algorithms. It automatically analyzes a large amount of data to obtain new knowledge, accumulate experience, make it continuously improve its own performance, and use these laws to identify existing data for prediction or classification. In the fatigue motion detection algorithm based on image processing, machine learning algorithms are mainly used to detect and identify athletes' fatigue states [1]. In the process of fatigue motion detection, some classical machine learning algorithms are used. For example, the AdaBoost algorithm is used to detect the facial region, and then the eye and mouth images are obtained for subsequent processes. Support vector machine (SVM) algorithm is used to classify the manually extracted feature vectors so as to identify the eye state. Using neural network algorithms for face detection and keypoint location, constructing convolution neural network to automatically extract athletes' fatigue features, classify and recognize them, and so on. The other is to automatically extract the fatigue characteristics of athletes by using convolutional neural

networks and construct two convolutional neural network models to perform classification tasks for eye and mouth states, respectively, that is, open or closed states [2].

2. Literature Review

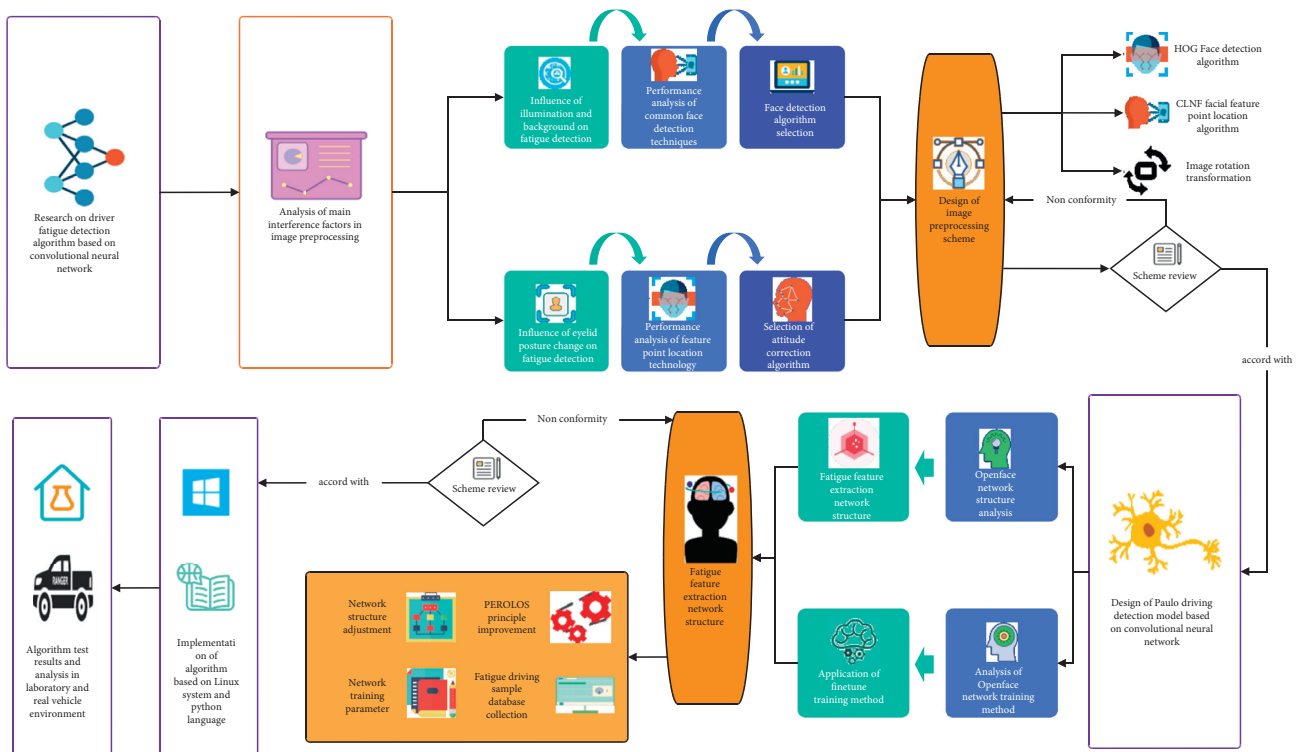
Liu Zhiqiang and others proposed a support vector machine (SVM) fatigue detection model based on the ASL eye tracker [3]. Wang Lei and others carried out a 36 h sleep deprivation experiment with an eye tracker to determine the thresholds of three fatigue judgment indicators: PERCLOS value, average eye closing time, and yawning frequency [4]. Nuevo and others used infrared devices to capture the eye movements of moving people and proposed a detection model based on AAM and PCA [5]. Jinjun Wang and others proposed a fatigue detection model based on the hidden Markov method based on simulated mover and infrared imaging [6]. Zeng Youwen and others also used contact instruments to collect physiological information from athletes. In the fatigue exercise experiment, they analyzed the correlation between EEG data and blink times and came to the conclusion that the EEG signal index and the blink time


Figure 1: Technical roadmap of the paper.

index can maintain the same conclusion when indicating the fatigue degree of athletes. There are also many studies on how to use machine learning methods to analyze EEG signals [7]. Ye Chun and others designed a fatigue detection system for sportspeople based on Morlet wavelet theory and EEG signals, which has the advantages of fast operation speed and strong real-time performance [8]. Xie Zhi and others used the fusion K-means clustering method to process EEG signals. This method can fully consider individual differences and achieve an 80% recognition effect [9]. Kwok Tai Chui and others used the SVM algorithm to process EEG signals. The algorithm has less computation, fast running speed, and an average processing delay of only 0.55 ms [10]. Chin Teng Lin and others used the principal component analysis method to process EEG signals, which has a large amount of calculation and high accuracy [11]. Lee and others made innovations in physiological signal acquisition instruments, using watch-type instruments to collect information such as ECG signals and arm movement status of athletes for fatigue early warning. This acquisition equipment is smaller, easier to popularize, and can ensure that the routine operation of athletes is not affected [12]. Xintong and others used the AdaBoost algorithm for face detection, combined with the prior knowledge such as the geometric proportion of facial features to locate the coordinates of eyes and mouth, finally used the gray-scale integral projection method to extract the opening of eyes and the roundness of mouth as fatigue features, and determined fatigue according to the PERCLOS principle [13]. Wu Minjie and others adopted a similar algorithm design idea, combined with the AdaBoost algorithm and template matching algorithm to

complete the function of fatigue feature extraction, and introduced the frequency of mouth opening and closing as one of the criteria into the fatigue detection system of sportspeople [14]. You Feng and others, as shown in Figure 2, after using the AdaBoost algorithm to detect a face, they use an elliptic curve fitting method to obtain eye-opening so as to judge fatigue [15].

Fatigue detection based on visual image processing has been a research topic for many years. However, due to the large interference of ambient light and human expression in the real scene, the accuracy of face detection and facial behavior feature detection still needs to be improved. To solve this problem, this paper proposes a cascade deep learning structure and a fatigue state detection model based on multiscale pooling networks (MSP net) [16]. The trained MTCNN model is used to detect the face, extract the data of eyes and mouth, put the data of eyes and mouth into the trained MSP net CNN for detection, judge the opening and closing of eyes and mouth, and finally jointly judge fatigue according to PERCLOS and frequency of open mouth (FOM). The specific process is shown in Figure 3.

3. Neural Network MSP Net

3.1. Pretreatment

3.1.1. Data Acquisition. The fatigue detection system in this paper adopts the cascade form of two deep learning models; one is MTCNN for detecting faces and extracting eye and mouth images, and the other is a multiscale pooled CNN for judging the state of eye and mouth images as proposed in
Figure 2: AdaBoost algorithm detection.
Figure 3: Algorithm flow.

this paper. Both networks require pretraining. Because the deep learning model has made remarkable achievements in face detection in recent years, this paper uses the existing excellent network to obtain the face and eye mouth area and focuses on the fatigue detection task [17]. The MTCNN model used in this paper is a trained model. The author uses the widerface database. There are about 200000 face images, including frame annotation and five key point information

(center coordinates of two eyeballs, nose tip coordinates, and two mouth corner coordinates). The regression of network training is the face frame and the coordinates of five key points. The data of eye and mouth image state judgment network training are independently collected by the author in practical work, including some actual athlete images and 21 volunteers. Considering that athletes have night training, the acquisition equipment uses infrared cameras in addition to ordinary cameras. In the process of image and video acquisition, various complex environmental problems of athletes during actual sports are comprehensively considered. The collected image data includes eyes closed, mouth open and closed, no glasses, wearing glasses, front and side, etc. After collection, we filter and eliminate some noise samples. Finally, the selected samples are classified as the opening, closing, opening and closing of ordinary cameras and the opening, closing, opening and closing of infrared cameras. Among them, there are 36764 samples in the eyes and 15185 samples in the mouth [18].

3.1.2. Data Preprocessing.
Because the brightness of the sample image collected by the infrared camera is generally low, the effect of directly putting it into the network training is not good, so the sample needs to be preprocessed. This paper uses the histogram equalization method. The purpose of histogram equalization is to enhance the local contrast. Its main steps are to calculate the cumulative probability of the gray level of the original image and map the original gray value to the new gray value according to the mapping relationship. For example, the gray-scale mapping relationship of gray-scale images with gray-scale values of 0–255 is as follows:

$$p_k = 255 \times \sum_{i=0}^{k} \frac{n_i}{n}, \quad k = 0, 1, 2, \ldots, L-1, \tag{1}$$

where p_k represents the gray value after mapping; k represents the kth gray level; L gray levels in total; n represents the number of all pixels; n_i represents the number of pixels of the i-th gray level; and the resulting p_k is rounded at the end.

3.2. Face Detection.
Traditional face detection algorithms, such as AdaBoost or frame difference, have poor robustness to complex environments. A deep learning model has great advantages in this regard. In this paper, the MTCNN model is used for face detection. The network structure of MTCNN is mainly divided into the following three layers:

(a) *P-Net*. Firstly, the image pyramid is constructed, and then the candidate face windows and bounding box reregression vectors are obtained through a fully convolutional network (FCN), which are used to calibrate the candidate face windows. Then, non-maximum suppression (NMS) is used to merge highly coincident candidate regions [19].

(b) *R-Net*. We put the candidate areas obtained by p-net into this network to further screen out a large number of wrong candidate areas and perform

calibration. Finally, NMS is also used to merge candidate areas.

(c) *O-Net*. This layer of the network is similar to R-Net, but this layer is made more detailed, and the candidate areas will be more strictly supervised. Finally, five more key point coordinates will be output [19].

MTCNN has good robustness and can still accurately detect the face rotated at a certain angle. The face is detected by MTCNN, and the eyes and mouth can be successfully marked according to the returned five key points.

3.3. Model Design.
The multiscale pooled convolutional neural network (MSP net) model is improved on the basis of the structure of RESNET, retains the concept of residual, and modifies the original max pooling to the multiscale pooling (MSP) proposed in this paper at the pooling layer to improve the recognition effect of images collected at different resolutions [20]. The structure of MSP is shown in Figure 4.

The steps of the MSP module are as follows: (a) first passed through twice max pooling to obtain a group of feature maps with side lengths four times smaller than the original feature map. (b) The original feature map is scaled, the side length is doubled, and then the new feature map is max pooled to obtain another group of feature maps with a side length of 1/4 of the original feature map. (c) Scaled the original feature map again, and the side length is reduced to 1/4 times of the original. (d) The three output feature maps are cascaded and introduced into the subsequent deep learning network [21]. The idea of a multiscale pooling model comes from the spatial pyramid pooling model. Compared with the spatial pyramid model, the advantage of multiscale pooling is that its substitution position is more flexible and can be used many times at the beginning, middle, or end of the network.

The structure of the MSP net network designed in this paper is shown in Figure 5. The training methods for the eyes and mouth are the same. Here, we take eyes as an example. In MSP net, the input image is 48×48 sizes gray image, after one convolution and MSP output $12 \times 12 \times 48$. The convolution kernel size is 3×3. After that, a residual block is passed. There are two layers of convolution in the residual block, and the size of the convolution kernel is still 3×3. Residual block output is $12 \times 12 \times 48$ feature maps. After another −max pooling, the output is $6 \times 6 \times 48$ feature maps. Then, the feature maps are converted into a one-dimensional vector and entered into the full connection layer. The input sequence length of the full connection layer is 1728, and there is a hidden layer with a length of 1000. Finally, the classification results are output by Softmax. The categories are divided into four categories: ordinary camera opening, infrared camera opening, ordinary camera closing, and infrared camera closing.

In order to verify the effectiveness of the MSP net, this paper not only uses the MSP net for experiments but also uses the classical Alex net and RESNET structures as comparison networks for training, testing, and related comparison experiments.

Characteristics of figure

FIGURE 4: Multiscale pooling (MSP) module.

FIGURE 5: MSP net structure.

3.5. Fatigue State Detection

3.5.1. PERCLOS.
PERCLOS is the ratio between the number of eye closure frames per unit time and the total number of frames per unit time. The calculation formula is as follows:

$$f_{\text{per}} = \frac{n}{N} \times 100, \tag{5}$$

where n represents the number of closed eye frames and N represents the total number of frames per unit time. PERCLOS can well quantify the degree of athletes' eye closure. When PERCLOS reaches a certain threshold, it can be judged that the athletes' eye closure time is too long, and it can be preliminarily considered that they have entered a fatigued state.

3.5.2. Mouth Opening and Closing Frequency.
FOM, similar to PERCLOS, represents the ratio between the number of frames with mouth open per unit time and the total number of frames per unit time. The calculation formula is as follows:

$$f_{\text{fom}} = \frac{n}{N} \times 100. \tag{6}$$

Like PERCLOS, n represents the number of shut-up frames and N represents the total number of frames per unit time. The greater the value of these two indicators, the greater the degree of fatigue. The final fatigue state detection needs to be considered together.

3.5.3. Fatigue State Detection.
After the pretraining of all deep networks is completed, the threshold of fatigue state is set according to PERCLOS and FOM, and the whole network system is applied to real-time detection. The specific steps are as follows: the camera captures the athlete's video, and MTCNN captures the face and five key points in each frame and extracts the eye and mouth areas. An MSP net is used to detect the state of the eyes and mouth captured in each frame and save them in a fixed long queue. The algorithm detects the change of the median value in the queue in real-time. When the distribution of all values in the queue reaches the threshold fatigue state, the alarm mechanism starts to remind athletes that they have entered fatigue.

3.4. Loss Function and Optimization Method.
Finally, the network uses the Softmax classification method, which is divided into four categories. The SoftMax function is defined as follows:

$$p_j = \frac{\exp\left(y'_j\right)}{\sum_{k=0}^{3} \exp\left(y'_k\right)}, \quad j = 0, 1, 2, 3, \tag{2}$$

where p_j represents the probability of class j; $y'_j = \sum_i h_i w_{i,j} + b_j$ represents the output of the last layer of the full connection layer, h_i is the output of the previous layer, and $w_{i,j}$ and b_j are the weight and offset of the last layer, respectively. The loss function is defined as cross-line and expressed as

$$L_m = -\sum_{j=0}^{3} 1\{y = j\}\log p_j, \tag{3}$$

where L_m represents the cross-line of the m-th sample; $1\{y = j\}$ represents the indicative function, that is, when $y = j$, the function is 1, and when $y \neq j$, the function is 0. (3) is the loss function of a single sample. When there are M training samples, the loss function needs to be averaged and it is expressed as

$$L = \frac{1}{M} \sum_{m=1}^{M} L_m. \tag{4}$$

The optimization method uses adaptive motion estimation (Adam).

FIGURE 6: Model loss on eye dataset model_loss.
FIGURE 7: Model accuracy on eye dataset model_accuracy.

4. Experimental Results and Analysis

This paper constructs a neural network model based on the deep learning framework and uses the framework of multithreaded input data provided by tensor flow to combine the training data (batch) and disrupt the data order, which can improve the efficiency of model training. During training, we set the batch_ size = 100 and learn_ rate = 0.01. When the evaluation index is no longer improved, the learning rate decreases 10 times to 0.001 and the lowest to 0.00001. One epoch means that all training sets are trained once. In this paper, 50 epochs are trained on the training set, the Adam adaptive moment estimation optimization algorithm is used for backpropagation, the callback function is set to monitor the loss val_loss of the verification set, and the network model with the minimum loss on the verification set is saved as the final training model. The graphs of training loss and verification loss val_loss are shown in Figure 6, and the graphs of accuracy rate train accuracy on training set and accuracy rate val_accuracy on verification set are shown in Figure 7.

The verification dataset and test dataset are used to test the model saved after training. The detection accuracy on each dataset is shown in Table 1.

In order to verify the performance of the algorithm proposed in this paper, using the public CEW dataset, our algorithm is compared with the eye state recognition algorithm proposed in recent years. The detection accuracy is shown in Figure 8.

TABLE 1: Detection accuracy on each eye dataset.

Dataset	CSW data	Yaw DD data (%)	Self-built data (%)	Average detection accuracy (%)
Validation set	0	98.7	98.6	98.65
Test set	97.87%	98.2	98.44	98.17
Average detection accuracy	97.87%	98.45	98.54	98.42
FIGURE 8: Performance comparison of different eye state detection algorithms.
FIGURE 9: Model loss on dataset model_loss.

The algorithms proposed in the above other references collect monocular images to analyze the eye state, while our algorithm analyzes the athlete's eye state through binocular images. Compared with monocular images, the proposed algorithm can extract more abundant features and has higher detection accuracy. The images in the CEW dataset are ideal, and there are few postures such as head deflection and tilt. The experimental results show that our algorithm has high detection accuracy compared with other algorithms. In the yaw

DD dataset, the head posture of athletes is changeable, and there will be inclination, deflection, and other situations, where the detection effect of other algorithms will be worse.

After preparing the training dataset, the next step is to train the network and verify the performance of the network model. This paper uses the framework of multithreaded input data provided by tensor flow to combine training data (batch), which also disrupts the order of training data. In the training process, we set the
FIGURE 10: Model accuracy on mouth dataset model_accuracy.
FIGURE 11: Detection accuracy on each mouth dataset.

batch_size = 100 and learn_rate = 0.01. When the evaluation index is no longer improved, the learning rate decreases 10 times to 0.001, and a total of 50 epochs are trained. In this paper, the Adam adaptive optimization algorithm is used for backpropagation, the callback function is used to monitor the loss of the verification set, and the network model with the least loss on the verification set is saved as the final training model. The graphs of training loss train_loss and verification loss val_loss are shown in Figure 9, and the graphs of accuracy on the training set and accuracy val_accuracy on verification set are shown in Figure 10.

The model saved after training is tested with the mouth verification dataset and the test dataset. The detection accuracy on each data set is shown in Figure 11.

In order to verify the performance of the algorithm proposed in this paper, using the public yaw DD dataset, our algorithm is compared with the mouth state recognition algorithm proposed in recent years. The experimental results are shown in Figure 12. Compared with other mouth state recognition algorithms, the algorithm proposed in this paper performs mouth correction, so the detection accuracy is higher when the athlete's head posture is tilted and deflected. Experimental results also show that the proposed algorithm is better than other algorithms.

It can be seen from Figure 13 that videos of athletes under normal exercise, talking/laughing, and yawning are selected from the test dataset. The following two figures are the results of analyzing the fatigue degree of athletes through the state of their mouth. When the system detects that the
FIGURE 12: Performance comparison of different mouth state detection algorithms.
FIGURE 13: Two different mouth states: (a) Normal and (b) Yawning.

athlete is yawning (Figure 13), an audible warning is issued to remind the athlete to pay attention.

5. Conclusion

In this paper, a cascade deep learning structure and a real-time fatigue detection system based on multiscale pooled convolutional neural networks are designed. Firstly, the athlete's face is detected by MTCNN to extract the key positions of eyes and mouth. Then the eye and mouth images are sent to the multiscale pooled MSP net for the state test, and a fixed-length queue is set. The queue saves the detection results of each frame in unit time, and the fatigue state is judged jointly by PERCLOS and mouth opening and closing frequency (FOM). Experiments show that the proposed algorithm has high detection accuracy, can achieve the effect of real-time detection, and has high robustness in complex environments. The method proposed in this paper will be further transplanted and optimized for the embedded platform.

This paper presents a big data analysis and prediction system based on convolutional neural networks. Continuous template matching technology is used to analyze the distributed data structure of big data, and the information fusion processing of cloud service combination big data is combined with matching related detection methods, frequent item detection, and association rule feature extraction of high-dimensional fusion data. A clustering method is adopted to realize the classification and mining of cloud service portfolio big data. The hardware equipment of the car to detect the surrounding environment is complicated, and the combination of the convolutional neural network and the camera to detect the surrounding environment has become a research hotspot. However, simply using the convolutional neural network to process the camera data to control the turning angle of the car has the problems of long training time and low accuracy. An improved convolutional neural network is proposed. The experimental results show that the accuracy of data mining by this method is 12.43% and 21.76% higher than that of traditional methods, and the number of iteration steps is shorter, indicating that the timeliness of mining is higher. This network structure can effectively improve the training speed of the network and improve the accuracy of the network. It is proven that the convolutional neural network has faster training speed and higher accuracy.

1. Introduction

All walks of life have begun to carry out artificial intelligence research in an all-around way, the most critical of which is the deep learning technology (Figure 1). "Deep learning" is a multilayer neural network, and "deep" in a sense refers to the number of layers of artificial neural networks. This is a brand-new field in machine learning research. This method aims to simulate human's intelligent behavior by simulating human thinking process so that, after training, the machine can show intelligent behavior that looks like a human, so that the ability of machine learning can be displayed. There is a possibility of surpassing human intelligence [1]. Deep learning has led to the rise of artificial intelligence. Traditional artificial intelligence algorithms rely on artificially summarized rules to program solutions to problems. But deep learning is different. It does not require artificial extraction of the characteristics or rules of the problem. It can learn from the input. A large amount of data spontaneously summarizes the law, adaptively adjusts its own structure so as to draw inferences from one another and generalize it to a case that has never been seen before [2]. To sum it up in one sentence, the most important feature of deep learning is that it can automatically learn W from data. Basic deep learning models can be divided into two categories: generative models and discriminative models. The former mainly includes restricted Boltzmann machine (RBN) models, autoencoder (AE) models, and deep belief network (DBN) models, which are generally used to express high levels of data. Order correlation or joint statistical distribution describing data; the latter mainly include convolutional neural network (CNN) model, recurrent neural network (RNN) model, deep stacking network (DSN) models, and long short-term memory network models, are usually used to classify the internal pattern of the data or describe the posterior distribution of the data [3].

The convolutional neural network is the most widely used deep learning network in computer vision. It has
Figure 1: Multilayer neural network of deep learning technology.

achieved good results in various image recognition tasks in various fields, such as face recognition, fingerprint recognition, license plate recognition, and target tracking [4]. However, changes in illumination and viewing angles still present certain challenges to image recognition. In order to solve this problem, Li B. proposed a color image recognition method that combines image feature data and a deep trust network to construct image color data. Under the premise of the field, wavelet transform is used to describe the multiscale features of the image, and finally, the deep trust network is trained unsupervised, but the recognition rate needs to be further improved [5]. Rao M. et al. proposed an image recognition method based on the CNN-GRNN model and designed a new image recognition model that extracts multilayer features in the image through a convolutional network and uses a generalized regression neural network to replace the reverse spread the neural network to improve the generalization ability and robustness of the classifier [6]. Clabaut, T. fused Bayesian networks and artificial neural networks to create a model. The fusion model can well reflect the correlation of road traffic flow in time and space. The study verifies the prediction results of the fusion model by using the traffic flow data collected by large floating vehicles installed on the Roman road network. The verification results show that the spatial structure of the Bayesian network is effective in road traffic flow prediction under general conditions. In a few cases of nonrecurring congestion, it is more valuable to use a single-dimensional time series method to process data [7].

On the current basis, this paper proposes a kind of information fusion processing based on the combination of cloud services and big data. First, frequent item detection and association rule feature extraction are performed on the high-dimensional fusion data. Then, they use a convolutional neural network classifier to classify the extracted association rules. Combine the feature compression method to reduce the dimensionality of the classified output cloud service portfolio big data and use the clustering method to realize the classification and mining of the cloud service portfolio big data; the designed network structure adopts unsupervised bipartite K-means and convolutional neural networks. Compared with the traditional convolutional neural network, the combined method of (CNN) can reduce the training parameters and eliminate the problem of gradient dispersion.

2. Distributed Structure Model and Feature Extraction of Big Data

2.1. Feature Distribution Model of Cloud Service Portfolio Big Data. In order to realize the optimized mining of cloud service combination big data, firstly build the distributed data structure model of big data under the cloud service combination mode and use the quadruple G to represent the distributed storage center of cloud service combination big data, $G=(V, E, W, C)$ [8]. Assuming d is the phase space embedding dimension of the cloud service combination big data interaction, the multi-nonlinear component joint statistical method is used to reconstruct the high-dimensional feature space of the cloud service combination big data, and the clustering method is used for the adaptive classification of big data. Based on the above analysis, the overall structure model of the cloud service portfolio for big data mining is constructed, as shown in Figure 2.

There are many disturbance factors in the process of cloud service portfolio big data mining, which are time-varying and random [9]. The clustering method is used for big data information fusion, and the association rule term constraint equation is used to express the information flow model of cloud service portfolio big data, and it is expressed as

$$x_n = x(t_0 + n\Delta t) = h[z(t_0 + n\Delta t)] + \omega_n, \qquad (1)$$

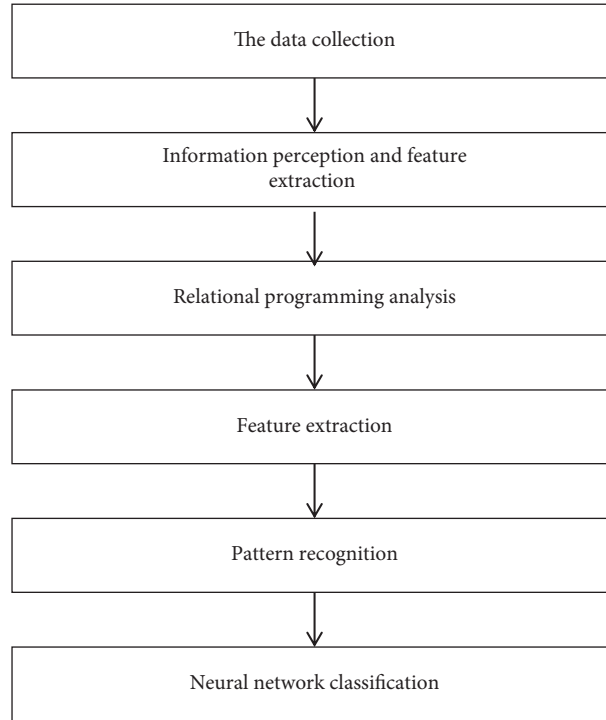
where h is the distributed time series of cloud service combination big data, expressed as a function with a multidimensional data structure model and ω_n is the observation or measurement error of big data multisensor information fusion tracking. The distribution function description formula of the distribution structure model of cloud service portfolio big data is


FIGURE 2: The overall structure model of cloud service portfolio big data mining.

$$X_p(u) = \begin{cases} p\sqrt{\dfrac{1-j\cot a}{2\pi}}\, e^{j(u2/2)\cot a} \displaystyle\int_{-\infty}^{+\infty} x(t)e^{j(u2/2)\cot a - jtu\csc a}\mathrm{d}t, & a \neq n\pi, \\[2mm] x(u), & a = 2n\pi, \\[2mm] x(-u), & a = (2n \pm 1)\pi, \end{cases} \tag{2}$$

where p is the order of the big data storage structure of the distributed cloud service combination and α is the time window width of statistical information sampling. Then we construct a temporal structure model of cloud service portfolio big data distribution.

The mined cloud service combination big data is reconstructed according to the five-tuple of the association rule item characteristics, the association rule knowledge base is constructed, and the characteristic identification function of the cloud service combination big data data structure is given as $P_c = \sum_{i=0}^{n}\sum_{j=0}^{n} a(i,j)P(i,j)$. The statistical regression analysis method is used to construct the nonlinear time series model of the cloud service combination big data, and the linear combination model is obtained as

$$x_k = \sum_{n=0}^{(N/2)-1} 2\left(a_n \cos\frac{2\pi kn}{N} - b_n \sin\frac{2\pi kn}{N}\right), \quad k = 0, 1, \ldots, N-1, \tag{3}$$

where a_n represents the magnitude of the cloud service portfolio big data linear programming model. For a set of continuous cloud service combination big data, the continuous template matching technology is used to analyze the distributed data structure of big data, and the information fusion processing of cloud service combination big data is combined with matching-related detection methods. The data flow processing is shown in Figure 3.

2.2. Data Feature Extraction. Suppose the amount of cloud service combination big data nodes is m, and the closed frequent itemset feature extraction output of each node is expressed. Based on the extreme learning method for the global optimization of data feature extraction, the mathematical expression of the linear programming problem for constructing cloud service portfolio big data mining is as follows:
FIGURE 3: Distributed data structure of big data.

$$\min(f) = \sum_{i=1}^{m} \sum_{j=1}^{n} C_{ij} X_{ij},$$

$$\text{s.t} \begin{cases} \sum_{j=1}^{m} X_{ij} = a_i, & i = 1, 2, \ldots, m, \\ \sum_{i=1}^{m} X_{ij} = b_i, & j = 1, 2, \ldots, n, \\ X_{ij} \geq 0, & i = 1, 2, \ldots, m; j = 1, 2, \ldots, n. \end{cases} \tag{4}$$

Assuming that the current number of cloud service portfolio big data distribution nodes is $n, N_{1n}, \ldots, N_n$, the load of the big data to be mined in the link layer is $L_1, \ldots, L_n$, and the estimated characteristics of the cloud service portfolio big data mining output are $P_1^{\min}, \ldots, P_n^{\min}$ [10]. In the linear programming model, the feature decomposition of cloud service portfolio big data is carried out, wavelet entropy is obtained, and the information fusion processing of cloud service portfolio big data is combined with matching correlation detection methods. Perform frequent item detection on high-dimensional fusion data to realize the feature extraction of association rules, which is expressed as

$$\begin{cases} \rho_t^I = \dfrac{\sum_1^{N_I} s(i,t)}{V} = \dfrac{N_I}{V}, \\ \rho_t^R = \dfrac{\left| \sum_1^{N_R} s(i,t) \right|}{V} = \dfrac{N_R}{V}, \\ \rho_t^s = \dfrac{N_S}{V}. \end{cases} \tag{5}$$

A multivariate statistical characteristic equation is used to describe the fitting state model of cloud service portfolio big data as

Among them, N_1, N_R, and N_s, respectively, represent the average mutual information feature quantity and state distribution set of cloud service portfolio big data [11].

2.3. Data Classification and Mining Technology Optimization

2.3.1. Convolutional Neural Network Classification.
Based on the abovementioned large data distributed data structure analysis and association rule feature extraction using continuous template matching technology, the optimization design of data classification mining algorithms is carried out. This paper proposes a big data classification mining technology based on convolutional neural networks, using statistical average methods to build a regression analysis model of the big data that needs to be mined and it is expressed as

$$\begin{cases} \min \sum_{1 \leq i \leq K e \subseteq k(e)} \sum \dfrac{f(e(i))}{C(e,i)}, & 0 \leq f(e,i) \leq C(e,i), \\ & F = \text{const}, \end{cases} \qquad \sum_{1 \leq i \leq K, e \subseteq k(e)} \dfrac{f(e(i))}{C(e,i)} + \sum_{e \subseteq k(e)} \dfrac{f(e'(i))}{C(e',i)} \leq k(v). \tag{6}$$

$$\begin{pmatrix} X \\ P(X) \end{pmatrix} = \left\{ \begin{matrix} a_1, a_2, \ldots, a_m \\ p(a_1), p(a_2), \ldots, p(a_m) \end{matrix} \right\}. \tag{7}$$

Among them, $0 \le p(a_i) \le 1$ $(i = 0, 1, 2, \ldots, m)$ and $\sum_{i=1}^{m} p(a_i) = 1$ represent the autoregressive statistical characteristic parameters of cloud service portfolio big data. A convolutional neural network classifier is used to classify the attributes of the extracted association rules of cloud services combined with big data [12]. The convolutional neural network is a three-layer network structure, and the input and output iteration equation of the convolutional neural network classifier is

$$W(n+1) = W(n) - \eta \frac{\partial E}{\partial W} + \partial \Delta W(n). \tag{8}$$

Assuming that the learning step size of the convolutional neural network for big data recognition is

$$w_{sij}(n_0 + 1) = w_{sij}(n_0) - \eta_{sij} \frac{\partial J}{\partial w_{sij}}. \tag{9}$$

Using the learning algorithm of the convolutional neural network, the adaptive learning weighting coefficient of the cloud service portfolio big data classification is obtained as

$$a_{\text{desira}}^{i} = a_1 \cdot \frac{\text{Density}_i}{\sum_i \text{Density}_i} + a_2 \frac{\text{AP}_i}{\text{AP}_{\text{init}}}. \tag{10}$$

Under the constraints of $B \Rightarrow D$, $A \cap B \Rightarrow D$, and other rules, the attribute set of cloud service portfolio big data classification satisfies

$$\begin{cases} a_1 + a_2 = 1, \quad a_1, a_2 \in [0, 1], \\ \\ a_2 = \dfrac{\max_i(\text{AP}_i) - \min_i(\text{AP}_i)}{\text{AP}_{\text{init}}}. \end{cases} \tag{11}$$

The statistical quantitative set of data is $(u, v) \in E$, suppose $A \subset V$, $B \subset V$, and $A \cap B = \phi$. The convolutional neural network classifier is used for attribute classification to realize the big data reorganization and data structure rearrangement of the cloud service portfolio. The neuron structure of the convolutional neural network is shown in Figure 4.

2.3.2. Data Feature Dimensionality Reduction and Classification Mining Output.
Based on the use of convolutional neural network classifiers for attribute classification, in order to reduce the computational cost, combined with the feature compression method, the dimensionality reduction processing of the cloud service composite big data output by the classification is performed [13]. The feature compressor is described as

$$F = \overline{p}(x, y) = p(x, y) \left(\frac{v(x)}{v(y)} \right)^{1/2}. \tag{12}$$

Among them
Figure 4: Convolutional neural network neuron structure.

$$p(x, y) = \frac{k(x, y)}{v(x)},$$
$$v(x) = \sum_y k(x, y). \tag{13}$$

The conceptual grid node of cloud service portfolio big data obtained by using a convolutional neural network classifier is

$$X' = \left(x'_{i0}, x'_{i1}, \ldots, x'_{i(n-1)}, y'_{i0}, y'_{i1}, \ldots, y'_{i(n-1)} \right)^T. \tag{14}$$

The dimensionality reduction of the cloud service portfolio big data output by classification is performed, and the clustering method is used to realize the classification mining of the cloud service portfolio big data [14].

3. Method for Predicting Lateral Turning Angle of Trolley Based on Bipartite K-Means Convolutional Neural Network

3.1. Trolley Lateral Control. The lateral control of the trolley is divided into image acquisition, image preprocessing, CNN model establishment, and prediction angle in this article. The overall process is shown in Figure 5.

3.2. Building a Dataset. A camera is preinstalled on the front, left, and right parts of the front end of the trolley, and then the trolley is manually controlled to avoid obstacles, and the image data of the three cameras are obtained from the upper computer. The data of the three cameras are divided into three parts: front, left, and right. At the same time, the steering gear angle is converted into a digital signal through an adjustable resistor, and then the digital signal is converted into the rotation angle of the front wheel of the trolley by the host computer [15]. In the process of data collection, in order to ensure the validity of the dataset in a variety of complex situations, the data collection should meet the following requirements:

(1) In order to avoid the influence of light, weather, and other factors on the camera, the dataset should be collected under different light and weather conditions in the same environment.

(2) In order to avoid the occurrence of too many abnormal quantities, we try to keep the angle similar to the original under the same environment, and try to avoid the appearance of the angle that deviates too much from the original [16]. When the above conditions are met, the article collected more than 400 images at each of the front, left, and right positions of the trolley. The comparison of the accuracy of data mining is shown in Figure 6.

3.3. Dataset Preprocessing. In order to ensure that the number of images is sufficient to prevent the occurrence of overfitting, this article amplifies the dataset by adding Gaussian noise and salt-and-pepper noise to the original image, and finally obtains more than 1,400 images in each of 3 locations, totaling more than 4200 image dataset, the time-domain waveform of data mining is shown in Figure 7.

Since the turning angle is converted by a digital signal, the change of the turning angle in time is not smooth. In order to smooth the data, this article selects a moving average and calculates the average with 3 time units (0.3 s) as a window. Figure 8 is a comparison diagram of the original data and the smoothed data over time.

3.4. Establishment of Convolutional Neural Network Model Based on Bipartite K-Means

3.4.1. Network Structure. This section explains the improved convolutional neural network structure for the prediction system of the lateral turning angle of the trolley. There are 1 K-means layer, 3 ordinary convolutional layers, 2 fully connected layers, and 2 dropout layers [17]. Among them, 3 convolutional layers and 2 fully connected layers are trainable layers. The height and width of the convolutional layer decrease as the depth of the network structure increases. The output node of the fully connected layer of the last layer is 1. In front of the fully connected layer, add a dropout layer to improve the generalization ability of the network and prevent overfitting [18].

3.4.2. Input Layer. The preprocessed image pixels are 160×320, and the preprocessed images at the front, left, and right positions are used as the input of the input layer. The purpose is to preserve the image information of each position of the vehicle as much as possible.

3.4.3. Dichotomous K-Means Layer. When traditional convolutional neural networks are used in image recognition, a huge dataset is required for training, and it is prone to overfitting problems. Therefore, it is thought of clustering the pictures first. The classic K-means clustering algorithm is greatly affected by the initial clustering center and it is easy to converge to the local minimum, so the bipartite K-means algorithm is used [19]. Using the bisection K-means algorithm can reduce the amount of training overhead, overcome the local optimal problem caused by the uneven distribution of the dataset, and the clustering effect is better. The images at the front, left, and right positions are passed through the bisected K-means layer in turn, and the k clustering results obtained are used as the input of the next layer. The k value of the dichotomous K-means layer designed in this paper is set as 3.

3.4.4. Convolutional Layer. The convolutional layer extracts the characteristics of the input image through convolution calculation. The network structure designed in this paper has 3 convolutional layers, and each convolutional layer decreases in turn as the network depth increases. The first convolutional layer has 16 filters, and the size of each filter is $8 \times 8 \times 3$, and the step size is 4; the second convolutional layer has 32 filters, and the size of each filter is $5 \times 5 \times 3$, and the step size is 2; the third convolutional layer has 64 filters, each filter has a size of $5 \times 5 \times 2$, and the step size is 2. There are many types of activation functions in convolution calculations. Among them, the sigmoid function is the most commonly used, and it can also be a modified linear unit (ReLu). The modified linear unit used here is to speed up the training of the network and reduce the calculation time of the network (Figure 9).

$$f(x) = \max\left(0, \sum_i w_i a_i\right). \qquad (15)$$

In the formula w is the connection weight and a is the output of the previous layer.

Figure 11: The first comparison of results based on the bipartite K-means convolutional neural network and the traditional convolutional neural network.
FIGURE 12: The second result comparison between the bipartite K-means convolutional neural network and the traditional convolutional neural network.
FIGURE 13: Comparison of training results based on the bipartite K-means convolutional neural network and the traditional convolutional neural network.

3.4.5. Output Layer. The output layer of the network structure is a fully connected layer, and the output node of the fully connected layer is 1. In order to avoid overfitting, a dropout layer is added in front of the fully connected layer, and the dropout rate of the dropout layer is 0.5. A dropout layer with a dropout rate of 0.2 is also added to another fully connected layer of the network structure. The network structure of the classification layer is shown in Figure 10.

4. Experimental Results and Analysis

The training results of the convolutional neural network based on dichotomous K-means and the traditional convolutional neural network are shown in Figures 11–13, and the comparison results of accuracy and error results are shown in Figures 14 and 15.

It can be seen from Figure 13 that although the two networks eventually tend to converge, if only the convolutional neural network is used for angle prediction, more iterations are needed to gradually converge. If a bipartite K-means convolutional network is added, the image category can be determined faster, so that fewer iterations are required.

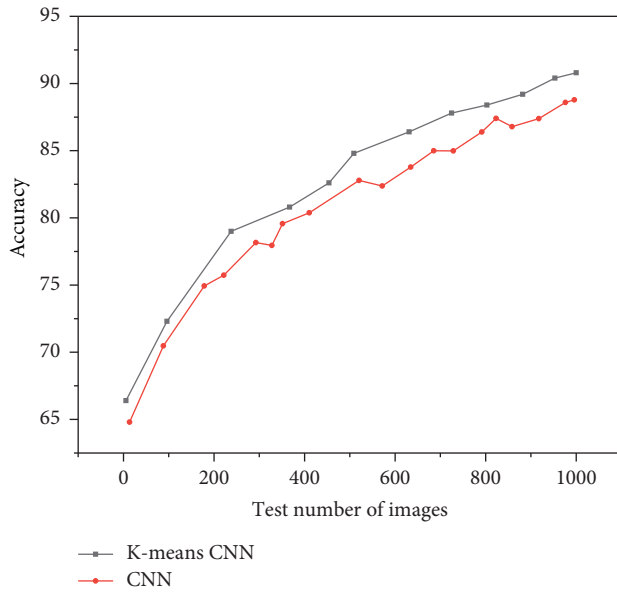
It can be seen from Figures 14 and 15 that the recognition rate of the two network structures increases with the increase of the number of test pictures.


FIGURE 14: Comparison of accuracy based on the bipartite K-means convolutional neural network and the traditional convolutional neural network.
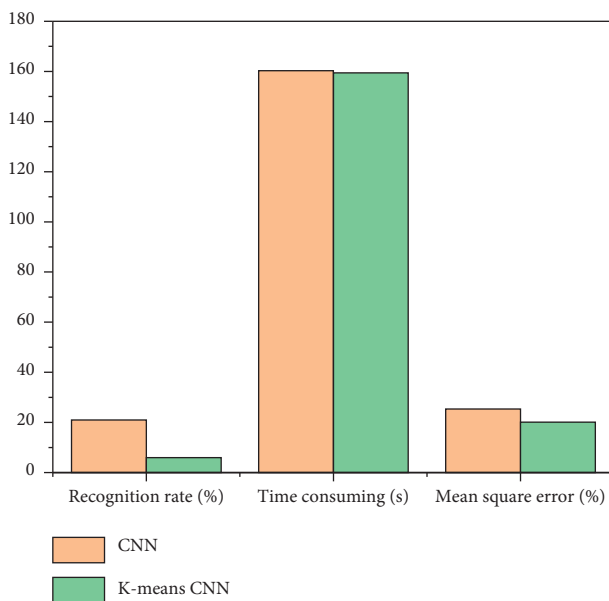

FIGURE 15: Error comparison between the bipartite K-means convolutional neural network and the traditional convolutional neural network.

5. Conclusion

A convolutional neural network classifier is used for attribute classification, combined with a feature compression method to reduce the dimensionality of the cloud service portfolio big data output by classification, and a fuzzy clustering method is used to realize the classification and mining of cloud service portfolio big data. The bisection K-means clustering method is added to the traditional convolutional neural network for optimization, and it is

verified on the image data collected by the smart car camera. The improved convolutional neural network uses the binary K-means clustering method to perform clustering learning first, so that the convolutional neural network can obtain richer input information, thereby reducing the training parameters of the convolutional neural network, accelerating the training speed of the network, and improving training accuracy. The experimental results show that the improved convolutional neural network model has faster training speed and higher accuracy than the traditional convolutional neural network.

Commercial banks are of great value to social and economic development. Therefore, how to accurately evaluate their credit risk and establish a credit risk prevention system has important theoretical and practical significance. This paper combines BP neural network with a mutation genetic algorithm, focuses on the credit risk assessment of commercial banks, applies neural network as the main modeling tool of the credit risk assessment of commercial banks, and uses the mutation genetic algorithm to optimize the main parameter combination of neural network, so as to give better play to the efficiency of neural network. After verification of various evaluation models, the accuracy of the evaluation model designed in this paper is more than 65%, while the acceptability of the evaluation results optimized by the mutation genetic algorithm is more than 85%. Compared with the accuracy of about 50% of the traditional credit scoring method, the accuracy of the credit risk evaluation using neural network technology is improved by more than 10%. It is proved that the performance of the optimized algorithm is better than that of the traditional neural network algorithm. It has important theoretical and practical significance for the establishment of the credit risk prevention system of commercial banks.

1. Introduction

The credit risk assessment has developed for a long time, and its measurement method is also changing, and the model method has been adopted for the credit risk assessment. The evaluation and management of credit risk is of more important practical significance for commercial banks [1]. The credit risk evaluation of commercial banks is a typical fuzzy problem because there are not only many factors affecting credit risk but also one factor often has multiple levels. Therefore, it is necessary to explore the index system, evaluation method, and practical application of comprehensive evaluation of credit risk. Therefore, it will be of great significance to accelerate the research work of the credit risk assessment, find the credit risk assessment method and model suitable for the actual situation of commercial banks as soon as possible, provide the basis for loan decision making of commercial banks, and finally improve the competitiveness of commercial banks [2]. To solve the

problem of the credit risk assessment, neural network technology has its unique advantages in which the most important is the nonlinear mapping ability of neural network. Through the forward neural network, the nonlinear relationship between credit index and rating can be described quantitatively, so as to meet the classification of customer credit rating according to index data [3].

Based on the in-depth study of the current situation and application characteristics of the credit risk assessment of commercial banks, combined with the characteristics of data mining and neural network technology, this paper puts forward a credit risk assessment system [4], improves and verifies the proposed model, and provides a feasible solution for the credit risk assessment. In the assessment system, the core task of data mining is credit risk classification. There are also many data mining methods that can realize classification, such as decision tree and neural network. According to the application characteristics and data characteristics of the credit risk assessment, neural network has better pertinence

and applicability than other classification methods. Therefore, neural network method is used to undertake the core task of data mining [5], namely, credit risk classification. However, the collected data cannot be directly used to train the neural network classification model, but must go through certain preprocessing and pattern division. Preprocessing includes supervised discretization, which is to determine split points in a way that maximizes the purity of the interval. However, in practice, this approach may require arbitrary determination of the bin purity and minimized bin size. To address this, some statistics-based methods divide the interval with each attribute value and create larger intervals by merging adjacent intervals similar to those based on statistical tests. The outlier analysis function of data mining is used to find the samples containing outlier data in the training samples, and discard or flatten these samples so that the neural network model can more truly reflect the mapping relationship between credit indicators and credit ratings [6]. In fact, pattern division is also classification. It distinguishes enterprise customers according to their financial data so that the financial data of the same kind of enterprise customers fall within a reasonable range, to improve the classification accuracy of the neural network model [7]. Although BP algorithm has been widely used, the main disadvantage is that the training process is uncertain. The genetic algorithm is a global optimization algorithm. This algorithm is essentially different from the single-point search method. It adopts the method of processing multiple individuals in the search space at the same time. It has good global search performance and effectively reduces the possibility of falling into the local optimal solution [8]. Therefore, the emergence of the genetic algorithm makes the training of neural network have a new look. Using the genetic algorithm instead of BP algorithm to search the connection weight of neural network is expected to solve the problem of BP network falling into local minimum. To sum up, the credit risk assessment system studied in this paper uses neural network to complete the function of the credit risk assessment [9].

In this paper, genetic algorithms are introduced to optimize the network established by backpropagation algorithm to form a hybrid algorithm. For the credit risk, a backpropagation network includes input layer, output layer, and several hidden layers. The principle of the network for the credit risk assessment of commercial banks is to take the index information used to measure the financial and non-financial status of loan enterprises as the input vector of God and network, the classification result is used as the output vector of neural network, and the network is trained with training samples to obtain different output values. After the training, it can be used as an effective tool for the credit risk assessment and prediction. After the training, credit risk can be effectively predicted. This paper compares and analyzes the prediction results of neural network optimized by the mutation genetic algorithm to verify its application in the credit risk evaluation of commercial banks. The experimental results show that the mutation genetic algorithm has the ability to optimize the training of neural network, and it is feasible and effective to apply the neural network model optimized by the mutation genetic algorithm to the credit risk evaluation of commercial banks.

2. Related Work

The credit risk assessment is the core content of bank risk management. Credit risk will lead to bank bankruptcy. Therefore, since the birth of the bank, banking experts have begun to explore the credit risk assessment [10]. The evaluation of creditability involves many factors, generally including the following five independent and related factors, namely, economic strength, growth ability, asset management ability, solvency ability, and profitability. Since the 1980s, the evaluation of credit risk has changed from relying on the experience and subjective analysis of banking experts to a credit scoring model based on financial indicators, mainly including linear probability model, logit model, probit model, and discriminant analysis model [11]. In the late 1980s, some experts at home and abroad began to use artificial intelligence theory and neural network theory to improve the accuracy and accuracy of distinction. The application of these methods overcame the requirements of the above traditional statistical methods for assumptions and the shortcomings of statically reflecting credit risk. Since the 1990s, the loan profit of commercial banks has continued to decline and the risk of off-balance sheet business has increased, which has prompted banks in various countries to pay more attention to the management and prevention of credit risk. Many Western banks have begun to explore the use of modern financial theory and mathematical tools to develop new credit risk measurement models [12]. They began to develop new and more complex credit evaluation systems, changing from simple single loan risk to measuring centralized risk. All these efforts have made great progress in the measurement and control technology of credit risk in the Western banking industry and produced a series of successful quantitative management models of credit risk. Comprehensive models can be divided into two categories: one is the combination theory model, such as JPMorgan's Credit Metrics and KMV method [13] and the other is the default model, such as credit risk + of Credit Suisse and portfolio view model of McKinsey. The biggest difference between the two models is that the default model estimates the future default distribution of the portfolio based on theoretical analysis, while the portfolio theoretical model estimates the future default distribution of the portfolio from historical data [14].

In the research of the credit risk identification, the most commonly used neural networks are BP neural network [15], RBF neural network, and probabilistic neural network. BP network is a one-way propagation multilayer feedforward network [16]. Due to its good mapping ability to approximate nonlinear functions and parallel processing, it can approximate any nonlinear mapping relationship to obtain the solution of the problem; instead of relying on the prior knowledge and rules of the problem, it has strong adaptability and is very suitable for solving the classification and pattern recognition problems of irregular, multiconstraint, or incomplete data [17, 18]. Due to the perfect theoretical

basis and few restrictions that can solve the characteristics of data samples, neural network is widely favored in solving classification problems, especially the test data generation based on genetic algorithm. This method first converts the structural coverage problem into a numerical function optimization problem and then generates the expected test data [19]. The genetic algorithm (GA) was first proposed by American scholar Holland in 1975. It is a computational model simulating Darwin's genetic selection and natural elimination of biological evolution. Its outstanding feature is that it contains steps very similar to biological genetics and evolution [20]. The main advantages of GA are simple, universal, strong robustness, suitable for parallel distributed processing and wide application range [21]. The search performance of genetic algorithm is mainly realized by three operators: selection, crossover, and mutation, especially the mutation operator. It can expand the search range of the algorithm and is more likely to find the global optimal solution. However, due to the wide search range, the convergence speed is affected, so it is very important to design adaptive mutation operation. The traditional genetic algorithm and various improved algorithms use the method of randomly selecting a bit to flip the variable value in the mutation operation, which cannot effectively improve the search performance and stability of binary coding. Variation testing was first proposed by Demilo and Hamlet et al. It is a software testing technology to measure the effectiveness and completeness of test case set [22]. In order to carry out variation test, first, make grammatical small changes to a certain statement of the program to produce a new program, which is called a variant.

3. Neural Network Algorithm Optimized by Mutation Genetic Algorithm

3.1. Network Structure of Evaluation Model. Neurons and the relationship between them define the structure of neural networks. For the credit risk assessment model, its structure can be expressed by the number of input and output nodes, the number of hidden layers, and the number of nodes in each hidden layer of backpropagation network. In the network structure of the evaluation model, the number of input nodes can be obtained intuitively, which is the number of credit risk evaluation indicators. The number of output nodes of the model can be one or multiple. For the classification model, the number of output nodes is related to the number of classification categories. Assuming that the credit rating is m, the number of output nodes of the evaluation model can be m or $\log_2 m$. In most cases, in order to simplify the structure and improve the training efficiency, a network model with multiple outputs is generally transformed into multiple network models with one output [23]. The structure of each model is the same, but each part is given to a separate model to ensure that the same weights are not applied to the entire image. This paper avoids full weight assignment and keeps weight sharing local; then, each model performs convolution and max pooling and generates some kind of output that outputs a dense layer. Based on this principle, this paper simplifies the output of the evaluation model. Firstly, according to the business needs, there are five levels

of credit rating: $A++$, $A+$, A, $B+$, and B; secondly, referring to the credit scoring method, the output of the evaluation model is converted into a continuous variable. Different value ranges of variables correspond to different credit grades, as shown in Table 1.

In order to evaluate the model, it is very important to determine the reasonable number of hidden layers and the number of nodes in each hidden layer. It is generally believed that increasing the number of hidden layers can reduce the network error and improve the classification accuracy of the evaluation model, but it also makes the model complex, the training time is too long, and it tends to "overfit."

The error bound of the credit risk assessment model is calculated according to Table 1. Taking class $A++$ credit rating as an example, when calculating the model output error, $A++$ takes 0.95, while when converting the assessment model output to credit rating classification, the value of $(0.9, 1.0)$ interval is mapped to class $A++$, and the maximum difference is used to calculate the output error of the model, and the following can be obtained

$$E = \frac{1}{2} \sum_{k=1}^{l} (d_k - y_k)^2. \tag{1}$$

Considering the convergence speed and classification accuracy of the evaluation model, $E^P = (1/2)(0.85 - 0.8)^2 = 0.00125$, the error bound E of the evaluation model is 0.001. In the process of network training, the error threshold should be predetermined according to the actual situation. The selection of the error threshold is completely determined by the convergence speed of the network model and the learning accuracy of the specific sample. When the E value is selected to be small, the learning effect is good, but the convergence speed is slow and the training times increases. The opposite is true if the E value is larger.

Generally, when the neural network model enters the later stage of training, the more stable is the connection weight between neurons; at this time, the learning rate should tend to be smaller, because the larger learning rate is easy to cause oscillation in the modification process of weight W. At the beginning of training, in order to speed up the convergence of the network, the learning rate is often adjusted to a large value, which needs to change the learning rate dynamically in the learning process. The standard for adjusting the learning rate is whether the error function can be reduced, and the adjustment formula is as follows:

$$\eta_{t+1} = \begin{cases} \alpha\eta_t, & \alpha > 1, \\ \beta\eta_t, & \beta < 1. \end{cases} \tag{2}$$

Among them, η is the learning rate; t is the training times; α, β, and k are ratio factors; and E is the error function,

$$\eta_t = \begin{cases} \alpha\eta_{t-1}, & E_t < E_{t-1}, \\ \beta\eta_{t-1}, & E_t > kE_{t-1}, \\ \eta_t, & \text{others}, \end{cases} \tag{3}$$

and the values in this paper are as follows: $\alpha = 1.05$, $\beta = 0.7$, and $k = 1.04$.

Table 1: Relationship of output of evaluation model and credit rating.

Credit rating	Output of training phase evaluation model
$A{+}{+}$	$(0.9, 1.0]$
$A{+}$	$(0.8, 0.9]$
A	$(0.7, 0.8]$
$B{+}$	$(0.6, 0.7]$
B	$(0, 0.6]$

In order to avoid model training trapped in shallow local minima, momentum term can be considered [24]. The weighted adjustment formula with momentum term is

$$w(t+1) = w(t) + \frac{\eta \cdot \partial E}{\partial W_t} + \alpha^2 \Delta(t), \qquad (4)$$

where α is the momentum factor, and its value is discussed in the previous section of this paper. The effect of introducing momentum term is to make the η value change equivalently instead of being a constant value in the learning process, to make the adjustment change toward the average direction of the bottom without large oscillation; that is, momentum plays the role of buffer and smoothing, and finally speeds up the learning speed of the evaluation model.

The momentum adding method is suitable for batch learning. In this way, the error is the sum of the output errors of all training samples, that is,

$$E = \frac{1}{2} \sum_{p=1}^{P} \sum_{k=1}^{l} \left(d_{p,k}^2 - y_{p,k}^2 \right). \qquad (5)$$

Moreover, the error backpropagation is started after the learning of all training samples; that is, the connection weights of each layer are updated. Error backpropagation is that the output error is transmitted back to the input layer by layer through the hidden layer in some form, and the error is allocated to all units of each layer, so as to obtain the error signal of each layer, which is used as the basis for correcting the weight of the unit. The credit risk assessment model optimized adopts the mutation genetic algorithm.

3.2. Neural Network Optimized by Mutation Genetic Algorithm.

The credit risk assessment system is the core part of credit management information system and the basis for other credit businesses. Its main function is to realize the bank's internal credit rating and provide the basis for other credit businesses and credit risk management. The general structure of the credit risk assessment system consists of three components:

(1) Input. Input the index data of credit rating. After preprocessing, the index data are used by the evaluation system. The selection of credit rating indicators plays a very important role in the credit risk assessment, which will be discussed below.

(2) Evaluation model. The credit risk assessment model is the core part of the credit risk assessment system. The assessment model reflects the mapping relationship between credit assessment indicators and credit rating, and this relationship can be self-adjusted with the change of environment.

(3) Output. From a business perspective, the output is the result of credit rating, that is, credit rating, such as $A{+}{+}$, $A{+}$, or $B{+}$, which can be summarized as classification results. From the perspective of the evaluation model, the output may be a continuous value, which can be converted to the credit rating required by the business after a certain mapping relationship.

Normalization of indicator data refers to scaling the indicator data to make it fall into a small specific interval [25]. The general iterative method is easy to fall into the trap of local minima and the phenomenon of "infinite loop" occurs, which makes the iteration impossible. The genetic algorithm overcomes this shortcoming well and is a global optimization algorithm. Normalization is particularly useful for classification algorithms, such as algorithms involving neural networks or distance metric classification algorithms such as nearest neighbor classification and clustering. For the credit risk assessment model using BP algorithm, standardizing the input values of training samples will help to speed up the learning speed of the assessment model.

The order of the mutation genetic algorithm is selection, crossover, and mutation. We adopt adaptive crossover and mutation probability, as shown in formulas (5) and (6), respectively:

$$p_c(g) = \frac{p_c(g-1) - [p_c(0) - 0.25]}{\max}, \qquad (6)$$

$$p_m(g) = \frac{p_m(g-1) - [0.25 - p_m(0)]}{\max}, \qquad (7)$$

where g represents the generation algebra, and max is the maximum number of generations.

The basic flow of the mutation genetic algorithm is shown in Figure 1. Similar to the biological evolution process in nature, the operation process of the genetic algorithm is also a repeated iterative process. The population of generation t is recorded as $P(t)$. After one generation of mutation, inheritance, and evolution, the population of generation $t+1$ is obtained. They are also a population composed of m individuals, recorded as $P(t+1)$. This population continues to undergo mutation, inheritance, and evolutionary operation, and each time, according to the rules of survival of the fittest, more individuals with higher fitness values are inherited to the next generation. In this way, a good individual c^* will be obtained in the group, and its corresponding phenotype x will reach or close to the optimal solution x^* of the problem.

3.3. Implementation of BP Neural Network Algorithm Optimized by Mutation Genetic Algorithm.

According to the theoretical analysis, we implement the process of mutation genetic neural network algorithm according to the following steps:
FIGURE 1: The basic flow of the genetic algorithm.

(1) Build hidden layer

 (i) It does not have a fixed formula to apply. It is usually to get a more appropriate value from experience and multiple tests. Through the repeated tests of the test samples in the previous section, the number of nodes in the hidden layer is set at 16.

(2) Coding

 (i) In this experiment, 18 neuron nodes are set in the input layer of the variant genetic neural network as risk prediction, 6 nodes are set in the output layer, the number of hidden layer nodes is 16, and the coding length formula is as follows:

$$m_n = i \cdot m_i + j \cdot m_i, \tag{8}$$

 (ii) i is input layer, j is output layer, and mi is hidden layer.

(3) Initialization function

 (i) Here, we initialize through the initializega function. The initialization function used in this paper is initp$p$ = initializega (pop, A+, "gabpeval")

(4) Fitness function

 (i) Each chromosome in the genetic algorithm corresponds to a solution of the genetic algorithm. Generally, we use fitness function to measure the advantages and disadvantages of this solution. The formula of fitness function in this paper is

$$f = k \sum_{j=1}^{n} abs\left(y_j, x_j\right)^{-1}, \tag{9}$$

 (ii) where k is the coefficient, n is the number of network output nodes, yi is the expected output, and x_i is the predicted output of the i-th node.

(5) Set the parameters of genetic algebra of variation

 (i) Here, the genetic algebra is set at about 100. In the selection operation, choose those with a larger proportion of fitness values to the sum.

(6) Cycle step 2 to step 5 to obtain the simulation results optimized by the mutation genetic algorithm until the training goal is reached or the number of iterations reaches the upper limit goal.

3.4. Credit Risk Evaluation System Architecture of Commercial Banks. The credit risk assessment system is a data analysis system based on pattern recognition. Firstly, a specific learning algorithm is used to find out the patterned relationship between customer data and credit rating from a large amount of historical data, and then expresses and stores this relationship in the form of the evaluation model for future credit risk evaluation. Therefore, from the perspective of its function, the credit risk assessment system should include the following contents: data collection, data storage, data preprocessing and data maintenance, assessment model training, assessment model management, and assessment model application. Figure 2 shows the overall architecture of the credit risk assessment system.

Among them, evaluation model training and evaluation model application constitute the core module of the credit risk evaluation system. The main function of the evaluation model training module is to generate and train the model, and store the evaluation model in the model base.

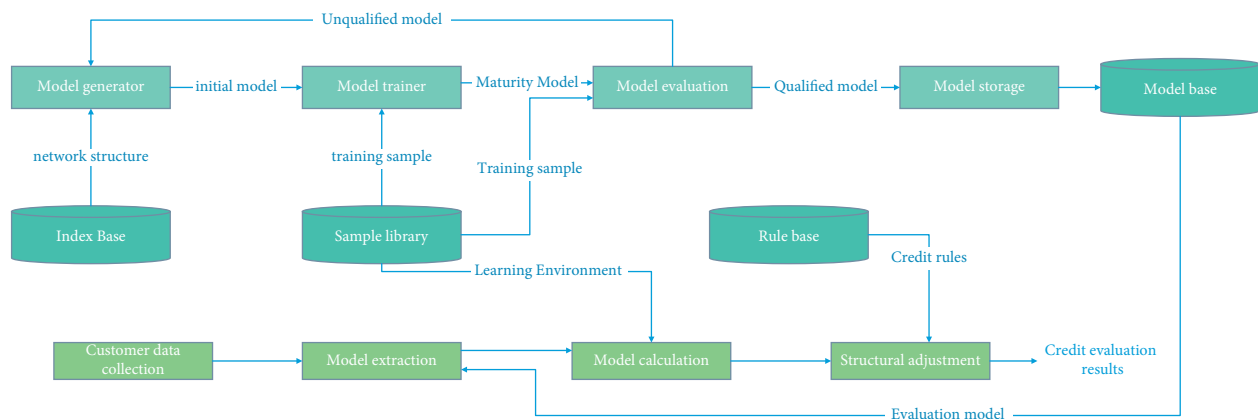
Figure 3 shows the structure of the evaluation model training module. As can be seen from the figure, the model
Figure 2: General framework of the credit risk assessment system.


Figure 3: Structure diagram of application module of the credit risk assessment model.

training module is mainly composed of model generation, model training, and model evaluation:

(1) Model generation. Model generation first obtains the mode category of the model to be trained (generally classified by industry) from the user interface and then obtains the number of all indexes participating in the evaluation under the mode from the index library. From this number, the number of input neurons and output neurons of the neural network model can be obtained, and the number of neurons in the hidden layer can be calculated. Another main function of the model generator is to initialize the weights or thresholds of the model and learning parameters.

(2) Model training. Model training reads out the training samples of the corresponding pattern category from the sample database, processes the data, learns the processed data, and adjusts the weight and threshold of the initial model.

(3) Model evaluation. Obtain test samples from the sample library, test the trained evaluation model, and check the evaluation accuracy of the evaluation model. If the accuracy is greater than the accuracy set by the system, the model will be put into storage. Otherwise, discard the model and start training again. The first mock examination is repeated. Sometimes, it is necessary to train the evaluation model of the same pattern type for many times to get the highest accuracy evaluation model.

4. Experiment and Analysis

4.1. Preparation of Sample Data. A total of 360 data samples were collected in this paper, which were distributed in five industries. After the mode division in the previous section, 360 samples are divided into 7 credit risk assessment modes, and each mode contains more than 30 samples. This section takes industrial enterprises as an example to introduce sample data preparation and preprocessing.

Industrial enterprises include two evaluation models: small industrial enterprises and large- and medium-sized industrial enterprises. Among them, small industrial enterprises include 34 samples and large- and medium-sized industrial enterprises include 45 samples. Figure 4 shows the distribution of credit rating classification in the sample.

The sample data consist of training samples and test samples. The test samples are randomly selected from the overall samples, generally accounting for about 20% of the total samples. In order to ensure the rationality of the test, this paper requires that each credit rating level contains at least one test sample, and the distribution of credit rating in the test samples is similar to that of the overall samples. The distribution of test samples under the two evaluation modes is shown in Figure 5, while 0101 evaluation mode contains 7 test samples and the remaining 27 samples are used as training samples, and 0102 mode contains 9 test samples and the remaining 36 samples are used as training samples.

Before model training, sample data need to be pre-processed to improve the efficiency of model training and evaluate the accuracy of the model. The main idea of the BP algorithm is to input the learning samples and use the backpropagation algorithm to repeatedly adjust the weights and deviations of the network to make the output vector as close to the expected vector as possible. When the training is completed, the weights and biases of the network are saved. In this paper, the collected qualitative and quantitative indicators of enterprises are standardized, and the index data are transformed into dimensionless data in (0, 1) interval, so as to meet the requirements of input data of variant genetic neural network model. Data processing is divided into two parts: qualitative index processing and quantitative index processing.

4.2. Credit Risk Assessment Classification Model.

Firstly, the basis and activate function of neuron operation at each node of the evaluation model are selected. According to the general definition of variant genetic neural network model, the basis function of the evaluation model adopts linear function,

$$u = x^T w - \theta. \tag{11}$$

The activation function adopts sigmoidal function,

$$f(u) = [1 + \exp(-\lambda u)]^{-1}. \tag{12}$$

Secondly, the neural network structure of the credit risk assessment classification model is determined. According to the discussion in Section 3.4 of this paper, the evaluation model adopts the variant genetic neural network model with three-layer structure, and its structure can be expressed as $n \times m \times l$ where n is the number of input nodes, and the value is the number of evaluation indicators; l is the number of input nodes, and the value is 1; and m is the number of hidden layer nodes, and the value is related to many factors. Next, taking the evaluation model of industrial enterprises as an example, the hidden layer node is determined.
Figure 4: Classification and distribution of credit rating.
Figure 5: Classification and distribution of credit rating in test samples.

The evaluation model structure of industrial enterprise evaluation model is $28 \times m \times 1$, and the number of training samples for small- and medium-sized enterprises is 27, and the number of training samples for large- and medium-sized enterprises is 36. According to the rule that the number of hidden layer nodes is between 50% and 70% of the sum of the number of input nodes and output nodes, the value range of the number of hidden layer nodes m is about $14 < m < 21$. In order to determine the reasonable number of hidden layer nodes, this paper constructs an evaluation model for each value within the value range and determines the most reasonable number of hidden layer nodes by comprehensively comparing the training efficiency and classification accuracy of each model. Table 2 shows the training efficiency and classification accuracy corresponding

TABLE 2: Model training under a different number of hidden layer nodes.

Mode code	Number of hidden layer nodes	Simulation convergence
	5	Within 2000 training times, the simulation does not converge
	10	>1500 training,
0101	15	>1300 training,
	20	<1200 training
	25	<1100 training
	5	Within 3500 training times, the simulation does not converge
	10	Within 3500 training times, the simulation does not converge
0102	15	>1800 training
	20	<1800 training
	25	<1600 training

to the number of nodes in different hidden layers under the same other conditions.

After comparison, we finally selected a three-layer mutation genetic network structure with 16 hidden layer nodes as the evaluation model, and the specific structure is $28 \times 16 \times 1$; that is, the evaluation model includes 28 input nodes, 16 hidden layer nodes, and 1 output node. The learning and calculation process of the evaluation model, for example, K, under this mode can be obtained.

According to the analysis on the setting of learning times, target error, and learning rate in the previous chapters, after establishing the variant genetic neural network with MATLAB software, the initial parameters of these three parameters need to be set before network training on normalized samples, where net.trainparam.epochs is the number of network training, net.trainparam.goal is the network target error, and net.trainparam.lr is the network learning rate. When the initial parameters of the three are set, the train function is called to train the input training samples. The general form of the function is [net, tr] = train (net, P, T), net on the left side of brackets represents the genetic neural network before training, tr storage training records, including the number of network training and the error of each training, can generate the network error variation curve in real-time; net on the right represents the mutation genetic neural network obtained after sample training, T is the vector set of expected output of training samples, and P is the vector set of training samples.

The procedure is as follows:

(i) %Set training parameters

(ii) net.trainParam.show = 50

(iii) net.trainParam.epochs = 3000

(iv) net.trainParam.goal = le- 3; net.trainParam.Ir = 0.3

(v) %Network training

(vi) [net, tr] = train (net, p, t)

4.3. Training Process and Results. In the variant genetic neural network model, there are several very important learning parameters: the main one is the learning rate η and momentum factor α. The setting of these parameters has a great impact on the training efficiency of the credit risk assessment model. In Section 3.1, it is determined that the value of convergence error bound e is 0.001. In order to

enhance the convergence efficiency, a large learning rate η is usually used, but η too large may lead to oscillation near the stable point or even nonconvergence.

For the above situation, this paper analyzes different learning rates η and momentum factor α simulation investigation is carried out to determine the appropriate learning parameter value. Firstly, 28 are generated by MATLAB neural network toolbox $\times 18 \times 1$, and initialize, and then train the network. Set the convergence error bound $e = 0.001$, the maximum training times $T_{max} = 2000$, and select traingdm as the learning function η and α take values for network training. The network training error curve is shown in Figures 6(a) and 6(b). Figures 6(a) and 6(b) reach the predetermined accuracy within T_{max}, but the training times are very different when they reach the predetermined accuracy. Figure 6(a) takes 1178 steps to reach the predetermined accuracy, and Figure 6(b) takes 544 steps to reach the predetermined accuracy.

In the process of network learning, although the initialization of connection weights and thresholds is set randomly, they have a very important impact on the training process of evaluation model, which is embodied in the convergence efficiency and classification accuracy of evaluation model. Under the same conditions, when the initial network weights and thresholds are different, some training processes can converge within the set T_{max} range, while some learning processes cannot reach the predetermined accuracy after learning T_{max} times. In this case, it is necessary to regenerate the network weights and retrain. In the process of practical application, it is often necessary to initialize the network connection weights and thresholds for many times, and compare the training process and test results for many times to obtain the most reasonable evaluation model. Table 3 shows the initial weight training and test results of different networks.

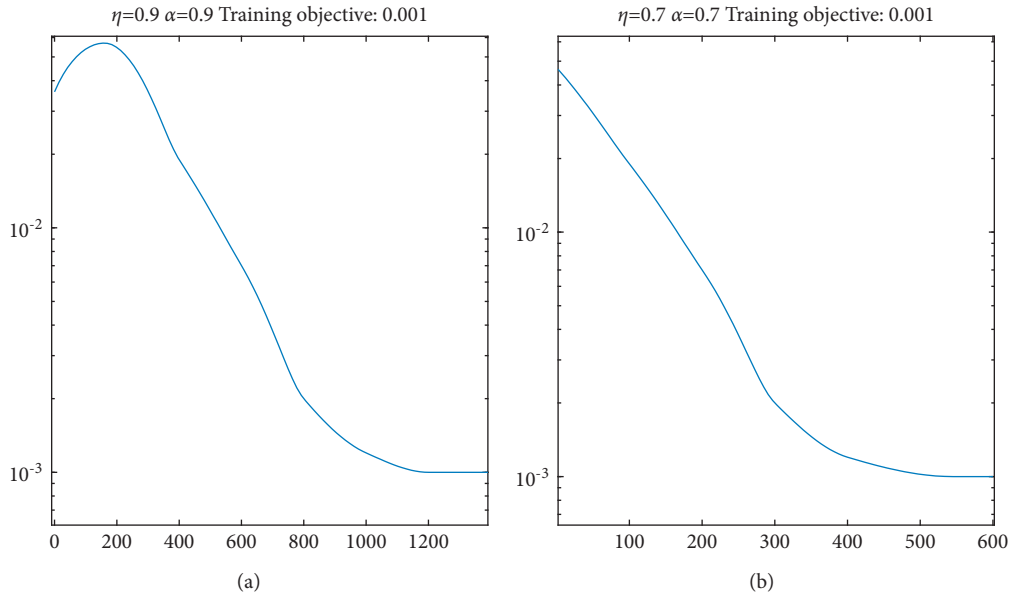
4.4. Comparative Experiment. Firstly, a simple three-layer mutation genetic neural network structure is used to evaluate credit risk without adding genetic algorithm. Then, the weight and threshold of neural network are optimized by the mutation genetic algorithm. Its operation speed shows greater advantages in speed and quality than BP neural network, and achieves higher accuracy. The training results are shown in Figure 7. Comparing the training time with the original data, Table 4 is obtained.


FIGURE 6: Training error function under different η and α. (a) Training times: 1178; (b) training times: 544.

TABLE 3: Model training under different network initial weights.

Mode code	Network weight sequence number	Simulation convergence	Number of classification errors
	Initialization 1	Within 3500 training times, the simulation does not converge	15
0101	Initialization 2	Simulation convergence, training steps 1875	12
	Initialization 3	Simulation convergence, training steps 1168	10
	Initialization 4	Simulation convergence, training steps 1050	11
0102	Initialization 5	Simulation convergence, training steps 978	9
	Initialization 6	Within 3500 training times, the simulation does not converge	11
	Initialization 7	Within 3500 training times, the simulation does not converge	14
0103	Initialization 8	Simulation convergence, training steps 2238	10
	Initialization 9	Within 3500 training times, the simulation does not converge	12
FIGURE 7: Comparison of training accuracy between the two algorithms. (a) BP algorithm; (b) our algorithm.

From its fast operation speed and high accuracy, it can be concluded that the variant genetic neural network has strong advantages in the evaluation of credit risk of commercial banks.

The improved mutation genetic algorithm evaluation model has not only improved the training speed, but also greatly improved the classification accuracy. First select 1000 times to see whether the final training reaches the target error. Then increase or decrease the training times according to the situation. If the training times are the same each time, the degree of training results is very small. It is recommended to increase the number of training times. In the experiment, 2000 times is the best training times. Under the same training steps (set as 2000 steps in this paper), the error

TABLE 4: Comparison of training efficiency between the two algorithms.

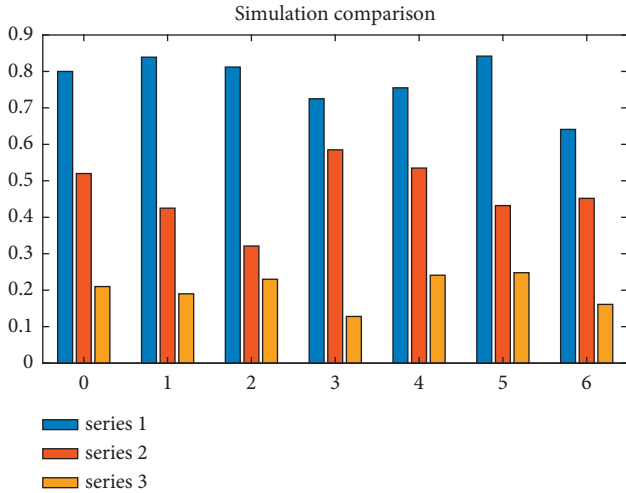
	BP algorithm	Our algorithm (s)
Training time	7.230 s	4.836


FIGURE 8: Simulation comparison of evaluation models under two algorithms.

accuracy of the basic BP algorithm evaluation model can just reach the accuracy of 0.001, while the error accuracy of the improved mutation genetic algorithm evaluation model can reach 0.0001 at 2000 steps. As shown in Figure 8, the simulation comparison diagram of the evaluation models under the two algorithms is shown, in which series 1 is the expected output, series 2 is the improved algorithm's simulation output, and series 3 is the simulation output of the unmodified algorithm. The number of classification error samples of the evaluation model is 4 by using the unmodified BP algorithm, while the number of classification error samples of the evaluation model is reduced to 2 by using the improved mutation genetic algorithm.

5. Conclusion

The credit risk assessment model established in this paper adopts a three-layer mutation genetic neural network structure. For different assessment models, the assessment model has different network structures, which is embodied in the different number of input layer nodes, hidden layer nodes, and their network connection weights. Taking industrial enterprises as an example, the experimental results show that there are two evaluation modes of credit risk: small industrial enterprises and large- and medium-sized industrial enterprises. Their network structure is the same, $28 \times 18 \times 1$. In the learning algorithm, this paper uses the combination of variable learning rate and momentum term to improve the training efficiency and learning rate of the evaluation model η value 0.8, momentum factor α value 0.9, and error accuracy ε set to 0.001. According to the above network structure and learning parameters, the credit risk

assessment model is established, and the qualitative index standardized data and quantitative index standardized data are used to train the two assessment models, respectively. Due to the randomness of connection weight initialization, this paper initializes and trains each mode for many times and takes the model with the best test accuracy as the final model. Under the same conditions, the training convergence speed of the improved mutation genetic algorithm evaluation model is very different from that of the basic BP algorithm evaluation model. The training speed of the improved BP algorithm evaluation model has been qualitatively improved. The basic BP algorithm evaluation model takes 1178 steps to meet the accuracy requirements, while the mutation genetic algorithm evaluation model takes only 544 steps to meet the progress requirements. It can be seen that the credit risk assessment model based on neural network has high accuracy and can be used as an important tool for loan decision making of commercial banks.

With the advent of artificial intelligence and proliferation in the demand for an online dialogue system, the popularity of chatbots is growing on various industrial platforms. Their applications are getting widely noticed with intelligent tools as they are able to mimic human behavior in natural languages. Chatbots have been proven successful for many languages, such as English, Spanish, and French, over the years in varied fields like entertainment, medicine, education, and commerce. However, Arabic chatbots are challenging and are scarce, especially in the maintenance domain. Therefore, this research proposes a novel framework for an Arabic troubleshooting chatbot aiming at diagnosing and solving technical issues. The framework addresses the difficulty of using the Arabic language and the shortage of Arabic chatbot content. This research presents a realistic implementation of creating an Arabic corpus for the chatbot using the developed framework. The corpus is developed by extracting IT problems/solutions from multiple domains and reliable sources. The implementation is carried forward towards solving specific technical solutions from customer support websites taken from different well-known organizations such as Samsung, HP, and Microsoft. The claims are proved by evaluating and conducting experiments on the dataset by comparing with the previous researches done in this field using different metrics. Further, the validations are well presented by the proposed system that outperforms the previously developed different types of chatbots in terms of several parameters such as accuracy, response time, dataset data, and solutions given as per the user input.

1. Introduction

Every generation of the computer device is becoming more complex than the last one, and the troubleshooting task becomes more difficult for the end-user [1]. Computer problem detection is a complicated process that demands a high level of knowledge and skills. Troubleshooting is the process of locating the cause of a problem in a system and resolving it [2]. On average, computer repair technicians charge globally $60 per hour. Besides, the hourly rate can range from $40 to $90 per hour [3]. Some of these repairs can be addressed by providing assisting through a chatbot to the user. Furthermore, one of the remarkable artificial

intelligence applications that have proven its efficiency recently is a chatbot. The chatbot is a simulating program that analyzes and processes human conversation, either written or spoken. It interacts with the end-users via digital devices as if users are communicating with a real person [4]. It provides 24-hour availability, instant answers, endless patience, personalization, and customized dialog to the end-user. Additionally, it extends to benefit various companies in this matter by saving the cost of hiring manpower, achieving customer satisfaction, and reaching new customers [5]. Chatbot relies heavily on Natural Language Processing (NLP), commonly used to make human spoken language understandable for computer machines [6]. The goal of NLP

is to take the unstructured input and produce a structured representation of the text that contains understandable language for textual chatbot conversation [7]. Also, Natural Language Processing is known as a model trained which belongs to an Arabic chatbot's textual input and output [8]. The essential part of building chatbots is the conversational interfaces. Since the chatbot responds in terms of text to the user query, NLP yields an adequate textual conversation for the chatbot [9]. In this paper, we rely on NLP to process Arabic language by using the presented framework. The research has identified and minimized the gaps existing in the field of dialects in Arabic language and the advancements in the chatbots by comparing the performance of the proposed system with the previously developed researches.

The rest of this paper is organized as follows: next, we present motivation and contributions and a tiny backdrop. We discuss the challenges for developing Arabic chatbots. We then present comparison with existing systems and describe our framework. After that, we illustrate chatbot mechanism used in this paper including experimental result and a preliminary user evaluation.

1.1. Motivation and Contributions. The motivation behind this work has portrayed the fact that Arabic chatbot does not reach the required limit in terms of response speed, dataset type, and how the chatbot handles user input. The outcome of this paper will lie in the implementation based on industrial applicability in building an Arabic Chabot that is capable of assisting end-users to solve troubleshooting problems in Arabic. This framework incurs repair costs by an expert troubleshooting system. It will aid to diagnose IT troubleshooting and solve technical issues within a few seconds. The contributions of this research work are given as follows:

 (i) To study the background on previously developed chatbots and the challenges of using Arabic chatbot in multiple domains;

 (ii) to propose the novel IT troubleshooting chatbot framework for Arabic language;

 (iii) to create the dataset from various sources including multiple companies such as Microsoft, HP, Samsung, Huawei, and different websites that address common IT problems/solutions and apply preprocessing tasks for further uses;

 (iv) to compare the proposed chatbot with previous researches on varied dialogues, writing the parameters;

 (v) to evaluate the proposed chatbot by comparing it with other chatbots on different functional evaluation metrics;

 (vi) to develop a service-based chatbot to provide idiomatic solutions for common IT problems that can be considered for practical industrial applications.

2. Background

The revolution of information technology during our era predetermines that all governmental and private sectors need rapid progress of digital transformation and mounting development. Our lives are not devoid of using technologies, especially those that involve artificial intelligence techniques. Technology has gathered the world societies in a common cyber environment, where every technology that emerges in any place spreads to all applicable societies.

Artificial intelligence relies on data as input; then it is processed via specific approach to generate the demand output like-human thinking. Even though, there is a concern whether AI application will rescind the need of human thinking gradually. In fact, AI works as extension of human brain to solve complex problems and process huge amount of data at the same time. One of AI techniques used with different language by machine learning is the acknowledgment of city names. The promising study application areas in the realm of postal automation are the recognition of handwritten city names. For recognition, use a nonsegmentation method (Holistic approach). The role of the convolutional neural network (CNN), which is one of the deep learning techniques, is deconstructed in this paper [8], detecting hand signs, by anticipating the next word or recommending the most relevant word, and then generating the word that deaf persons communicate with people using sign language.

2.1. Arabic Chatbot. Before time, chatbot was described as a text-interaction between human and machine learning by simulating an online conversation (chat) with a user in natural language. Chatbot was first introduced in 1996. Precisely, ELIZA was the first chatbot created in MIT, which arguably came close to imitating a human reply. ELIZA was given an input sentence and it identifies keywords and patterns to match those keywords against a set of preprogrammed rules to generate appropriate responses [10]. Late in 1971, Kenneth Colby at Stanford created PARRY, a preprogrammed chatbot act-like schizophrenia diagnosed patient and was able to express fears, anxiety, and beliefs. By the time, chatbot's discoveries increased in 1995 by Richard Wallace who created A.L.I.C.E chatbot, using English conversation patterns in AIML files such as (<category>...<pattern></pattern>....</category>). AIML is a subordinate of web extensible mark-up language XML. After that, during the millennium, many forms of chatbot were invented. To get a sense, all millennium chatbot inventions refer now to modern chatbots in the AI industry.

The Arabic language is considered as one of the Afroasiatic languages. Due to built-in alphabetical structure, it is a notoriously difficult language in categories of programming text processing, because of reading and writing direction, from right to left, which is the opposite direction of English language. To further complicate things, the form of Arabic letter is totally different than English language and vowels are omitted from written Arabic. Globally, there are 422 million Arabic speakers around the world [11]. According to a British council report, Arabic language took

the second place for each native speaker who lived in northern Africa such as Algeria and Morocco and western Asia such as Georgia and Azerbaijan and took the first place at Arabian Peninsula such as Saudi Arabia and United Arab Emirates. Moreover, it took the 4th place as a useful language in the trade market in the UK and Arabic countries as well [12].

In this respect, significant work has been done on chatbots. However, the Arabic language is rarely used in chatbot especially in the IT sector. Additionally, few numbers of Arabic chatbots applications/websites are available for the end-user. For instance, in educational domains, Nabiha, one of Arabic chatbots, is concerned about helping college students using informal Arabic via automatic conversation with student inquiries [13]. On the other hand, BOTTA is a fun Arabic conversational chatbot aiming at using an Egyptian accent to have fun chat with users [14]. Also, Quran chatbot is an Arabic one answering users' inquiries religiously, by generating extracted replies from the Holy Quran [15]. Also, Tafsir Al-Ahlam is an Arabic robot specialist interpretation of dreams using a smart search engine to generate output from a local database of a wide range of interpretations taken from the books attributed to Ibn Sirin and Nabulsi son of Shaheen and other accredited authors in the Islamic heritage books, following the origins and rules of interpretation of dreams from the Quran and the Hadith [16]. In medical domain, NALA is an application that provides medical consulting under the supervision of the Ministry of Health [17].

Customers may use service-oriented chatbot to find information on big, complex domains that are difficult to navigate. This is recognized as "service-based chatbot;" the main reasonability for this chatbot is to provide a service, contrary to other chatbots acting as only an entertainer. Many users find it difficult to find the details that they need from website search engine results due to the site's abundance of data. During a conversation with the user, the service-oriented chatbot serves as an automated customer service agent, providing natural language responses and more targeted information. This virtual agent is also programmed to assist with general IT-related questions [18].

2.2. Chatbot Framework.
A framework is a term commonly used in IT software development which is referred to as a structure consisting of many phases that work together as a foundation for software developers to build programs for a specific platform [19]. As it follows by bot framework, a set of processes and requirements guide the developer while he/she is programming the bot as well as solving any potential problems met by the developer at the same phase. Bot framework provides tools, services, and skills needed which facilitates the developer's job [20].

Most frameworks share certain fundamentals phases, but they differ according to the purpose of creating the framework itself, based on the most proposed framework that is currently going on in the field of chatbot development. A five functional phases are listed as follows. Automatic speech recognition (ASR) is a technology that provides a voice identifier with a computer interface through the human voice that allows a human being to interact with a computer in such a way that it seems very close to the real human. Natural language understanding (NLU) is highly connected to machine reading comprehension. The process of selecting parts of sentences and analyzing the meaning is tedious because the machine needs to determine the correct syntactic structure and semantics of the language used. Dialogue management is mainly responsible for coordinating the various components of a chatbot. Natural language generation is mainly relating to the process of retrieving and producing the answer. Lastly, there is text to speech. The answer is ready to be retrieved for the end-user [21]. The following is a brief description of some frameworks used for chatbots in Arabic.

2.3. Comparison with Existing Systems.
The first framework is the framework of an intelligent Arabic chatbot for teaching Islamic history. The main goal of this framework is to help and guide designers for the efficient use of chatbots and simulations for teaching Islamic history. It consists of three phases explained as follows.

2.3.1. Interaction.
This phase includes the user input such as query, and it is stored immediately in the Heroku cloud server. This framework adopts a cloud computing server to avoid standard dedicated server's problems and costs.

2.3.2. The Processing Phase.
This phase includes the use and implementation of many programming languages for handling, storing, processing, searching, and retrieving the data. After that, determining the size of storage might be needed since the content of Islam history is too large to be handled on smartphone's capacity. So, the framework presents the MongoDB technique to be used in this phase.

2.3.3. Learning Phases.
This phase enables the bot to be recordable and learnable, by sorting user input/query at bot memory. The program manager will update the bot's memory by matching words or queries with the appropriate answer. Finally, the last process is using some advanced programs such as neurolinguistic programming (NLU), and it can be implemented manually by human review or automatically by NLU. The current NLU program cannot support Arabic language but it can be replaced with any suitable text processing techniques [22].

The second framework is Facebook Arabic chatbot based on deep learning using RASA framework aimed at answering student inquiries at the University of Islam in Indonesia via Facebook message. College students often need immediate information like asking for something to help desk, especially during this COVID-19 pandemic, due to Facebook popularity in Indonesia. There were 166.500.000 Facebook users in Indonesia in August 2020, which accounted for 60.8% of its entire population. Thus, RASA framework has been developed to match with Arabic content [23].

To construct an Arabic chatbot, most of the existing research relies on third-party framework platforms likewise PANDORABOT platform. As a result, some difficulties in dealing with Arabic letters have arisen as well as HTML tags, database scope, response, and input processing. The following framework will overcome these gaps by using programming Python groundwork. In terms of Arabic content, the framework uses AI to improve NLP and machine learning techniques; see Table 1.

As shown in Table 1, most of the Arabic chatbot applications used premade platform like Pandorabots API. This kind of platform has subscribed package followed by yearly/monthly fees. The developer is in charge of renewing the subscription fee. Eventually, the developer gets exhausted with unnecessary additional costs and limited features, gaining complexity at run time. This conceded on the top list of solutions provided by the proposed framework. Also, code-based application frameworks are rarely supported with Arabic content. This research focuses on solving the problems of complexity and user-friendly programming support with effective applications.

3. The Proposed Methodology

This research introduces a novel IT chatbot framework for troubleshooting supporting Arabic language. The framework comprises four phases: GUI, Arabic text processing, AI services, and database. Figure 1 demonstrates the components and the processes involved in the framework design.

The chatbot starts by receiving the input as "text format" from the end-user. The bot channels transfer the question/ inquiry regarding any potential IT troubleshooting as a query to the Arabic text processing phase. At this stage, the framework examines the match corpus from the existing knowledge in the database phase and extracts the answer as result to the end-user. Along with that, get the benefit from AI services to enhance the learning process in the database phase for nonexisting knowledge and improve generally text process in Arabic text processing phase. Text processing phase not only provides NLP, but also provides named entity recognition (NER) by labelling named "real-world" objects, like persons, companies, or locations. Entity linking (EL) removes the uncertainty of meaning from an ambiguous sentence, phrase, or other linguistic units. Text processing is useful for more than just decoding and analyzing text back to its origins. Rather, it goes above and above to generate data that aids in the usage of chatbot measures. As it is a real number, it is very easy to do statistical and arithmetical calculations towards NLP, making it suitable for use in statistical ML models and finally using bot channels to retrieve the solution in GUI format through a friendly interface. Moreover, one of the goals intends to contribute to the NLP uses of the Arabic language. The proposed framework endeavor deeply presents how to process Arabic text in the IT domain.

Moreover, every chatbot has its dataset or in other terms corpus. The Quran chatbot is one of the Arabic chatbots that adapted the Java program to produce an Arabic AIML dialogue corpus [15]. BOTTA is another Arabic application using AIML files through the Pandora's platform to generate a dialogue corpus [14]. However, there is no Arabic chatbot that has been adopted in Python programming language and generates the corpus via Python environment. So, we built a service-based chatbot to provide idiomatic solutions for common IT problems using python. Besides, build a knowledge base of IT troubleshooting, which can be reused by other researchers.

3.1. Chatbot Builder. The work has been implemented on a personal laptop with specific features. To deal with the capabilities of the chatbot system, CPU, which is a Dual-Core Intel Core i7 with 8 GB RAM, is used. The processing speed of the CPU is essential in the programming and data mining phases. The mean programming language used is Python and any related library/package is used to run the chatbot mechanism.

3.2. Dataset. The incredible amount of data on the Internet is a rich resource for any chatbot application. Web scraping is the process used in this project to transform unstructured data into a specific classification, thus to extract data using web scraping with Python including nltk library to reprocessing Arabic content. And use an open-source project corpus for the Saudi dialect called MADRA PROJECT by data analysts from Jordan. A corpus is a selection of different input statements and responses for the bot to practice with. This project allows Arabic developers to use more than 26 Arabic dialects [24]. But, here in this project, we build our corpus called chattest.text, with the benefit of merging MADRA's corpus and our corpus.

3.3. Arabic Text Handling. By using online 50 contents as database source, whether structured as csv or unstructured as text/yml, some problems occur. Thus, we apply text preprocessing with nltk: tokenization, by splitting the Arabic text into smaller pieces or "tokens." **Normalization** aims to put all Arabic content in one level. Noise removal cleans up the text from extra white spaces.

Tables 2 and 3 list the details on the dataset and websites used for extracting the data. In total, 50 texts have been retrieved with nested content, with difficulty in forming data according to the classification prepared previously in the research and some python's library/package, not supporting Arabic language. But by using core web sm for the latest version and scan of the HTML tag of required content, use the HTML attribute to specify the content.

The result of data after applying the classification process is shown in Figures 2 and 3.

3.4. Chatbot Mechanism. After generating a dataset that is suitable for the IT problem/solution domain, the implementations were done using Python programming language. Python is more suited to make changes to an existing legacy system and offers different methods/libraries such as NumPy, pandas, PyBrain, and SciPy that help expedite AI development. For example, you can leverage proven

TABLE 1: Comparison of a few of the relevant works pertaining to the Arabic chatbots.

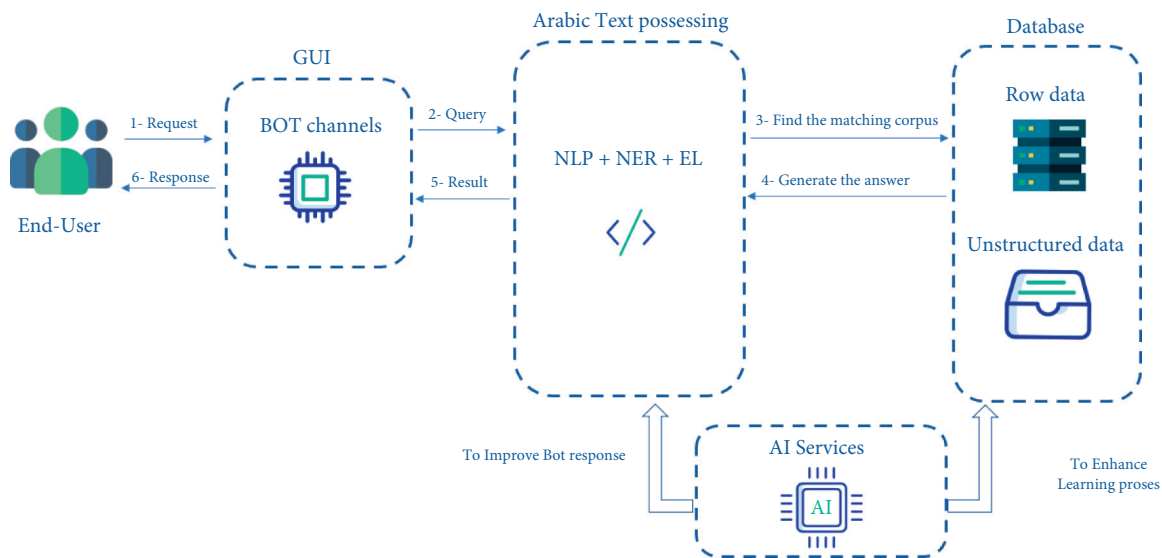
Ref no.	Motivation	Datasets used	Obtained accuracy	Limitations
[13]	This article introduces Nabiha, a new Arabic dialect chatbot dedicated to assisting college students	The datasets collected are 248 inputs/outputs from the KSU IT students' accounts in Askme.com. The methods used in this work are premade platform which is called PANDORABOT platform	The result of this paper shows that 15.38% of the total answer is not accurate, 53.85% is somewhat accurate, and 30.77% is very precise	The dataset should be expanded; we need to address the issue of HTML tags as well as Twitter's text area constraints
[14]	BOTTA's goal is to create a conversational environment and connect with as many Arab users as possible. She's the first chatbot to speak in an Arabic dialect, which helps her achieve her goal of amusing people who are used to conversing in the language	BOTTA is using AIML and launched it on the PANDORABOT platform	BOTTA's pattern matching will be able to correct 85.1 percent of the spelling errors observed in spontaneous Arabic typing	Using corpus-based machine learning approaches, BOTTA's pattern matching has to be improved. Further development will involve morphological analysis of the input and experiments with lemma-based pattern matching using existing tools for Egyptian Arabic processing


FIGURE 1: System proposal framework of devolving an Arabic troubleshooting chatbot to diagnose and solve technical issues.

libraries like scikit-learn for ML and use regularly updated libraries like Apache MXNet, PyTorch, and TensorFlow for DL and bots' projects that support text possessing in Arabic field.

Thus, we create a greeting message for the chatbot and then create (AI keyword matching) for the chatbot's corpus. We use (AI) intelligent search through the corpus using spacy and Python environment. Keyword matching works on using a keyword that appears in the query. And it identically matches any word in a chatbot corpus. In a basic retrieval system, keyword matching cannot be functional without having the full sentence or query to retrieve the relevant answer. But, by using AI keyword matching, the chatbot does not analyze the whole user input but focuses on searching words on phrases defined in the user says [25]. The best way to explain the behaviour of AI keywords is to use a

realistic example as shown in Table 4. In case the chatbot cannot find the entry that matches a keyword, it will return: "I'm sorry! I do not understand you."

4. Experimental Results

The proposed framework is evaluated in terms of effectiveness. The comparison of the chatbot developed is compared with other chatbot's platforms using different parameters including time of response, type of dataset, and dealing with user input. The two versions of the chatbot are developed, one by using the proposed framework and the other by using an external framework/platform which is Pandorabot [26]. Both chatbots were fed by the same datasets. To measure the variation between the two bots, different experiments have been performed. Table 5 shows

TABLE 2: Some of the open-source websites with the common companies for IT troubleshooting.

TABLE 4: Presentation of an example of an Arabic dialogue implemented by the chatbot.

Dialogue in Arabic

"مساعد الذكي: آسمي المساعد الذكي,أذكر لي مشكلتك؟ وسأحاول جاهدا لحلها"

"مستخدم: أريد إزالة تحديث في جهازي"

Here, the user uses only 2 words that match with chatbot corpus: "إزاله" and "تحديث" and still the chatbot diagnoses the problem by saying "إزالة تحديث مثبت في ويندز"

مساعد الذكي: إزالة تحديث مثبت في ويندز:

And retrieve the most relevant answer:

"وصي بإزالة أي من التحديثات التي تم تثبيتها ومع ذلك، إذا كان من الضروريّ إزالة أحد التحديثات، فيمكنك القيام من ال بذلك في محفوظات التحديثات"

Translation of the dialogue

Chatbot: hi, my name is "the smart assistant" tell me your technical problem? And I will try to help you

User: I want to remove an update on my device

Chatbot: we do not recommend removing any installed updates. However, if it is necessary to remove an update, you can do it in the update history."

TABLE 5: Comparison of the chatbots (our chatbot and Pandorabot).

Comparison criteria	Chatbot produces by using our proposal framework	Chatbot produces by using Pandorabot platform
Type of dataset	- Use unstructured Arabic data (text/yaml). And there is no need to define each question/answer because our chatbot can search through all corpus within seconds to retrieve the data.	- Use AMIL file required to define each question as `<pattern></pattern>` and the answer as `<template></template>` for each dialog. - The question must be in capital letter (English case). - The data must not have any kind of punctuations because the platform will ignore it immediately and will not deploy it.
Time of response	The answer was retrieved immediately.	The answer took around 30 seconds to retrieve, and it could be "apologize message."
Dealing with user input	- The user can insert any Arabic input by using the formal and informal Arabic language.	- The user can insert only the exact question already fixed in the AIML file. Except that, the chatbot will ignore the question and retrieve "apologize message."
The experimentation	We insert the same dataset for both bots. And we use the same question format. The question used is "نسقمة يت مرور جوالي الايفون" and the answer should be "نسقمة كلمة تغيير > والأمن السر كلمة [اسمك] على انقر<الإعدادات>في الايفون" اي دي ابل" مرور كلمة يت السر" which contained diagnosis of the problem followed by the solution.	- If the question is in informal Arabic language, the bot retrieves "apologize message." "نسقمة الايفون جوالي مرور كلمة يت" Input: Output: the bot retrieves error "apologize message." - If the question is in an exact AIML file premade, the bot retrieves the correct answer. Input: نسقمة في الايفون" اي دي ابل" مرور كلمة يت Output: the bot retrieves the correct answer.
The result	- If the question is in informal Arabic language, the bot retrieves the correct answer. Input: "جوالي الايفون سرورم كلمة يت" Output: the bot retrieves the correct answer.	
Finding	- Our chatbot was capable of having any type of Arabic data without having strict inputs to a specific form. The bot uses AI keyword matching to analyze user input and match it with the most relevant problem/solution.	- Pandorasbot working as simple chatbot was capable of matching a text string and offering an answer only when the exact sentence match is found.

the type of dataset used, time of response, and how to process the inputs and then illustrate the question chosen to test both chatbots. After that, there are the result and findings.

5. Evaluation

Goal-oriented chatbots are a form of currently popular chatbot whose main function is to assist users with a specific set of tasks, such as "how can I unlock my Samsung (mobile) device?" Some publications with goal-oriented chatbots conducted evaluations that were related to the chatbot's objectives. The metrics include the number of successful conversations ended by the system, percentage of the problem solved, average dialogue length, and average of user utterance length [27].

The participants comprised 6 participants from the different educated background like engineering, linguistic, and finance background. Two were females, 4 were males, 3 were aged between 25 and 34, and 2 were aged between 35 and 44. All participants who participated were not having any IT background.

Sample of chosen dialog/ participant to be tested on the Functional evaluation phase

The interface of the chatbot dialog:

Dialog 1
Name of task: Assume that you need help Installing the HP printer by using a wired
network,(Kindly use your own Arabic language).

Part 1:

   - Personal information of the participant:

Name: Albandary abdullah
Gender: F
Age: 36
Level of education: Master's degree.
Education/work field: Linguistics.

Part 2:

   - Implement the task by the participant:

FIGURE 4: Goal-oriented chatbots evaluation for "المساعد الذكي" chatbot.

5.1. Goal-Oriented Chatbots Evaluation for "المساعد الذكي" Chatbot. We have presented the key findings of designing an Arabic chatbot unescorted by any third-party platforms, based on our proposed framework. The components of our framework are crafted thoughtfully; each phase can add/upgrade your bot mechanism into AI chatbot using the Arabic language.

Most of the current Arabic chatbots use the basic dialog (Q/A), third-party platforms, and complex AIML files [28]. However, we found that our framework directs the developer to get leverage of AI open-source package. In this project, we adopt a Python library to preprocess over 50 Arabic common IT problems/solutions and trained the bot

to diagnose the problem (input), then generating the solution (output) as shown in Figure 4.

5.2. Performance Measures. The performance of our chatbot has been tested through experiments performed between chatbots, developed from zero starting point, and the other has been tested by using an external platform which is Pandorabot, Arabic troubleshooting chatbot [29, 30]. Both were suited to have any type of Arabic data (formal/informal) without having strict inputs to a specific form. The analysis is shown in Table 6.

TABLE 7: General analytics of goal-oriented evaluation part 2.

Dialogs	Dialogue length (in sentence/line)	User utterance length (in sentence/line)	Number of times in which the participant paraphrases the question
D1	16 sentences	5 sentences	3 times
D2	13 sentences	4 sentences	1 time
D3	17 sentences	8 sentences	4 times
D4	11 sentences	4 sentences	0 times
D5	7 sentences	3 sentences	0 times
D6	14 sentences	7 sentences	3 times
The average	13.17	5.17	1.8

The bot uses AI keyword matching to analyze user input and match it with the most relevant problem/solution. AI keyword matching is a Python package deal [31, 32] with Arabic letters intelligently, needlessly to afford subscription fees to third-party platforms for creating an Arabic chatbot. Figures 5 and 6 show the solved cases in terms of evaluating the performance of the proposed chatbot.

Another testing method of "مساعد الذكي" chatbot is using goal-oriented chatbots evaluation. The result shows that 67% of the total problems are solved successfully and the average dialogue length is around 13 sentences per/conversation. Moreover, the average user utterance length is 5 sentences per/conversation. People usually speak over 8–10 sentences in one minute. Thus, chatbot's conversation does not exceed one minute from the end-user to receive useful information as shown in Table 7. The performance has been evaluated using metrics [33].

6. Conclusions

In this paper, an introductive framework for devolving Arabic troubleshooting chatbot to diagnose and solve technical issues is developed. A framework that supports Arabic text for better machine's understanding is implemented. The framework takes advantage of AI to enhance NLP and machine learning techniques in terms of Arabic content. This chatbot is a service-based chatbot. Thus, 10 websites were scanned to gain 50 problems and their reliable solutions. Chatbot evaluation shows that after comparing two previous built Arabic chatbots on the same dataset the proposed troubleshooting chatbot is capable of diagnosing and answering users' input more effectively. It is more convenient for the users to use their own accent (informal Arabic language) and receive the required answer.

For the evaluation techniques, this research classified them into two main categories, stated as comparison of the chatbot produced by following the proposed framework and others on chatbots platform. The evolution of the chatbot is done by the real users using functional evaluation matrices. Despite the findings of the research, there are some limitations because the majority of Arabic chatbot application has limited type of question answering (QA) corpus via NLP. To make interaction with the Arabic language easier, libraries for programming languages must be developed.

This knowledge is an important basis for future Arabic chatbot development. The framework is developed using the latest released package of Python and Arabic language, by leveraging a variety of AI including keyword matching techniques. However, the Arabic language branched out into special grammar, character, and forms that may be difficult for the Python language to identify in this research. The findings can be used as a guide for potential chatbot developers to choose appropriate evaluation methods for their chatbots based on their design, domain, aim, and evaluation intent. Also, it is possible to add voice bots by using voice-to-text recognition after incorporating the required technology. Furthermore, the outcomes of chatbot evaluations could be compared through various chatbots that were evaluated independently.

Data Availability

This paper is the result of an ongoing project; the dataset is developed and cannot be released at this stage.

Conflicts of Interest

The authors declare that they have no conflicts of interest to report regarding the present study.

As one of the most widely used languages in the world, English plays a vital role in the communication between China and the world. However, grammar learning in English is a difficult and long process for English learners. Especially in English writing, English learners will inevitably make various grammatical writing errors. Therefore, it is extremely important to develop a model for correcting various writing errors in English writing. This can not only be used for automatic inspection and proofreading of English texts but also enable students to achieve the purpose of autonomous practice. This paper constructs an English writing error correction model and applies it to the actual system to realize automatic checking and correction of writing errors in English composition. This paper uses the deep learning model of Seq2Seq_Attention model and transformer model to eliminate deep-level errors. Statistical learning is combined with deep learning and adopted a model integration method. The output of each model is sent to the n-gram language model for scoring, and the highest score is selected as output.

1. Introduction

As one of the most widely used languages in the world, English plays a vital role in communication with the world. Now, China has become the country with the most English learners in the world. English test is an important item in the test of students' ability, and English writing ability is often the focus of the test of English proficiency. For students, due to the impact of mother tongue transfer, they often make some grammatical errors, which affect their expression. As we all know, in order to improve the level of English writing, students must do a lot of writing exercises. However, based on the teacher-student ratio, it is difficult for an English teacher to correct a large number of English compositions of each student. In this way, students cannot get timely feedback on their writing, thus failing to achieve the purpose of autonomous learning. Therefore, it is particularly necessary to develop an automatic error correction model for

English writing. With the advancement of science and technology and the development of natural language processing technology, the use of computers for automatic error correction of English writing becomes more feasible at this time [1–5].

English writing inspection includes the structure and content analysis of the upper level, as well as the spelling and sentence grammar error detection and correction. At present, there are relatively good commercial tools for word spelling error detection and correction. However, the correction of grammatical errors in students' English writing is a boring and headache problem, and there is no mature solution at present. If the computer can quickly identify writing errors in sentences and give reasonable suggestions for corrections in time, learners will have a better experience in English learning. However, some of the current commercial or open writing error detection and correction tools have relatively ordinary effects. For example, the

grammatical error checking function in Microsoft Word cannot detect common grammatical errors such as subject-verb agreement and misuse of prepositions. And the recognition rate of other errors is relatively low. The error detection rate in the automatic checking function of English writing provided by Juku.com in China is also relatively low. It is not very practical in English learning. Therefore, the breakthrough of this problem will greatly promote the application of computer-assisted English learning [6–10].

Common types of English writing grammatical errors include article errors, preposition errors, verb morphological errors, noun singular and plural errors, and subject-predicate coincidence errors. Automatic error correction in English writing is considered an extremely difficult thing, mainly for the following three reasons. (1) Many grammatical errors are context-related. They are composed of correct words. Without context, it is impossible to distinguish which word is wrong in the context. (2) The frequency of each error is relatively low, but the error modes are diverse. (3) There may be many errors in single-day sentences, which increase the difficulty of machine grammatical error correction. Early machine learning methods cannot cover complex and diverse language models, and their accuracy is low, making it difficult to achieve satisfactory results. The automatic error correction task of English writing has also ushered in new development opportunities, which reduces the influence of corpus on the task of English writing error correction to a certain extent [11–15].

Based on the deep neural network, this paper proposes a new automatic error correction model for English writing. The main contributions are as follows: first, the Seq2Seq_Attention baseline model is determined. Then, a Seq2Seq_Attention model based on the subword BPE algorithm is proposed. Next, today's hot Transformer network is used to build an automatic error correction model for English writing and introduce curriculum learning strategies and masked sequence-to-sequence strategies to improve model performance. Besides, the performance of the model is improved based on data processing and data amplification. Finally, the method of model integration is introduced to further improve the performance of the model.

2. Related Work

Rule-based methods were widely used in grammar checkers. Errors that were easier to find could be checked with simple rules, such as repeated punctuation. If an English sentence was more complicated, it needed to be checked with more complicated rules. The earlier versions of the rule-based grammar checker included EasyEnglish [16] and Park's grammar checker [17]. The most widely used tools were Microsoft Word, WordPerfect [18], and Grammarian Pro X [19], all of which could be used in multiple languages. They all used certain grammatical rules to check sentences or phrases. Therefore, the main disadvantage was that it is restricted by different languages, and a rule could not be reused by multiple languages. EasyEnglish was an English writing checker developed by IBM. It used the syntax tree represented by

the network diagram to check and find errors. It used patterns to formalize writing errors and then matched them with the constructed syntactic tree. This was a writing checker developed based on a rule-based approach and English groove grammar. However, when a sentence could not be parsed correctly and a complete grammar tree could not be constructed, the writing checker would not work well. In addition, whether it was a commercial or free tool, the grammar checker currently had no publicly released version. Park's grammar checker was a writing checker specially developed for English learners who used English as a second language to check typical errors in composition. It was a writing checker implemented by combining the rule method and the Prolog method. The writing checker could manually add rules, and new rules could replace invalid old rules. These rules could give users feedback information but would not return any information for the correct sentence.

Another method that was widely used in grammar checking was the method of statistical data analysis. Due to the rapid development of statistical machine learning methods, corpus linguistics, which used corpus as the research foundation and object, had risen rapidly. This method had been more and more recognized by researchers and had been widely used [20]. Literature [21, 22] proposed a grammatical error correction technology based on the noise channel model, which used the context of the entire sentence to correct the sentence. The basic theory of the noise channel model mainly included two parts, namely the basic language model and the noise model. The former was a probabilistic model, which generated a sentence without errors according to a given probability. The literature [23] used a variety of vocabulary and part-of-speech features, including verb phrases and nouns of adjacent prepositions, part-of-speech tags, word lemmas, to evaluate a large amount of data including newspaper news articles and English articles of intermediate and advanced English students. The error correction range covered 34 commonly used prepositions, and the final accuracy of the maximum entropy algorithm was 69%. Literature [24] used complex grammatical features, WordNet category features, and various types of part-of-speech features. At the same time, some grammatical relations extracted from the syntactic tree were also used. These grammatical relationships could be used as strong preposition checking features. Then, the data subset of the British National Corpus was used as the test set, and the correct rate was 75.6%, which was a relatively good result. Literature [25] proposed a method based on memory learning to select articles. The features he used were extracted from the Pennsylvania sentence database, for example, the part of speech of the head word, the head word of the noun phrase, and other qualifiers in the noun phrase. There were also some features extracted from the translation system from Japanese to English, such as the semantic category of the head word of noun phrases and the tendency of countability. The highest check accuracy rate obtained by the model was 83.6%. Literature [26] used the applied log-linear model to automatically recover the missing articles. It described a competitive classification model to generate and

describe the articles, thereby recovering the correct sentence. Literature [27] described a method that uses a maximum entropy classifier to select articles for noun phrases, and some features of the context are used in this process. When the training set size of the classifier reached 6 million noun phrases, the accuracy of the classification method reached 87.99%.

3. Method

This chapter first determines the baseline model of Seq2-Seq_Attention (S2SA). Then, based on data preprocessing and data amplification, the performance of the baseline model is improved. Then, a Seq2Seq_Attention model based on the BPE subword level is proposed called S2SA-BPE. Then, an English error correction model is built based on Google's Transformer model and introduced curriculum learning strategies and masked sequence-to-sequence training strategies to further improve the correction results. Finally, the N-gram language model and the deep learning model are integrated.

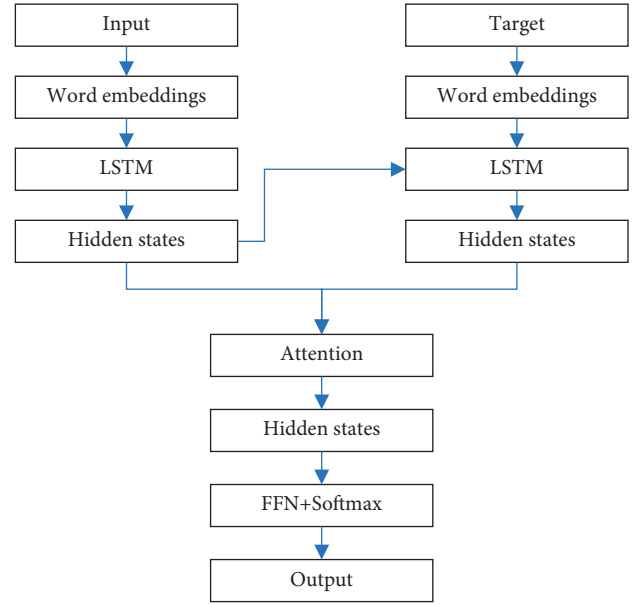
3.1. Error Correction Based on S2SA. This paper chooses to build an error correction baseline model based on the S2SA model for the following reasons. (1) S2SA model is a more classic model in neural network translation technology, and its position in neural network translation is equivalent to that of word2vec in the text representation. This model introduces the Attention mechanism, which breaks the restriction that the decoder can only use the encoder to finally fix the vector result. This allows the decoder to focus on the input text that is important for predicting the next target word. In addition, you can also observe the changes in the attention weight matrix to know the source input text corresponding to the target word. This helps to deepen the understanding of the model. (2) The idea of the S2SA model is relatively simple, easy to understand, and its code structure is relatively simple, which will speed up the deployment of the model. Even if the baseline model is not the final model, it can be iterated quickly, thereby reducing unnecessary time costs. (3) The baseline model is easier to deploy, generally consists of relatively few trainable parameters, and can quickly match the data without much processing. The most important thing is to facilitate research; that is, most of the errors encountered can be easier to locate the errors in the data or the defects of the model. (4) The baseline model is conducive to understanding the data, and finding out the errors in the process of constructing the baseline model is very constructive for discovering deviations and specific errors in the data. (5) The baseline model is conducive to understanding the task and helps to understand which part of the project is more difficult and which part is simpler. According to this idea, it is helpful to locate which aspect of the model should be improved, so as to better solve the difficult part. The structure of S2SA is illustrated in Figure 1.


FIGURE 1: The structure of S2SA.

Encoder input is the word embedding, and the output is the hidden layer state.

$$h_t = E_{LSTM}(x_t, h_{t-1}), \tag{1}$$

where E_{LSTM} is LSTM encoder.

Decoder input is the word embedding, and the output is the hidden layer state.

$$s_t = D_{LSTM}(y_t, s_{t-1}), \tag{2}$$

where D_{LSTM} is LSTM decoder.

The context vector c_i is a weighted average of the hidden layer state.

$$c_i = \sum w_{ij} h_j. \tag{3}$$

The weight for the hidden layer state is calculated as follows:

$$w_{ij} = \frac{\exp(e_{ij})}{\sum \exp(e_{ik})}. \tag{4}$$

The weight with the hidden state is calculated as follows:

$$e_{ij} = \text{score}(s_i, h_j). \tag{5}$$

The context vector, as well as the hidden state, is concatenated as follows:

$$p_t = \tanh(W_c[c_t; s_t]). \tag{6}$$

The final output probability is calculated as follows:

$$p = \text{softmax}(W_s p_t). \tag{7}$$

3.2. Error Correction Based on S2SA-BPE. The S2SA model based on word level has the following disadvantages: (1) There are usually many words in the vocabulary that share a

vocabulary unit but have different grammatical forms. (2) There are unknown words and rare words. Unknown words refer to words that are not in vocabulary and are marked as OOV words. Rare words refer to some words in the vocabulary that appear too few times in the training corpus so that they cannot be fully trained to obtain good word vectors. (3) There is no perfect word segmentation algorithm in any language. An excellent word segmentation algorithm should be able to divide any sentence into a sequence of lexical units and grammatical forms. Therefore, this paper uses a Seq2Seq_Attention model (S2SA-BPE) based on the BPE subword level, which effectively alleviates the problem of unknown and rare word translation and improves the performance of the model. The S2SA-BPE algorithm implements a text representation unit that is between characters and words and is also different from character n-grams, achieving a more balanced state in terms of vocabulary capacity.

Byte pair encoding is a data compression method that uses an unfamiliar byte to replace the byte that frequently appears in the sentence. We use this algorithm to split words and merge characters or character sequences. The steps of the BPE learning algorithm are as follows: (1) the symbol vocabulary is initialized and added all the characters to the symbol vocabulary. Special symbols are added to the end of words. (2) All the symbols are counted, find the most frequent character pair, and replace it with a new character. (3) Each time it is merged, and a new character is generated, which means n-gram character. (4) Common n-grams characters will be merged into one symbol at the end. (5) The final symbol vocabulary size is the sum of the initial size and the number of merge operations. The number of operations is the only hyperparameter of the algorithm. The structure of S2SA-BPE is illustrated in Figure 2.

Existing word segmentation algorithms generally target normal texts and apply standard word segmentation algorithms to the task of correcting English texts. Segmentation of texts with errors will lead to mis-segmentation. Moreover, the word segmentation algorithm itself has the problem of ambiguity segmentation; that is, the word segmentation process will introduce additional error information with a high probability. In addition, the existing translation models based on word level generally limit the size of the vocabulary to alleviate the problem of excessive calculation of the softmax function. The limited vocabulary size will cause rare words to become unknown words, which will damage the performance of the model. Therefore, the S2SA-BPE method can alleviate the above problems to a certain extent.

3.3. Error Correction Based on Transformer.

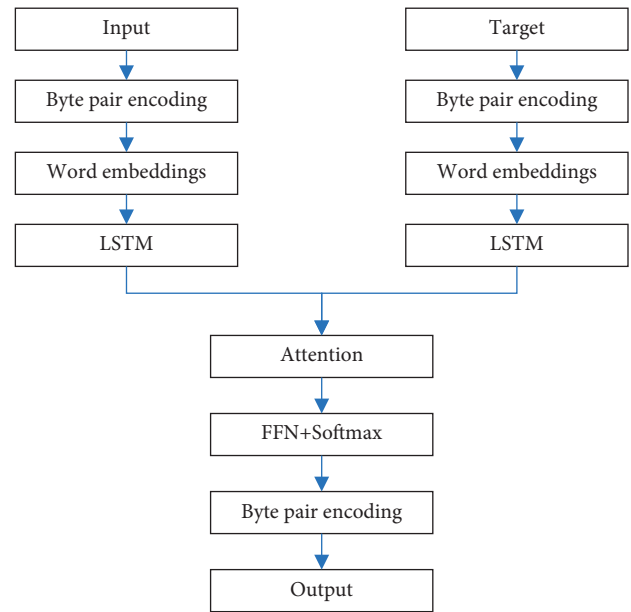
3.3. Error Correction Based on Transformer. This paper builds an English writing error correction model based on the Transformer network because of the following points. (1) In terms of parallel computing capabilities, the current input of the RNN network depends on the input at the previous time, which makes it impossible to parallelize. The Transformer introduces the Attention mechanism to reduce the distance between any two characters in the text to a constant, which helps to alleviate the problem of RNN's long-distance


FIGURE 2: Structure of S2SA-BPE.

dependence. And due to matrix operations, its parallel computing power is also better than RNN. (2) In terms of computational efficiency, self-attention is more computationally efficient than RNN and CNN. (3) In terms of semantic feature extraction capabilities, Transformer surpasses RNN and CNN. (4) In terms of long-distance feature capture capability, the CNN feature extractor is significantly weaker than the Transformer. (5) In terms of comprehensive feature extraction capabilities represented by machine translation tasks, Transformer has a higher performance than RNN.

Based on the above five factors, this paper chooses to build a Transformer-based error correction model for English writing to further improve the effect of error correction. A big advantage of Transformer is the global receptive field; that is, RNN/CNN can only see part of the context at a time. In Transformer, each node can directly interact with other nodes. But, there are pros and cons, because Transformer does not introduce a strong prior. Therefore, a large amount of data is needed to learn a certain statistical relationship of the data from scratch. Practice has proved that the effect of Transformer on small data sets is not as good as RNN/CNN. But when there is a large amount of training data, Transformer will have a higher upper limit.

3.4. Curriculum Learning Strategy. Curriculum learning is similar to the human learning mechanism, that is, learn simple skills first and then learn difficult skills. If the training data are input in a specific order, in other words, the model first learns from simple data and then learns difficult data after the model has a certain ability, which is in line with human intuition. At the same time, from the perspective of machine learning, this method can also avoid falling into a bad local optimal solution prematurely. This can increase the generation speed and speed up the convergence speed and find a better local minimum in the nonconvex training data.

The curriculum learning method is sensitive to hyperparameters, and this paper uses a curriculum learning method with only one adjustable hyperparameter, called competence-based curriculum learning [28].

There are two crucial concepts in the learning strategy method of this course: difficulty and competence. Difficulty represents the difficulty value of a training sample. Its value is determined by the sentence length and the relative word frequency of the word. The calculation is as follows:

$$\text{diff}(s_i) = -\sum_{k=1}^{N} \log(f_k), \tag{8}$$

where s_i is the ith sample, N is the length of the sample sentence, f_k is the relative word frequency of the kth word in the sample.

Competence is a value between 0 and 1, which represents the progress of model training and is defined as a function of the model state. Specifically, this method defines the model's ability $c(t)$ at time t as the proportion of training data allowed to be used at time t. The training samples are sorted according to their difficulty, and the model only allows their top $c(t)$ part to be used at time t. Linear function and root function are two calculation methods.

$$\text{comp}_L(t) = \min\left(1, \frac{(1-c_0)t}{T} + c_0\right),$$

$$\text{comp}_R(t) = \min\left(1, \left(\frac{(1-c_0^m)t}{T} + c_0^m\right)^{1/m}\right), \tag{9}$$

where c_0 is the initial value, T is the time step threshold. When the threshold is exceeded, the model is considered to be fully capable, and t is the time step.

In this paper, the curriculum learning strategy is applied to the English writing error correction task to achieve the purpose of improving performance. The model is illustrated in Figure 3.

The competence of this paper is in addition to the linear form and root form mentioned above. A method for selecting training data based on loss is also proposed. The most intuitive reflection of the strength of the model is the loss of the model. The calculation formula is as follows:

$$\text{comp}_{\text{Loss}}(t) = \min\left(1, \left(\frac{1-\text{loss}}{T+c_0}\right)^{1/2}\right). \tag{10}$$

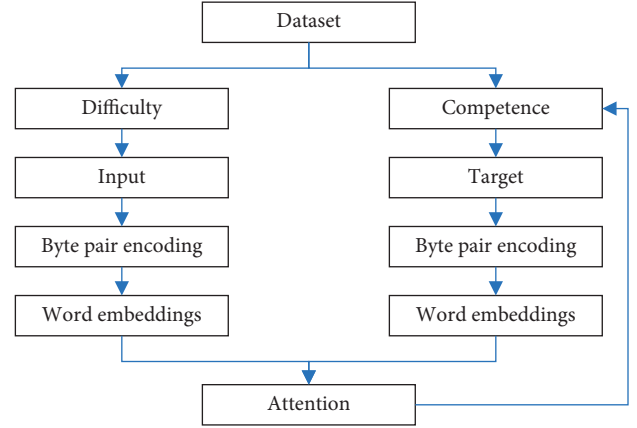
3.5. Masked Sequence-to-Sequence Strategy.
Most of the existing pretraining models are based on natural language understanding tasks and have achieved excellent results, which have attracted more and more attention. However, in sequence-to-sequence natural language generation tasks, such as machine translation, summary generation, automatic question and answer, few pretrained models are targeted for such tasks. Literature [29] proposed a pretraining method for natural language generation tasks: masked sequence-to-sequence pretraining (MASS). This


Figure 3: Based on the curriculum learning model frame diagram.

method uses the encoder-decoder framework to reconstruct a sentence segment: its encoder randomly masks multiple consecutive features of the input sentence. Then, the decoder tries to predict the features that are concealed, and its model architecture is shown in Figure 4.

MASS pretrains the encoder and decoder jointly in two steps. (1) By predicting the feature of the sentence that is masked in the encoder, MASS forces the encoder to understand the meaning of the feature of the unmasked sentence. (2) By masking the decoder input that is not masked at the source, MASS forces the decoder to rely more on the representation of the source. So as to better promote the union between encoders.

The MASS method has the following advantages: (1) The decoder side masks all words to facilitate the decoder to extract more information to improve the prediction results, thereby facilitating joint training. (2) In order to provide more information to the decoder, the encoder is forced to extract the information of the unmasked words, thereby improving the ability of the encoder to extract information. (3) Decoder is used to predict the continuous words that are obscured, which can promote the language modeling ability of the decoder. In order to improve the effect of the error correction model, this paper introduces the MASS pretraining method to the error correction task for the first time. This paper generates masking data based on char and word. It should be noted that the features are masked sequentially, not randomly.

3.6. Data Preprocessing and Data Amplification.
The reasons for data preprocessing and data amplification in this paper are as follows: (1) The higher the quality of the training data, the better the model performance. The quality of the data determines the upper limit of task performance, and necessary data preprocessing techniques can be used to approach the upper limit of task performance. (2) The more the training data, the better the model performance. Data are the core driving force of neural network models. Massive training data are one of the important reasons for the success of neural network models.
FIGURE 4: MASS method architecture diagram.

Processing the data is essential while developing a deep learning model in order to lessen the data's complication. A suitable model is established, which will help the model fit the data better and increase the pace at which it converges and improves the model's effectiveness.

Therefore, based on the above viewpoint, this paper uses edit distance to process the corpus. Edit distance [30] is also called Levenshtein distance, which is a tool to measure the similarity of two texts. Its specific meaning refers to the minimum number of editing operations required to convert one text to another. The editing here generally includes three types: inserting characters, deleting characters, and replacing characters.

In the field of natural language processing, data amplification is generally achieved in three ways. (1) Direct method searches for data related to the task and directly performs data amplification. (2) The indirect method, through the pretraining model, directly fine-tunes the trained model based on the data of its own task. This method generally requires higher hardware. (3) The method of data modification, that is, the four simple operations of synonym substitution, random insertion, random exchange, and random deletion, is used to achieve data amplification. But in the field of natural language processing, this method is rarely used, because simple addition, deletion, and modification operations can easily damage the performance of the model. In the data amplification experiment in this chapter, the direct amplification method is used to combine different corpora.

3.7. Model Integration.

Model integration is to build a series of models and uses a certain strategy to combine the built models. Then, a model with higher accuracy, better stability, and generalization effect can be obtained. At present, model integration has become a weapon in various competitions or tasks. There are many existing integration methods, but the most classic methods are Bagging and Stacking. Many methods have also been developed from this. The main idea of Bagging is to randomly select a part of the sample from the overall sample with a replacement for training and obtain multiple models by repeating the operation multiple times. Then, the average is voted or taken as the resulting output. Stacking is a layered model integration method. The input of the first layer is the original training set, and the second layer uses the output of the first layer model as the training set for training.

The model ensemble method of this paper is to learn from the Bagging method. N-gram, S2SA, S2SA-BPE, Transformer, Curriculum learning strategy-based Transformer (CL-Transformer), char-based masked sequence-to-sequence strategy Transformer (MC-Transformer), and

word-based masked sequence-to-sequence strategy Transformer (MW-Transformer) is combined for integration. The output results are scored using the N-gram language model. The highest score is used as the final output, and its multimodel integration framework is shown in Figure 5.

4. Experiment and Discussion

4.1. Experimental Environment.

The models used in this chapter are all end-to-end learning networks, and a suitable experimental environment is built according to the characteristics of the end-to-end learning network. This paper is based on the Python language and uses the PyTorch framework to code the model. The experimental environment is shown in Table 1.

4.2. Dataset and Metric.

The training forecast in this article is mainly divided into two parts. The first part comes from the International Corpus Network of Asian Learners of English (ICNALE), and the second part comes from the Brown Corpus. The testing is expected to come mainly from the learner corpus.

The F value evaluation is commonly used internationally to evaluate the effect of grammar checking. F value evaluation is also a commonly used evaluation standard in the field of natural language processing, and its calculation formula is

$$F_{\beta} = \frac{\left(1 + \beta^2\right)PR}{\beta^2 P + R},\tag{11}$$

where β is the parameter, P is precision, and R is recall rate. The calculation formula of P and R is as follows:

$$P = \frac{A}{A + B},$$
$$R = \frac{A}{A + C},\tag{12}$$

where A represents the number of sentences that actually contain grammatical errors among the sentences marked by the model as containing grammatical errors. B represents the number of sentences that do not contain grammatical errors among the sentences marked by the model as containing grammatical errors. C represents the number of sentences with grammatical errors that are not marked by the model.

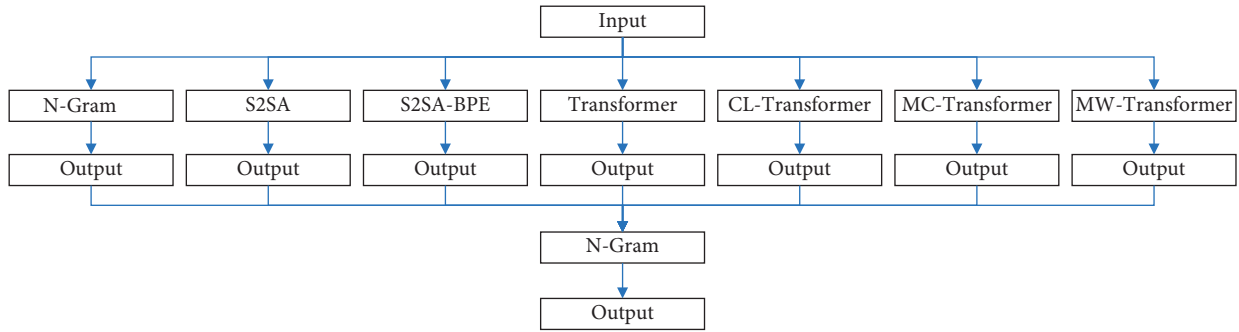
This article uses $F_{0.5}$ instead of F_1, because in practical applications, we focus more on accuracy. In $F_{0.5}$, it is emphasized that the accuracy rate is twice the recall rate, and in F_1, the accuracy rate and the recall rate are equally important.


FIGURE 5: Multimodel integration framework diagram.

TABLE1: The experimental environment.

Item	Type
CPU	Intel core i7-8700K
GPU	NVIDIA GeForce RTX 3090ti
Operating system	Ubuntu 20.04
Deep learning framework	Pytorch 1.8

4.3. Evaluation on S2SA. S2SA is the baseline model of this paper. It uses word vectors to represent the input text. Both encoder and decoder use a two-layer two-way LSTM network. In order to obtain better text representation, two kinds of word vectors are used, namely Word2vec word vector and GloVe word vector. The result is illustrated in Figure 6.

The data results show that the performance of the baseline model based on the Word2vec word vector is slightly lower than that of the baseline model based on the GloVe word vector. The latter achieves 1.1%, 1.8%, and 1.6% performance improvements on three performance indicators. In subsequent experiments, GloVe word vectors are used.

4.4. Evaluation on S2SA-BPE. To solve the problem of unknown words and rare words that often appear in the word level model, BPE subword technology is introduced. The word segmentation tool used is a trained BPE subword model, and the remaining model parameters are consistent with the baseline model settings. In order to verify the effectiveness of this model, S2SA-BPE and S2SA are compared, and the experimental results are shown in Figure 7.

The data results show that under the same data and the same parameters, the performance of the model based on S2SA-BPE surpasses the performance of the model based on word level. The improvements in the three performance indicators are 1.2%, 1.8%, and 1.7%. The subword strategy can improve the performance.

4.5. Evaluation on Curriculum Learning Strategy. The curriculum learning strategy imitates the human learning mechanism, that is, learn simple knowledge first, and then learn difficult knowledge. This learning method can reduce the probability of falling into a local optimal solution and speed up the convergence speed of the model. The input of the model is that the difficulty value of the input text is less
FIGURE 6: Evaluation on S2SA for different word vectors.
FIGURE 7: Evaluation on S2SA-BPE.

than the current ability value of the model, and three experiments are set up according to the different calculation methods of competence. They are the linear method, root

method, and loss method, and the rest are consistent with the Transformer model parameters. The result is illustrated in Figure 8.

It can be seen that curriculum learning strategies can effectively improve the performance of error correction in English writing. It should be noted that compared with the traditional Transformer method, no matter which strategy can obtain performance improvement. But compared with the linear and root methods, the loss method designed in this paper can achieve the best performance improvement. This proves the effectiveness of this design in this paper.

4.6. Evaluation on Masked Sequence-to-Sequence model.
The pretraining method is used to indirectly increase the size of the data set. The encoder and decoder are jointly trained by masking the sequence-to-sequence model, breaking the limitation that the pretraining model can only train a certain part. The model first uses the preprocessed corpus for pretraining, and the pretraining part can be divided into two parts. One is a model based on word level, and the other is a model based on word level. In order to compare these two different methods, this paper conducts a comparative experiment, and the results are shown in Figure 9.

It can be seen that the MASS strategy can effectively improve the performance of error correction in English writing. It should be noted that compared with the traditional Transformer method, no matter which strategy can obtain performance improvement. But compared with the word method, the char method designed in this paper can achieve the best performance improvement, which can achieve 0.7%, 1.1%, and 1.2% gains on precision, recall, and $F_{0.5}$.

4.7. Evaluation on Data Preprocessing and Data Amplification.
In this paper, data preprocessing and data amplification are carried out on the data used in the experiment. In order to verify the effectiveness of this data processing method, this paper conducts a comparative experiment. The performance of each model with data processing and without data processing is compared, and the experimental results are shown in Figure 10. CL-T is CL-Transformer. MC-T is MC-Transformer. MW-T is MW-Transformer.

It can be seen that after using data preprocessing and data amplification methods on each individual model, the error correction performance of the model will be improved accordingly. This experiment proves the effectiveness of the data processing method in this paper.

4.8. Evaluation on Multimodel Aggregation.
The writing error correction model designed in this article is an aggregation model, which is aggregated from S2SA, S2SA-BPE, Transformer, CL-Transformer, MC-Transformer, and MW-Transformer. In order to verify the effectiveness of this aggregation model, this paper compares the separate model with the aggregated model. The results are shown in Table 2.
FIGURE 8: Evaluation on curriculum learning strategy.
FIGURE 9: Evaluation on masked sequence-to-sequence strategy.

The data show that the aggregation model can achieve the best performance compared to each individual model. This proves the reliability and correctness of the error correction algorithm for English writing based on the aggregation model proposed in this paper.

4.9. Comparison with Other Methods.
In order to further verify the effectiveness of the method in this paper, the aggregation model is compared with other English writing error correction methods. The compared methods in this work include the naive Bayesian model (NBM), decision tree model (DTM), maximum entropy model (MEM), and KNN. The result is illustrated in Table 3.
Figure 10: Evaluation on data preprocessing and data amplification.

Table 2: Evaluation on multimodel aggregation.

Model	P	R	$F_{0.5}$
S2SA	89.5	77.7	84.8
S2SA-BPE	90.7	79.5	86.5
Transformer	91.0	80.8	86.9
CL-transformer	91.8	81.9	88.2
MC-transformer	91.7	81.9	88.1
MW-transformer	91.5	81.7	87.4
Ours	92.5	84.3	89.5

Table 3: Comparison with other methods.

Method	P	R	$F_{0.5}$
NBM	79.8	68.1	73.5
DTM	84.3	72.5	77.8
MEM	87.5	81.4	84.3
KNN	89.3	82.1	85.8
Ours	92.5	84.3	89.5

Compared with other error correction methods, the aggregation model method designed in this paper can obtain the best performance. Compared with the best KNN method listed, the three performance indicators have been improved by 3.2%, 2.2%, and 3.7%, respectively.

5. Conclusion

With the development of artificial intelligence and computer science and technology, natural language processing technology has developed rapidly, providing a theoretical and technical basis for the intelligent assistance of English. A large number of teaching and tutoring software has emerged in the following. As an important part of English learning, writing has become a difficult challenge for learners in the learning process. For students, the strength of the ability to use English writing directly affects the level of English proficiency. At the same time, this will also affect English reading and speaking skills. Based on the deep neural network, this article is dedicated to developing an intelligent model for correcting various errors in English writing. This can not only be used for automatic inspection and proofreading of English writing but also enable students to achieve the purpose of autonomous practice. First of all, this paper determines the S2SA baseline model. Then, an S2SA-BPE model based on the subword BPE algorithm is proposed. Afterward, we used the now hot Transformer network to build an error correction model for English writing. And the curriculum learning strategy and the masking sequence-to-sequence strategy are introduced to improve the performance of the model. Then, the model performance based on data processing and data amplification is improved. Finally, the method of model integration is introduced to efficiently aggregate the various submodels designed. This can further improve model performance.

Intelligent production line is the abbreviation of intelligent production line. Intelligent production line refers to a form of production organization that uses intelligent manufacturing technology to realize the production process of products. The actual manufacturing process includes different levels and links, and each step cooperates to create a high-efficiency production line. The intelligent production line includes 3 levels covering automation equipment, digital workshops, and intelligent factories and runs through 6 major links of intelligent manufacturing (intelligent management, intelligent monitoring, intelligent processing, intelligent assembly, intelligent inspection, and intelligent logistics). The emergence of the Internet of Things system has changed the way of information dissemination. The system combines radio frequency automatic identification and global positioning system technologies to achieve functions such as information exchange and processing, enabling information processing to be intelligent and improving resource utilization. Big data processing includes multiple data processing procedures, but data quality is the most important link in the entire process, and each data processing link will have an impact on the quality of big data. The big data processing process mainly includes data collection, data preprocessing, data storage, data processing and analysis, data display, data visualization, data application, and other links. This article aims to study the new progress of artificial intelligence algorithms for big data processing of IOT systems on intelligent production lines. It is hoped that through the development of intelligent production lines and big data processing technologies, ways to optimize artificial intelligence algorithms can be found. This study proposes a metadata replication method based on a separate replication strategy, which separates the replication process of the data operation log, each is independent, and shortens the data replication time. Combining the existing intelligent production line network platform in the laboratory and carrying out the research of the intelligent production line network state prediction system based on the neural network to design a network prediction system can prejudge the operation status of the intelligent production line network. The experimental results in this article show that when the Namenode mode is used to read data and when the number of clients reaches 8, the data processing basically remains unchanged. When the NCluster system reads data and when the number of clients is 6, the data is processed 1256. When the number of clients is 20, the data is processed 2100, the NCluster system will remain stable when the number of clients reaches 12, and compared with the Namenode system, it has obvious advantages.

1. Introduction

The scope of artificial intelligence applications is very wide, including medicine, diagnosis, financial trade, robot control laws, scientific discoveries, and toys. Artificial intelligence, also known as AI, has produced many aspects to solve the most difficult problems in computer science. However, with the ever-expanding social production field, people are increasingly raising production standards, which urgently requires the continuous optimization of artificial intelligence algorithms to reach higher standards. As an important part of the Internet, the Internet of Things can form a new ecosystem of the physical world and the information world, further realize the information sharing of people, machines, and things, make the information exchange between the information world and the physical world closer, and improve social production efficiency and meet people's growing needs. With the increasing popularity of Internet technology, the information data in life have increased exponentially, so the concept of big data came into being. Big data refers to the amount of data involved is so large that cannot be retrieved, managed, processed, and organized in a reasonable time through mainstream software tools to help enterprises make business decisions more positively. How to find the required information from the massive data has become a major challenge for big data processing. With the continuous optimization of big data processing technology, people have been able to select the required information by keywords, which also improves work efficiency and saves time. At present, the development time of artificial intelligence is relatively short, and the algorithm has not been perfected. How to optimize calculation with the help of big data processing and the Internet of Things technology has become a current research hotspot.

Although artificial intelligence is still under development, its future still has many uncertainties, but the rise of artificial intelligence will promote industrial changes and profoundly affect people's lifestyles. There has been a broad consensus that this technology will definitely be a technological revolution with far-reaching impact, so the exploration of artificial intelligence is very necessary. Artificial intelligence technology will have a profound impact on the country's international competitiveness, change the pattern of international industrial division of labor, and reshape the development of the world economy. And focusing on the research of artificial intelligence technology is an important way to improve international competitiveness. In daily life, artificial intelligence technologies such as deep learning, image recognition, and voice recognition have been widely used in smart terminals, smart homes, mobile payments, and other fields to provide ordinary people with wider coverage, better experience, and better convenience in life service.

In view of the characteristics of mass, this article summarizes the related work of the cloud-centric the Internet of Things and summarizes and analyzes the current solutions and research status for the massive data of the Internet of Things. In view of the current research status of the Internet of Things data processing at home and abroad and the analysis of the demand for complex event processing of the

Internet of Things, the data processing technology system architecture of the Internet of Things is proposed. Introducing an intelligent recommendation model and using a knowledge base to provide users with a scientific algorithm recommendation plan through the ability of rough set theory to classify knowledge can realize the intelligent recommendation of the algorithm.

2. Related Work

Although artificial intelligence technology is a current hot research field, it has a short development time and is not mature enough to integrate with the production field to achieve high-efficiency production. Therefore, how to optimize artificial intelligence algorithms has become a current problem. Yi-Yu systematically proposed the strategies, methods, and engineering theories of intelligent lean manufacturing of traditional Chinese medicine in response to the "six scientific problems" and "five technical challenges" of intelligent manufacturing and lean production of traditional Chinese medicine. The holistic view of traditional Chinese medicine draws on the concept of international advanced pharmaceutical technology and applies the theory and method to six traditional Chinese medicines including Sanqi Panax Notoginseng injection. Based on this theory and method, a number of intelligent production lines have been designed and built, which has greatly accelerated the digital, networked, and intelligent manufacturing of CM. In summary, this theory and application provide a technical demonstration for the technological upgrading and high-quality development of the CM industry [1]. The Internet of Things has a significant impact on the development of manufacturing technology. Therefore, based on the analysis of the challenges and opportunities faced by the manufacturing industry, Liu took the assembly process of mechanical products as the research object and analyzed the characteristics of the manufacturing system based on the Internet of Things. In order to improve the interconnection, perception, efficiency, and intelligence of the assembly system, the author proposed the concept of an intelligent assembly system for mechanical products based on the Internet of Things. Then, introduced the IIASMP framework based on advanced technologies such as information and communication technology, sensor networks, and radio frequency identification. The key technologies such as assembly resource identification, information interaction technology, multisource data perception and fusion, intelligent assembly agent, and data value-added and dynamic adaptive optimization under this framework are described [2]. Wang proposed a new hybrid method that uses an integrated data fluctuation network and multiple artificial intelligence algorithms, called the DFN-AI model. In the proposed DFN-AI model, the author uses complex network time series analysis technology as the preprocessor of the original data to extract fluctuation characteristics and reconstruct the original data, and then uses artificial intelligence tools to model the reconstructed data and predicts the future data. To verify these results, the author checked daily, weekly, and monthly price data from the Cushing Crude Oil

Trading Center in Oklahoma. The empirical results show that the proposed DFN-AI model is significantly better than its corresponding single AI model in terms of prediction direction and prediction level. This confirms the effectiveness of the proposed nonlinear model modeling hidden in crude oil prices [3]. Bao uses the Java programming language to design and develop an RPO analysis software based on artificial intelligence (AI) algorithms. The software integrates five different AI algorithms, which can be used for RPO solutions in different situations. Users can quickly select the appropriate RPO calculation algorithm according to the actual situation, and the calculation results can guide the grid company to optimize parameters such as reactive power compensation capacity and transformation ratio. The software mainly includes a project management module, data editing module, RPO calculation module, and control variable editing module. It has a BPA-Matpower data interface, compatible with BPA data format, and can complete the accurate conversion of BPA data to Matpower data. The software can directly edit the BPA data of different grid structures without reprogramming and has the characteristics of high precision and strong versatility [4]. Dou proposed an independent regional connection model in the context of sensor networks to ensure global connectivity and satisfactory data service quality. The author also studied the optimization of deterministic and random deployment of sensor coverage and regional connections in industrial IOT systems. First, a new optimal network that achieves full sensing coverage and ensures regional connectivity is proposed for deterministic deployment. In addition, the optimal model is derived and the advantages of the proposed model are analyzed. Secondly, based on the assumption that a given sensor is deployed as a Poisson point process, a theoretical analysis is proposed to determine the minimum number of sensors for random deployment to achieve a certain coverage and connectivity. Numerical results show that the model is effective for the application of sensor networks in industrial IOT systems [5]. IOT devices are usually small, low-cost, and limited in resources, which makes them vulnerable to physical, side-channel, and cloning attacks. In order to solve this problem, Aman proposed a lightweight mutual authentication protocol based on the physical unclonable function of the Internet of Things system. Two scenarios of protocols are provided, one is when the IOT device and the server want to communicate, and the other is when two IOT devices want to establish a session. The security and performance analysis of the protocols show that they can not only resist different types of attacks but are also very efficient in terms of computing, memory, energy, and communication overhead [6]. Kim proposed an enhanced Access Reservation Protocol (ARP) with a Partial Preamble Transmission (PPT) mechanism for the narrow band Internet of Things (NB-IOT) system. The proposed ARP can improve ARP performance by reducing the occurrence of preamble collisions and is compatible with traditional NB-IOT ARP. At the same time, an analysis model is provided that can capture the performance of the proposed ARP in terms of false alarms, false detections, and collision probability. In addition, the author studied the trade-off between

false detection and collision probability and optimized the proposed ARP based on the system load. The results show that the proposed ARP is better than the traditional NB-IOT ARP, especially under heavier system load [7]. Device capture attacks usually threaten the realization of signcryption on unattended devices by extracting encryption keys from the captured devices. Inspired by this problem, Yang proposed a novel and specialized obfuscable aggregatable signcryption scheme (OASC) and signcryption algorithm obfuscator. The design of the scheme considers that the computational and communication costs should be small enough (lightweight), in order to adapt to the applications in resource-constrained embedded devices. The proposed obfuscator can protect the signcryption program from key extraction attacks by converting the program into an incomprehensible obfuscation program [8]. Although these theories have explored artificial intelligence algorithms and big data processing technology to a certain extent, the two fields are less integrated and not practical.

3. New Development Methods of Artificial Intelligence Algorithms for Big Data Processing in IOT Systems on Intelligent Production Lines

3.1. Big Data Processing. Big data brings many problems to data processing. Taking traffic security data as an example, after years of informatization construction, public security, and government departments have collected massive amounts of traffic security-related data resources, the scale and complexity of which have exceeded the management and processing capabilities of traditional databases and software technologies. Since the Internet of Things technology has been promoted, big data is everywhere in daily life, and the scope of application continues to expand [9, 10]. With the emergence of the scale of big data, it is urgently required to classify and process big data. In this context, a big data system has emerged [11], and the structure of the big data system is shown in Figure 1:

The big data processing system mainly includes data integration layer, data storage layer, data processing layer, data analysis and application layer, and platform management, and other components. The data integration layer is responsible for adapting between external data sources and the internal data storage layer of the big data processing system to achieve efficient data import and export.

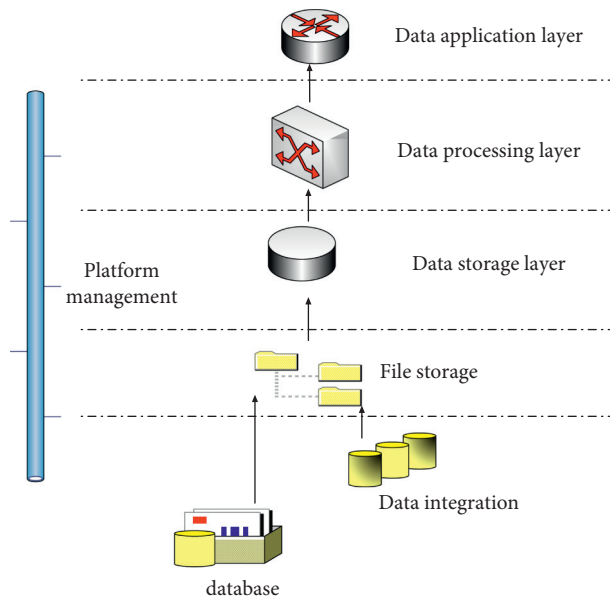
With the development of sensor technology, more and more data are collected, prompting the Internet of Things to realize the concept of universal connection to connect every item at any time and place [12, 13]. Using sensors of different specifications to collect data has different data formats, so there will be heterogeneous data, which requires the data to be preprocessed before the data is analyzed [14, 15]. From the original database to the mining database, the operation on the data is called data preprocessing. Preprocessing of data is a complicated process, and different processing programs need to be written for different situations [16]. The data preprocessing structure diagram is shown in Figure 2.


FIGURE 1: Big data system structure.
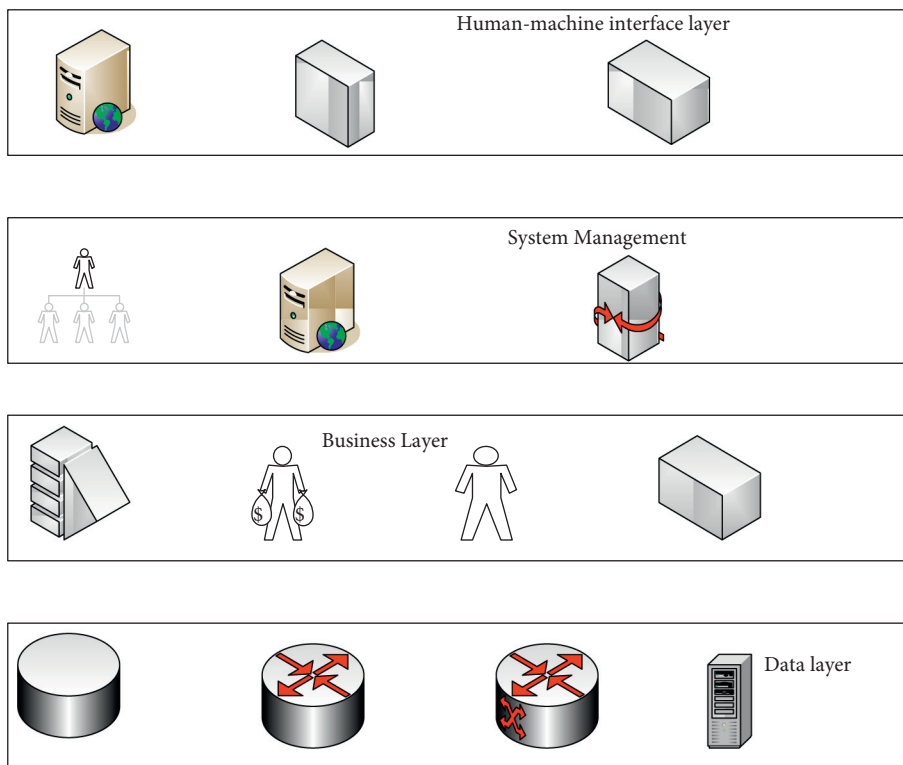

FIGURE 2: Data preprocessing structure.

3.2. Artificial Intelligence Algorithm. This section mainly discusses related theories about artificial intelligence algorithms, deepens the understanding of artificial intelligence algorithms through the discussion of related theories, and prepares for in-depth discussion [17]:

$$y(a \mid c) = \frac{y(c \mid a) y(a)}{y(c)} = \frac{y(c \mid a) y(a)}{\int y(c \mid a) y(a) da}, \quad (1)$$

where $y(c \mid a)$ represents the likelihood function, and $y(a)$ represents the probability density.

$$y(c_1 \mid a_2) = \int y(c_1 \mid c_2)dc_2. \tag{2}$$

Formula (2) represents a functional expression for predicting the current probability density function.

$$y(c_1 \mid a_2) = \frac{y(c_1 \mid a_1)y(c_1 \mid a_2)}{\int y(c_1 \mid a_1)y(c_1 \mid a_2)da_1}. \tag{3}$$

Formula (3) represents multiple integral operation.

$$W = \int_S H(a)da, \tag{4}$$

where S is a random area in the space, and W is a multiple integral.

$$W = \int_S h(a)y(a)da. \tag{5}$$

In formula (5), $y(a) \geq 0$ and $\int_S y(a)da = 1$.

$$h_k = \frac{1}{k}\sum_1^k h(a_1). \tag{6}$$

Formula (6) represents the arithmetic average value.

$$Q(1) = Q(h(a)) = \frac{1}{k}\sum_1^k h(a_1), \tag{7}$$

where $h(a)$ is an unbiased estimate of Q.

$$Q(j(a)) = \int j(a)y(a)da, \tag{8}$$

$$Q(j(a)) = \int j(a)\alpha(a)\beta(a)da. \tag{9}$$

Among them, $\beta(a)$ represents the density function, and $Q(j(a))$ represents the expected estimate.

$$Q(j(a)) = \frac{1}{l}\sum_1^l j(a)\beta(a), \tag{10}$$

where $\beta(a) = y(a)/w(a)$.

$$w(a) = w_1(a_1)w_2(a_2 \mid a_1)\cdots w_c(a_c \mid a_1 \cdots a_c), \tag{11}$$

where a represents a scalar or a vector.

$$y(a) = y_1(a_1)y_2(a_2 \mid a_1)\cdots y_c(a_c \mid a_1 \cdots a_c). \tag{12}$$

In the actual measurement process, each step is independent of each other, so formula (12) represents the density expression of the objective function.

$$\beta(a) = \frac{w(a) = w_1(a_1)w_2(a_2 \mid a_1)\cdots w_c(a_c \mid a_1 \cdots a_c)}{y(a) = y_1(a_1)y_2(a_2 \mid a_1)\cdots y_c(a_c \mid a_1 \cdots a_c)}. \tag{13}$$

Formula (13) represents the importance weight.

$$\beta_j(a_j) = \beta_{j-1}(a_{j-1})\frac{y_j(a_{j-1})}{w_j(a_{j-1})}, \tag{14}$$

$$y(a_j \mid g_j) = \sum_1^h \beta_j^l \iota(a_j - a_j^l), \tag{15}$$

where $y(a_j \mid g_j)$ stands for posterior probability.

$$\beta_j^l = \beta_{j-1}^l \frac{y(g_j \mid a_j^l)y(a_j^l \mid a_{j-1}^l)}{w(a_j^l \mid a_{j-1}^l, g_j)}. \tag{16}$$

Formula (16) represents the approximate posterior probability density of sampled particles.

$$y(a \mid g) = \sum_1^h \beta_k^h \iota(a_k - a_k^h), \tag{17}$$

where $y(a \mid g)$ stands for prior probability.

$$\beta_j^l = \frac{y(a_j^h \mid g_k)}{w(a_j^h \mid g_k)}. \tag{18}$$

Formula (18) represents the expression of particle weight function.

$$y(a \mid g) = \frac{y(g_j \mid a_{1-j}, g_{j-1})y(a_{1-j} \mid g_{j-1})}{y(g_j \mid g_{j-1})}. \tag{19}$$

Formula (19) represents the expression of the posterior probability density function.

$$y(a_j \mid a_{j-1}, g_j) = y(a_j \mid a_{j-1}). \tag{20}$$

Formula (20) represents the importance density function in the particle filter algorithm.

3.3. IOT System.

The Internet of Things is a comprehensive information processing technology based on the network and serving the purpose. It not only makes the way of communication between people leap forward but also makes it possible to communicate between people and things and between things and things. In a word, the Internet of Things technology has turned the whole world into a whole [18, 19]. Networking, IOT, interconnection, automation, perception, and intelligence are the basic characteristics of the Internet of Things. Although the function of the Internet of Things is very powerful, the foundation of the Internet of Things is still the Internet, but the Internet of Things is expanded on the basis of the Internet [20–23]. From the current research progress, the Internet of Things can be divided into perception layer, application layer, and network layer, as shown in Figure 3:

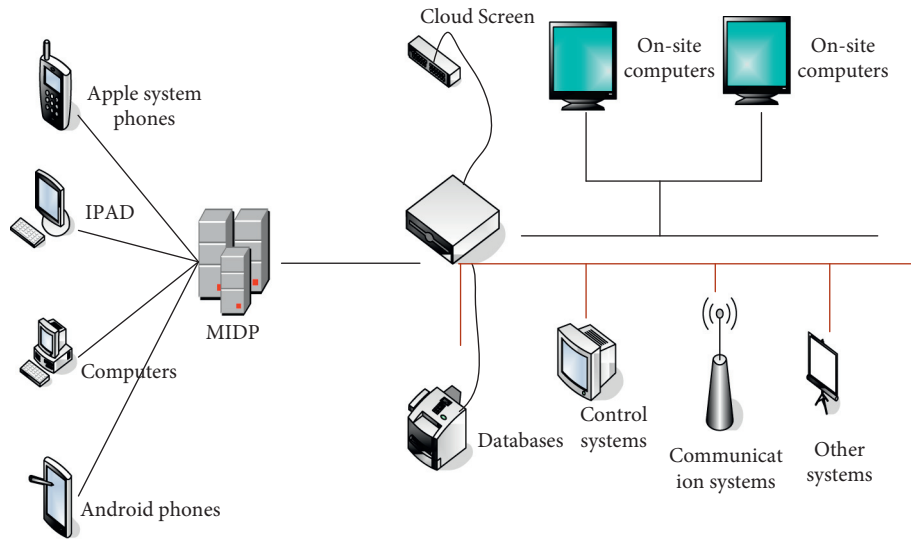
The job of the recognition layer is to recognize the target and record the corresponding information [23]. In this


Figure 3: Internet of Things platform architecture diagram.

process, network sensor technology or recognizer equipment is involved, and only when multiple technologies cooperate with each other can accurate recognition of the target be achieved [24, 25].

The transportation layer is actually the control backbone of the Internet of Things, which is responsible for the transmission and processing of data information. It includes various corresponding communication networks and networks integrated with the Internet, which are relatively mature parts, such as the Internet, radio and television networks, and so on [26, 27].

The application layer is composed of data collection, monitoring, and energy management. The data collection and monitoring system is to monitor and control the equipment with the computer as the core in order to understand the various data in the system. The management system involves statistics and management functions. All in all, the application layer is the technology that combines the Internet of Things technology with other fields to obtain new intelligent solutions.

The Internet of Things is a product of the continuous development of information technology. Information technology was first used in the telegraph and telephone. With the continuous innovation of science and technology, the Internet of Things technology has also been continuously developed. The traditional communication structure of the Internet of Things is shown in Figure 4:

The Internet of Things technology is now regarded by workers as the core of the information industry. In the field of the Internet of Things, various elements can communicate with each other and only need to realize information sharing through the Internet of Things technology. The data in the Internet of Things have the characteristics of heterogeneity, mass, and real time. And it has the following characteristics:

(1) Transmissibility. The Internet of Things technology can realize the transmission of information by relying on relevant networks and complying with the corresponding network protocols.

(2) Comprehensive perception. The Internet of Things is a collection of perception abilities for things and people, it uses technologies such as QR codes to extract information, and it has organizational capabilities, which breaks the dependency of traditional network technologies.

(3) Automatic control. Through the use of fuzzy recognition and other corresponding control technologies, related objects can be intelligently managed and used.

(4) Intelligent processing. The intelligent processing of the Internet of Things refers to the technology that uses the corresponding data processing technology to process the native data and then transmit it to the user.

With the continuous development of science and technology, wireless communication technology has become increasingly mature, and monitoring technology has also been widely used. The early monitoring system used instrument monitoring, followed by a computer monitoring system, which consisted of controlled objects, detection parts, and execution devices. In actual production, some equipment is becoming more and more dispersed, and the independent monitoring of each equipment can no longer keep up with the requirements of monitoring, so a distributed control system appears. The transmission provides centralized monitoring that may follow the needs of social production. Traditional monitoring technology has been unable to adapt, so a distributed control system appears and wireless sensors are produced under this situation. In actual use, multiple wireless sensors are combined to form a wireless sensor network, multiple sensors are placed in the monitoring area to monitor the targets that need to be monitored in real time, and finally, the collected information is systematically analyzed. The core principle of wireless sensor network is that in a specific environment, certain nodes require higher energy, stronger communication
Figure 4: The traditional communication structure of the Internet of Things.

distance, and stronger processing capabilities, even including GPS positioning and other functions, and can temporarily act as cluster heads or base stations to provide the function of external network connection. Its specific structure is shown in Figure 5:

By randomly spreading or manually deploying a large number of sensor nodes in the monitoring area, real-time monitoring and collection of the sensing objects that observers are interested in, and then using the node embedded processing system to analyze and process the collected information. The data collected by the nodes in the cluster are aggregated to the cluster head node and then routed to the base station in multihop communication after the cluster head node data is merged. The base station finally transmits the data to the user terminal through wireless or wired means, realizing the user to the remote real-time monitoring of targets.

Currently in the era of information explosion, how to quickly obtain effective information is the focus. Wireless sensors can obtain a large amount of information by virtue of their distributed characteristics and are widely used in various fields of social production. Wireless network sensors were first used in the military field. Because of their strong concealment, they can play a role on the battlefield. They can monitor and evaluate the situation on the battlefield and can provide a scientific basis for military strategy decisions. In addition to outstanding performance in the military field, wireless sensors have also fully demonstrated their functions in the medical field. The tiny sensor is installed in the patient's body to monitor the patient's physical condition in real time. In case of emergencies, it can be discovered in time for rescue time. Environmental experts can use the data collected by sensor nodes to study the ecological environment to monitor and track the migration of migratory birds and wild animal life, to monitor the forest environment and fire warning, as well as problems that occur during the mining of mineral resources, such as gas concentration monitoring and water seepage conditions.

4. New Progress Experiment on Artificial Intelligence Algorithms for Big Data Processing of IOT Systems on Intelligent Production Lines

4.1. Experimental Hardware. This study discusses the operation of the Internet of Things system in artificial intelligence algorithms, especially when the Internet of Things technology is needed. Different specifications of the system hardware will also have different effects on the experiment. Table 1 is the hardware parameters of this experiment.

According to the data in Table 2, the storage of the server used in this experiment is 16 TB, the RAM is 64 GB, the network card standard is 2 Gbps, the CPU is 4 cores, and the hard disk is 2 TB.

4.2. Detector Performance Parameters. There are many different types of artificial intelligence algorithms, in order to find the best intelligent algorithm, we need to detect and analyze each algorithm. Table 3 lists the comparison data of specific artificial intelligence algorithms.

4.3. Simulation Environment Parameters. Different algorithms have different functions. In the specific experiment process, performance analysis and evaluation of different types of algorithms are required to ensure the authenticity of the data. The simulation parameters used in this article are all obtained based on the data of real nodes in the IOT experimental platform. The specific conditions are as follows:

According to the data in Table 4, the parameters of this IOT experimental platform are as follows: the transmitting and receiving energy consumption is 50 nJ/bit, the number of nodes is less than 100, the initial node energy is 0.7 J, the time slice is 32 s, the voltage is 3.6 V, the data queue length is 15 kb, the transmission distance is greater than 20 m, the
Figure 5: Structure diagram of wireless sensor network.

Table 1: System parameters.

Systems	Memory (GB)	Hard disk (GB)	Mainframe
Domain controller	3	30	2 core
Attendance system operating environment	3	30	1 core
Vcenter server	6	30	2 cores
Database server	3	30	2 cores
ESXI server	3	30	2 cores

Table 2: Experimental environment configuration table.

Configuration items		Parameters
Servers	64 GB	64 GB
	2 Gbps	2 Gbps
	4 cores	4 cores
	2 TB	2 TB
	64 bit	64 bit
Storage	16 TB	16 TB

Table 3: Comparison of detection algorithms.

Algorithms	Network	Parameters (MB)	mAP
RefineDet	VGG-16	138	82
Faster-RCNN	Resnet-50	122	77
EHN-B0	HourglassNet-B0	14	76
EHN-B3	HourglassNet-B3	36	83
StairNet	VGG-16	135	80

data processing energy consumption is 7 nJ/bit, the node data transmission rate is 130 kb/s, and the area is 200 m * 200 m.

According to the data in Figure 6, during the transition from 1 to 256 parallel output degrees, the normalized area of the computing unit is getting higher and higher. When the parallel output degree is 1, the normalized area is 0.35, and

when the parallel output degree is 2, the normalized area is 0.36. When the parallel output degree is 4, the normalized area is 0.37, when the parallel output degree is 8, the normalized area is 0.42, and when the parallel output degree is 16, the normalized area is 0.45. When the parallel output degree is 32, the normalized area is 0.5, when the parallel output degree is 64, the normalized area is 0.57, and when the parallel output degree is 128, the normalized area is 0.7. When the parallel output degree is 256, the normalized area is 0.98. These data show that the shared analog-to-digital conversion circuit can indeed effectively reduce the area of the computing array.

5. New Developments in Artificial Intelligence Algorithms for Big Data Processing of IOT Systems on Intelligent Production Lines

5.1. Data Reading Performance Analysis. In the actual use process, data sources may be diverse, there are multiple copies in each metadata, and any copy can send a metadata read request in response to the request of the client.

According to the data in Figure 7, four different copies were used for data reading and analysis in this experiment. During the reading process, the client is in an increasing state. According to the specific data, the data processing of Namenode copy is very general. When the number of clients

TABLE 4: Simulation environment parameters.

Name	Value	Name	Value
Energy consumption for transmitting and receiving	50 nJ/bit	Data queue length	15 kb
Number of nodes	Less than 100	Transmission distance	Greater than 20 m
Initial energy of nodes	0.7 J	Data processing energy consumption	7 nJ/bit
Time slice length	32 s	Node data transfer rate	130 kb/s
Voltage	3.6 V	Area	200 m * 200 m
FIGURE 6: Output parallelism of computing unit.
FIGURE 7: Data reading performance analysis.

is 6, 376 data are processed, when the number of clients is 8, 473 data are processed 473, and when the number of clients is 10, 480 data are processed. When the number of clients is 12, 483 data are processed, when the number of clients is 14, 482 data are processed, when the number of clients is 16, 481 data are processed, when the number of clients is 18, 486 data are processed, and when the number of clients is 20, 485 data are processed. According to this data, it can be seen that the Namenode mode reads data very poorly. When the number of clients reaches 8, the data processing basically

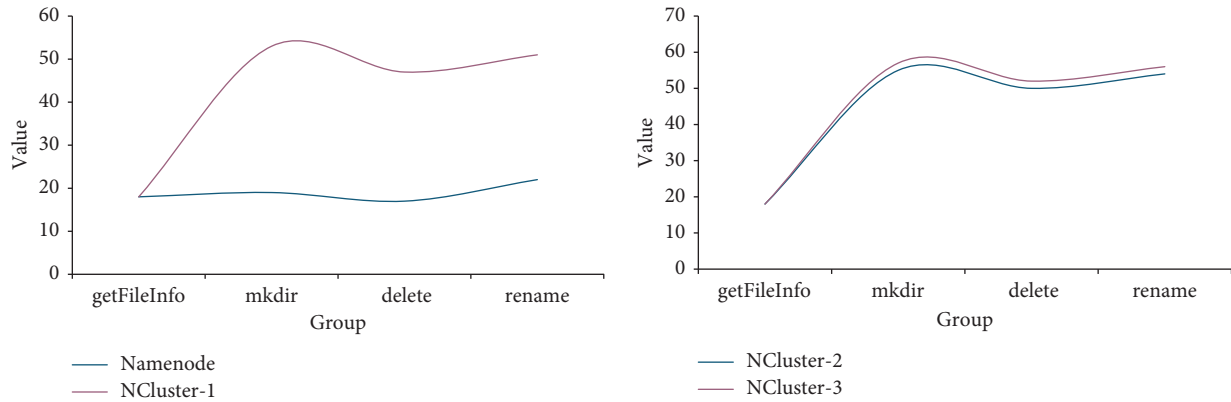
remains unchanged. When the NCluster-1 system is used for data reading, the data processing speed is improved, and as the number of clients increases, the reading speed becomes faster and faster. When the number of clients is 6, 720 data are processed. When the number is 20, 1323 data are processed, but according to specific data, when the number of clients reaches 12, the data reading speed of the NCluster-1 system will remain stable. The NCluster-2 system is used for data reading, when the number of clients is 6, 1000 data are processed, and when the number of clients is 20, 1557


FIGURE 8: Data time-consuming comparative analysis.

data are processed. The NCluster-3 system is used for data reading, when the number of clients is 6, 1256 data are processed, when the number of clients is 20, 2100 data are processed, and the NCluster system will remain stable when the number of clients reaches 12.

According to the data in Figure 8, when the Namenode mode is used for data reading, the creation time is 18 ms, the running time is 19 ms, the deletion time is 17 ms, and the output result time is 22 ms. According to the data, the completion times of the four operations in the Namenode mode are relatively close. When using NCluster-1 mode for data reading, the creation time is 18 ms, the running time is 53 ms, the deletion time is 47 ms, and the output result time is 51 ms. When using NCluster-2 mode for data reading, the creation time is 18 ms, the running time is 55 ms, the deletion time is 50 ms, and the output result time is 54 ms. When using NCluster-3 mode for data reading, the creation time is 18 ms, the running time is 57 ms, the deletion time is 52 ms, and the output result time is 56 ms. According to the experimental data, when operating in NCluster mode, the running, deleting, and outputting times of the system have increased significantly, and there is no obvious difference between the creation time and the Namenode mode.

5.2. Big Data Processing Optimization Analysis. At present, big data is in a state of explosive growth, and big data has penetrated all aspects of daily life. For example, shopping websites that commonly used in daily life can recommend products to customers according to their preferences, saving time and improving user experience. In actual use, the performance of different modes is different.

According to the data in Figure 9, in the big data processing process, the data processing efficiency of different mapping methods is also different. The basic mapping of VGG1 is 20 Gop/s, and the hybrid mapping is 175 Gop/s. The basic mapping of VGG2 is 220 Gop/s, and the hybrid mapping is 590 Gop/s. The basic mapping of VGG3 is 430 Gop/s, and the hybrid mapping is 970 Gop/s. The basic mapping of VGG4 is 600 Gop/s, and the hybrid mapping is 793 Gop/s. The basic mapping of VGG5 is 1180 Gop/s, and the hybrid mapping is 1183 Gop/s. The basic mapping of LeNet1 is 5 Gop/s, and the hybrid mapping is 170 Gop/s. The

basic mapping of AlexeNet1 is 230 Gop/s, and the hybrid mapping is 600 Gop/s. According to the data, the performance of hybrid mapping in all modes is higher than that of basic mapping. The performance of VGG in the basic mode is 13 Gop/s, the mapping performance is 30 Gop/s, and the pipeline optimization performance is 231 Gop/s. The performance of AlexeNet in the basic mode is 38 Gop/s, the mapping performance is 40 Gop/s, and the pipeline optimization performance is 545 Gop/s. According to the data, the performance of the AlexeNet mode is better than that of the VGG mode.

5.3. Data Access Analysis. In the process of data access, the physical address and virtual address need to be converted, and there will be a large search loss during the operation. In order to determine the specific conversion situation, this article analyzes the different access modes. The details are as follows:

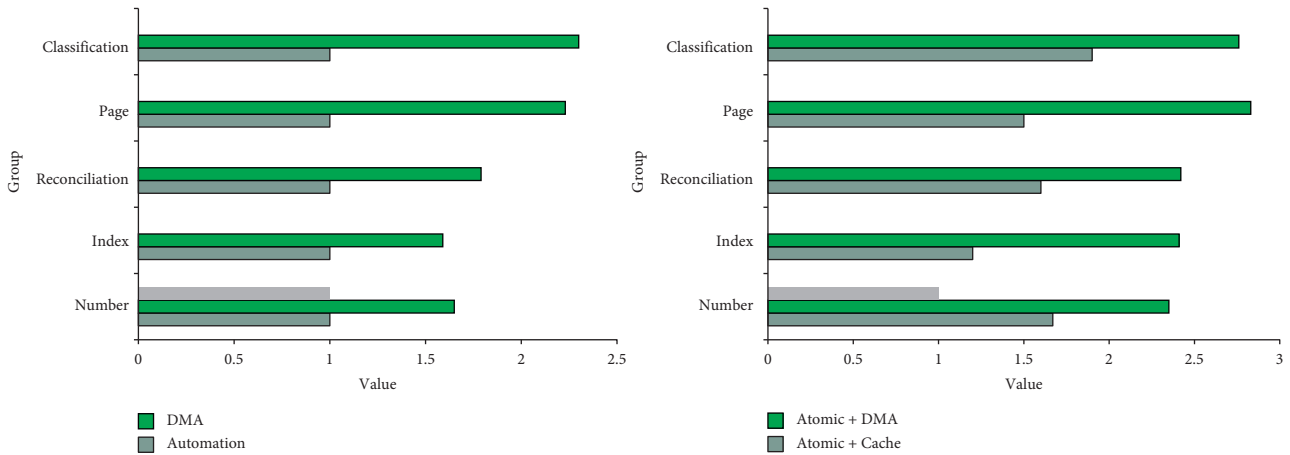
According to the data in Figure 10, the performance of the system is different in different operating modes. In automation mode, the system's thesaurus performance can be improved by 1 time, the index performance of the system has been improved by 1 time, the adjustment performance of the system has been improved by 1 time, the page performance of the system has been improved by 1 time, and the classification of the system performance has been doubled. In the DMA mode, the system's thesaurus performance can be improved by 1.65 times, the index performance of the system is improved by 1.59 times, the adjustment performance of the system is improved by 1.79 times, and the page performance of the system is improved by 2.23 times, and the system classification performance has been improved by 2.3 times. In atomic + cache mode, the system's thesaurus performance can be improved by 1.67 times, the system's exponential performance by 1.2 times, the system's adjustment performance by 1.6 times, the system's page performance by 1.5 times, and the classification performance has been improved by 1.9 times. In the atomic + DMA mode, the system's thesaurus performance can be improved by 2.35 times, the system's exponential performance by 2.41 times, the system's adjustment performance by 2.42 times, the system's page performance by 2.83 times, and the classification performance has been improved by 2.76 times.
FIGURE 9: Big data processing optimization analysis.


FIGURE 10: Analysis of data operation patterns.

6. Conclusions
