The rapid development of China's economy has led to the development of science and technology, and artificial intelligence technology is the focus of current research. Artificial intelligence technology can help human beings enter into unknown areas to explore, expand the scope of knowledge, improve the speed and accuracy of human work, make full use of existing data, and complete the work better. However, due to the short development time of artificial intelligence technology, there are some shortcomings in the actual application process. Therefore, this article aims to study the new development of artificial intelligence algorithms for big data processing in the Internet of Things system on intelligent production lines. It is hoped that through the development of intelligent production lines and big data processing technologies, a way to optimize artificial intelligence algorithms can be found. Although some progress has been made, there are still some shortcomings: (1) this article aims to use the Internet of Things technology to deal with big data problems, but the data security issues are not considered in the actual application process. (2) The application field needs to be further broadened. Function optimization is only one aspect of the optimization field and solving different problems requires readjusting the model and parameters of the algorithm.

Accurately detecting and locating the center of the tropical cyclone is critical for the trajectory forecasting. This study proposed an automatic method for centers' location of the tropical cyclones based on the visible or the infrared satellite images. The morphological structure of the tropical cyclone is modeled using the circular pattern. The tropical cyclone center is located based on regional pixels instead of skeleton points. All pixels in a segmented cloud cluster vote for a 2-dimensional accumulator. The center of the cloud cluster is computed by the mean voting distances, which are calculated by fitting quadratic functions in every column of the two-dimensional (2D) accumulator. Then, a linear function is fitted according to the functional relationship between the mean voting distance and voting angle. The fitted coefficients of the linear function are the center coordinates of the tropical cyclone. The proposed method for centers location of the tropical cyclones is tested using visible and infrared satellite images. The results of center location are compared with the best track provided in JMA datasets.

1. Introduction

The tropical cyclone is a kind of atmospheric circulation systems, which may cause disasters and lead to economic loss in coastal areas. The trajectory forecast [1, 2] of tropical cyclones is very significant in order to avoid the destruction by tropical cyclones. Meteorological satellites offer a reliable solution to observe tropical cyclones [3, 4]. The trajectory of a tropical cyclone can be analyzed and estimated based on satellite images [5]. The first comprehensive technique for analyzing tropical cyclones using satellite images was Dvorak techniques [6].

The center location for a tropical cyclone is important for the trajectory forecast of the tropical cyclone [7–9]. The center position of the tropical cyclone is estimated by finding the spiral origin [10] or by fitting the elliptic center [11]. Huadong et al. [12] and Ryglicki and Hart [13] investigated various methods of tropical cyclone center location and classified methods into two categories: morphological pattern analysis method and wind field analysis method.

The first kind of method is based on pattern analysis of morphological characteristics of the tropical cyclone [14, 15]. By using image processing techniques [16], the spiral center of the cyclone is determined by finding the origin of a logarithmic helix [17] or by locating the point where the gradient vectors of brightness temperature are converging [18]. In order to detect the tropical cyclone center, the density matrix [19] and the deviation angle variance [20] are exploited. The located center is accurate, but it does not work well when the morphological structure of the tropical cyclone is not apparent.

The second kind of method is based on the wind field analysis [21, 22]. The center of tropical cyclone is determined by finding the minimum value of wind speed or the maximum value of cyclone vortices [23]. In order to locate the center position of the tropical cyclone, a mathematical morphology method [24] or saliency detection method [25] are utilized. It can deal with the center location of weak circulation, but the wind field inversion is affected.

The current methods for center location of the tropical cyclone require applying an edge detector to extract skeleton

points in satellite cloud images. However, the extracted skeleton is usually inaccurate due to noise and disturbance. The tropical cyclones are often segmented from the images before the circle detection, so the shape of the tropical cyclone relies on the segmentation result. When the noise is incorporated into the segmentation result, the shape of the tropical cyclone is distorted. The circular skeleton is not enough definite for the successive circle detection. It will lead to the failure in the circle detection. In order to overcome the problem of edge extraction, the tropical cyclone center is analyzed and located based on regional pixels instead of skeleton points. The methods based on Hough transform can be used to detect circles [26, 27]. The voting of parameters determines the locations and the sizes of the circles. Using a modified Hough transform [28], the center position of the tropical cyclone is determined by fitting a linear function according to the functional relationship of the mean voting distance, which is calculated in each column of the accumulator by fitting a quadratic function.

2. Methods

The satellite cloud image is segmented; firstly, the segmented cloud cluster with the most pixels is selected. After regional pixels' vote, the center of a cloud cluster is determined by function fitting techniques. The proposed algorithm is made up of four steps: image binarization, Hough vote, searching voting distances, and solving the center coordinates. The flowchart of the proposed algorithm is shown in Figure 1.

2.1. Satellite Cloud Image Segmentation. The image is segmented using seed expanding and the threshold constraint [29–31]. Two thresholds are defined. The first threshold T1 is defined as the quantity of pixels whose intensity greater than T1 is less than 300. The second threshold T2 is defined as the quantity of pixels whose intensity greater than T2 is less than 30000. A pixel, whose intensity is greater than T1, can be selected as a seed. If the intensity of its neighboring pixel is greater than T2, the region is expanded [32].

The region with the most pixels is considered as a candidate of the tropical cyclone. An example of cloud image segmentation is shown in Figure 2. Although the shape of a segmented cloud cluster is irregular, it is modeled using a near-circular pattern. The circle center is considered as the center of a cloud cluster corresponding to a tropical cyclone.

2.2. Regional Pixels' Voting. In order to extract the center of the near-circular cloud cluster, a modified Hough transform is used. Instead of skeleton points, the regional pixels vote for a 2-dimensional accumulator. The voting formula is

$$\rho = x \cdot \cos \theta + y \cdot \sin \theta, \quad \theta \in [0 \ \pi), \tag{1}$$

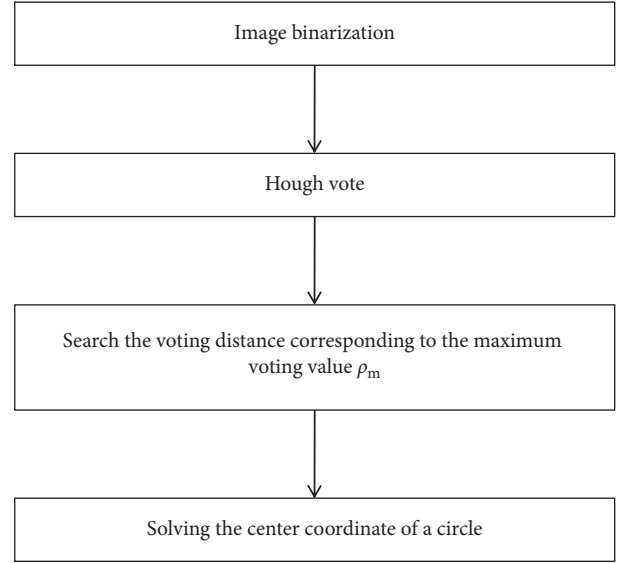
where θ is the Hough voting angle and ρ is the computed voting distance. For a voting angle θ_i, the validated voting distance ρ is limited. It is shown in Figure 3. ρ_m is the mean voting distance with respect to each voting angle θ. It is also the regional center voting for the 2D accumulator. The voting value $H(\theta, \rho)$ increases from 0 to the maximum and


FIGURE 1: The flowchart of the proposed algorithm.
FIGURE 2: Extraction of the cloud cluster.

then decreases to 0. Let $\rho_m(\theta)$ be the mean voting distance corresponding to the voting angle θ.

After all regional pixels have voted for the 2D accumulator, a quadratic function is fitted using the voting information in each column of the 2D accumulator.

2.3. Quadratic Functions' Fitting. The voting value $H(\theta, \rho)$ corresponding to distance ρ_j and angle θ_i is illustrated in Figure 4. The voting value is

$$H(\rho, \theta) = 2 \cdot \sqrt{r^2 - (\rho - \rho_m)^2}. \tag{2}$$

Thus, the functional relationship of the voting value $H^2(\theta, \rho)$ with respect to the voting distance ρ is a quadratic polynomial function, whose maximum is located at the mean voting distance ρ_m. Therefore, ρ_m can be obtained by
FIGURE 3: Voting of regional pixels.
FIGURE 4: Voting value $H(\theta,\rho)$.

fitting a quadratic function using the voting values in each column of the 2D accumulator.

In column θ_i of the 2D accumulator, all cells with nonzero votes are searched, and a quadratic function f is fitted to the data pairs (H^2, ρ). The fitted function is denoted as

$$f: H^2(\rho, \theta) = a_2\rho^2 + a_1\rho + a_0. \tag{3}$$

Figure 5 shows an example of the quadratic function fitting. The mean voting distance is determined by

$$\rho_m = \rho \left| \frac{\partial f}{\partial \rho} = 0. \right. \tag{4}$$

2.4. Linear Function Fitting. For each voting angle θ, the computed mean voting distance $\rho_m(\theta)$ is located at ρ whose voting value is the maximum. Following Figures 3 and 4, the line corresponding to maximum voting value passes through the center of the circular region, which means the center

(x_0, y_0) of a cloud cluster always votes for the distance ρ_m; therefore, there is the following formula:

$$\rho_m(\theta) = x_0 \cdot \cos\theta + y_0 \cdot \sin\theta. \tag{5}$$

Thus, the relationship between the computed mean voting distance $\rho_m(\theta)$ and the voting angle θ is a sine function, whose coefficients rely on the coordinates (x_0, y_0) of the region center. The center can be calculated by fitting a sine function. In order to calculate the center coordinates, conveniently, the sine function is linearized as

$$\frac{\rho_m(\theta)}{\cos\theta} = x_0 + y_0 \cdot \tan\theta. \tag{6}$$

Thus, the functional relationship between $\rho_m(\theta)/\cos(\theta)$ and $\tan(\theta)$ is linear. We fit a linear function g using data pairs $(\rho_m(\theta_i)/\cos(\theta_i), \tan(\theta_i))$. When the voting angles equal 40°, 48°, 56°, 64°, 72°, 80°, 88°, and 96°, the corresponding data pairs $(\rho_m(\theta_i)/\cos(\theta_i), \tan(\theta_i))$ are shown in Table 1, and the linear function fitting is illustrated as Figure 6. In addition, to avoid the setting of θ to 90°, θ is often sampled at the discrete values around 90°.

$$H^2(\theta, \rho) = -2.6156\rho^2 + 1874\rho - 330374$$

The center coordinates (x_0, y_0) of the cloud cluster happen to be the fitted coefficients. The calculated center of the tropical cyclone is labeled in Figure 7.

3. Results

3.1. Implementation Details. The dataset used to test the proposed method is from Meteorological Satellite Observation Images of Typhoon Saomai (No. 200608) and Maria (No. 201808) provided by the Japan Meteorological Agency (JMA). Both the visible images and the infrared images are tested. With the satellite observation images, the cloud cluster of the tropical cyclone is extracted and its center is located.

The satellite cloud images are segmented using seed expanding techniques and threshold constraints. The segmented cloud cluster with the most pixels is recognized as the tropical cyclone; its center is calculated by voting and fitting. The center location results on two visible images and two infrared images are shown.

3.2. Experiments' Analysis. In Figure 8, it is noted that, despite of either the visible images or the infrared images, the proposed method is able to extract the regions of tropical cyclone. Based on the regions, the centers of the tropical cyclone can be further determined. In addition, the method can also deal with both eye cyclones and noneye cyclones. It is largely attributed to the fitting for the shape of the cyclone regions. Even though the shapes of tropical cyclones are irregular, the shapes are still approximated by circles. Once the circles are found, the centers can be determined. The located centers of typhoons are also compared with the Best Track (BT), and the averaged location errors are shown in Table 2. Because the size of typhoons is in itself large enough, these location errors can be tolerated. The experimental results show that the proposed center location method provides reliable estimates of tropical cyclone centers.

As illustrated in Figures 9 and 10, the segmentation of the typhoons region has great influence on the determination of the centers. When the segmented region covers most of the tropical cyclone, the shape of the cloud region is more likely to be a circle. As a result, the accuracy in the fitting of the circle is significantly improved. In Figure 7(a), while the tailor of the tropical cyclone is discarded, the segmentation maintains the central part of the tropical cyclone. The central part almost covers the whole tropical cyclone. Compared with the segmented cloud in Figure 9(a), the tropical cyclone in Figure 10(a) undergoes the deformation. It is obvious that the shape of the tropical cyclone in Figure 10(a) is irregular. It further causes the error in the estimation of the center of the tropical cyclone. Although it is inevitable for the error to be produced, the increase in the number of voting angle θ will reduce the error.

Like other methods for centers' location, the estimation of centers depends on the segmentation of the typhoons' region. The locating results are improved by using function techniques. A set of quadratic functions are fitted to voting values corresponding voting distances, and a linear function

x₀=212.04   y₀=288.53
FIGURE 7: Center location.

is fitted to mean voting distance with respect to the voting angle.

4. Discussion

In general, due to the existence of cloud tailors, small cloud clusters, and so on, it is difficult for the segmentation to generate the result of the tropical cyclone with the regular circular shape. Hence, it is important for the method to resist against the noises inherent to the segmentation results. The proposed method alleviates the errors in the estimation of centers caused by the irregular typhoons regions. Similar to other methods based on the morphological pattern analysis, the proposed method also relies on the organization structure of the tropical cyclone. Different with other methods, the proposed method uses not only skeleton points but also regional pixels. Therefore, the edge extraction, which is very sensitive to disturbance and noise, is not necessary. The proposed method is more robust than methods based on skeleton information. The robustness is largely attributed to the setting of multiple voting angles.

From Figures 11–18, the voting process of the parameters related to the circular region covering the typhoons region in Figure 2 is shown. At the same time, the fitting process is also given in these figures. In detail, a quadratic function is adopted to fit the relationship between the voting angle and the voting distance. To acquire the two-dimensional center location, it requires that at least two fitting functions are offered. In fact, the typhoons' region is often irregular, so the center location solved by two fitting functions is coarse. It means that more fitting functions are needed so as to give rise to an accurate estimation. In Figures 11–18, the voting angles are, respectively, sampled at 40°, 48°, 56°, 64°, 72°, 80°, 88°, and 96°. As a result, eight fitting functions are obtained. Among them, while the estimations of the voting distance in Figures 11 and 12 nearly distribute

FIGURE 10: (a) The region of the tropical cyclone is extracted from a visible satellite image by the segmentation. It is filled with the blue color. (b) The center of the tropical cyclone is determined based on the region of the tropical cyclone.

Quadratic function fitting (θ=40)

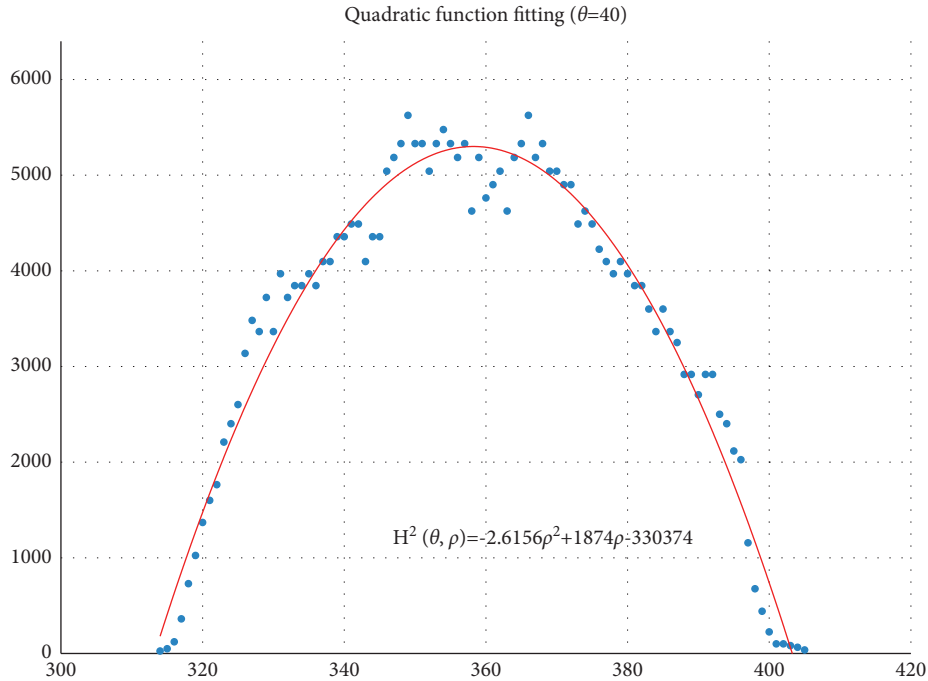
$H^2(\theta, \rho)$=-2.6156ρ^2+1874ρ-330374


FIGURE 11: The voting angle θ is set to 40°. When the voting distance ρ is 358.24, $H(\theta,\rho)$ reaches the peak.

around the quadratic fitting functions, some points in Figures 13 and 14 significantly deviate from the fitting function. Along the lines with the angles 56° and 64°, the invagination of the shape inhibits the points from scattering around the quadratic functions. These points are more likely to be outliers. Hence, if only the points in Figures 13 and 14 are given, the quadratic functions estimated by these points cannot accurately represent the boundary enclosing the tropical cyclone. In Figures 17 and 18, θ is sampled at 88° and 96°, respectively, which are close to 90°. It avoids the setting of θ to the trivial value of 90°.

In the proposed method, the center location is usually located at the line with maximal voting distance. However,

once the shape of the typhoon region is an irregular circle, it is possible for the estimated center to be far away from the real center of tropical cyclone. The usage of the fitting function removes the lines existing in the form of outliers. In Figure 13, the distribution of the points representing the voting distances in the proximity of the peak of the quadratic function is in chaos. Since that, in theory, the voting values corresponding to the regular circle should satisfy the quadratic function, the quadratic fitting to the function excludes those values that are not in favor of the estimation of the circle. Hence, it is obvious that the fitting to the quadratic function enhances the robustness of the estimation. The fitting functions with respect to more voting angles lead to
FIGURE 12: The voting angle θ is set to 48°. When the voting distance ρ is 350.62, $H(\theta,\rho)$ reaches the peak.

In the chart: Quadratic function fitting (θ=48)

$H^2(\theta, \rho) = -2.6801\rho^2 + 1879.4\rho - 324129$
FIGURE 13: The voting angle θ is set to 56°. When the voting distance ρ is 336.85, $H(\theta,\rho)$ reaches the peak.

In the chart: Quadratic function fitting (θ=56)

$H^2(\theta, \rho) = -2.8581\rho^2 + 1925.5\rho - 318805$

more candidate centers. The regression over these centers can generate the reliable center. However, more fitting functions incur heavier computation burden, and it reduces the speed of finding the centers of tropical cyclones. Sometimes, the speed is important for the alert of the tropical cyclones.

In addition, the method is not sensitive to the type of images. Whatever the infrared image or the visible image is, the cloud cluster can be approximated as a near-circular region. Therefore, the center location method can be applied to the visible channel and infrared channel of meteorological satellite images.

FIGURE 18: The voting angle θ is set to 96°. When the voting distance ρ is 259.01, $H(\theta,\rho)$ reaches the peak.

5. Conclusions

An automatic method for cyclone center location is proposed based on regional pixels instead of skeleton points. The morphological structure of the tropical cyclone is modeled using the circular pattern. The skeleton extraction is avoided. By fitting a linear function, the center coordinates of the tropical cyclone happen to be the coefficients of the fitted function. The method can deal with both visible images and infrared images and both eye cyclones and noneye cyclones. The reliable estimates of tropical cyclone centers are obtained in spite of the variability of TC morphological structure in visible or infrared images. At present, the thresholds for the image binarization are manually selected. It cannot adapt itself to the segmentation requirement. In the future, it is possible for the adaptive image binarization to be brought into the image segmentation.

Data Availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also form part of an ongoing study.

Research Article

Virtual Reality Technology Based on Embedded Image System Simulates Urban Disasters

Yuanyuan Wang and Surng Gahb Jahng

Graduate School of Advanced Imaging Science, Multimedia & Film in Chung-Ang University, Seoul, 156-756, Republic of Korea

Correspondence should be addressed to Surng Gahb Jahng; 171843186@masu.edu.cn

At present, urban disasters are generally valued by various companies and organizations. Although many companies claim to have effectively tested their urban disaster recovery plans, the effectiveness, completeness, and efficiency of their test plans still exist in many aspects. Therefore, it is very important to effectively check the city's disaster recovery plan. Nowadays, both the scientific research community and the industrial community have paid enough attention and research to urban disaster backup. This is a shield of a guaranteed simulation system. The research in this paper belongs to the category of urban disaster virtual reality technology. Urban disaster virtualization is an integral part of virtual reality technology in the current information technology field. Based on the embedded image system, this article divides the virtualization of urban disasters into two meanings: one is to virtualize various disasters into one type of disaster, so as to focus attention on the process and mechanism of disasters on the information system. The meaning is to virtualize different disaster response methods in the standard process, and all links are interrelated and interdependent so that the highest level of disaster response can be implemented. The main goal of disaster virtualization is to integrate different disasters into a comprehensive model. This paper studies urban disasters through embedded image systems and uses virtual reality technology to establish a simulation system to complete the test.

1. Introduction

At present, society pays great attention to all aspects of urban disasters, and at the same time, they have carried out pre-plans [1]. Many companies or organizations have conducted comprehensive tests on urban disaster recovery plans and have a complete set of procedures, but almost half of the tests are unsuccessful [2]. This phenomenon has led to many negative effects such as increased risks, increased costs, and impacts on corporate brands, customer experience, and customer loyalty [3]. Although many companies consider it very important to test urban disaster plans, there are still many IT personnel who have not worked out effective methods to improve the test plan, and one of the ideas for testing urban disaster recovery plans is the urban simulation system and the disaster-to-information system [4]. Since we only focus on the impact of the disaster on the information

system, rather than the disaster itself, as long as we know what impact the disaster has on the information simulation system, we can simulate the disaster [5]. In this way, the verification of the disaster recovery plan comes down to the simulation of the disaster [6]. Therefore, the urban disaster simulator designed in this paper relies on virtual reality technology to simulate the impact of fire, earthquake, and network information on the urban system [7]. It is more detailed, more comprehensive, and more effective than direct conversion to verify the disaster backup mechanism [8]. The disaster simulator is divided into three main modules: LAN IP address, disaster evolution module, and disaster on information system impact module. The LAN IP address module uses tools to find IP addresses and select nodes for simulation; the disaster evolution module uses FLEX technology to simulate disaster evolution process, dynamic simulation of the impact of time and space on the outbreak

of disasters; the disaster impact module on the information system uses the schtasks statement in the DOS statement, which is intended to connect to the target node remotely, then copy the simulated program, and finally execute it on the target node of the system the disaster simulation program is used to simulate the consequences of a disaster, so as to simulate the impact of the disaster on the information system. The main research work of this paper is to simulate the occurrence, development, and impact of urban disasters on the information system. Then, based on the embedded image system, the evacuation problem is studied [9]. This is an important safety factor in modern society and has attracted attention from all walks of life [10]. Aiming at the evacuation of people in urban disaster emergencies, combined with the uncertain factors in the evacuation process, a multiagent-based evacuation simulation model is established in a multidisaster environment in order to study the laws of people's behavior in disasters [11].

2. Related Work

The literature shows the general requirements of disaster simulators and the knowledge and technologies involved in this article, namely, JavaScript, JBoss, JSP, FLEX. The literature proposes a crowd evacuation simulation system in a multihazard environment and conducts a simulation test for the evacuation of the system [12]. The simulation results show that the system better demonstrates the impact of the disaster environment on the evacuation of the people, and the simulation effect on the evacuation is more realistic [13]. It embodies the scientificity and rationality of the crowd evacuation model and establishes a mathematical model based on current disasters [14]. Fire, explosion, and the spread of irritating toxic smoke are the main disasters. This model focuses on the impact of fire and explosion sound on human health and establishes a human perception model and makes it as true as possible based on the actual location of each person. The information is imitated that people can perceive in the environment. The literature shows that FEKO creates a true and false target model in the SAR image, and according to the simulation results, starting from the scattering mechanism, it analyzes the effect of the difference in the geometric structure of the true and false target on the echo scattering [15]. According to the analysis result, a method is proposed. Combining the target feature extraction algorithm of gray and texture, the validity of SAR image authenticity target recognition is determined. The literature shows the definition and characteristics of virtual reality technology and its application advantages in urban disasters, as well as the definition of disaster process exploration mode and disaster processing mode steps [16]. A lot of research on the theoretical basis of virtual city disaster platform research has also been carried out. The literature shows the concept and meaning of unit testing, integration testing, and system testing, and lists some test cases, evaluates the final test results, and compares them with similar solutions and similar products, and finally shows the development and operating environment of the system.

3. Embedded Image System and Virtual Reality Technology

3.1. Embedded Image System

3.1.1. Embedded System. The development of the embedded system from centralized to a system application platform, open system structure, resource service, intelligent management decision, and green direction is not only a technical upgrade but also meets the needs of practical applications. The system architecture is not only highly modular but also supports reconstruction, modification, and expansion. Chinese universities and scientific research institutes have accumulated some research foundations in embedded systems and reliability calculations, and some scientific research institutions have accumulated rich research experience in embedded systems and microprocessors. Based on the strategy of vigorously developing the advanced manufacturing industry, China has carried out embedded system research in the industrial field and puts forward the requirement of combining intelligence and industrialization. The equipment manufacturing industry is the basic requirement for industrialization. Hardware and software are used in the design of CNC machine tools in the software industry. It is very important in the manufacture of machine parent equipment. CNC system is a typical application of the embedded real-time system in the industrial field.

In foreign countries, the design of embedded systems is also a matter of close concern in academia and industry. Some countries have incorporated the research of embedded systems into the national key strategic research plans and support related research centers.

Now, in the international manufacturing industry, mechanical or electrical components are completely embedded in controlled equipment to create a dedicated computer system designed for specific applications. In the future, embedded systems will develop into cyber-physical systems (CPS) in the industrial field. There will be a large amount of data exchange between sensors, actuators, and computing devices, with the purpose of adapting to different application environments. Data interaction and cooperation are affected by the uncertain factors of the physical world, and it is also a new challenge to the reliability of the system. The design of embedded systems is more inclined to the requirements of low power consumption and higher reliability.

3.1.2. Image Simulation. In the image simulation process, when electromagnetic waves are reflected on the target, a random elevation difference is added to the diameter of the tracking tube to simulate the scattering characteristics of the target surface. On this basis, the combined electromagnetic scattering mode of the target in a complex scene is established as follows:

$$P'_j = P_j + \Delta H_j \cdot \widehat{n}_i. \tag{1}$$

On the surface of the rail pipe with random elevation, the normal direction of the original reflecting surface is

corrected, and $\hat{n}\_\hat{i}$ is the normal direction of the triangle facet after the elevation difference is introduced.

$$\hat{n}'_i = \frac{(P'_2 - P'_1) \times (P'_3 - P'_1)}{(P_2 \cdot -P'_1) \times (P_3 \cdot -P'_1)}. \tag{2}$$

Rayleigh distribution:

$$P_r(x) = \frac{2x}{\alpha} \exp\left(-\frac{x^2}{\alpha}\right). \tag{3}$$

Lognormal distribution:

$$P_l(x) = \frac{1}{x(\pi\alpha)^{1/2}} \exp\left(-\frac{(\ln x - m)^2}{\alpha}\right), \tag{4}$$

where m and α represent the mean and variance of lnx, respectively, which can be obtained by maximum likelihood estimation:

$$\left\{ \hat{m} = \frac{1}{N} \sum_{i=1}^{N} \ln(X_i)\hat{\alpha} = \frac{2}{N} \sum_{i=1}^{N} [\ln(X_i) - m_{ML}]^2. \tag{5}\right.$$

Weibull distribution:

$$P_w(x) = \frac{\gamma}{\omega}\left(\frac{x}{\omega}\right)^{\gamma-1} \exp\left[-\left(\frac{x}{\sigma}\right)^{\gamma}\right] \tag{6}$$

It can be obtained by the maximum likelihood estimation method:

$$\left\{ \begin{array}{l} \hat{\gamma} = \left\{ \frac{6}{\pi^2} \frac{N}{N-1} \left[\frac{1}{n} \sum_{i=1}^{N} (\ln(X_i))^2 - \left(\frac{1}{n} \sum_{i=1}^{N} \ln(X_i) \right)^2 \right] \right\}^{1/2} \\ \\ \hat{\omega} = \exp\left[\frac{1}{N} \sum_{i=1}^{N} \ln(X_i) + 0.5772\hat{\gamma}^{-1} \right] \end{array} \right. \tag{7}$$

K distribution:

$$P_k(x) = \frac{2}{\alpha\Gamma(\mu+1)}\left(\frac{x}{2\alpha}\right)^{\mu+1} K_\mu\left(\frac{x}{\alpha}\right). \tag{8}$$

In the case of a large number of sea clutter samples, the second-order and fourth-order methods are the most effective. The results are as follows:

$$\left\{ \begin{array}{l} \hat{\mu} = \frac{(25/16 - M_{5/2}/M_{1/2}M_2)}{(M_{5/2}/M_{1/2}M_2 - 5/4)} \\ \\ \hat{\alpha} = \frac{M_1}{\sqrt{\pi}\,\Gamma(\mu+1)\Gamma(\mu+1.5)} \end{array} \right., \tag{9}$$

where

$$M_n = \frac{1}{N} \sum_{i=1}^{N} X_i^n. \tag{10}$$

is the central moment of order n of the statistic.

The KS test method is a test method to test whether the data distribution is consistent with the commonly used theoretical distribution. The KS value is the maximum value of the difference between the cumulative empirical data distribution function and the expected cumulative distribution function, denoted by De, used to test the statistics of sample data distribution, where De is expressed as

$$De = \max_{1<i<l}|F(x_i) - F_l(x_i)| = \max_{1<i<l}\left|\frac{n}{N} - F_l(x_i)\right|. \tag{11}$$

KL distance is a measure of information theory. If the assumed distribution is $F(x_i)$ and the actual distribution is $F_l(x_i)$, the expression of the measure is

$$D(F_l F) = \int_{i=1}^{N} F_l(x_i)\log_2\left(\frac{F_l(x_i)}{F(x_i)}\right)dx_i. \tag{12}$$

For the discrete case, the expression can be simplified to

$$D(F_l F) = \sum_{i=1}^{N} F_l(x_i)\log_2\left(\frac{F_l(x_i)}{F(x_i)}\right). \tag{13}$$

The detection mean square error can be defined as

$$mse = \sum_{i=1}^{N} \frac{[F(x_i) - F_l(x_i)]^2}{N}. \tag{14}$$

Sum the data of all subsegments and average them to obtain the power spectrum of the signal to be estimated, which can be expressed as

$$\overline{P}_{per}(\omega) = \frac{1}{L} \sum_{i=1}^{L} \hat{P}^i_{per}(\omega). \tag{15}$$

The removal of phase imbalance can be removed by the following formula:

$$I_{rot} = [I - Q^* \sin(\beta)]sqrt(1 - \sin(\beta)^2). \tag{16}$$

The actual parameters of the measured scene are sea temperature 7.6°C, wind speed 5.3 m/s, 0° is true north, wind direction 300°, radar appearance direction 125.6°, maximum sea wave height at sea 0.8 m, distance direction 2575–2768 meters, a total of 196 meters, the distance resolution is 30 m, and the target distance tar A is in the seventh unit. The seventh distance unit data is selected as the analysis object. Figure 1 shows the amplitude-time characteristics of the seventh unit under the same data polarity. The maximum amplitude under VV polarity is 39.38, and the maximum amplitude under HH polarity is 111.5.

Figure 2 shows the statistical probability density function of the echo amplitude.

Tables 1 and 2 respectively, check the distribution of the distance unit clutter under VV polarity and HH polarity. From the mean value test, under the condition of VV polarization, the clutter amplitude is very suitable for the K distribution. In the case of transformation, the amplitude of the clutter fits well with the Weibull distribution.

The clutter distribution test of the seventh distance unit of Document 54 is shown in Table 2:

3.2. Virtual Reality Technology. When a fire occurs, the nearby temperature rises and produces flames, smoke particles, and toxic gases. The harmful gases produced by the

Test mean	3.8493	0.3534	0.4722	0.9032

fire have psychological and physiological effects on the evacuation of people. Since there are many substances produced by fire in practice, the impact on evacuation may be more complicated. Only by simplifying the factors considered in the fire can a corresponding fire model be established. The size of the fire is determined by the power of

the fire source, which shows the area of the flame. The diameter D and height L of the bottom of the fire range can be calculated by

$$D = \sqrt{\frac{4Q}{\pi Q_e}},$$

$$H = -1.02\,D + 0.235Q^{2/5}. \tag{17}$$

After a fire occurs, smoke is often produced and diffused to the edge, and its diffusion rate is generally determined according to the gas molecule velocity distribution function.

$$V = 1.6\sqrt{\frac{RT}{M}}. \tag{18}$$

At the initial moment, the concentration and temperature distribution in the air mass are uniform, and the gas concentration is calculated according to the stable continuous point source smoke flow model.

$$C(x, y, h, H) = \frac{Q}{2\pi u \sigma_y \sigma_z} \exp\left(-\frac{y}{2\sigma_y^2}\right) \cdot \left\{\exp\left[\frac{-(h-H)^2}{2\sigma_z^2}\right] + \exp\left[\frac{-(h+H)^2}{2\sigma_z^2}\right]\right\}. \tag{19}$$

The steady-state sound pressure level formula is used to calculate the sound pressure level at a certain position.

$$L_p = L_w + 10\lg\left(\frac{Q}{4\pi r^2} + \frac{4}{R}\right). \tag{20}$$

During the evacuation process, fires often produce smoke and other toxic gases, and other irritating odors may also appear. Pedestrians can perceive the existence of such irritating gases through their sense of smell during travel, which affects people's evacuation routes to a certain extent. Judgment, it also causes certain harm to pedestrians. After a gas leak occurs, people can use the location information and the above equation (18) to calculate the corresponding gas concentration. By obtaining the gas concentration within the range of the person, the human sense of smell can be realized. If the leaked gas is toxic, it will have a significant impact on human physiology. Assuming that the dose of poisonous gas a person bears is S and the probability of causing harm to the person is Ps, the probability formula can be calculated as follows:

$$P_s = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\gamma-5} \exp\left(-\frac{u^2}{2}\right) du. \tag{21}$$

Among them, the random variable Y can appear in the form of a nonlinear equation. When the toxin concentration does not change with time, its toxin value can be calculated as follows:

$$Y = k_1 + k_2 In(C^n t). \tag{22}$$

From this, a simple calculation formula for the degree of physiological influence β can be calculated as follows:

$$\beta = \frac{P_s + \theta}{\theta}. \tag{23}$$

This article derives a rough calculation following formula for the degree of psychological influence based on empirical data:

$$\alpha = \left(\frac{L_{left} + L_{right}}{2} - 120\right) \cdot \sigma. \tag{24}$$

4. Urban Disaster Simulation System Design and Application Analysis

4.1. System Characteristics and Target Analysis

4.1.1. System Analysis. The disaster simulator is mainly used to remotely control the local information system, simulate the impact of the disaster on the information system, and simulate the consequences of the disaster. The key question is how to simulate the impact of the disaster on the information system. In order to accurately simulate the disaster effect, this paper divides the disaster simulator into three modules in the design process: scan to obtain IP address, disaster development module, and simulate the impact of disaster on nodes. First, the network is scanned to obtain the IP address module to achieve the simulation target and delimit the simulation range; that is, the simulator starts; then, the disaster development module can display the changes of the disaster over time and space, truly restore the occurrence and evolution of the disaster, and finally simulate the disaster. The node impact module is the core of the disaster simulator. The simulator creates three states of the information system so that it can truly simulate the impact of the disaster on the information system. The three states are error, malignant change, and crash. Errors indicate the system's failure. The calculation result is incorrect. Malignant change means that the system is running in a random state; crash means that the system is down.

The simulator simulates the impact of disasters on the information system, but only as a simulation. Therefore, security must be considered, and no irreversible impact on the system must be taken into account. In this way, efficiency and security can be achieved at the same time, and a real simulation effect can be achieved.

In addition to its functions, the system must also meet the following characteristics:

Security: Because it is only a disaster simulation, it will not have an irreversible impact on the system. For programs that attack the system.

Clean up after the simulation.

Convenience: Easy to implement and run, the simulator is flexible and convenient, and user operation is simple.

Scalability: Due to technological progress and continuous changes in business conditions, this simulator must have a certain degree of scalability, which can be further expanded and improved.

Efficiency and safety are the basic requirements of this disaster simulator. Convenience and scalability are the

highest requirements for the disaster simulator and are the guarantee for improving the quality of the disaster simulator.

After analyzing the functions listed in the requirements, the simulator can be divided into 3 modules.

Automatically, the network is scanned to find the IP address: to obtain the IP address in the local network, you can select the node that simulates the disaster and enters its physical location. Here, you must select the node that needs to be simulated, or you can select all, because sometimes users do not want all the nodes on the local area network. The machines are simulated, so you can choose.

Disaster propagation time and space effects are simulated: the type, intensity, and environmental factors of the disaster are selected to simulate the disaster propagation process. When the disaster spreads to a certain node, the simulator will simulate the impact of the disaster on the system on that node.

Simulation of the impact of disasters on nodes: The consequences of disasters on simulated nodes are realized through remote control. This module is the basic part of the disaster simulator, which can simulate the occurrence, development, and impact of disasters on information systems in detail and truly.

4.1.2. The Goal of the System. The basic use of the disaster simulator is to detect the disaster backup mechanism by simulating the impact of fire, earthquake, and disaster virus on the information system and to simulate the occurrence of disaster and the impact on the information system.

In order to achieve the goal of the disaster simulator to simulate the impact of the disaster on the information system, the simulator must achieve the following effects:

(1) Detailed and realistic simulation of the occurrence, development, and impact of disasters on information systems

(2) Check the status of the information system after the attack, and check the stability of the system

(3) Check the backup mechanism of the information system and provide data for user analysis

(4) Check the database backup mechanism, which can be analyzed and improved by the database administrator

(5) Check the stability and security of the network

(6) Test all users' disaster recovery plans. Only when these overall effects are achieved, the goal of the disaster simulator can be achieved

Many staff members participated in the operation, operation and cooperation of the disaster simulator, the main relevant participants: users, user system administrators, network administrators, database administrators, user system administrators, and disaster backup personnel. The following is a brief introduction of the main personnel.

User: The user needs to use the disaster simulator correctly according to the operation manual, input various effective parameters of the simulation, and clean up the simulated program according to the operation manual.

System maintenance personnel: System maintenance personnel not only analyze its related data but also check the impact on the system.

Network administrator: The network administrator is mainly responsible for two parts: checking and setting up the network, ensuring the normal use of the emulator, and checking the security and stability of the network according to the attack effect of the emulator.

Database administrator: Pay attention to the impact of the simulator on the database. The stability and backup mechanism of the database should be carefully checked.

User system administrator: The user system administrator needs to analyze and check the effect of the simulator, especially to check its security and stability.

Disaster backup personnel: When analyzing the entire operation process, disaster backup personnel monitors and improves their disaster backup mechanism.

The development and design of disaster simulators need to fully consider relevant personnel so that the effects of disaster simulators are more perfect.

4.2. Overall System Design. As a traditional tool, the flow chart of the disaster system is mainly used to describe the physical model of the system. It is a graph that uses some graphic symbols to describe the process of the system. It is required to describe various components, such as tables, files, and programs, and display them.

The function of the flow chart of the disaster system is manifested in the following aspects: The flow chart of the disaster system is a tool for business operators, administrators, and system analysts to communicate with each other. Through the flow chart of the entire disaster system, members can communicate well. Another function of the system flow chart is to allow the system analyst to effectively understand the overview of the disaster system business processing, which is also the basis for the disaster system analyst to make further analysis, and it is also the beginning of the system design.

The flowchart system not only understands the entire disaster system but can also analyze the rationality of the business process of the disaster system.

From the analysis of the requirements of disaster software to the completion of the final development, the most important step is the use case diagram. The use case diagram describes how people use the disaster system and shows the relationship between users and what services users need so that users of the system can understand more easily. The purpose of these elements is also convenient for software developers to finally realize these elements. Use case diagrams are generally used by various development activities, many of which are used to describe systems and subsystems. The system can be divided into very specific units, so it has become an excellent tool for software developers.

As shown in Figure 3, this system mainly has six use cases.

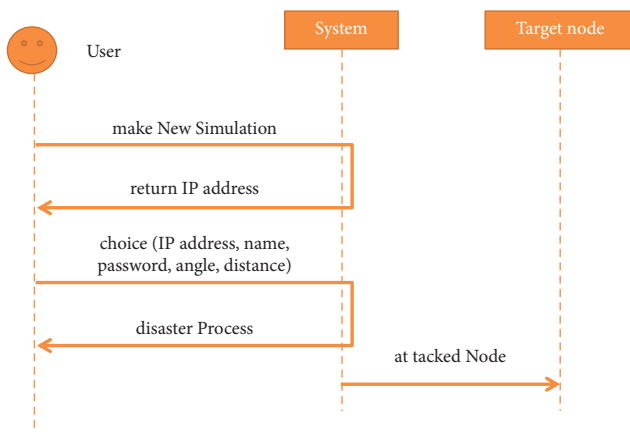
Figure 4 shows the interaction events between the users of the system and the disaster system: first, the system is started, and then, the system returns all the IP addresses of the local area network, and then, the user selects the node,
FIGURE 3: System use case diagram.


FIGURE 4: System sequence diagram.

the disaster type, and environmental factors to simulate, and finally, the system simulates the evolution process of the disaster. The system simulates the consequences of implementing a disaster on the node.

The system sequence diagram is a fast and simple product that illustrates the input and output events related to the system in question. The system sequence diagram is the input to the operation contract and object design, which shows the external participants directly interacting with the disaster system, and the participants initiated system events. For some use cases, system sequence diagrams should be drawn for the main success scenarios of each use case, as well as frequently occurring or complex alternative scenarios.

4.3. System Function Design. Receiving IP address module: There are four methods for receiving IP addresses, DNS, SNMP, ping command, and Traceroute command, but these contents are not the key issues of the disaster simulator, and we can obtain IP addresses by using tools. There are many such tools and found that these tools are more complicated and confusing, not suitable for disaster simulators. Finally, this article found a simple and practical tool. Local area network IP auto-configurer, its interface, and operation are relatively simple and can be used in the disaster simulator designed in this paper. This module is to start the disaster simulator, find all the IP addresses on the device LAN, and then select the node to be simulated to achieve complete

simulation, and the distribution map of the target node can be formulated according to the node selected by the user and input parameters for later dynamic demonstration.

Disaster evolution module: First, you need to use animation technology to simulate the evolution of fires, earthquakes, and computer viruses and make models. The simulator uses FLEX to achieve the simulation effect. Flex uses a non-Flash path to interpret the .mxml files to organize components and create corresponding files. Among them, this article uses FLEX technology to simulate the time and space effects of the disaster spread on the page, that is, dynamically simulate the evolution process of disasters. After the user selects the parameters, the background program formulates the evolution formula according to the parameters, and the page changes according to the evolution simulation to simulate the change of the disaster. For fires, earthquakes, and computer viruses, different evolution models are created to adapt to the different nature of disasters and try to truly simulate the evolution process of disasters in the local area network in reality.

System impact module: The core of the disaster simulator is the system impact module. To start using this module, you need to complete the following steps: (1) To set up a link to each target node, you must first be able to connect to each target node; (2) to create an empty folder in the designated area of the target node, it is best to create this folder on the C drive, because most computers have a C drive; (3) to copy the simulation program to an already created folder; (4) to remotely start the simulation program. The simulation program is mainly composed of bat files, VBScript programs, and enhanced computer code viruses. The process of system error, system malignancy, and system crash must be realized. These steps must be controlled by the background program, adapt to the disaster evolution process, and be able to cover all target nodes. This module is essential for simulating disasters. It must be able to accurately and timely implement the simulation, and it must realistically simulate the consequences of the disaster. Therefore, the simulation program must be designed to be effective and powerful.

The disaster evolution structure is shown in Figure 5.

4.4. System Test Analysis. In the development process of the entire disaster system, unit testing is the lowest level of testing. When testing a unit, the unit that needs to be tested is isolated from other parts. Unit testing is repeatable. Test units can be tested repeatedly to make the test results more accurate. Therefore, the maintenance of unit testing cannot exceed the life cycle of all software.

The unit test case style is shown in Table 3.

The main purpose of integration testing is to combine different modules to test to find problems and defects in each interface. If data are not transmitted through the interface, the interface does not have a connection effect; the two modules are integrated together and affect each other, resulting in failure of function realization; after the integration, the module did not achieve the expected function and so on.
FIGURE 5: Disaster evolution structure diagram.

TABLE 3: Test case style.

Test case number	Test-01
Test item	Disaster simulator
Test title	Test of the disaster simulator
Importance level	High
Parameter input	Test
Execution steps	—
Expected result	Achieve the desired goal

TABLE 4: Test case IPA-001.

Test case number	diSimulator-IPA-001
Test item	Disaster simulator
Test title	Perform integration test on the module for obtaining the IP address
Importance level	High
Prefabricated conditions	—
Parameter input	Start IP address, end IP address
Execution steps	Automated tool execution
Expected result	Obtain all IP addresses in the selected segment of the LAN

TABLE 5: Test case T-001.

Test case number	diSimulator-T-001
Test item	Disaster simulator
Test title	System test of disaster simulator
Importance level	High
Prefabricated conditions	Select multiple simulation nodes
Parameter input	Choose fire, earthquake, computer virus separately, choose different intensity, choose different environmental factors
Execution steps	—
Expected result	All selected nodes eventually crash

The IP address module integration test case is obtained, as shown in Table 4.

System testing is a combination of software, hardware, external equipment, network, interface, and other elements required for system operation, and then, the overall test is performed to verify whether the system functions, performance, and functions meet the requirements of the entire system and to understand which areas are not. The requirements are met, and targeted changes and improvements are made. After testing the system and discovering the problem, it is necessary to be able to locate the problem and know where the problem is, so as to facilitate the improvement of the problem. The system test requirements can cover all the main functions, including not only the test

software but also other components such as hardware, external equipment, and networks, interfaces.

Disaster simulator system test cases are shown in Table 5.

5. Conclusion

This paper focuses on the simulation of evacuation in an urban disaster environment based on virtual reality technology and establishes an evacuation awareness model. Compared with the research on evacuation based on perception patterns at home and abroad, this paper combines people and the environment and combines the environment and perception evacuation research from the perspective of human perception, and expounds the impact of disasters on

evacuation. It also simulates the impact of fires, earthquakes, and information systems on the city. According to the analysis of the impact of urban disasters on the urban information system, the entire framework is designed. The simulator is divided into three functional modules: IP address acquisition, disaster evolution, and the impact of the system. The three modules were designed, developed, and tested in sequence, the three modules were integrated, and the system was tested, and a disaster simulator was deployed. In order to better respond to urban disasters, it is necessary to improve the recommendations and norms of disaster response, and it is urgent to conduct disaster simulation research. This paper has done a lot of research on fire, earthquake, and information system simulation, and this direction will inevitably become a new and valuable research direction.

Data Availability

The data used to support the findings of this study are currently under embargo while the research findings are commercialized. Requests for data, after the publication of this article, will be considered by the corresponding author.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

This paper examines the problem of athletes' training in sports, exploring the methods and means by which athletes can perform difficult movements in which they normally make minor training errors in order to achieve better competition results and placements. To this end, we test the explanatory and predictive effects of a theoretical model starting with planned behaviour and then use exercise planning, self-efficacy, and support as variables to develop a partial least squares regression model of sports to improve the explanation and prediction of sporting athletes' intentions and behaviour. An improved RBF network-based method for player behaviour prediction is proposed. On the basis of the RBF analysis, the number of layers and the number of neurons in the hidden layer of the network are adjusted and optimised, respectively, to improve its generalisation and learning abilities, and the athlete behaviour prediction model is given. The results demonstrate the advantages of the improved algorithm, which in turn provides a more scientific approach to the current basketball training.

1. Introduction

What if, after countless hours of practice, a sportsperson realises that there is only a 50% chance of successfully completing one of the most difficult manoeuvres of the entire competition and that the athlete might miss the most important and critical moment of the competition? What does the athlete do when faced with these potential threats? Many scholars have suggested adjusting one's breathing to regulate one's emotions, controlling oneself from thinking that the action has a high probability of being wrong, adjusting one's mental state so that he can perform the technique successfully, etc. [1]. However, numerous studies have shown that the use of intentions alone is not a good predictor of behaviour change. Action plans and coping plans are self-adjustment strategies. In many domains, behavioural intentions are supported after planning and execution as a motivation is received. The addition of a theory of planned behaviour appears to be the most appropriate as the theory of planned behaviour lacks sequential

structure. It has also been found that when using behavioural interventions, research has not found an effect on behaviour by making implementation intentions, and on the basis of existing research, planning is more important as a mediating variable, and this paper will continue to examine and explore the forecasting effects of planning as an intermediate variable [2].

Currently, most of the research studies in the field of video-based motion human analysis are focused on motion behaviour recognition, but not on motion behaviour prediction. However, in real life, prediction of human movement based on the video is more valuable than behaviour recognition [3]. The public security department can be alerted to the predicted criminal behaviour in time to take corresponding measures. This not only reduces the amount of manpower and material and financial resources spent on security investigations but also provides effective prevention of sudden crime [4]. In the sports sector, a comprehensive set of video-based human movement prediction technologies can be used to accurately capture the game data of some

of the best teams during sports training and to create a predictive discriminator for each athlete [5, 6].

The contributions of this paper are as follows:

We start from the planned behaviour to test the interpretation and prediction effect of the theoretical model and then take the exercise plan, self-efficacy, and support as variables to establish the partial least squares regression model of sports, so as to improve the interpretation and prediction of aerobics athletes' intention and behaviour.

We propose a team member behaviour prediction method based on the improved RBF network. The RBF network is analyzed. Based on the RBF analysis, the number of network layers is adjusted and optimized to improve its generalization and learning abilities, and the athlete behaviour prediction model is given.

Based on the analysis of the sports competition video, the improved RBF is used to predict the athletes' behaviour, and the prediction results are compared with the traditional prediction results. The results show that our algorithm has advantages.

2. Related Work

At present, the research of individual sports is mainly reflected in the movement recognition and analysis of athletes [7–9] using target detection and tracking technology, the moving target is extracted from the diving video, and the moving target is video synthesized. A motion recognition method based on the human contour curvature scale space template is proposed and applied to the motion recognition of players in tennis competition [10]. The movements of ice hockey and football players are analyzed and studied. The movement direction of players is identified by using the histogram of oriented gradient (HOG) and hidden Markov model (HMM) [11–13]. The player's gestures in the low-resolution tennis game video are recognized [14]. By tracking the key points of some body parts of ballet dancers, the dance trajectory is obtained, and the automatic analysis of dance movements is realized [15]. It realizes the recognition of four swimming strokes in the swimming competition video.

In recent years, as research on individual sports analysis has matured so has research on multiplayer team sports [16]. Zhong and Xiao [17] investigated the patterns of passes that help to score goals in football and used multiscale analysis to cluster passes hierarchically and to mine the pattern categories of passes; Chen et al. [18] classified the trajectory and landing point of the ball as special cases in tennis and used an improved Bayesian network to fuse these two features. Li and Zhang [19] proposed a method for two-sided team possession situations, which is based on the ball position and

the detection of the interplay, the local minima of the ball motion trajectory velocity of a player's possession start, the local minima of the ball position coordinates, the player's position, and the ball acceleration start point to infer the player's touch point. Li et al. [20] integrated a variety of information on the pitch in the ritual to achieve automatic analysis of football game tactics.

3. Development of a Regression Model for Sports Training

Simplify the data structure and correlation analysis of bivariate variables, greatly facilitating multivariate data analysis [21]. It uniquely suits to deal with small sample sizes and independent variables with significant multiple correlations between variables. However, the partial least squares regression model can be expressed as the original regression equation for all variables. The partial least squares regression method selects principal components that also include all variables and does not fully address the more severe multivariate correlations, especially in the case of some independent variables and small sample conditions [22].

In this paper, data from sports athletes regarding physical training were used to conduct partial least squares regression modelling in terms of the explanatory and predictive power of three variables—exercise program, self-efficacy, and social support—on exercise intention and behaviour and their role in the intention-to-behaviour process. The subjects of this paper were 10 players of a sports team. The first group of variables was exercise planning, self-efficacy, and social support. In this study, social support consisted of two types, family social support and friend social support, which were not effective predictors of exercise intention. The second group of variables was the training performance indicators of the sport players, which were rotation, bending, and high jump. The raw data are shown in Table 1, and the correlation coefficient matrix is shown in Table 2.

The simple correlation matrix of these six variables shows that an exercise program and self-efficacy are positively correlated; work program and self-efficacy are negatively correlated with social support, and rotation, bending, and high jump are positively correlated.

The partial least squares regression model is calculated by presenting two components t_1 and t_2, which have a cross-validity of $Q_2^2 = -0.1969$. The regression equation for the standardised variable $\overline{y_k}$ on component t_1 in this paper is as follows:

$$\overline{y_k} = r_{1k}t_1 + r_{2k}t_2, k = 1, 2, 3. \tag{1}$$

The resulting partial least squares regression equation for component t_1 is

$$\overline{y_k} = r_{1k}\left(w_{11}^*\overline{x_1} + w_{21}^*\overline{x_2} + w_{31}^*\overline{x_3}\right) + r_{2k}\left(w_{21}^*\overline{x_1} + w_{31}^*\overline{x_2} + w_{32}^*\overline{x_3}\right)$$
$$= \left(r_{1k}w_{11}^* + r_{2k}w_{12}^*\right)\overline{x_1} + \left(r_{1k}w_{21}^* + r_{2k}w_{22}^*\right)\overline{x_2} + \left(r_{1k}w_{31}^* + r_{2k}w_{32}^*\right)\overline{x_3}. \tag{2}$$

TABLE 1: Physical training data.

No.	Exercise program	Self-efficacy	Social support	Rotate	Bend	High jump
1	91	36	50	5	162	60
2	89	37	52	2	110	60
3	93	38	58	12	101	101
4	63	35	62	12	105	37
5	89	35	46	13	155	58
6	82	36	56	4	101	42
7	67	34	60	6	125	40
8	76	31	74	15	200	40
9	54	33	56	17	251	250
10	69	34	50	17	120	38

TABLE 2: Correlation coefficient matrix.

	x_1	x_2	x_3	y_1	y_2	y_3
x_1	1	0.8702	−0.3658	−0.3897	−0.4931	−0.2263
x_2	0.8702	1	−0.3529	−0.5522	−0.6456	−0.1915
x_3	−0.3658	−0.3529	1	0.1506	0.225	0.0349
y_1	−0.3897	−0.5522	0.1506	1	0.6957	0.4958
y_2	−0.4931	−006456	0.225	0.6957	1	0.6692
y_3	−0.2263	−0.1915	0.0349	0.4958	0.6692	1

The calculations for $r_h = (r_{h1}, r_{h2}, r_{h3})$ are

$$\overline{y_1} = -0.07\overline{x_1} - 0.489\overline{x_2} - 0.122\overline{x_3},$$
$$\overline{y_2} = -0.15\overline{x_1} - 0.5244\overline{x_2} - 0.054\overline{x_3}. \tag{3}$$

The following equation is obtained by reducing the normalized variables $\overline{y_k}, \overline{x_k}\,(k = 1, 2, 3)$ to $y_k, x_k\,(k = 1, 2, 3)$, respectively:

$$y_1 = 47.97 - 0.07x_1 - 0.87x_2 - 0.99x_3,$$
$$y_2 = 612.71 - 0.39x_1 - 10.2477x_2 - 0.71x_3, \tag{4}$$
$$y_3 = 183.949 - 0.13x_1 - 2.49x_2 - 0.01x_3.$$

4. RBF Radial Neural Network Prediction Model

From a structural point of view, the RBF nerve network consists of three layers: an input layer, an implicit layer, and an output layer. The number of nodes in this layer is determined by the actual number of input variables; the number of nodes in the implicit layer is difficult to determine and is determined by the complexity of the problem being described [23]; the output layer is used to output the results of the input and output processing of the system. In the RBF neural network, the transformation from the input space to the hidden space is a nonlinear transformation, and the transformation from the hidden layer to the input layer is a linear transformation. Assuming that the RBF neural network has only one hidden unit [24], the training sample of the RBF neural network can be expressed as $\{X_n, d_n\}\,(n = 1, 2, \cdots, N)$. In this formula, $X_n = [x_{n1}, x_{n2}, \cdots, x_{nM}]^{\mathrm{T}}\,(n = 1, 2, \cdots, N)$ is the sample input; $d_n\,(n = 1, 2, \cdots, N)$ is the desired sample output, and the corresponding actual output is $Y_n\,(n = 1, 2, \cdots, N)$; the radial basis function $\varphi(X, t_i)$ is the output of the ith hidden unit, and $[t_{i1}, t_{i2}, \cdots, t_{im}, \cdots, t_{iM}]^{(i=1,2,\cdots,I)}$ is the centre of the basis function; $w_i\,(i = 1, 2, \cdots, I)$ is the connection weight between the ith hidden unit and the output unit.

The topology of a specific single-output RBF network is shown in Figure 1.

When the network input training sample is X_n, the actual output of the network can be expressed by the following equation:

$$Y(X_n) = \sum_{i=1}^{\varepsilon} w_i \varphi(X, t_i). \tag{5}$$

Currently, there are many RBF functions in the field of RBF neural networks, the most common of which are the Gaussian function, the multiple quadratic function, and the thin-slab spline function.

The purpose of data normalisation is to transform all data to values in the range [0, 1] to make subsequent calculations more convenient [25]. The data normalisation formula is

$$X = \frac{x - x_{\min}}{x_{\max} - x_{\min}}. \tag{6}$$

The network parameters are updated by the following equation:

$$v_i = v_{i-1} + K_i e_i,$$
$$K_i(zxn_y) = P_{i-1}B_i\left[R_i + B_i^T P_{i-1}B_i\right]^{-1}, \tag{7}$$
$$P_i = \left[I_{zxz} - K_i B_i^T\right]P_{i-1} + q_0 I_{zxz}.$$

In the above equation, $v_i = [w_0^i, w_1^i, c_1^i, \delta_1^i, \cdots, w_K^i, c_K^i, \sigma_K^i]^{\mathrm{T}}$ represents the state of the parameter shown for the ith sample after it has entered the network.
FIGURE 1: Topology of a single-output RBF network.
FIGURE 2: Typical training sample of the head state detection classifier.

The calculation is carried out for all hidden node outputs $\sigma_k = (o_{k1}^i, \cdots, o_{kj}^i, \cdots, o_{kn_y}^i)$, $i = 1 \cdots N$, $k = 1, \cdots, K$, $j = 1, \cdots, n_y$, and $\|o_{j,\max}^i\| = \max(\|o_{1,j}^i\|, \|o_{2,j}^i\|, \cdots, \|o_{K,j}^i\|)$, $(j = 1, \cdots, n_y)$. The specific normalized output vector formula is

$$r_{kj}^i = \frac{\left\|o_{k,j}^i\right\|}{\left\|o_{j,\max}^i\right\|} \ (k = 1, \cdots K). \tag{8}$$

If all $r_{kj}^i < \varepsilon_2$ are established, then the kth hidden node can be deleted.

5. Experimentation and Analysis

In order to verify the effectiveness of the method, we experimented on an Intel Core 2 T6500 PC with 3 G RAM, implemented using VVC++6.0 with the OpenCV vision library programming [26]. To train the FSAMME-based head state classifier, we manually intercepted 800 head images from 100 basketball game videos, 100 images from each class. A typical training sample is shown in Figure 2. In addition, 100 nonhead images were intercepted as a negative example training set, consisting mainly of local stadium background blocks and blocks of other body parts of the players. Figure 3 shows the relationship between the relative size (ratio to sample side length) of the small square area extracted from the training sample and the recognition accuracy. In the training process, we set τ_{accuracy} of the head image detection classifier to 0.9, the learning rate τ_{rate} to 0.1, and τ_{accuracy} of the nonhead image detection classifier to 0.4. We selected another 400 head images as the test set, 80 images of each class, and the experimental results are shown in Table 3.

As can be seen from Table 3, the misjudgements were mainly in the discrimination of two adjacent head poses. This is mainly due to the low resolution of the head image in the basketball game video, the interference of motion blur and noise, and the similarity of the adjacent head postures themselves. From the experimental results, it can be seen that the covariance descriptor, which incorporates a variety of underlying features, is well adapted to the above situation and achieves satisfactory experimental results, with the average recognition rate of various head poses.

In order to verify that the covariance descriptor can improve the accuracy of head state recognition after fusing the original underlying features, we have selected a subset of feature vectors in the section for comparison experiments, respectively, and the experimental results are colour features, gradient features, texture features, colour-gradient features, colour-texture features, gradient-texture features, and colour-gradient-texture features, as shown in Figure 4.

In addition, we also experimented with the method in this article in the case of partial occlusion of the player's head. Test cases were manually occluded from the top, bottom, left, and right directions, with each direction taking up 10%, 20%, 30%, 40%, and 50% of the total head image area, shown in Figure 5.

As can be seen from the graph, the accuracy of head pattern recognition is generally higher when the left and

right occlusion occurs than when the top and bottom occlusion occurs. When the occlusion rate is reached, the lowest upper occlusion recognition rate is also higher than the best right occlusion recognition rate by a close margin. It can be seen that the method in this paper also achieves better results when dealing with partial occlusion.
FIGURE 5: Average head state recognition in different occlusion situations.

TABLE 4: Comparison with two existing methods in terms of average recognition rate.

Method	Method in this paper	Orozco	Siriteerakul
Average identification accuracy	96.5%	71.7%	78.6%

Finally, the method is compared with two state-of-the-art methods for low-resolution cephalosporin recognition. As can be seen from Table 4, this method outperforms the other two methods in terms of average head pattern recognition rate.

6. Conclusions

The above analysis shows that the RBF neural network has strong generalization and learning abilities in dealing with the prediction of nonlinear problems, and the above construction shows that the algorithm proposed in this paper has more advantages and accuracy in the prediction of sports behaviour, thus proposing a new scientific training method for the scientific training of current sports.

In the real world, there are a variety of situations that require strategy control, that is reinforcement learning, as a method for studying the decision-making and behavioral strategies of intelligence. It has received a lot of research and empirical evidence on its functions and roles and is also a method recognized by scholars. Among them, combining reinforcement learning with sentiment analysis is an important theoretical research direction, but so far there is still relatively little research work about it, and it still has the problems of poor application effect and low accuracy rate. Therefore, in this study, we use the features related to sentiment analysis and deep reinforcement learning and use various algorithms for optimization to deal with the above problems. In this study, a sentiment analysis method incorporating knowledge graphs is designed using the characteristics of the stock trading market. A deep reinforcement learning investment trading strategy algorithm for sentiment analysis combined with knowledge graphs from this study is used in the subsequent experiments. The deep reinforcement learning system combining sentiment analysis and knowledge graph implemented in this study not only analyzes the algorithm from the theoretical aspect but also simulates data from the stock exchange market for experimental comparison and analysis. The experimental results illustrate that the deep reinforcement learning algorithm combining sentiment analysis and knowledge graphs used in this study can achieve better gains than the existing traditional reinforcement learning algorithms and has better practical application value.

1. Introduction

Reinforcement learning is a commonly used framework as a way to handle sequential decision-making tasks. On the other hand, deep learning can be used for the representation and storage of feature aspects [1]. So far, the combination of these two different models is by far the best answer in terms of learning good state representations of very challenging tasks that are designed to solve not only simulated scenario domains but actually challenging real-world problems. Reinforcement learning, as a subset of machine learning, which in turn is an important branch of artificial intelligence, has gained more and more importance in the last years [2]. The classical approach to creating AI requires programmers to manually code every rule that defines the behavior of the software [3]. A clear example is Stockfish, an open-source AI chess engine developed with the help of hundreds of programmers and chess experts who translated their experience into the rules of the game [4]. In

contrast to rule-based AI, machine learning programs develop their behavior by examining large amounts of example data and finding meaningful correlations.

In creating a machine learning-based chess engine, instead of providing rules for each game, engineers created a basic algorithm and trained it using data collected from thousands of games played by human chess players [5]. The AI model would scrutinize the data and identify similarities between winners. When offered a new game, the AI will decide on the moves most likely to lead to a win based on examples it has previously seen. While machine learning and its more advanced subset deep learning can solve many problems previously thought to be infeasible for computers, they rely on large amounts of annotated, quality training data. This limits their application to areas where labeled data are scarce [6]. This is where reinforcement learning comes into play. Humans and higher animals are able to engage in continuous interaction with their external environment to understand, explore, and sense it. This

is due to the fact that humans and higher animals have the ability to continuously learn, to continuously learn and accumulate experience, and to reuse existing experience to make current decisions more rational and superior. The implication of machine learning is that machines have the same learning and perceptual capabilities as humans and can mimic the action habits of humans or higher animals in continuous interaction [7]. Machine learning has a number of advantages over human learning, and it has been shown that machine-based knowledge far exceeds the capabilities of the human brain in terms of memorizing knowledge, understanding, and comprehension. As a result, humans tend to rely more and more on machine-based knowledge. The value of utilizing machine learning in finance is becoming increasingly evident. As banks and other financial institutions strive to enhance security, streamline processes, and improve financial analysis, machine learning is becoming the technology of choice [8]. While it is true that traditional finance is not at the forefront of adopting machine learning, its use in finance is now a hit. It offers new technological services for financial forecasting, customer service, and data security. Profitable stock trading strategies are vital for investment firms [9]. It is used to optimize capital allocation, thus allowing for the maximum utilization of performance, such as expected returns. Earning maximization is based on an estimate of the potential return and risk of the stock. However, it is challenging for analysts to consider all relevant factors in a complex stock market [10].

In the strategy of this study, first, the covariance matrix of expected stock returns and stock prices is calculated. Then, the optimal portfolio allocation is found by maximizing the return for a fixed risk of the portfolio or minimizing the risk for a range of returns. The optimal trading strategy is then extracted by following the optimal portfolio allocation. However, implementing this method can be very complex if the manager wants to modify the decisions made at each time step and consider the transaction costs. The process of stock investment trading can be thought of as a Markov decision process (MDP). Then, we formulate the trading objective as a maximization problem. Considering the stochastic and interactive nature of the trading market, the problem formulation of stock trading, we solve the stock trading problem by considering the stock trading process as a Markov decision process (MDP) and calculate the optimal strategy through dynamic programming ideas. However, the scalability of the model is limited by the huge state space in dealing with the stock market. In this study, however, our work is a study of stock market sentiment analysis and investment strategy algorithms based on deep reinforcement learning, which first uses knowledge mapping techniques to improve the relevance of news headlines, uses them in sentiment analysis to derive the sentiment coefficients of the corresponding stocks for each news item, and applies them to a modified deep recurrent Q-learning network (DRQN) to find the optimal trading strategy in a complex and dynamic stock market.

2. Related Work

In recent years, various methods based on deep reinforcement learning have been used to deal with various types of decision problems. Although the scheme of using deep learning and reinforcement learning in unison has been used in the past, deep reinforcement learning actually got a start in terms of both quality and efficiency after DeepMind proposed the DQN (deep Q network) algorithm, which accomplished the result of playing Atari games using only pure images as input and using a training intelligence throughout [11]. DeepMind then published a modified version of the previously proposed DQG in nature, which was noticed by the academic community, and it is because of this opportunity that deep reinforcement learning has gradually become a cutting-edge research in the direction of deep learning. Most of these reinforcement learning methods can be further divided into model-free-based reinforcement learning and model-based reinforcement learning [12]. In model-free-based reinforcement learning algorithms, the algorithms are able to be applied in several ways. Since it is not necessary to construct a model, all decision-making studies of intelligence are obtained by interacting with the environment [13]. Among the representative methods are Q-learning and some of its improved versions, the Monte Carlo method.

Without a model, the intelligence needs to explore the external environment by interacting with the system with information all the time and training the model with a lot of trial-and-error experience in the process [14]. This is actually one of the drawbacks of model-free reinforcement learning algorithms: the efficiency of using data for simulation is too low. For these reasons, model-free-based reinforcement learning algorithms usually require millions of explorations and environments. With the above analysis, model-free-based reinforcement learning methods are actually like violent exploration, but model-free-based reinforcement learning methods are guided by the strategy of violent search [15]. Moreover, model-free-based reinforcement learning methods tend to be poorly robust, and especially after the external market environment and training work tasks change and evolve, the intelligence can generally ask us to retrain and explore [16]. Model-free methods can directly learn from experience, meaning that they can perform actions in the real world (e.g., robots) or in computers (e.g., games). They then collect rewards (either positive or negative) from the environment and update their value function. This is the main difference with model-based approaches.

The model-free approach works in the real environment for learning. Instead, the model-based algorithm reduces the interaction with the real environment during the learning phase [17–19]. The goal is to build models based on these interactions with the environment and then use that model to simulate other events. Rather than in the actual environment, it is applied to construct the model and obtain the results returned by that model. As mentioned earlier, this has the advantage of accelerated learning, as there is no need to wait for the environment to respond or to reset the environment to some state to resume learning. However, the downside is that if the model is not accurate, we risk completely learning something different from reality. Learning a model involves performing operations in a real environment and collecting feedback [20, 21]. We call this

experience. Thus, for each state and action, the environment provides new states and rewards. Based on these experiences, we try to derive models, which are nothing but supervised learning problems. There are also methods that learn models with the help of neural networks and optimize reinforcement learning methods based on models using traditional theories of optimal trajectories. Such algorithms include those proposed by Levine at Berkeley and Abbeel at OpenAI. Creating a probabilistic model of the system, using a Gaussian process or probabilistic neural network to learn the model, and using the probabilistic model in planning are approaches such as the PILCO family of algorithms, mainly proposed by Rasmussen et al. in the Machine Learning Laboratory at Cambridge University.

In the model-based reinforcement learning methods, if we can define our own cost function, we can apply the model to compute the optimal operation. Control theory has a strong influence on model-based RL [22]. Recent advances in model-free reinforcement learning demonstrate the ability of rich value function approximators to master complex tasks [23]. Dai and Kong pointed out that the multivariate forecasting method can greatly improve the forecasting ability of bond yield [24]. However, these model-free methods require access to an impractically large number of training interactions for most real-world problems. In contrast, model-based reinforcement learning methods can use learned models to quickly achieve near-optimal control under rather restricted classes of dynamics. In environments with nonlinear dynamics, the complex dynamics in model-based reinforcement learning methods require high-volume models, which in turn tend to be overfitted [25–28]. The two forms of reinforcement learning methods have distinct advantages and disadvantages: the expression value estimation model-free methods achieve good asymptotic performance but poor sample complexity, while the modeled methods exhibit learning with good results but struggle with complex tasks.

3. Knowledge Graph-Based Sentiment Analysis of the Stock Market

3.1. System Design. The framework of the knowledge graph-based sentiment analysis system for the stock investment market implemented in this study contains three main modules, knowledge graph module, embedding layer module, and recurrent convolutional neural network (RCNN) module. Relevant news headlines are identified at the top of the website and preprocessed using natural language processing techniques such as removing HTML tags, marking sentences, removing banned words, and so on. Subsequently, the knowledge graph is built by putting the relevant information of the stock corresponding companies, and the preprocessed news headlines are put into the knowledge graph for distance comparison. The news headlines with appropriate distances are filtered in the knowledge graph as the input of the embedding layer module, and then, the sentiment results are output through the sentiment analysis module after vectorizing the text data

in the embedding layer. The specific algorithm flow is structured in Figure 1 below.

The technical development routes for constructing knowledge graphs can be generally divided into two types, one of which is top-down while the other is bottom-up. One of the top-down solutions for constructing a knowledge graph is to find information such as ontologies and relationships from inside the good data and append it to the knowledge base with the help of structured data sources such as encyclopedias. The bottom-up approach to build the knowledge graph is to use specific guidelines to collect data from public resource models to obtain highly reliable information to add to the base knowledge. The knowledge graph constructed in this chapter is based on the cloning of web resources as data input, and therefore, a bottom-up approach to constructing a knowledge graph is used. The input data may be structured, unstructured, or semi-structured, and based on this information data we can apply mainly our own set of systematic automated or semi-automated technical research solutions to obtain the elements of relevant knowledge, i.e., the physical-economic relationships with each other, from the very first data, and then place them in the module layer above the corresponding knowledge base and in the data layer. The construction of the knowledge graph as a process of cyclic change changes by obtaining the relationships of knowledge, and each iteration contains three stages: (1) knowledge extraction: the mutual relationships that exist inside the entities, attributes, and entities are obtained in each data source, and the dynamic knowledge representation is formed based on this logic; (2) knowledge integration: in order to obtain new knowledge after eliminating contradictions and ambiguities such as some entities can be more than one expression, there exists the possibility of some special calls corresponding to a different number of entities; (3) knowledge processing: quality assessment of new knowledge can be placed after their integration before the ranking part of the knowledge base to ensure the quality of the knowledge base. There are two possible problems with the use of remote supervision in relational extraction. First, the knowledge base and the text will use heuristic alignment in remote supervision, which may lead to errors in the annotation of the data. Second, in previous methods, specific features are used in statistical models to achieve classification, but the noise caused by specific features sometimes produces bad results. In this study, multiple example learning and PCNNs are applied to deal with the above two problems. Figure 2 shows the structure of PCNNs.

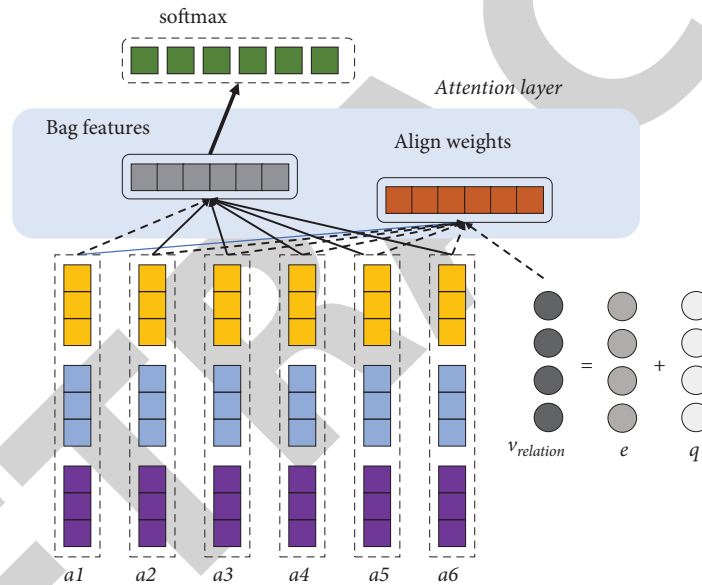
3.2. Market Sentiment Model Construction. After determining the direction and class of the relationship, we represent the relationship as a form of three tuples (h, r, t). h and t represent the head and tail entities (firms), respectively, and r represents the relationship between the head and tail entities. For example, (Company A, AG, Company B) indicates that Company A holds Company B. After placing the triples into the Neo4j database, the construction of the knowledge graph is completed. The use of vector form to
FIGURE 1: Flowchart of knowledge graph-based sentiment analysis algorithm.


FIGURE 2: Structure of PCNNs.

represent the knowledge graph can be developed to make it more convenient for various social workers afterward; therefore, the goal now is to encode and compress the triad (h, r, t) into a low-dimensional distributed vector. After completing the construction of the knowledge graph, if new news data are directly added to the knowledge graph for relevance analysis, the ordinary Euclidean distance is difficult to meet the processing of various application requirements. In recent years, trans-series models have been widely used for knowledge representation learning of knowledge graphs. Compared with traditional training methods, trans-series models have simple parameters, are easy to train, and are less prone to these problems of overfitting.

Simply put, the relationship inside the triple instance (h, r, t) is compared to the interpretation from entity h to entity t. The implementation keeps adjusting h, r, and t (vectors of h, r, t) so that ($h + r$) is as close as possible to t, i.e., $h + r = t$.

The knowledge graph, trained with feature vectors, can better represent the relationship between knowledge from different graph databases. The news headline data used in this chapter can calculate the distance between the knowledge by inputting it into the knowledge graph for similarity comparison, which can be limited to a fixed distance as a metric for finding implicit relationships between stock companies. A distance smaller than this indicates that this news headline has a closer relationship with the corresponding stock, and there will be factors that affect the rise or fall of the stock, which can be used as input to the sentiment analysis module. News headlines that exceed this distance can be considered as having noisy data and are not used as input for the sentiment analysis module.

The word vector output from the text data after the embedding layer can be used as the input to the sentiment analysis module. The sentiment analysis model network in

this chapter has three layers, i.e., LSTM (recursive) layer, convolutional layer, and output layer. The first layer is the RNN implemented as (LSTM). The LSTM layer introduces the stored elements into the network. This layer is very effective in extracting sentence representations, allowing our model to analyze long sentences. The input gate directs the amount of change in the input vector of the current time LSTM unit to the messages in the memory model, the forgetting gate acts as the degree of influence of the previous moment's history on the messages in the current time memory unit, and the output gate controls the amount of output of the messages in the memory unit. The input gate, output gate, and forgetting gate are denoted as it, ot, and ft below.

The second layer creates a convolution kernel that convolves with the input in a single spatial dimension to generate a tensor. This layer is used for a one-dimensional maximum pool of pool length four. This layer extracts semantic information from the word embeddings provided by the embedding layer. Where said convolution window has a large interference of size etc., similar to the selection to achieve the final classification result of the selected local feature n words, then the representation in the contextual semantic information, i.e., full-text semantic embodiment, is obtained. A convolutional operation window is set to carry out a size of $a * b$, the number of words within the window is a, and the word vector space dimension is b. Multiple convolutional kernels are applied to generate a feature map, then, a maximum pooling layer operation is implemented, and finally, softmax is run to perform the classification.

3.3. Deep Learning for the Decision Process.

Markov decision process, or MDP for short, has been used by a large number of researchers as a general architecture used to solve most reinforcement learning problems and to initiate subsequent theoretical research. The Markov decision process is explained by means of a 5-tuple (S, A, P, R, and γ), where Z is the set of states, which is finite in number, B is the set of actions, which is also is finite, P is the state transfer probability from one current state to the next, R is the reward function in the network, and γ is the discount rate for each cumulative calculation that can be used to calculate the cumulative reward, as shown in Figure 3.

The state transfer probability of the MDP is

$$\widetilde{A}_{x_{II}} = \sum_{i=1}^{q} \chi_{ii} \Leftrightarrow \mu_A(x) = 0. \tag{1}$$

The meaning refers to the map from the operational state of the strategy to the notation used to represent the strategy π, which refers to the chosen state when Z, in the presence of the set of assigned actions, can be expressed as follows:

$$\widetilde{A} = \widetilde{B} = \sum_{i=1}^{q} \mu_{ii}(x) \Leftrightarrow \mu_A(x) = 0. \tag{2}$$

This system is fully visible inside the MDP, which means that the observation is in the same state as the environment: $\omega t = st$. At each time step t, the probability of moving to $zt + 1$ is given by the state transition function $T(zt, bt, zt + 1)$, and the reward is given by the bounded reward function $R(zt, bt, zt + 1) \in \mathcal{R}$. At each step, the intelligence takes action to change its state in the environment and provide a reward.

$$W_{i+1} = W_i - a\frac{\partial L}{\partial q}. \tag{3}$$

The specific meaning of decision-making is available by learning conditions for the probability distribution. Decision-making in reinforcement learning is generally stochastic, and the benefit of using stochastic decisions is the ability to integrate search into the sampling step. Search here is where the intelligence goes through other actions to arrive at a better decision. In practice, various kinds of noise are prevalent, which tend to obey a normal distribution curve, and how to reduce this noise also requires the use of probabilistic aspects of the theory. The goal of reinforcement learning is to find the best decision, and through this best decision found to continue the search for the corresponding best reward, where the best is the one that maximizes the total reward in the end. The cumulative reward is defined.

$$V_{\text{map}} = \frac{\{a_1, a_2, a_3, \ldots, a_n\}}{\max P(X, Y)}. \tag{4}$$

Under different decisions and environments, the value of G is uncertain. Since it is simulated under a stochastic decision π, the cumulative reward is also stochastic. However, the reward E is a value that can be determined by and we are able to perform an interpretation of the state value function. Such a function can represent the state values: when said decision agent is used by π, the cumulative reward can be seen as an allocation, in which E denotes the cumulative value returned by the Z state is in the equation Z value.

$$V_{\text{np}} = \frac{\arg v_j \{a_1, a_2, a_3, \ldots, a_n\}}{\prod P(X, Y).} \tag{5}$$

The corresponding equation for the $z - b$ value function is

$$P_{x,y} = \frac{N \sum_{i=1}^{n} X * Y}{\sqrt{\sum_{i=1}^{n} (X + Y)}}. \tag{6}$$

The Bellman equation for the z-valued function and the z-b-valued function are given below. From the defining equation of the z-valued function, it can be obtained that the Bellman equation for z can be expressed as

$$V_{\text{map}} = \frac{\{a_1, a_2, a_3, \ldots, a_n\}}{\max P(X, Y)} = P(X, Y \mid v_j)p(v_j). \tag{7}$$

4. Experiments and Result Analysis

4.1. Experimental Data and Preprocessing.

Reinforcement learning is really about finding the best policy by simulating the Markov decision process of the environment and then deriving the optimal reward over the best policy by
Figure 3: Calculation of cumulative reward.

simulation. To evaluate the effectiveness of the algorithms in this chapter, a large amount of historical data on thousands of stock codes, with both outdated price information and outdated news headlines related to stock codes, is accessible using an interface provided in the financial section. This provides a rich corpus of data that can be used to train agents to correlate their interpretation of headlines with actual changes in stock prices. The site's historical data can be mined and used to train the model. It can then also be examined on a daily basis to make predictions to make predictions. Next, for each news headline, we remove the deactivated words and tokenize them. Each token is then checked for the presence of an organizational node relationship with the particular company of interest in a knowledge graph within a predetermined distance. In the experiments in this chapter, the size of the distance measure chosen is important. Choosing a walking distance longer than this would result in too much noise, while any shorter walking distance would mean that few implicit relationships would be found. The value was empirically adjusted based on conducting some manual experiments. Once any marker in the title was found to be within a predetermined distance of the stock-related organization, by extension, the entire title could be considered relevant to the organization under consideration. In this experiment, 9,463 news headlines for 100 different ticker symbols and 26,017 daily quote instances within the same time frame were collected. The raw HTML data were parsed and filtered to obtain raw tuples of <date, headline> and <date, and quote> instances, which were then sorted by date and merged to provide instances that the model could learn from. As shown in Figure 4, a particular quote instance is classified as RISE or FALL if it is up or down by more than 10% of the previous day's price; otherwise, these data are treated as "None." The prior probabilities of RISE, FALL, or NOTHING in all collected data are 0.014672, 0.008354, and 0.987639, respectively.

4.2. Model Training Setup and Comparison. Because the model has many variable hyperparameters and it is impractical to experiment with the optimal parameters one by one in huge parameter space, the experiments in this section use a grid search approach to perform parameter optimization. To reduce the chance of tuning the parameters for training, the experiments refer to the three-time cross-validation method. For the training process, 80% of the headlines are randomly sampled from the crawled news headline dataset as the training set, 10% of the headlines are randomly sampled as the validation set in the testing process, and the remaining 10% of the headlines are set as the test set to find the best hyperparameters by comparing the three experiments. In this experiment, 9,463 news headlines for 100 different ticker symbols and 26,017 daily quote instances within the same time frame were collected. The loss function is used for cross-entropy, and the gradient descent method for the training optimization process uses SGD stochastic gradient descent method to find the best learning rate through experiments. The results of a simple control experiment show that the best prediction results are obtained when the learning rate is 0.001. Due to the limitation of space, some of the best parameter results derived from the grid search are directly given here, which are the convolutional kernel size 64, the number of convolutional kernels is 4, the number of LSTM hidden cells is 128, the dropout retention ratio is 0.6, and the knowledge graph ontology distance is 5. On this basis, the optimal parameter comparison results for the word vector dimension are made as shown in Figure 5.

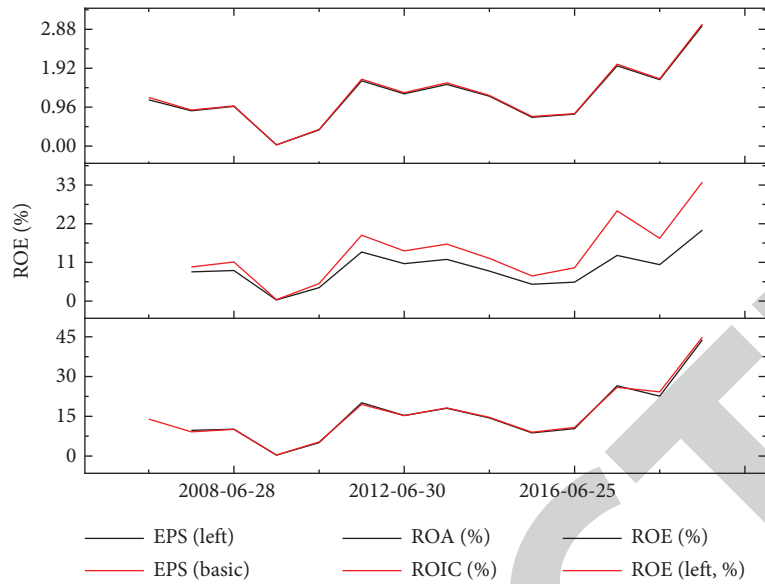
The accuracy of KGRCNN is above 86% in the best combination of hyperparameters. The experiments comparing the model in this study with other methods reveal that the KGRCNN method has a great advantage over the common LR and SVM models, while the RCNN model can classify the stock market sentiment better and simply using a CNN or RNN approach does not affect the results and the


FIGURE 4: Collation of financial data.
FIGURE 5: Experimental results of tuning the optimal word vector dimension under three cross-validations.

RCNN. A random sample of 90% of the data was used for training, and 10% was reserved for testing. The data chosen for training and testing are randomly selected at runtime. This assumes abstraction of any temporal information that may be present in the data that may affect classification. That is, the training instances were considered independent of each other and only dated so that citations could be matched to titles. The increased amount of training data (of which 10% was reserved for testing and not used for training) was tested against the agents. The experiments were conducted in two of them, the analysis of the prediction accuracy results of the sentiment analysis module without and with the knowledge graph technique.

Experiment 1. First, the first experiment was performed using the full sentiment analysis module, on which the experiments were separately performed on the effect of using or not using the knowledge graph technique on the results of the experiments and the results are shown in Figure 6 below.

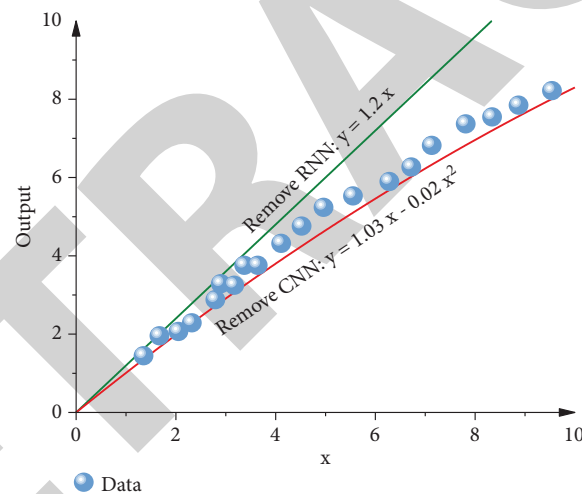
Experiment 2. The second experiment uses the knowledge graph technique but removes RNN and CNN from the sentiment analysis module, respectively, to test the effect on the results of the experiment, with the following results in Figure 7. To reduce the chance of tuning the parameters for training, the experiments refer to the three-time cross-validation method.
FIGURE 6: Effect of using or not using knowledge graph technology on experimental results.


FIGURE 7: Effect of removing RNN and CNN on experimental results.

Experiment 3. The third experiment did not use knowledge graph techniques and removed RNN and CNN from the sentiment analysis module, respectively, to test the effect on the experimental results, which are shown in Figure 8 below.

From the above figure, it can be seen that the combined knowledge graph algorithm used in this study is enough to obtain better accuracy compared to the model without using knowledge graph techniques under the same sentiment analysis module and training data share. The sentiment analysis module using LSTM + CNN also works better than the experiments using only CNN and LSTM. The reason for this is that the internal correlation between real stocks is fully taken into account using the knowledge graph, avoiding the limitation of using only stock price data to measure correlation. RCNN can draw on the advantages of both RNN and CNN. The maximum pool extraction of the convolutional layer extracts the best

representation of the input. The recurrent nature of the network captures a greater degree of pre- and post-textual information when learning text data. The accuracy, recall, F1 scores, and other results of the algorithm steadily improve as the training data increases, and we demonstrate the effectiveness of the algorithm. Based on the idea that knowledge graphs can discover implicit relationships between data, an improved research method for analyzing sentiment problems incorporating relevant knowledge graphs is implemented, and the analysis of the algorithm used in the system reveals that by simply applying a recurrent neural network (RNN) classifier for sentiment analysis, it is unable to identify distinguishing phrases that appear in different orders. In contrast, the convolutional layer can fairly identify the ambiguous phrases in the text through the maximum pooling layer. Thus, the convolutional neural network (CNN) can better reflect the context of the word as
Figure 8: Comparison of accuracy rates in sentiment analysis.

compared to RNN. The system thus chooses recurrent convolutional neural network (RCNN) as the sentiment analysis module for sentiment classification. The maximum pool extraction of the convolutional layer extracts the best representation of the input. The recurrent nature of the network will capture the preceding and following textual information in a greater possible way when learning textual representations. The final experimental results show that when the amount of training data is boosted, the accuracy of the prediction results accordingly increases.

Applying the combination of deep recurrent Q networks (DRQN), prioritized experience replay mechanism, sentiment analysis, and knowledge graph to stock investment strategy research, a deep reinforcement learning algorithm PERDRQN based on deep recurrent Q networks (DRQNs) and prioritized experience replay are proposed to perform stock investment strategy research methods. Simulation experiments using deep learning libraries such as TensorFlow are conducted to verify that the algorithm proposed in this chapter can effectively perform the stock investment strategy task. The algorithm uses an end-to-end training model that combines the feature refinement and combination capabilities of deep recurrent convolutional neural networks and the good strategy formulation capabilities of reinforcement learning, which can obtain information about a stock and its company by crawling data on websites and some publicly available datasets, and after processing it through the knowledge graph and using it as input to the RCNN model, the sentiment of the company's stock is output after network processing, and then, this sentiment analysis combined with the stock information is added inside a deep reinforcement learning model to output an investment strategy. The deep recurrent Q network (DRQN) algorithm combines a convolutional neural network and a recurrent neural network to train the target value function compared to previous Q learning-based reinforcement learning algorithms, optimizing the previous Q learning scheme of training through tables or using linear regression, allowing the algorithm to represent a larger space of action states.

5. Conclusions

The machine has certain intelligence after using deep learning and reinforcement learning. In the process of expanding the theory and practice of machine learning, the theory and results of some disciplines have been integrated, including artificial intelligence, psychology, biology, game theory, and cybernetics, and also interact with many disciplines to get some innovative research directions. Reinforcement learning theory has become one of the hot research directions in the artificial intelligence community after years of pioneering development. However, there are still many problems that need to be improved, such as the balance between exploration and exploitation, the long training period, and the "dimensional disaster." Because the previous work is basically gathered in theoretical research, deep reinforcement learning is relatively little applied in financial investment. In this study, we apply the deep reinforcement learning algorithm PERDRQN, which combines the sentiment analysis method of knowledge graph with the deep reinforcement learning method of prioritized experience replay, based on the study of deep reinforcement learning algorithms for stock investment strategies. Then, the technique of prioritized empirical replay is analyzed and its use in combination with DRQN reduces the time required for convergence and gives better results. The algorithm showed better results in the comparison experiments, indicating that the sentiment analysis approach combined with knowledge graphs is helpful for the deep reinforcement learning strategy framework used in this study. In the future, the accuracy, recall, F1 scores, and other results of the algorithm steadily would be improved as the training data increase.

The core of the value of artificial intelligence is to integrate with the real economy and become more dependent on local industries. In the entire artificial intelligence + industry development process, many new changes have appeared. This article mainly studies how to promote regional economy based on smart technology. In the context of rapid economic development, the significance of artificial intelligence and the necessity of regional economic transformation are put forward. The model has designed the national science and technology mechanism framework from the four directions of technology guidance, technology service, technology innovation, and technology balance; following the cultivating ideas from products to innovative industries to innovative intelligent environments, due to the low income elasticity of product demand, technological innovation is mainly based on the dissemination of emerging technologies outside the industry and the lack of coordination between companies under the fiercely competitive market structure; the focus is on promoting the continuous improvement of labor productivity. The experimental results prove that the emerging technology industries of enterprises can promote economic transformation in the era of artificial intelligence, provide a reference for better optimization of industrial innovation and development, and provide methodological support for the government to establish sound emerging technology business models and optimized management methods.

1. Introduction

With the continuous development of computer network technology, artificial intelligence has become a product of technology in the new era. At present, there are many artificial intelligence in life, such as smart TVs, smart phones, and so on, which bring convenience and speed to people's lives. It can be seen that artificial intelligence, a modern technology, has an important impact on people's lives. In artificial intelligence, the application of computer network technology plays an important role. The two influence each other and gradually achieve better development. However, the technical equipment of China's traditional manufacturing industry is relatively backward in general, and the penetration rate of intelligence in traditional manufacturing is low. Traditional manufacturing is still under pressure to adjust structure, reduce production capacity, reduce costs, and increase efficiency, all of which make traditional manufacturing intelligent. Upgrading brings great difficulty.

Artificial intelligence is a modern advanced technological productivity. The application of artificial intelligence technology has brought profound changes in production methods and lifestyles, as well as further liberation of the labor force [1, 2]. The artificial intelligence industry will drive the development of the intelligent economy and will also become a new economic growth point in China in the future. Artificial intelligence technology will become a powerful engine for China's national economic and social development [3, 4]. The artificial intelligence industry will promote the real economy to move towards equipment intelligence, structural optimization, and industrial transformation and quality improvement. At the same time, the evaluation index system of emerging technologies affects

traditional industries from the perspective of integrated innovation based on the mechanism of action refines the dimensions of the impact of emerging technologies on traditional industries, which is a further deepening of existing evaluation research and promotes more focused and targeted evaluation analysis. It enriches the perspective of the evaluation research on the impact of emerging technologies on traditional industries.

Foreign research related to financial support to promote economic growth mainly focuses on the relationship between financial growth and economic growth, and considerable progress has been made. Foreign countries use emerging technologies to strengthen the real economy as an important strategic measure and actively promote comprehensive reform and innovation from manufacturers to innovative systems, from business structures to organizational forms, and from development concepts to business models. Goel believes that traditional industries are still playing an important role in promoting the development of new technology industries [5]. Wright proposed that traditional industries can promote and cultivate emerging industries [6]. Arencibia-Jorge et al. use the benign interaction between traditional industries and emerging industries to achieve "two-wheel drive," which is the key to promoting China's economic growth and ensuring sustainable economic development [7].

In terms of domestic industrial structure, due to the modern technological revolution and the rapid growth of productivity, the industrial structure has gradually moved towards modernization. However, traditional industries use primitive production methods for production; that is, they rely on traditional production technologies, and primitive production technologies particularly rely on directly available resources for production, and the use of labor and capital is inefficient. The rise of emerging technologies contributes to the rise of emerging technology industries and economic growth. The optimization and upgrading of Bychkova's traditional industries can make full use of external factors to develop emerging industries [8]. Harris uses examples of high-tech applications in traditional industries to prove that there is a mutually beneficial relationship between high-tech industries and traditional industries [9].

This paper conducts a longitudinal comparative analysis of the influence of emerging technologies on traditional manufacturing steel in the country and horizontally compares the results of traditional equipment manufacturing and the steel industry; on the basis of clarifying the degree of influence of emerging technologies on traditional industries from the perspective of integrated innovation, corresponding countermeasures and suggestions are put forward. At the same time, electronic interviews were conducted with 4 experts, and the data obtained from the interviews were processed and analyzed. The penetration level of emerging technologies into traditional industries reached 0.420, and the level of absorption and absorption of emerging technologies by traditional industries reached 0.512. Therefore, emerging technology industries have the ability to promote regional economic transformation and upgrading very effectively.

2. Research on the Path of Enterprise's Emerging Technology Industry Promoting Regional Economic Transformation and Upgrading

2.1. Internet of Things. Judging from the current situation, the system structure of the Internet of Things is not complete [10, 11]. As we know, the Internet of Things is divided into three layers: perception layer [12], network layer [9], and application layer [10]. Its structural model is shown in Figure 1.

2.2. Smart Environment. The smart environment is a very interactive system. The environment must be able to perceive people's behavior or situation and be able to accurately read the behavior or situation so as to make judgments to provide the people with corresponding intelligent services [13–15]. Among them, self-perceived mobility and intelligent recognition technology are hot and difficult points of current research. Human-friendly built-in hardware devices, convenient two-way communication mechanism, and security and reliability are one of the most basic technologies for building a smart environment [16, 17]. Due to the complexity of computing components in the environment, many differentiation issues have also been brought about in the design of system applications. In order to protect the differences in the bottom layer, deletion and merging must be performed at a higher level. Standard service description, registration, and inquiry complete a series of customized automated processes at the top of the call and the call, reflecting the functions of the intelligent environment [18, 19].

Smart environment is a new idea and new technology that people put forward in order to make it more convenient for them to serve themselves. Not only must the technical factors be checked, but also personal, cultural, moral, social, and legal factors must be further checked to create a truly intelligent environment [20]. Therefore, the smart environment includes many related industries, including distributed intelligence and data exchange. Distributed intelligence means that ASON realizes the distributed intelligence of the network, that is, the intelligence of network elements, which is embodied in the realization of network topology discovery, route calculation, automatic link configuration, path management and control, and service protection by relying on network elements and recovery functions. Data exchange refers to the process of establishing a temporary interconnection path for data communication between multiple data terminal devices for any two terminal devices.

2.2.1. Related Technology. Intelligent environment technology is the cornerstone of the knowledge search system created in this article, mainly used to solve the problem of knowledge acquisition and integration. The smart environment is essentially a structured semantic network, stored in the form of graphs. The technical fields related to the
Figure 1: Internet of Things system composition diagram.

smart environment are very extensive [21, 22]. Here, the environment-based computers, technologies related to wireless sensors, and activity recognition technologies are analyzed. These three are key areas in the intelligent environment and are closely related to each other: environment-driven computer environment acquisition, modeling, representation processing, and sensor technology are interrelated and closely related. There are many ways to identify activities, and this article uses a method based on sensor activity. The process of reasoning and recognition activities is the upper and lower processing and combined analysis of the environment [23].

2.2.2. Edge Computing in a Smart Environment.
There are usually two ways to create a smart environment: a top-down approach and a bottom-up approach. The top-down construction method is an ontology-based construction method, using highly structured encyclopedias and other sites as data sources, from which the constraints and rules of the ontology are extracted and supplemented in the knowledge base, while the bottom-up construction method is simple [24, 25]. By identifying patterns and formulating rules, and then adding them to the smart environment, the collected data is used to identify entities, attributes, and relationships. Due to the rapid development of the Internet of Things, the popularity of wireless network technology, and the rapid increase in the number of edge network devices, the data generated by advanced devices has not yet been effectively processed. This is mainly reflected in the linear growth of computing power and massive data. The transmission of network edge devices to the central node leads to a sharp increase in network transmission, which leads to network delays. Network acne data includes privacy, and transmission of raw data to host nodes may leak privacy. In edge computing, data requests come from the local area and are (pre)processed locally and then sent to the remote server. Data processing and transmission are bottom-up methods.

2.2.3. Integrated Smart Environment.
In view of the fact that most research results are based on specific data sources and specific methods, and the built-in intelligent environment of the discipline exposes limited breadth and depth, the universal intelligent environment of the discipline based on bibliographic information design integrates the advantages of various tools and accurately reveals the development of the discipline status quo and the realization of multimethod verification for specific problems [26, 27]. A variety of visualization construction methods integrate a single relationship with data sources, such as keyword co-word relationship clustering tree diagram analysis to reflect the macro structure of the subject, and multidimensional scale analysis to reflect the macro structure of the subject.

2.3. Emerging Technologies Affect the Role of Traditional Industries

2.3.1. The Proliferation of Emerging Technologies.
Dissemination of emerging technologies to traditional industries refers to the provision of emerging technologies to potential technology users through certain channels. This proliferation is mainly due to the technological gap between the two parties and the transformative power of traditional industries. At the same time, many external groups are promoting the spreading process, restrictions, and risk factors. It mainly comes from the technological gap between the two sides and the transformation power of traditional industries. At the same time, the diffusion process is affected by many external promotions, constraints, and risk factors. Only when there is a technological gradient between emerging technologies and traditional industries and there are appropriate external conditions to drive them, emerging technologies will diffuse through the market or other intermediaries and transfer to traditional industries, as shown in Figure 2.

2.3.2. Acceptance of Traditional Industries.
When emerging technologies are transferred to traditional industries through the former market or other intermediaries, the effective penetration of emerging technologies will depend on the acceptance and recognition of emerging technologies by traditional industries. The main body of technology acceptance in traditional industries is enterprises, and the research process of evaluating the impact of emerging technologies on traditional industries from the perspective of specific acceptance of integrated innovation is as follows: enterprise decision makers conduct market demand analysis in combination with the market environment, and on this basis, according to the enterprise's own resource conditions and technical capabilities, it decides whether to adopt and which appropriate emerging technologies to adopt to transform the enterprise, so as to achieve the improvement of the technical level, as shown in Figure 3.

2.3.3. Integration of Emerging Technologies and Traditional Industries.
As the latest technology in the current field, emerging technologies have the characteristics of high penetration. With the penetration of emerging technologies in traditional industries, traditional industries will undergo qualitative changes in terms of technological foundation,

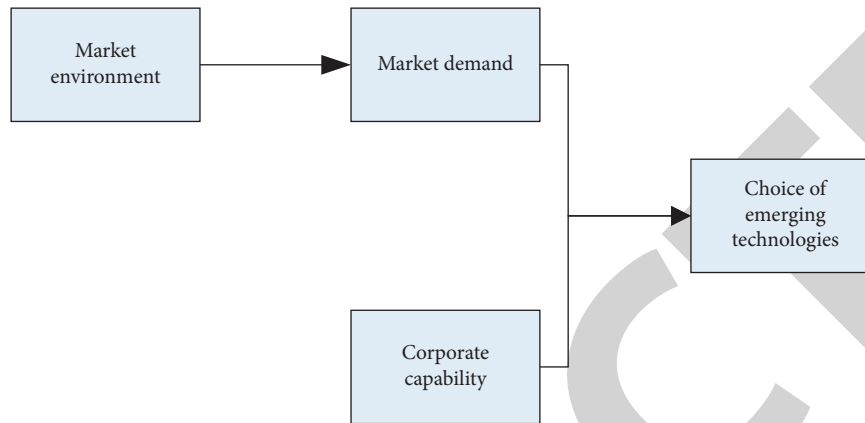
FIGURE 2: Flowchart of the diffusion of emerging technologies to traditional industries.


FIGURE 3: Flowchart of traditional industries' acceptance of new and new technologies.

product structure or overall industrial structure. These changes will form interactions in the external environment. The specific fusion process is shown in Figure 4.

As shown in Figure 4, after traditional industries accept the entry of emerging industries, traditional enterprises start from five major aspects, including products, process equipment, and management methods. Promote the improvement of the technological level of enterprises and realize the upgrading of traditional industries.

2.4. The Relationship between Emerging Technologies and Traditional Industries.

The role of integrated innovation is to promote the integration of technological resources and industrial development. The essence of the role of emerging technologies and traditional industries is to accept, integrate, and integrate emerging technologies from traditional industries, thereby promoting the transformation and upgrading of traditional industries. It can be seen that integrated innovation is an important aspect of industrial development [28, 29]. Therefore, this article explores the relationship between emerging technologies and traditional industries from the perspective of integrated innovation. Through the analysis of the tone, stage, and specific impact of emerging technologies affecting the transformation of traditional industries, the specific relationship between emerging technologies affecting traditional industries is discussed from the perspective of integrated innovation, and the theoretical basis of innovation is discussed theoretically.

The impact of emerging technologies on traditional industries is not only the process of technological progress, but also technological and economic activities. On the one hand, the essence of the transformation of traditional industries from emerging technologies is to gradually

upgrade the industrial structure through the diffusion and penetration of emerging technologies, thereby realizing the progress of the industrial structure and leading technological progress [30]; on the other hand, emerging technologies have also provided great help to the transformation and upgrading of traditional industries. The factors of production are being stabilized, as well as the existing economic organizations' understanding of emerging technologies and their participants. This process can effectively improve the production technology level of traditional industries, increase production efficiency, improve corporate governance, effectively reduce product quality, effectively reduce resource consumption and environmental pollution, eliminate useless production capacity, and maintain efficient production capacity. Only when emerging technologies gradually penetrate into traditional industries, and traditional industries decide to accept them, can the two achieve integration and integration, and diffusion and absorption are deeply embedded in the integration process. Therefore, from the perspective of integrated innovation, the essence of the process of emerging technologies affecting traditional industries is the optimal allocation and synergistic integration of existing production factors of traditional industries and innovative factors of emerging technologies.

The introduction of emerging technologies will penetrate all aspects of traditional industries and then lead to a series of changes in traditional industries, such as business philosophy, production management, employment, and systems. It is a process of coordination and integration of various themes or elements, reflecting the characteristics of the system. The impact of technology on traditional industries not only involves the application of new technologies and new processes, but also includes enhancing traditional industries' awareness of concepts, management, markets, and
FIGURE 4: Flowchart of integration of emerging technologies and traditional industries.

technological innovation through technology penetration; marketing is one of them. Basically, according to the market environment, it can play its potential from emerging technologies and the sources of emerging technologies and play a role in traditional industries. The impact of emerging technologies on traditional industries is also in line with the basic laws of market economy; the process of emerging technologies operating in traditional industries is a technological and economic activity. The fundamental purpose of using emerging technologies to operate in traditional industries is to promote the transformation and upgrading of traditional industries and optimize production capacity through structural adjustments, thereby stimulating economic growth. It can be regarded as an investment and development behavior, and it is a feature of high technology. In contrast, the biggest feature of emerging technologies is "Xing," which means that they are emerging and coming into effect. In other words, the usefulness of emerging technologies usually takes some time. The use of emerging technologies to transform traditional industries will be a long-term process of change. The absorption of emerging technologies by traditional industries will not only be based on the immediate transformation of emerging technologies, but will also make full use of them. The potential energy of emerging technologies is improving and adapting to the industry.

3. Experimental Research on the Path of Enterprise's Emerging Technology Industry Promoting Regional Economic Transformation and Upgrading in Intelligent Environment

3.1. Test Subject.
In this study, four experts who are most interested in innovation theory or industrial development were invited to evaluate indicators at all levels of the integration and integration of emerging technologies and traditional industries. Experts include 2 X University professors and 2 bosses who have successfully transformed design and manufacturing enterprises. The scoring format is completed through electronic interviews. By constructing a questionnaire about the relationship between evaluation indicators of emerging technologies affecting traditional industries from the perspective of comprehensive innovation, it provides a data basis for analytic hierarchy process used to obtain the weight of each indicator.

3.2. To Gather Data.
According to the expert questionnaire survey, calculate the average value of the expert data, a matrix X can be obtained, which needs to meet $a_{ij} > 0$, $a_{ij} = 1/a_{ji}$, $a_{ii} = 1$, where $i, j = 1, 2, \ldots, n$.

$$X = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{bmatrix}. \tag{1}$$

The square root method is used to measure the weight of each index. The specific formula is shown as follows:

$$h_i = \sqrt[n]{\prod_{i=n}^{n} a_{ij}}. \tag{2}$$

The weights w_i of the possible indicators are as follows:

$$w_i = \frac{h_i}{\sum_{i=1}^{n} h_i}. \tag{3}$$

The calculated indicator weight is only lower than the indicator weight of each standard level. The weight of each indicator in the entire indicator system should be further converted according to the dimensions of the standard level.

3.3. Experiment Procedure

3.3.1. Experiment Preparation Stage.
By reviewing relevant literature, construct a questionnaire on the relationship between the evaluation indicators of emerging technologies affecting traditional industries so that the volunteers can perform the next step in the trial phase.

3.3.2. Experimental Stage.
Interviews were conducted with 4 experts via telephone voice to obtain experimental data. And these data were organized for the next step to calculate the data, and analyze the conclusions of the next step through these results.

3.3.3. End of Experiment.
Discuss and analyze the data results obtained in the experimental stage, combine some knowledge theories and horizontally compare the results of traditional equipment manufacturing and steel industry, and put forward corresponding suggestions on the basis of clarifying the impact of emerging technologies on traditional

industries from the perspective of integrated innovation countermeasures and suggestions.

3.4. Data Processing.
By sorting out the scoring tables filled out by 4 experts, 4 judgment matrices for the integration effect of emerging technologies and traditional industries were calculated. The judgment matrix of the second-level index is u; the judgment matrix of the third-level index is u_1. Since this paper has a three-level index system, it is necessary to carry out a multilevel fuzzy comprehensive evaluation. That is, the first-level comprehensive evaluation is carried out on the first-level scope, and then the second-level comprehensive evaluation is carried out according to the evaluation results, and so on.

$$u = \begin{bmatrix} 1 & 0.9 & 3 \\ 1 & 1 & 5 \\ 0.3 & 0.2 & 1 \end{bmatrix},$$

$$u_1 = \begin{bmatrix} 1 & 0.78 \\ 1/0.78 & 1 \end{bmatrix}. \tag{4}$$

The statistical data used in this article has a different unit dimension for each index data, so the corresponding calculation cannot be directly performed in the overall evaluation. First of all, index data must be processed without dimension, that is, normalization. The common method of data standardization is usually min-max standardization. This method can evenly distribute the index data to the range [0–1]. The indicators selected in this paper have practical significance and are all positive indicators, so it is more suitable to use this method for dimensionlessization. The calculation formula of this method is shown in

$$x = \frac{x - \min}{\max - \min}. \tag{5}$$

The specific formula is as follows:
Large trapezoidal distribution:

$$r(x) = \frac{x - c}{d - c}, \quad c < x < d. \tag{6}$$

Small trapezoidal distribution:

$$r(x) = \frac{b - x}{x - a}, \quad a < x < b. \tag{7}$$

For the ideal score value, it can usually be set as the middle value of each interval. This paper divides the evaluation grades into five grades, and the index data after normalization processing all fall in the [0–1] interval.

3.5. Clustering Algorithm Based on Intelligent Technology.
Clustering originated from data taxonomy, so clustering and classification have a certain connection and similarity, but there is still a certain difference from classification. The clustering algorithm is shown in Figure 5.

As shown in Figure 5, it can be seen that the essence of clustering is not knowing the category or other prior knowledge of each sample in a batch of samples in advance.

3.5.1. Cohesive Hierarchical Clustering Method.
Contrary to the split hierarchical clustering method, the agglomerative hierarchical clustering method first treats each object as a class and then aggregates these nodes in turn to form the nodes of the upper level tree until all the nodes are merged into one large category, or until a termination condition is reached, as shown in Figure 6.

As shown in Figure 6, let the random matrix be W, and let $\lim W^m$ be the primitive random matrix of $W = \lim W^m = \begin{bmatrix} c^\infty & 0 \\ r^\infty & 0 \end{bmatrix}$; then, the following matrix is a stable random matrix as follows:

$$W = \lim W^m = \begin{bmatrix} c^\infty & 0 \\ r^\infty & 0 \end{bmatrix}. \tag{8}$$

Suppose a set of samples is a_i, and the sample has n features; then, the sample vector is

$$a_i = \{a_1, a_2, \ldots a_n\}. \tag{9}$$

Taking Euclidean distance as the distance between the sample and the cluster center, the process of minimizing the transition of the clustering process is given by

$$f(a, b) = \sum_{j=1}^{d} u_{ij}. \tag{10}$$

Finding the smallest point (a, b) in formula (10), Euclidean distance is

$$u_i = \frac{\sum_{j=1}^{d} u_{ij} * a^i}{\sum_{j=1}^{d} u_{ij}}. \tag{11}$$

The cluster center u_{ij} of the class is

$$u_{ij} = \frac{1}{\sum_{i=1}^{c} \left(2/d_{ij}\right)^2} * \left(\frac{2}{d_{ij}}\right)^2. \tag{12}$$

The clustering feature tree is a highly balanced tree that is used to store the feature information of the cluster, and it occupies a small space and can be stored in the memory, thereby improving the clustering speed and scalability of the algorithm on large data sets, as shown in Figure 7.

As shown in Figure 7, the algorithm is mainly divided into two stages: the first stage uses hierarchical clustering; after meeting certain requirements, other division methods are used for macro-clustering processing.

It is assumed that the current optimal position of the entire fish school is to speed up the search speed of the algorithm. In the rear-end collision operation, the global optimal position at this moment is used to replace the optimal position of the individual fish neighborhood.

$$a_i = a_i + \text{rand}(\text{step}) \frac{a_{g\text{best}} - a_i}{\left\| a_{g\text{best}} - a_i \right\|}, \tag{13}$$

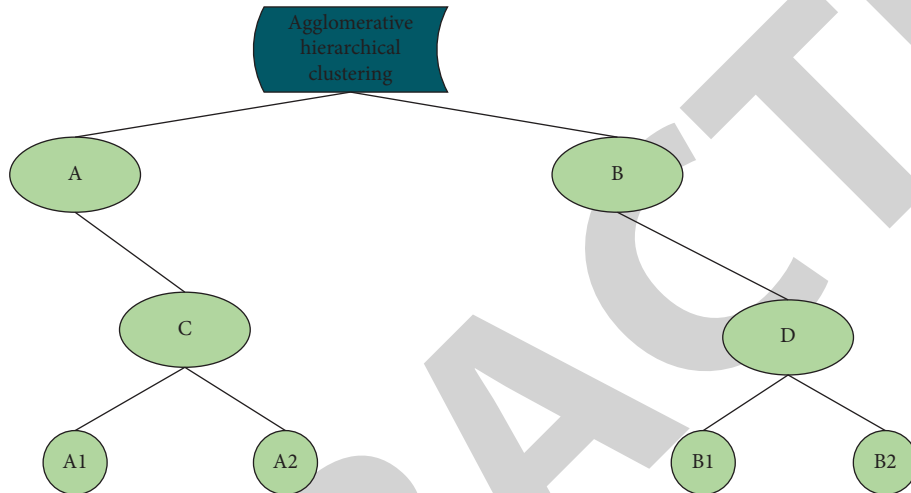
where $a_{g\text{best}}$ represents the optimal position of the entire school of fish.
FIGURE 5: Clustering algorithm.


FIGURE 6: Agglomerative hierarchical clustering method.
FIGURE 7: Clustering feature tree.

Then, the access sequence length weight can be calculated as

$$lw_i = 1 - \left| \frac{len_i - len}{len_{max} - len} \right|. \tag{14}$$

Taking lw_i as a penalty factor means that the closer the length of the access sequence is to the length of the average access sequence, the larger the value of the factor is, and vice versa, the smaller the value of the factor is.

3.6. *Data Preprocessing Based on Smart Technology.* Preprocessing is the most critical link to ensure that the correct and useful patterns can be discovered efficiently and quickly. The function of this module is to process log files in different types of formats and convert them into data in a unified format that the system can handle; at the same time, it is necessary to complete the cleanup of log data and the identification of access sequences, as shown in Figure 8.
Figure 8: Data preprocessing.

As shown in Figure 8, in this general model of intelligent computing, the key issue is to study how simple individuals can form high-level systems with complex intelligent behaviors under the guidance of simple interaction rules, as shown in Figure 9.

As shown in Figure 9, a complex computing task is completed by a large number of nonsimultaneous computing behaviors of computing units; all the characteristics of the units performing these tasks 3 are unknown to other units and even the system itself; the behavior of a large number of units is determined based on the fact that they are based on incomplete knowledge of the system and delayed or even contradictory information.

4. An Experimental Analysis of the Path of Enterprises' Emerging Technology Industry in Promoting Regional Economic Transformation and Upgrading in an Intelligent Environment

4.1. Analysis of the Weight of Emerging Technology Industry in Promoting the Transformation and Upgrading of Regional Economy. According to the formula of calculating the index weight by the analytic hierarchy process, the weight of the first-level index can be obtained, and the reliability CR = 0.022 is less than 0.05, so the weight distribution meets the requirements. Furthermore, the weight of each secondary indicator can be obtained. The reliability CR = 0.013 is also less than 0.05, and the weight distribution also meets the requirements. Therefore, the weight of each three-level

indicator can be obtained and converted into the overall indicator weight. The impact of emerging technologies on traditional industries is shown. The total weight of the impact evaluation is shown in Table 1.

It can be seen from Table 1 that the data obtained from the experiment is processed and analyzed. The impact level of emerging technologies on traditional industries reaches 0.420, and the external support level is only 0.114, which can make the traditional industries absorb emerging technologies as high as 0.512, so the emerging technology industries are promoted. The transformation and upgrading of the regional economy has been very effective.

4.2. Comparative Analysis of Indicators within and between Industries over the Years

4.2.1. Comparative Analysis within the Industry. Figure 10 shows the impact level of emerging technologies on the traditional equipment manufacturing industry and the steel industry, the level of digestion and absorption of traditional industries, the level of external support, and the effect of integration from 2015 to 2020. On this basis, corresponding countermeasures and suggestions are put forward, as shown in Figure 10.

It can be seen from Figure 5 that, as time goes by, the integration and integration of emerging technologies and traditional equipment manufacturing has continued to increase. First, the penetration level of emerging technologies in the traditional equipment industry is on the rise, reaching the highest level by 2019. The main reason is that the traditional equipment industry has continuously strengthened
FIGURE 9: Intelligent computing theoretical model framework.

TABLE 1: Weight distribution of evaluation index system.

Level indicator	Secondary indicators	Level-three indicators	Weights
The effect of the integration of emerging technologies and traditional industries	The level of influence of emerging technologies on traditional 0.420	Emerging technology introduction expenditure 0.132	0.372
		Technology and absorption expenditure 0.113	0.238
		Technical transformation expenditure 0.063	0.136
	Traditional industries' digestion level of emerging technologies 0.512	New product sales revenue 0.217	0.367
		The total profit 0.057	0.112
		Number of new product development projects 0.118	0.210
	External support level 0.125	Funds for scientific and technological activities 0.050	0.429
		Tax deduction for technology development 0.057	0.547

the introduction and absorption of new technologies in recent years. Under the influence of new technologies, there is a steady-increase investment in existing technology transformation and R&D.

4.2.2. Comparative Analysis between Industries. Through internal comparison, we can discover various reasons or factors of how emerging technologies in industry effectively affect traditional industries. In order to further analyze the common factors of the impact of emerging technologies on different traditional industries, it is also necessary to conduct a horizontal comparison and analysis of the evaluation results of different industries to find common points and make

more comprehensive recommendations, as shown in Figure 11.

It can be seen from Figure 6 that from the perspective of the penetration level of emerging technologies in the traditional equipment industry and the steel industry, the introduction of emerging technologies in the steel industry was earlier and led the traditional equipment industry before 2015. Since 2015, the traditional equipment industry has been stable. However, the steel industry has experienced a shocking decline. The steel industry is gradually surpassing the traditional equipment manufacturing industry. The traditional equipment industry is more receptive to emerging technologies, and the ability to raise funds from all aspects is becoming stronger.
Figure 10: Comparative analysis of various indicators of traditional equipment manufacturing.
Figure 11: Comparison of penetration levels of emerging technologies in the two major industries.

After a comprehensive analysis of the results, we found that the evaluation results of the integration and fusion of traditional equipment manufacturing and steel industry with emerging technologies are all on the rise, which shows that the integration and integration of emerging technologies and traditional industries is increasing. The bad gradually turned into better or even very good. This also reflects from the side that my country's traditional equipment manufacturing industry and steel industry have effectively used emerging technologies to promote the gradual innovation and development of the industry.

4.3. Analysis of Hausman Test Method

4.3.1. LM Detection Analysis. This document uses the least squares method to estimate the usual table data model, which does not consider the spatial correlation, and then verifies the spatial correlation of the model residuals. The main test methods are Lmsar, Lmerr, R-Lmsar, R-Lmerr,

and so on. If Lmsar is better than Lmerr, and R-Lmsar is important, and Rt-Lmerr is not important, the spatial delay table data model is better than the spatial error table data model. See Figure 12.

According to the results of the LM test, determine whether the spatial measurement model should use fixed effects or random effects. The result of LM test passed the significance test of 0.005. Therefore, this article will deal with fixed-effect time models, fixed-space models, and dual fixed-space and time models. The estimated results are shown in Table 2.

Combining the results of Figure 7 with the results of Table 2, it can be seen that the coefficient of determination and the adjusted coefficient of determination of the spatial panel regression results are significantly better than the ordinary panel regression results, which indicates that the spatial table data model is effective in affecting coupling and coupling. Factors have stronger explanatory power. Commonly used tabular data model analysis industry and traditional industry.

4.3.2. Unit Root Risk Analysis. The test methods are Lmsar, Lmerr, R-Lmsar, and R-Lmerr through natural logarithmic transformation to obtain their ADF statistic values at 1% critical value, 5% critical value, and 10% critical value and perform a unit root test on it as shown in Figure 13.

It is easier to obtain ADF test statistics and the corresponding critical values of Lmsar and Lmerr sequences. When the significance level is 1%, the value of statistical control is greater than the critical value, so the Lmsar and Lmerr sequences are both nonstatic sequences, and both are 1. The level differences of R-Lmsar and R-Lmerr tests are both smaller than the corresponding critical value. It can be seen that R-Lmsar and R-Lmerr are stable. Therefore, it can be determined that the root unit roots of Lmsar and Lmerr are a series of first-order integer monosyllables, satisfying the hypothesis of coupling test.
Figure 12: LM test results.

Table 2: The results of the LM test.

Variable	Fixed effect		
	Fixed time	Space fixed	Fixed time and space
Lmsar	0.187	0.176	0.148
Lmerr	3.122	0.469	0.332
R-Lmsar	0.134	0.114	0.085
R-Lmerr	3.117	0.452	0.324
Figure 13: ADF inspection result graph's approximate value.

5. Conclusion

This article mainly expounds the concept of intelligent computing technology and regional economic transformation. In the method part, it proposes a clustering algorithm based on artificial intelligence technology and uses the clustering algorithm to analyze how to play its role in promoting regional economic transformation. As an important subject of development economics, regional economy has strict connotations: how to effectively use human, material, and financial resources to achieve optimal development in a geographical area with basically similar natural environment and humanistic conditions. It is indispensable to constantly update. The research results show that the intelligent computing technology industry has a strong impact on the domestic regional economy in both the short term and the long term, and cities, especially megacities, have further improved the production automation and production. The degree of intelligence, and at the same time, more and more capital replacement labor, has promoted the increase in total factor productivity and promoted the high-quality development of the regional economy; the vigorous development of the domestic regional economy has promoted the sound development of intelligent computing technology, but the intelligent computing technology has further expanded regional economic development differences. Finally, in order to promote intelligent computing technology to promote the high-quality development of regional economy, it is proposed to further create a good innovation environment for the development of intelligent computing technology.

The influence of the integration of emerging technologies with China's traditional arms industry and steel industry is steadily increasing every year. This shows that from the perspective of integrated innovation, the impact of emerging technologies on Chinese traditional industries is increasing every year, which is consistent with the emergence of emerging technologies. Traditional industries have relatively low direct consumption rates and overall consumption rates for strategic emerging industries, while consumption rates for new energy, new materials and latest equipment industries are relatively high. For the new generation of information technology, the consumption rate of organic, energy-saving, and environmentally friendly, and the new energy automobile industry is very low.

Correspondence should be addressed to Tianxin Hua; huatx@jlnu.edu.cn

With the rapid development of computer network technology, the concept of "Internet +" has become more and more popular in recent years. The combination of the Internet and finance has particularly attracted people's attention, and the operating modes of many industries have also changed. Since the use of Internet technology can achieve data sharing and information exchange, the "Internet + Finance" model has broken the barriers of information asymmetry in the financial sector in the past and has made great contributions to China's multiple improvements. The financial market is very important to China's economic development. The identification of the ID function of the wireless sensor network is susceptible to interference and the identification accuracy is reduced. We propose an adaptive identification feature recognition algorithm based on an improved minimum gray tree. After calculating the similarity, the nearest neighbor matching algorithm is directly used to obtain the minimum matching cost corresponding to the wireless sensor network registration that is regarded as the recognized identity so as to realize the identity function adaptive recognition. In this regard, the simulation results show that the proposed algorithm has high recognition accuracy. With the pace of financial innovation, financial institutions have achieved rapid development on the basis of Internet service platforms. At the same time, as the core of preventing money laundering activities, financial institutions are also facing many issues in identifying "customers" in their work. This article analyzes the main content, implementation effects, and difficulty of customer identification in financial institutions and proposes relevant improvement plans.

1. Introduction

First, the recognition based on the characteristics of the action requires high-precision recognition of the action. With the increasing popularity of wireless object networks and the continuous development of wearable sensors, the value of building sensor-based human behavior and identity recognition systems is getting higher and higher [1]. With the rapid development of information globalization in today's society, the digitization and ambiguity of user ID caused by the Internet will lead to serious disclosure of personal information, which will undoubtedly bring new challenges to identification and technology. The security authentication methods currently in use include combined authentication of user names and passwords, authentication of special authentication objects, and so on [2]. These authentication methods are easy to be stolen or imitated due to

excessive human factors in the authentication process and cannot achieve high-level and high-precision security prevention and control [3]. Due to the convenience of storage such as password authentication and identification technology, users often use passwords and other reasons are relatively simple. There are illegal uses of general username and password combinations, a Bluetooth database has been established, and general IDs have been collected on a large scale. The combination of authenticated username and password has a serious impact on personal privacy and information security [4]. Although it is difficult to avoid the danger due to objective factors, it can be eliminated by the authentication method using biometric properties. Because it is difficult to change the user's biometric characteristics, it is more difficult to imitate, so the possibility of theft is very small. It is now widely used in government, military, banks, welfare companies, social security bureaus, e-commerce, and

other fields [5]. The Internet finance model has been favored and valued by more and more users and enterprises for its advantages of high efficiency, low threshold, convenience, and low cost [6]. It is booming. Various Internet finance platforms are growing exponentially, giving China's financial industry a boost [7]. Development has brought new opportunities. However, the development of new things often has two sides, and the rapid development of Internet financial platforms has led to a saturation trend in the market. Therefore, in order to seize the opportunity in the fiercely competitive Internet financial market, major platforms often invest heavily in various lucrative activities to attract users. Summarizing the previous literature discussion and empirical research, we propose specific targeted anti-fraud prevention and control countermeasures for Internet financial platform users from the three directions of improving the level of Internet financial supervision, using financial technology to combat fraud, and building industry moral order [8]. Internet platforms provide prevention and control suggestions to reduce company losses and provide more ideas and methods for Internet financial platforms to combat fraud [9].

2. Related Works

According to the literature, the identification of mobile phone users based on biometrics as well as the identification of the use of passwords and patterns is not appropriate [10]. Therefore, the focus of the research is to be able to simply access and recognize the mobile phone sensor data. In order to solve the problem of low stability of dynamic matching recognition, the literature proposes a combination of the D-S evidence theory and mobile phone 3D gesture sensor data [11]. Related researchers have proposed a method called OpenSame to collect data from 200 experimenters in a total of 389,373 tuples [12]. In order to perform implicit authentication of mobile phone users in a sustainable manner without interrupting the normal use of mobile phones, Lee et al. proposed a system based on multiple sensors [13]. Experimental results show that this method is more efficient, the training time is less than 10 seconds, and the verification time is less than 20 seconds. The literature proposes that a platform that provides loans to applicants through the Internet is called an online lending platform [14]. The literature proposes that traditional financial services rely on Internet technology to operate, which can be understood as "finance + Internet".

3. Research and Implementation of User Identity Recognition System in Wireless Sensor Network

3.1. Biometric Technology for Wireless Sensor Network Users. With the rapid development of information globalization in today's society, electronic equipment has become an indispensable part of scientific research and daily life. These devices provide many convenient functions through network interconnection, but the digitization and invisibility of user ID caused by network information is a serious privacy leakage problem [15]. As a result, the requirements for ID recognition

and verification technology have become higher [16]. Among them, the more commonly used methods are security authentication methods including user name and password combined authentication, user-specific object authentication, PIN code authentication, and so on. These authentication methods are easy to be stolen or imitated due to excessive human participation factors and cannot achieve a high degree of security prevention and control. It is very difficult to avoid the dangers brought about by these objective factors [17]. At the same time, some studies have shown that the user's biometric function is difficult to change, imitation and tampering are not easy, fingerprint recognition, facial recognition, iris recognition, movement feature recognition, etc., are very unlikely to be stolen. Figure 1 shows the application process of high-end biometric technology that combines voice and skull fingerprints.

Traditional identification methods usually use identification items (striped codes, QR codes, magnetic cards, keys, etc.) and identification knowledge (passwords, etc.). Because the detection is dependent on foreign objects, if the identification items and identification knowledge are stolen or forgotten, these identities can be easily deceived or replaced by others. Because the biological characteristics are not easy to forget, the anticounterfeiting performance is good, and it is not easy to be tampered with and theft. It can be used at any time by taking advantage of the "portability." The characteristics of the human body are inherently unique to biology. Compared with traditional methods, biometric technology has improved security, privacy, and convenience because keys cannot be copied, stolen, or forgotten. At present, products related to biometric technology are realized through the latest computing technology, combined with the security surveillance system, to realize automatic ID identification and personal information management. According to the current statistical results of the International Biometric Group (IBG), the existing biometric technology is mainly divided into two applications: physiological characteristics and action characteristics, most of which are identification applications that use the characteristics of human physiology. For example, fingerprint recognition, facial recognition, and iris recognition as well as biometric technology based on user behavior characteristics, have multiple applications such as handwriting recognition, voice recognition, gesture recognition, and walking recognition. The indexes of these technologies are shown in Table 1. The biometric method based on action characteristics has the highest safety level and accuracy at the same equipment cost level, high convenience and stability, and low machine cost requirements. Therefore, it has become a new trend in the research field to use the user's behavior characteristics to authenticate the ID of the biometric technology and solve the traditional identification method in the process of vulnerability authentication.

3.2. Visual Sensor Network User Identification Algorithm

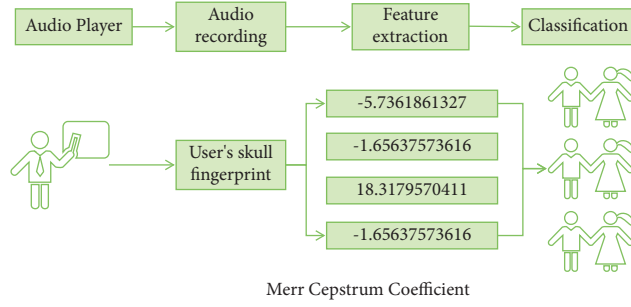
3.2.1. Self-Adaptive Recognition Algorithm for Identity Features. The target area environment is defined as a rectangle, and the grid lines are divided into m rows and n


Figure 1: High-end biometric technology using a combination of voice and skull fingerprints.

Table 1: Comparison of various biometric technology indicators.

Biometric technology	Convenience	Accuracy	Security level	Stability	Identify equipment cost
Fingerprint recognition	Higher	High	Medium	Higher	Medium
Face recognition	Extremely high	High	High	Higher	Medium
Speech recognition	High	Medium	Higher	Medium	Lower
Behavior feature recognition	Higher	Higher	Higher	Higher	Medium

columns. According to the corresponding matrix area detection requirements, the corresponding area detection matrix refers to the expansion matrix of all sensors. Define the corresponding restriction matrix suitable for the deployment position of the sensor. By analyzing the number and depth of the recognizable features of the face, the correlation level between the faces can be determined. In this paper, the pixel statistics iterative method is used, and the expression (1) is used to obtain the recognizable average offset vector of the face.

$$S_k(x) = \frac{\sum_{i=1}^{q} E(x_i - x/k)s(x_i)}{\sum_{i=1}^{q} E(x_i - x/k)s(x_i)} - x. \tag{1}$$

After the average offset feature vector of the face is extracted, in order to further improve the effect of identity recognition in the visual sensor network, it is necessary to perform gray-scale processing on the obtained image and apply it to the adaptive recognition of identity features. The specific steps are as follows:

$$\begin{aligned} g(x, y) &= T[f(x, y)] \\ \text{or } D' &= T(D). \end{aligned} \tag{2}$$

Assuming that the gray histogram distribution of the recognized original image is described by $P(x)$, then (2) can

be substituted into $P(x)$ and the gray of the original image can be converted using

$$y = g(x, y) = \frac{1}{c} \int_{x_0}^{x} P(x) dx . \tag{3}$$

The original image after gray-scale conversion was assumed to has a gray level of L and a resolution of $M \times N$. The gray level constant c calculated is as follows:.

$$c = \frac{M \times N}{L - 1}. \tag{4}$$

By substituting (4) into (3) and using (5) to obtain the histogram equalization function, the gray-scale distribution of the image can be made uniform, and the histogram equalization process can be realized.

$$y = \text{INT}\left[\frac{1}{c} \sum_{x_0}^{x} P(x)\right] = \text{INT}\left[\frac{(L-1)\sum_{x_0}^{x} P(x)}{M \times N}\right]. \tag{5}$$

First, a cost function for each gray-level pair corresponding to two images was defined, and the degree of consistency between the gray level at the position y and the gray level at the same gray level was described. Formula (6) is used to explain that the function is expressed as

$$C_p(y) = (1 - \alpha) \cdot \min(d_{iut}(y), \tau_1) + \alpha \cdot \min(d_{Fan}(y), \tau_2),$$

$$d_{\text{int}}(y) = \xi \cdot \frac{\sum_{\delta \in \Omega}\left[(I(y + \delta) - \overline{I}(y)) - (I'(y + \delta) - \overline{I'}(y))\right]^2 \times C_p(y)}{\sum_{\delta \in \Omega}(I(y + \delta) - \overline{I}(y))^2 + \sum_{\delta \in \Omega}(I'(y + \delta) - \overline{I'}(y))^2}, \tag{6}$$

$$d_{sra}(y) = \nabla I'(y) - \nabla I(y) \times C_p(y).$$

In this paper, $L(x, y)$ is used to represent the distance between two nodes (pixels) on the minimum gray tree (x and y), that is, the sum of the weights of the edges connected to the pixels. When the distance between two nodes in the minimum gray level difference tree is very close, the similarity of the corresponding two pixels will increase. On the contrary, if the distance between two nodes of the minimum gray level tree is very far, the similarity of the corresponding two pixels is very small. According to the abovementioned principle, formula (7) is used to calculate the similarity between two pixels.

$$S(x, y) = S(y, x) = \exp(-L(x, y)). \tag{7}$$

Regarding the structure of the minimum gray difference tree, the cost function previously defined for each node (pixel) is expanded to a cost function that converges to the entire tree $T(x)$ represented by

$$C_T(x) = \sum_{v \in F(x)} S(x, v) C_q(v). \tag{8}$$

Similarly, this article uses $C_{ST}(x)$ to describe the total convergence cost in the subtree $ST(x)$ with pixel x as the root node. At this time, the parent node $Q(x)$ of the node is as follows:

$$
\begin{aligned}
C_{ST}(x) &= \sum_{v \in ST(x)} S(x, v) C_q(v) \\
&= C_q(x) + \sum_{v' \in ST(x)} S(x, v') C_q(v'') \\
&= C_q(x) + \sum_{v' \in ST(x)} S(x, v') S(v', v'') C_q(v'') \\
&= C_q(x) + \sum_{Q(v')=x} S(x, v') \sum_{v' \in ST(v')} S(v', v'') C_q(v'') \\
&= C_q(x) + \sum_{Q(v')=x} S(x, v') C_{ST}(v').
\end{aligned}
\tag{9}
$$

The parent node of the subtree is used to perform line-by-line design for each layer, and formula (10) is used to establish the minimum gray-scale tree model.

$$C_{ST}(x) = C_q(x) + \sum_{Q(v')=x} S(x, v') C_{ST}(v'). \tag{10}$$

According to the matching cost calculation, the matching cost of the entire recognized image (size H•V) is obtained by adding up and normalizing at the same time, and finally, the matching cost (MC) of the image and the similarity of the two images are obtained.

$$MC(I, I') = \sum_h \sum_w C_T \frac{(x)}{(h \cdot w)}. \tag{11}$$

3.2.2. Support Vector Machine. The basic idea of a support vector machine (SVM) is to divide the data correctly. Therefore, important parameters such as the penalty

coefficient C and the kernel width γ of the kernel function must be set to appropriate values before applying actual problems. The penalty factor C plays an important role in minimizing fitting errors and balancing the complexity of the model. In the traditional method, these parameters are processed according to the grid search and the fastest descent method. However, these methods can be simply classified as local optimal solutions. In recent years, several meta-heuristic search algorithms based on Biological Hughstick have appeared. It is easier to find the best global solution than the traditional methods mentioned above. Based on the above analysis, an improved gray wolf optimization algorithm is proposed to optimize the selection of SVM model parameters. This method is suitable for the problem of crop lack of diagnosis.

In the sample space, the hyperplane of the sample can be divided by a linear equation.

$$w^T x + b = 0. \tag{12}$$

The support vector is constrained to be correct. That is, the support vector satisfies the following conditions.

$$y_i(w^T x_i + b) - 1 = 0. \tag{13}$$

Corresponding to the function interval, the geometric interval has better properties. The geometric interval of the sample points is defined as

$$\gamma_i = y_i \left(\frac{w^T}{\|w\|} x_i + \frac{b}{\|w\|} \right). \tag{14}$$

The geometric interval of the entire training sample set is defined as the minimum value of the geometric interval of all sample points.

$$\gamma = \min_{i=1,\dots,N} \gamma_i. \tag{15}$$

This is regarded as the original optimization problem, the Lagrangian pairing is applied, and the Lagrangian multiplier is added under the constraints of the equation. Therefore, the Lagrangian function of this problem can be expressed as follows:

$$L(w, b, \alpha) = \frac{1}{2} \|w\|^2 - \sum_{i=1}^n \alpha_i \left(y_i (w^T x_i + b) - 1 \right). \tag{16}$$

When all constraints are met, there are

$$\theta(w) = \frac{1}{2} \|w\|^2. \tag{17}$$

In other words, Equation (17) constitutes the basic form of SVM. Therefore, if satisfying all constraints, $\theta(w)$ is the same as direct minimization, and the objective function can be expressed as follows:

$$\min_{w,b} \theta(w) = \min_{w,b} \max_{\alpha_i \geq 0} L(w, b, \alpha) = p* \tag{18}$$

Swap the positions of the minimum and maximum functions to obtain the following information:

$$\max_{\alpha_i \geq 0} \min_{w,b} L(w, b, \alpha) = d*. \tag{19}$$

The conditions of the Lagrangian multiplier method was satisfied, and the partial derivative function of each component was taken, when the value is 0:

$$\frac{\partial L}{\partial w} = 0 \Rightarrow w = \sum_{i=1}^{n} \alpha_i y_i x_i,$$

$$\frac{\partial L}{\partial b} = 0 \Rightarrow \sum_{i=1}^{n} \alpha_i y_i = 0. \tag{20}$$

As shown in (21), the parameters w and b were deleted, and only the problem was converted into a variable.

$$\max_{w,b,\alpha} L(w, b, \alpha) = \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \alpha_i \alpha_j y_i y_j x_i x_j. \tag{21}$$

3.3. Wireless Sensor Network Data Collection and Processing

3.3.1. Collection of Geometric Features of Human Faces.
The core function of the system is the display of sensor information, and it is necessary to design a table for initial storage of data. SQLSERVER was choosen as a stable and reliable high-performance database management system because it has a large-capacity data storage system, a variety of data, and long-term storage time period characteristics. The design of the data table must be reasonable and comprehensive, the image of each person in the neutral facial image was registered to the visual sensor network, and the other three representation variables and three illumination variables were used as the detection image set. The collected functions are shown in Table 2.

After obtaining the correct geometric features of the face, it is necessary to collect the geometric features of various facial expressions. The detailed expression conversion is shown in Table 3.

3.3.2. Some Features Used in Gait Recognition.
Mark Nixon, a professor of electrical engineering and computer science at the University of Southampton in the United Kingdom, found that the way people walk is fundamentally different. There are subtle aspects in muscle strength, flexibility of tendons, length and density of bones, vision, and damage to muscles and bones. Difference: the walking process of a normal adult is based on the regular movement of taking the left foot one step forward and the right foot one step forward, which is called the complete walking cycle. In this chapter, it is divided into several short periods according to the adjacent minimum value on the Y axis of the acceleration sensor, so that it can easily determine the walking period corresponding to the data. According to statistics, the average time of a walking cycle is 1 to 1.5 seconds. These are based on complete walking time. The main characteristics considered are shown in Table 4.

TABLE 2: Geometric features of standard human faces.

Feature	Geometric characteristics	Measurements
F1	Inside and outside eye point width/cm	3.9
F2	Distance between inner eye points/cm	4.2
F3	Outer eye point interval/cm	10.3
F4	Height of nose/cm	1.4
F5	Nose tip angle of left and right wings	116°
F6	Eye point and nose angle in left and right	32°
F7	Nose volume/cm^3	7.9

TABLE 3: Acquisition of geometric characteristics of the 3D face model.

Feature	Smile	Frustrated	Pouting	Bulging
△F1/cm	0.9	1.5	0.2	0.2
△F2/cm	0.5	1.8	0.3	0.3
△F3/cm	3.5	2.6	0.4	0.3
△F4/cm	0.6	0.3	0	0
△F5	6°	5°	0	0
△F6	4°	10°	2°	4°
△F7	25°	8°	6°	5°
△F8	45°	26°	25°	25°
△F9/cm^3	4	2.6	0	0
Geometric similarity	0.58	0.45	0.60	0.55
Relevance similarity	0.64	0.71	0.63	0.59

3.3.3. Synchronization.
In theory, when the sampling frequency of different sensors is set to the same, the data needs to be collected at the same time. In other words, the time stamps of the sampling points are exactly the same. However, in actual situations, even if the same smartphone is set to the same sampling frequency, the returned sensor data will have a different sampling time. Therefore, in order to avoid the time difference between the same frame of data intercepted according to the length of different sensors, it is necessary to synchronize the original sensor data. This process is shown in Figure 2.

3.4. Simulation Experiment Results and Analysis

3.4.1. Evaluation Index.
According to the definition of the object problem, the user identification of the smartphone belongs to multiple classification problems. The model classification performance evaluation index proposed in this paper uses accuracy, F1 value, ROC curve, and AUC. The calculation formulas for the matching rate and reproduction rate of the k category are as follows:

$$P_k = \frac{\text{TP}_k}{\text{TP}_k + \text{FP}_k},$$

$$R_k = \frac{\text{TP}_k}{\text{TP}_k + \text{FN}_k}. \tag{22}$$

Accuracy is the most common evaluation index for classifiers. This is the ratio of the number of samples that are correctly identified (that is, correctly classified) for all sample sizes. For example, there are 1,000 students in junior high

TABLE 4: Some features used in gait recognition.

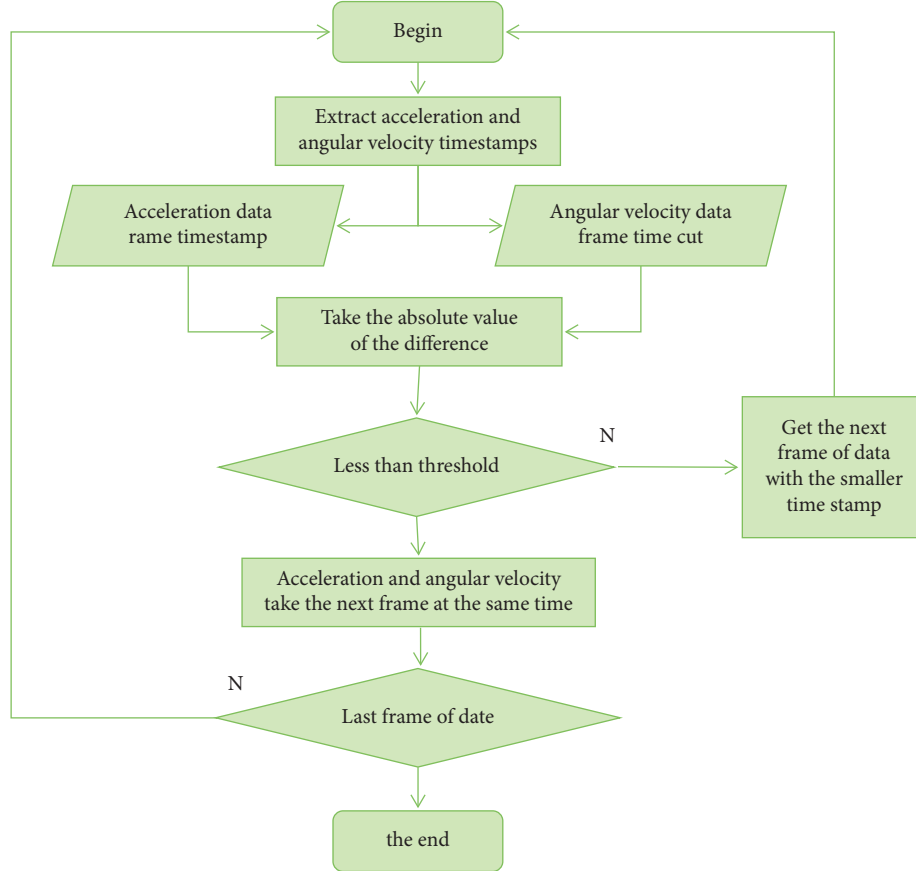
Feature	Description
Root mean square	The sum of squares in the three directions of X, Y, and Z is divided by 3, and the square is taken
Energy	Work done in the three directions of X, Y, and Z
Percentile value	The percentage of the number of samples below this sample value in the dataset to the total number of samples
Mean absolute deviation	The average of the absolute value of the deviation of each value from its arithmetic mean
Cadence	The number of complete gait cycles contained in 1 minute


FIGURE 2: Flow chart of sensor data synchronization process.

school. Obviously, there are two categories of students, boys and girls. Among them, 600 are boys and 400 are girls. If the classifier correctly determines the gender of 800 people (including 500 boys and 300 girls), then, the number of people correctly classified by the classifier will account for 80% of the total. In other words, the accuracy is 80% (800/1000). This paper shows the calculation method in following formula:

$$\text{accuracy} = \frac{1}{n_{samples}} \sum_{i=0}^{n_{sampls}-1} f(\widehat{y}_i = y_i). \qquad (23)$$

The F value is the weighted harmonic average of precision and precision. For multiple classification problems, the evaluation indicators of micro-F score and macro-F score are usually used. Because the coincidence rate and the reproduction rate may be mutually exclusive, it is necessary to consider these two issues together. In order to solve this

problem, the F value is proposed, and the calculation formula is as follows:

$$F_\beta = \frac{\left(1 + \beta^2\right) \times P \times R}{\beta^2 \times P + R}. \qquad (24)$$

3.4.2. Detailed Comparison of Recognition Performance. In order to further prove the effectiveness of the algorithm in this paper, on the basis of the abovementioned experiment, the performance of the two algorithms is statistically compared, and the results obtained are shown in Table 5.

3.4.3. Division Ratio Results. Figure 3 shows the experimental results of the ShakeLogin dataset under experimental conditions. For the model SSUI proposed in this paper, when the division ratio is 0.8, the accuracy rate reaches the

TABLE 5: Detailed comparison of the performance of the two algorithms.

Variable type	The recognition accuracy of the algorithm in this paper (%)	Recognition accuracy based on palmprint and facial feature algorithm (%)
Happy	100	84
Sad	97	76
Surprised	96	62
Light source 1	98	76
Light source 2	96	69
Light source 3	90	63
FIGURE 3: Performance graph of the ShakeLogin dataset with different division ratios.

maximum, and then, when the division ratio is increased to 0.9, the accuracy rate drops slightly.

The specific experimental results are shown in Figure 4. It can be seen from the broken line chart that as the proportion increases, the accuracy of walking and going up and down stairs increases, and the accuracy of going up and down stairs increases by more than 20%. The other three actions have changed, but when the ratio reaches 0.9, and all actions have reached the maximum accuracy.

3.4.4. Results of All Behavioral Experiments. The results of this series of experiments are shown in Table 6. The time-domain feature weighting parameter in this table changes from 1 to 2/3, 1/2, 1/3, and finally to 0. The frequency domain weighting parameter value ranges from 0 to 1/3, 1/2, 2/3, and finally to 1.

Figure 5 shows the performance of the SSI model in the Shakelogin dataset and the experimental results of the sample period. As shown in the figure, the sample period is too short (2 seconds), the accuracy is very low, and the obtainable value is less than 60%. The longer the sample time is, the higher the correct rate (2 seconds to 4 seconds, 60% to close to 80%) is.

4. User Identification Applications and Risk Prevention and Control Strategies in Internet Financial Platforms

4.1. Identification of Fraudulent Users in Internet Financial Platforms. The data in this article comes from the user transaction record data of a European online payment platform, which was collected and shared during the research cooperation process of the machine learning team of Worldline and ULB (University Libre de Bruxelles). Because each transaction data contains a category label (that is, whether it is a fraudulent transaction), this is actually a supervised classification machine learning task. This experiment will first perform data preprocessing, that is, subsamples were obtained by random undersampling, and then, feature engineering was performed, including feature scaling, outlier detection, and feature screening. Subsequently, four supervised machine learning algorithms are used to train and test the model, and finally, a variety of evaluation indicators are used to evaluate the effects of various models.

4.2. The Main Links of User Identification in Internet Financial Platforms

4.2.1. Verifying Customers. Confirm the customer and its actual manager, understand the natural purpose and transaction, confirm the identity of the customer, understand the actual beneficiary of the natural person and the actual management of the transaction, confirm the customer's valid ID card or other ID, register the customer's basic identity information and Relevant ID card copy information. This basic task is particularly important. The main reason is that in order to avoid legal sanctions when performing money laundering activities, criminals must
FIGURE 4: HHAR dataset (all behaviors).

TABLE 6: User identification results of ShakeLogin and HHAR datasets.

ShakeLogin (17 users, shake the phone arbitrarily)	Random 80% of the entire data set/remaining	85.46	87.25	92.07	81.98	75.33
HHAR (9 users, 6 behaviors)	All actions/all actions	92.56	97.12	92.56	97.23	94.88
	All behaviors/walking	90.08	96.87	97.75	96.85	100.0

conceal their true identity and actual transaction purpose. In order to effectively identify suspicious personnel and suspicious transactions of financial institutions, it is necessary to strictly and carefully determine and verify the true identity of customers and pay attention to daily business and financial transactions to ensure that abnormal situations are discovered in a timely manner.

4.2.2. Continuous and In-Depth Identification of Customers. During the duration of their business, financial institutions also need to continue to reexamine customer accounts and transaction activities. This process is actually a process for financial institutions to learn more about customers and confirm their identities. In order to effectively achieve continuous identification, financial institutions need to do the following.

As a work to prevent money laundering, the most basic thing is to be able to update customer information and related data in a timely manner. The staff at the counter of the basic relevant outlets needs to have sufficient sensitivity and attention to customer information and customer managers through early learning of the contact process of customer information. Then, continue to pay attention to the latest trends of customers, understand and update the money in the customer's account, and the actual owner or beneficiary of these funds. In the absence of a legal person or other legal person organization, the credibility of relevant information must be judged carefully. In order to understand and prevent all the customer's structure and internal management structure from being false, it is necessary to use the help of the propaganda platform to check and verify the offender as much as possible, to ensure that customers do not use false identities to hold stock or fund accounts and engage in money laundering activities.

Please pay attention to the customer's transaction behavior. Please note that whether the money in the customer's account flows regularly or is very different from other accounts of the same or similar type. The average daily occurrence of the account, the degree of frequent trading operations, the source of remittance funds and account outflows, and the fixed transaction objects. Please pay attention to capital accounts with common characteristics. Suspicious accounts such as frequent and rapid fund transfers, transactions of almost equal amounts between borrowers and credit cards in a short period of time, and unusually active account transactions.

Conduct customer surveys on a regular basis. In this work, the relevant staff must be familiar with the relevant business information of the customer, understand the industry in which the customer is engaged in advance, master the general financial settlement methods in the business process and whether they prefer cash settlement. In the practice of preventing money laundering, criminals frequently use cash transactions in order to avoid transfer of funds between banks or use promissory notes in the same city according to the needs of illegal and criminal activities. The information of the recipient, payer, and correspondent bank cannot be clearly displayed on the same bill, hide the source and location of funds, or personal accounts or frequent electronic remittances between units and personal accounts. Therefore, financial institutions cannot understand the actual parties behind the transaction and make decisions in a timely manner. Finally, it is necessary to strengthen system construction, establish customer electronic information database, establish customer credit database, and integrate system platform resources.

4.2.3. Due Diligence on High-Risk Customers. Usually, the age and occupation of the customer obviously do not match the transaction amount and transaction frequency or customer accounts belong to high-risk industries, such as offshore companies or entertainment facilities, or individual customer accounts registered on the blacklist, such as terrorists or politically sensitive. Digital and financial institutions must conduct detailed due diligence on them. The customer's due diligence must be carried out through the whole process of the financial institution's business start, decision-making, and postloan management. The content of the investigation includes the complete collection of the client's ID card, the understanding of the actual account manager or the actual beneficiary of the transaction, the confirmation of the client's valid ID or other IDs, the understanding of the source of funds, the use of funds, economic status or business status, and other information.

4.3. Development Strategies for Risk Prevention and Control of Internet Financial Platforms

4.3.1. Start with the Details of the Process, and Comb Out the Operating Guidelines and Implementation Standards Based on the Characteristics of Your Own Business. Financial institutions need to incorporate customer identification into the internal control construction system, improve operating standards, clarify business processes, and implement customer risk classification and related risk classification standards. Strengthen the specific conditions and recognition points of initial recognition, continuous recognition, and rerecognition. Government regulatory agencies, the People's Bank of China, financial institutions, public security, taxation, legal affairs, commerce, and foreign exchange administration departments provide advice and relevant professional support for the effective identification of various client ID information of financial institutions. Build a unified comprehensive information query system to solve the information problem of financial institutions' verification practices.

4.3.2. Make Full Use of Information Technology and Strengthen Identification Methods. One is to maximize the use of existing professional databases, such as World Check, to screen potential risks for customers, partners, transactions, and employees. World Check is public in the world. It contains public data on money launderers, scammers, terrorists, drug smugglers, fraud companies, etc. It is a recognized organization database. The second is to strengthen the use of advanced technologies such as fingerprint recognition, iris detection, and keyboard rhythm. At the same time, in order to improve the recognition accuracy of Internet financial services, in addition to general passwords and digital certificates, it is also necessary to increase the SMS and voice recognition of mobile phones. The third is to integrate the input and integration of scattered customer ID information, combine industries, regions, locations, other dynamic IDs, and automatic screening of high-risk customers to develop ID information tracking, monitoring, and analysis systems. With the rapid development of Internet technology, the conflict between traditional financial commerce and emerging Internet financial commerce has brought more difficulties and problems to the prevention of money laundering. In the new situation, financial institutions must respond in a timely manner. In order to maximize the use of the advantages of Internet financial services, effective countermeasures are taken on the basis of ensuring the identification to the greatest extent to achieve a balance between risks and benefits.

5. Conclusion

Based on wireless sensor networks, this paper studies the development of user identification and network finance. This paper studies the characteristics of wireless sensor data, better data reduction, and data classification algorithms and proposes a basic action recognition method based on wireless sensor data. Aiming to improve the shortcomings of traditional identification algorithms, an adaptive identification algorithm based on the improved minimum gray tree of the visual sensor network is proposed. The simulation results show that the algorithm shows a high accuracy of identification. On the other hand, wireless sensor call is simple and easy to obtain data, so it forms the basis of wireless sensor data research. Each user who uses the wireless sensor generates sensor data, and the sensor data is generated in different ways depending on the user. Therefore, the user can be identified through wireless sensor data. The prevention of money laundering is affected by the rapid development of Internet technology and the conflict between traditional financial commerce and emerging Internet financial commerce, and many new problems have emerged. Financial institutions in a new situation need to respond in a timely manner. The concept of the effectiveness and maximum guarantee of the countermeasures is to maximize the use of the advantages of Internet financial services to achieve

a balance between risks and profits. The establishment of a complete and effective customer information database will undoubtedly increase the human and material resources of various financial institutions. However, there are many problems such as information collection and information verification, and huge investment may be effective, which will have a certain degree of impact on the optimization and improvement of "customer identification."

Wireless sensor network is a multisensor wireless network system, which consists of multiple sensors and is configured independently. Because the network generates a large amount of data, the frequency, performance, and computing power of sensor nodes are limited, and they are particularly vulnerable to harsh environments and malicious attackers. This leads to the occurrence of malicious nodes, emergencies, and abnormal data in the sensor network system. Failures can also have a significant impact on sensor network services. The two main functions of wireless sensor network security are abnormal node detection and data anomaly detection. These two directions are mutually independent and complementary. Therefore, under the promotion of the rural revitalization strategy and the precision poverty alleviation strategy, China has increased its agricultural efforts. At this stage, all localities focus on the construction of rural financial systems to ensure that scattered farmers and rural small and microenterprises receive comprehensive financial services. The establishment of a rural financial system based on "intelligent forecasting" can improve financial development theories and build new ideas for rural financial development. And, the balance between realization and profitability, and then, through the use of Internet technology to make traditional financial institutions more effective in providing financial services, new online financial platforms can use them to make up for the existing shortcomings of traditional financial institutions as much as possible. In this article, through the research on the intelligent prediction of sensor data anomaly detection, it is applied to the development of rural finance and promotes the development of rural finance.

1. Introduction

In recent years, with the rapid development of computer technology, electronic equipment, wireless networks, and communication systems, wireless sensor networks have continued to emerge and have gradually become an important channel for people to obtain data and information [1]. Wireless sensor networks have the characteristics of limited node sources and are easy to break [2]. Although technologies such as mandatory passwords and secure routing have improved the security of sensor networks, there is still a lack of effective methods to detect abnormal information in the sensor network, making the sensor network more effective. Protection becomes difficult [3]. The improvement of data anomaly detection technology can greatly promote the future application and development of sensor

networks. Each sensor node maintains the trust value of neighboring nodes to reflect its previous decision-making behavior [4]. Two thresholds are used to reduce the false alarm rate and increase the incident. Area detection accuracy is used to achieve more accurate detection of malicious nodes without sacrificing normal nodes [5, 6]. The simulation results show that the two-threshold scheme is better than the single-threshold scheme [7]. After screening and removing malicious nodes in the sensor network, a fault detection method based on a distributed multilayer wireless sensor network is introduced [8]. Through the analysis of false datasets and real-time environmental data collection data, it is shown that compared with the central system and the reference system, the improved anomaly detection program can achieve a higher detection rate, false alarm rate, and lower communication utilization [9]. Finance

conducted a "Internet + Intelligent Forecasting" research. Using the concepts and theories related to the overview, firstly, it analyzes the status quo of rural financial development under the background of "Internet + intelligent forecasting" from the service functions of traditional rural financial institutions and the service functions of Internet rural financial institutions; Alibaba and CreditEase analyze and demonstrate the three typical rural finance "Internet + smart forecasting" cases to obtain development information: clarify the "Internet + smart forecasting" agricultural development strategic goals, make full use of big data, and promote the self-improvement of local financial institutions; By further analyzing the problems existing in the development of rural finance in the context of the "Internet," we found that there are various problems in rural financial risks. It is necessary to further expand the rural credit control system, improve Internet finance laws and regulations and rural network infrastructure, and increase the penetration rate of farmers' financial knowledge [10]. Finally, it puts forward targeted countermeasures to promote the development of rural finance under the background of "Internet + intelligent forecasting," establishes a political incentive mechanism for state intervention, strengthens the prevention and monitoring of rural financial risks, and promotes financial publicity and education in rural areas [11, 12].

2. Related Works

The literature introduces the application background of wireless sensor networks, describes the research background and practical significance of malicious nodes and abnormal data detection, analyzes the current status of the investigation of malicious messages and abnormal information detection technologies at home and abroad, and provides a complete, structured, and summarized summary [13]. The literature introduced the basic problems of wireless sensor networks, introduced the anomaly detection datasets commonly used in wireless sensor networks, and explained the architecture of wireless sensor networks in detail. The literature introduces a two-step detection system for malicious nodes on wireless sensor networks. Each sensor node maintains the trust of neighboring nodes to reflect its past behavior in the decision-making process [14]. The simulation results show that the two-tier plan is better than the single-tier project. The program provides a set of parameters whose values can be adjusted according to the application system to maximize efficiency. The literature introduces an abnormal data detection method for distributed wireless sensor networks based on hierarchical aggregation [15]. Through simulation analysis on artificially constructed datasets and datasets collected in real environments, it shows improved anomaly detection schemes and centralized schemes. Compared with the HSCBD scheme as a control, it can achieve a high detection rate and a low false alarm rate and reduce communication consumption. The literature introduces a distributed error detection system [16]. The algorithm includes two main steps: self-detection and intermediate pod detection. The algorithm makes full use of

the spatiotemporal data connection of data distribution in wireless sensor networks and divides abnormal data into two steps: time and location [17]. Carry out anomaly detection process on the basis of reliability improvement.

3. Design and Implementation of the Intelligent Prediction Method Based on Abnormal Detection of Sensor Data

3.1. Analysis of Wireless Sensor Network Architecture and System Requirements

3.1.1. Wireless Sensor Network Architecture. A sensor is usually a cheap device with relatively low battery life, computing power, and storage capacity. The main purpose of the network is to identify, store, process, and transmit environmental information in the area covered by the system. Related technologies mainly include three major technologies: sensor technology, information technology, and communication technology. The three architectural components of a wireless sensor network are sensors, sensing objects, and users.

There are many types of wireless sensor nodes, but a single node has a single function. It can generally be used to measure various indicators in the natural environment, such as earthquake, noise, temperature, humidity, and light intensity. It has a wide range of application prospects and is used in various parts of today's society. Figure 1 is a typical wireless sensor network architecture diagram, in which the sensor nerves are automatically distributed in the area of interest manually, and they work together to collect and process the data in the coverage area and transmit all or part of the data to the sewer or base station. After the summary data are sent, the measurement data can be processed into multiple items. The base station sends the metadata collected through satellite or wireless network back to the administrator for decision-making. The administrator can also send instructions to the base station through the network and send the instructions to each relevant sensor.

Most sensor nodes are very small. Because the technology development is not very mature, the computing power, memory, and communication capabilities of the nodes are limited. Network sensor systems are often used in unintentional or difficult environments, and the battery cannot be replaced, and the life cycle is relatively short. Many wireless sensor network power supply modules include wireless communication modules, processing modules, and sensors. With the development of single-chip technology and electronic integration technology, computer power consumption has been greatly reduced. In addition to collecting and processing local data, sensors must also cooperate with other entities to perform certain tasks under special conditions.

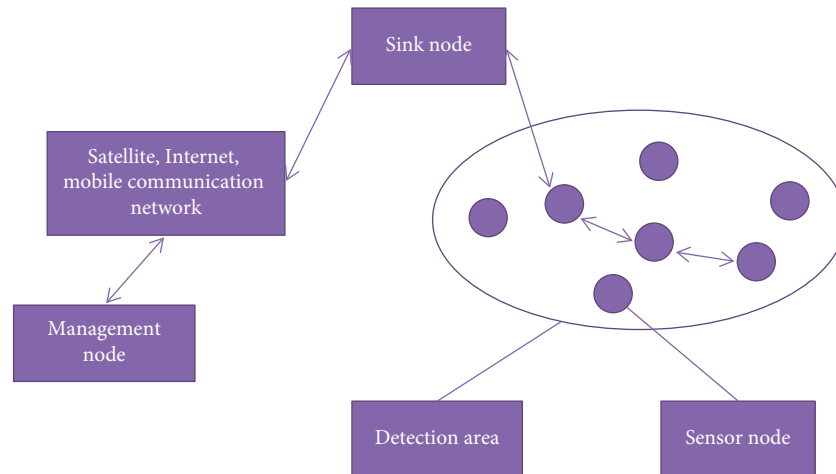
The convergence node is an intermediary between the sensor network and the external Internet, and can identify the exchange protocol between the Internet of Things and the Internet, processed by the network sensor, and sent to the management node after collection and processing.


FIGURE 1: Typical wireless sensor network architecture diagram.

The management node is the "stand-in" of the entire sensor network and generally directly controls the sensor identification system of the sensor network through it, and the network administrator can access the review intelligence through management, decision-making, and guidance clauses.

3.1.2. The Internal Node Composition of the Wireless Sensor. The wireless sensor network consists of a large number of randomly distributed sensors. For example, if we conduct an environmental audit, the data will collect various information in the environment (such as temperature, humidity, and air pressure) to form a self-hosted wireless network. Each sensor is sent finally to the management terminal and configuration terminal. There are two types of nodes in the network: ordinary sensor nodes and gateway nodes. Distributed sensor networks can communicate with each other and connect to a gateway node through multiple data. The gateway node collects and transmits data. The network can access the Internet through the gateway node. Communication with the entire site of the data controller and the entire system can be managed and controlled from the headquarters.

The internal structure of the sensor is shown in Figure 2. The data acquisition module is composed of two subunits: the sensor component and the analog-to-digital converter (AD/DC). The digital output signal is transmitted to the data processing module through the analog-to-digital converter. The power supply module supplies power to each sensor module and usually uses a battery to power the device. When designing sensor hardware components, save device power as much as possible and extend the life of the device. It is necessary to use components with the lowest power consumption possible, and the sensor should not communicate. Turn off some communication functions when needed. When developing communication software for sensor networks, you must consider the energy consumption of the network. By eliminating some unimportant network performance indicators, you can achieve higher power utilization and extend the life of the entire network.

3.1.3. Data Security Requirements of Sensor Networks. Wireless sensor networks have different security requirements in different application scenarios. Aiming at sensor network systems commonly used in industrial and agricultural production, this article divides the most important security requirements of wireless sensor networks into basic security requirements and network system security requirements (see Table 1).

The threats to wireless sensor networks are caused by environmental factors such as natural disasters and intruders, and face different threats in different fields such as data, communications, services, and hardware, as shown in Table 2.

Wireless sensor network nodes are large in number and widely distributed. In practice, sensor networks are usually deployed in areas where few or no people are on duty. In addition, the hardware fragility of sensors and some potential software defects cause further damage to the network.

An information attack is an attacker maliciously intercepting, threatening, accessing, or destroying data in the network, resulting in incorrect judgments of network data or errors in data reporting. False information is confusing and difficult to be discovered by people. Therefore, such attacks are very hidden and dangerous and should be considered. In response to such attacks, the sensor network data detection technology cannot analyze the dataset by the wireless sensor network to determine whether the node data are abnormal, thereby reducing the harm of data attacks.

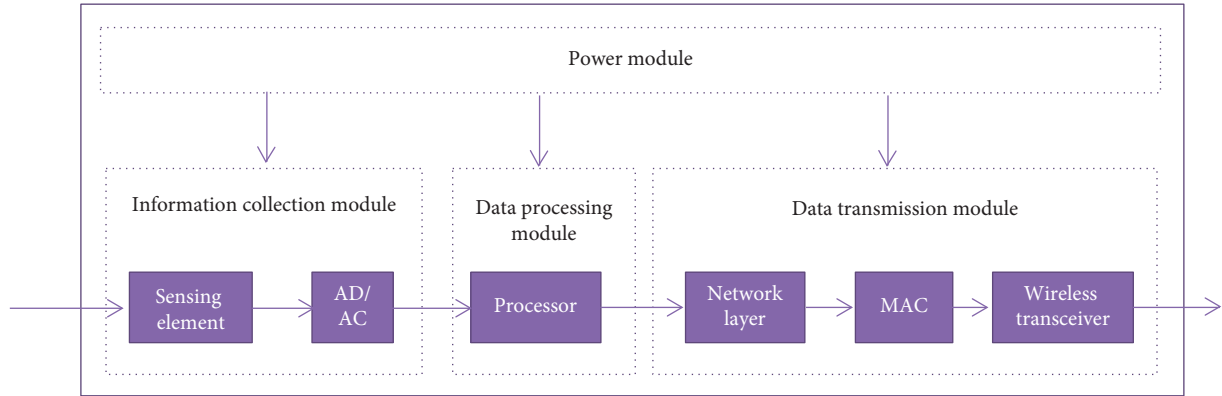
Attackers perform Sybil attacks by invading network nodes and then using authentication technology to impersonate multiple legitimate network nodes. This attack will destroy the network topology and disrupt normal network communication. Vulnerability attacks are mainly related to the attacker manipulating data to be sent after the intrusion part or all of the data are related, resulting in the loss of a large amount of normal data on the network and abnormal communication between messages. Most flood attacks have two attack methods. One attacker controls the node to continue trying to establish a connection with the attacked node to use the attacker's node connection resources, and the other is that the attacker controls the node to


FIGURE 2: Structure diagram of the internal composition of sensor nodes.

TABLE 1: Security requirements of wireless sensor networks.

Species	Feature	Demand details
Basic security requirements this An all	Confidentiality Availability	Ensure that authorized users access information and prohibit unauthorized access. Ensure that legitimate users do not deny the abuse of data and resources.
	Completeness	When inputting and forwarding, the data are not displayed, and it is illegal to agree to modify and destroy the information to protect the consistency of the information and data.
	Authenticity	Ensure the authenticity and credibility of the identities and information of both parties communicating with each other.
Need	Data security Self-healing and recovery ability	Unauthorized access, modification, or transmission of any data is not allowed. The network must have a certain degree of self-defense ability to resist unknown attacks.

TABLE 2: Security threats of sensor networks.

Field	Main threat
Data	Illegal eavesdropping, malicious data tampering, false data injection
Communication	Witch attack, black hole attack, flood attack, wormhole attack
Service	DDOS attack
Hardware	Theft, destruction, equipment hardware intrusion, natural disasters

continuously send invalid data to the attacked node. The request is forwarded by the attacked node, thereby destroying the computer and frequency band node resources. Both of these attack methods prevent the attacker from processing legitimate requests from other data and greatly increase the energy consumption of the attacked node. Most wormhole attacks target two malicious nodes that together form a communication tunnel. Even if the two malicious nodes are far apart, there is only one step between the two malicious nodes. In this way, the hop times of the two nodes are shorter than normal, so as to achieve the purpose of deceiving the right of way and destroying the normal routing path.

Service attacks are mainly carried out through distributed denial of service (DDOS) attacks. The purpose is to exhaust the communication resources or computing resources of the sensor network, causing the system service group network to be unavailable.

The purpose of hardware attacks is to control smart devices in a sensor network by destroying device hardware or intruding devices. Direct damage to such devices will

cause some system functions to be paralyzed. Smart device monitoring can be used as a spring trigger to attack sensor network systems, such as managing sensor data through data transmission, sending false monitoring data to attack network readiness, running malicious code to attack other devices, and preventing hardware attacks by installing protective shells and other security measures. It can prevent the physical security of network equipment. Using fault detection technology, a strict access control system can be established to detect faulty equipment in time and prevent intruders from entering the equipment.

Anomaly attributes are various network status indicators that appear when the sensor network is threatened. In order to use the K method to detect anomalies, information objects need to be grouped according to the anomaly attributes. Therefore, the basic principle and description of character selection is to confirm the K-mean algorithm detection result important factor.

Aiming at the threat of data attack, through analyzing typical data attack methods, the selected characteristics are shown in Table 3.

TABLE 3: Attack characteristics of sensor networks.

Typical attack method	Attack description	Representative characteristics
Malicious data tampering	Attackers maliciously modify the collected data or reported data in the network, causing abnormalities in the data transmitted and reported by the network nodes.	Perceived data such as temperature, humidity, luminosity, and data flow information
Fake data injection	Attackers use false control data or unsupervised data to compress the sensor network, causing network failures or unreliable data reported by nodes.	Sensing data such as temperature, humidity, luminosity, and data flow information entropy

The data collected by sensor nodes generally have several dimensions. Through the analysis of multiformat databases, the spatial interaction of sensor network data can be effectively used to detect data errors. The data can reflect the feasibility and statistical characteristics of sensor data flow. By introducing the work of this group of analysis, the statistical (time-related) characteristics of the dataset can be used to detect anomalies and improve the discovery results of the search system.

3.2. Research on Anomaly Detection Algorithm of Sensor Data

3.2.1. Standardization of Sensor Data. A sensor node can be composed of multiple sensor elements, and each discovery element is responsible for collecting one or more types of data. Therefore, the data center can store various types and different scales of information, such as temperature, humidity, air pressure, and brightness. This information has its own format and data count. If you cannot combine different data formats and dimension units, you cannot use multidimensional data horizontally. Therefore, if you want to use multiple datasets to perform sensor data anomalies, you need to normalize the data in various formats and then calculate the Euclidean distance between different data objects, which is used to measure the similarity of the data. The following anomaly detection methods in this article require standard data object management. A variety of data normalization methods have been proposed at home and abroad, among which the most commonly used in research are "minimum-maximum normalization," "Z-score normalization," "normalize by decimal calibration" and so on.

Then, calculate the minimum-maximum normalization by the following formula:

$$x' = \frac{x - \min_{X}}{\max_{x} - \min_{x}} \left(\max_{X}{}' - \min_{X}{}' \right) + \min_{x}{}'.$$ (1)

Z-score uses the standard method and the deviation of the original dataset to standardize the data. When maximum and minimum values of a certain attribute in the dataset are unknown or unpredictable, this method can be used for regular data.

The standardized formula for calculating Z-score is shown in the following formula:

$$X' = \frac{X - \overline{X}}{\sigma_J}.$$ (2)

The regularity of decimals is standardized by moving the decimal point of the X attribute. The absolute maximum value of the X attribute determines the number of decimal places that can be moved. Assuming that the value of the original data x of some X attributes in the dataset is assumed to be x', the following formula indicates

$$x' = \frac{x}{10^j}.$$ (3)

Because the range of data collected by wireless sensors is relatively fixed, the maximum and minimum values of data can be predicted based on objective physical facts, and a significant maximum value can be set for each attribute in advance, and the minimum value of the linear transformation of the original data can be selected—maximum normalization method calibration data.

Shannon used statistical probability methods to give the definition of information entropy:

$$H(X) = -\sum_{i=1}^{n} p(x_i)\log(p(x_i)).$$ (4)

The data collected by the sensor node T changes continuously with the change in the data retention time. Generally, the time t data are related to historical and subsequent data. The selection of the data collection period has a greater impact on this relationship. For a single sensor stream, the estimated time of collection is T, and the duration of the sensor flow can be expressed by the following formula:

$$X(t) = [\ldots, x(t - \Delta T), x(t), x(t + \Delta T), \ldots].$$ (5)

The sliding window model uses a sliding window of length W ($w > 0$) to divide the sensor data stream into window data and data outside the window, and the window contains W sample data. When the window slides, the data before the previous sampling time t exit the window, and the information of the next sampling time will appear in the window. Assuming that W and W are two adjacent windows, and the window scrolling distance is 1, the dataset (t) before its movement can be expressed by the following formula:

$$X_1(t) = [x(t - W^*\Delta T), \ldots, x(t - \Delta T), x(t)].$$ (6)

The data sequence $X(t)$ after moving the sliding window can be expressed by

$$X_2(t) = [x(t - (W - 1) * \Delta T), \ldots, x(t), x(t + \Delta T)]. \quad (7)$$

The data spacing (distance) is determined by the Euclidean distance, which is used to represent the actual distance between two data objects in the n-dimensional space. It can be used as a measure of the similarity of data objects. Generally speaking, the smaller the distance, the greater the similarity. For data objects $X(t)$ and $X(t)$, the distance can be expressed by the following formula:

$$D(X_1(t), X_2(t)) = \sqrt{\sum_{k=1}^{n} (x_{1k} - x_{2k})^2}. \quad (8)$$

For the information entropy $h(t)$ and $h_2(t)$ of the data sequence, the distance can be expressed by the following formula:

$$D(h_1(t), h_2(t)) = |h_1(t) - h_2(t)|. \quad (9)$$

Information entropy sequence calculation is given as follows:

$$p_i = P\{X = x_i\} = \frac{\text{count}(x_i)}{\sum_{i \geq 1} \text{count}(x_i)}. \quad (10)$$

Calculate the entropy of the sliding window information as a function of sampling probability:

$$h_j = \sum_{i21} p_i \log \frac{1}{p_i}. \quad (11)$$

While changing the window, the information of the window is calculated sequentially, so the duration of the information can be expressed by the following formula:

$$H(t) = \{h_1, h_2, h_3, \ldots, h_j, \ldots\}. \quad (12)$$

3.2.2. Data Anomaly Detection Indicators.

There are two main sources of anomalies in wireless sensor networks, namely, faults and events. The fault is the reading when the noise measurement value or the sensor fails. This kind of abnormality often occurs. The possibility of abnormality caused by the actual event is usually very low. Bad data usually show that the change in some data is significantly different from other data. Since bad data will affect the quality of the dataset, it should be detected and corrected as much as possible. Such anomalies usually last for a long time and change the normal trend of sensor data. However, if the sensor fails, a similar persistent anomaly will also occur, which makes it difficult to distinguish these two different types of anomalies only by looking at the sensor data stream from the node itself. In this case, anomaly detection technology may need to use the spatial similarity of sensor data, such as data from neighboring nodes, because, in general, sensor failures are not spatially related, while events are the opposite.

Supervised and semisupervised methods require a set of preclassified normal and abnormal data, and all normal and abnormal feature information is obtained in the learning stage, and then, the test data are compared with this learned classification prediction model. However, this kind of preclassified data is not always available, and it is difficult to obtain in real wireless sensor network applications. Although there is a preclassifier that can handle historical data well, it may not be able to distinguish between new normal data and abnormal data. In contrast, unsupervised methods do not require prelabeled data. On the contrary, some statistical data are used to identify abnormal. For example, in the nonremote control method, the normal mode is determined by the average distance between each data and its neighbors. If the distance between the measured values of the data provided to the nearest k-th neighbor is greater than this number, the data are considered anomaly, compared with supervised or semisupervised methods, unsupervised methods are more suitable for wireless sensor networks.

Table 4 shows the possible situations of abnormal data detection results of the wireless sensor network.

Wireless sensor networks usually use the following indicators to measure the effect of abnormal data detection: DR, FPR, FNR, and the quantitative indicators can be defined as follows.

DR is defined as the rate at which abnormal data are correctly detected as abnormal, expressed as

$$\text{DR} = \frac{\|\text{TN}\|}{\|\text{FP}\| + \|\text{TN}\|}. \quad (13)$$

FPR is the rate at which malicious data are detected:

$$\text{FPR} = \frac{\|\text{FP}\|}{\|\text{TN}\| + \|\text{FP}\|}. \quad (14)$$

FNR is the rate at which normal data are detected as abnormal data, which means

$$\text{FNR} = \frac{\|\text{FN}\|}{\|\text{TP}\| + \|\text{FN}\|}. \quad (15)$$

3.2.3. Updating the Trust Value to Detect Malicious Nodes.

From the perspective of v_i, two confidence values (weighting) are used to represent the reliability of node v_i.

In the absence of an event, a sensor node that fails or sends a "1" signal will reduce weight, shown as follows:

$$w_{ij}^0 = \begin{cases} \max(0, w_{ij}^0 - \alpha) & \text{for } b_j = 1 \text{ or } F_j = 1 \\ \min(1, w_{ij}^0 + \beta) & \text{for } b_j = 0 \end{cases} \quad (16)$$

Similarly, the weight of node v_i itself is also updated as follows:

$$w_{ii}^0 = \begin{cases} \max(0, w_{ii}^0 - \alpha) & \text{for } b_i = 1 \\ \min(1, w_{ii}^0 + \beta) & \text{for } b_i = 0 \end{cases} \quad (17)$$

The above improvements reduce the number of sensors marked by α as "1." On the other hand, sensor nodes with accurate measurements will increase their pods. In this process, the node reports a "1" or maliciously reports a "1"

TABLE 4: Various results of anomaly detection.

Result	General data	Abnormal data
Was detected as regular	TP (regular data are received and classified correctly)	FP (abnormal data are received, classification error)
Was detected as abnormal	FN (regular data rejected, misclassification)	TN (abnormal data are rejected, the classification is correct)

failure, and the node with a map error of "0" gets more pods during the update process and keeps the upper limit of the override value at 1.

If an event occurs, the node in the event area should report "1," the malicious node in the event area, and the card "0" failure node deliberately should report "0" to cause the wrong decision. The goal of the update now is to solve these problems:

$$w_{ij}^1 = \begin{cases} \max\left(0, w_{ij}^1 - \alpha\right) & \text{for } b_j = 0 \text{ or } F_j = 1 \\ \min\left(1, w_{ij}^1 + \beta\right) & \text{for } b_j = 1 \end{cases} \quad (18)$$

Similarly, the weight of node v_i itself is also updated as follows:

$$w_{ii}^1 = \begin{cases} \max\left(0, w_{ii}^1 - \alpha\right) & \text{for } b_i = 0 \\ \min\left(1, w_{ii}^1 + \beta\right) & \text{for } b_i = 1 \end{cases} \quad (19)$$

When updating the weight, the two parameters α and β play an important role. They affect the detection rate and detection interval of malicious nodes. If the value of α is large, some nodes can be sacrificed. For a given p_t and p_{ma}, condition P of the reported data is malicious and the probability of conflict with the actual data can be written as

$$P_{inv} = p_t\left(1 - p_{ma}\right) + \left(1 - p_t\right)p_{ma}. \quad (20)$$

Let N_d be the average number of event-free periods required to detect malicious nodes. Then, for a given α and β, the response time N_d can be derived from the following equation:

$$N_d\left(P_{inv} \cdot (-\alpha) + \left(1 - P_{inv}\right)\beta\right) = -1. \quad (21)$$

N_d can be given in the following ways:

$$N_d = \frac{1}{P_{inv} \cdot \alpha - \left(1 - P_{inv}\right)\beta}. \quad (22)$$

3.3. Simulation Experiment Design of Sensor Data Anomaly Detection

3.3.1. Distributed Detection Scheme.
Due to the high overhead of the wireless data communication system and the heavy load of battery-powered sensor nodes, the sensors must process the data locally before sending data to reduce repetition and improve efficiency. Figure 3 is a schematic diagram of data transmission in a distributed scheme.

Using the interconnection network, the wireless sensor network is divided into several closely interconnected networks. Each subnet operates to detect local anomalies.

According to the accessibility of data transmission, efficient data combinations and data combinations are sent to the master node level as soon as possible. The master node transmits to the receiving node layer by layer. The method based on hierarchical aggregation can reduce data communication, reduce network power consumption, and effectively extend network uptime.

3.3.2. Simulation Parameter Setting.
The detection rate is defined as the ratio of successfully detected failure data to the total number of failures, and the false alarm rate is defined as the ratio of the number of detected good and bad data to the total number of good reads.

Table 5 summarizes the simulation parameters of two different scenarios. Scenario 1 simulates a sparse network with an average of 5 neighbors per node, whereas scenario 2 simulates an indirect distributed sensor network. The requirements of the two systems are randomly distributed. All sensor readings are generated based on the characteristics of the actual displayed data. A good sensor has a reading range of 19–20°C, whereas a defective sensor has a reading range of 25–26°C. The sensor node is randomly selected to be faulty under normal distribution, and the probability range of sensor node failure in the network is 0.05–0.23.

3.3.3. Database Table Design.
In order to ensure the consistency and uniqueness of the data, the data filtering team must use the deduplication function to remove the duplicate data during data collection and the same data collection device. Most data collectors are responsible for backing up and reading the original data from the sensor network. The data table structure design of data storage is shown in Table 6, including numerical data, acquisition time, acquisition equipment type, numerical equipment, temperature data, humidity data, lighting information, and voltage data. The data collection module is located at the bottom of the system hierarchy. It provides an interface to receive the initial data collected from the target sensor array and is responsible for storing and reading the initial input data. It is the basis and source of information. It is normal in the anomaly detection system.

The memResult function is responsible for storing the detection results of the anomaly detection task in the database, and the detection results can be used as a backup for future review and analysis. The data structure layout of the recording detection result table is shown in Table 7, including 5 fields: number, name, detection time, device number of the sensor under test, and abnormal detection result of the test task.
FIGURE 3: Schematic diagram of distributed anomaly detection in the WSN.

TABLE 5: Simulation parameter settings.

Scenes	Scene 1	Scene 2
Network density	Discrete	Dense
Number of nodes	Twenty-four	53
Average number of neighbors	4	15
Data anomaly type	Anomaly model	Anomaly model
Abnormal probability	0.04–0.26	0.05–0.23

TABLE 6: Raw data table of the sensor network.

Serial number	Field	Type of data	Description
1	Id	Int (primary key)	The serial number, the primary key of the table, increases in sequence
2	Time	DateTime	Date and time, the format is 2020-01-01 11:11:11
3	NodeType	Int	Used to distinguish the deployment location of the data table, value 01 represents the sensor node, and value 02 represents the data control center
4	DeviceId	Int	Number of sensor device reporting data
5	Temperature	Float	Sensor collection temperature
6	Humidity	Float	Humidity collected by the sensor
7	Light	Float	Luminosity collected by the sensor
8	Voltage	Float	Device voltage of the sensor

TABLE 7: Test result table.

Serial number	Field	Type of data	Description
1	Id	Int (primary key)	The serial number, the primary key of the table, increases sequentially
2	DetectName	Varchar	The name of the anomaly detection task
3	DetectTime	DateTime	The time when the detection task was started, format
4	DeviceId	Int	For 2020-01-01 11:11:11
5	Result	Int	Device number of the detected sensor

3.3.4. Detection Threshold. The weighted median detection is based on the spatial correlation between the sensor data of a node and its neighbors. The working principle of the detection method is as follows.

According to the weight of the neighbor and the i-th item, calculate the average output of neighbor data:

$$\widehat{x}_i = \frac{\sum_{k=1}^{j} \lambda_{ik} x_{ik}}{j}. \tag{23}$$

Calculate the sensor data of the node *i*, the relative difference between xi and the median $\hat{x}_i$, namely,

$$\Delta_2 = \frac{|x_i - \widehat{x}_i|}{\widehat{x}_i}. \tag{24}$$

Decide whether to update the trust value according to the following formula:

$$\lambda_{ij} = \begin{cases} \max(0, \lambda_{ij} - \alpha) & \text{if } \Delta_2 > \theta_2 \\ \min(\lambda_{max}, \lambda_{ij} + \beta) & \text{if } \Delta_2 \le \theta_2 \end{cases} \tag{25}$$

The standard deviation σ is calculated as

$$\sigma = \sqrt{\frac{1}{T} \sum_{t=1}^{T} (x_t - \widehat{x}_t)^2}. \tag{26}$$

3.4. Simulation Experiment Results and Prediction Performance Analysis

3.4.1. Self-Test. This article uses the data from the real temperature sensor provided by Intel to train three time series prediction models. The real data and the values of the data estimated by the three models are shown in Figure 4.

3.4.2. Results of Comparison of Detection Accuracy. In this section, the three algorithms are compared based on detection accuracy, false alarm rate, and simulation time.

The detection accuracy of the three algorithms in the two cases is shown in Figure 5.

It can be seen from Figure 5 that the detection accuracy of A_TSC is close to 100% in both cases, and the algorithm shows that the detection accuracy can be improved. For the other two algorithms, the accuracy of TSC and iDFD in detecting scene 2 is much higher than that of scene 1. In fact, the error detection of these two algorithms largely depends on the error of the node. Therefore, as the average number increases from 5 to 13, the detection accuracy improves. In addition, the detection accuracy of the TSC and iDFD conversion algorithm will decrease as the probability of failure increases, and the increase in the probability of failure leads to a higher ratio of faulty neighbors, which in turn will reduce the accuracy of detection. However, the downward trend of the updated A_TSC algorithm introduced in this chapter is not clear. In fact, the self-test results are input into a medium pod test program, which makes the algorithm not strictly dependent on the density of neighbors like the other two algorithms.

Figure 6 shows the false alarm rates of the three algorithms in scenario 1 and scenario 2.

Figure 6 shows that in both cases, the false alarm levels of the TSC and A_TSC algorithms are kept at a low level. However, as the failure probability increases and the average number of neighbors decreases, the number of iDFD false alarms also increases. The results show that, compared with the algorithm based on spatial relationship, the algorithm based on the combination of spatiotemporal correlation can reduce the false alarm rate.

4. Research on the Development Strategy of Rural Finance Innovation under the Internet Background

4.1. Problems in Rural Financial Development in the Context of the Internet

4.1.1. Credit Risk. Credit risk is also called default risk, because it is in financial services where the parties to the transaction fail to fulfill the corresponding obligations stipulated in the contract due to various reasons. Farmers generally do not have a strong sense of risk, and their awareness of risk is increasing, which has become a frequent occurrence of financial fraud. Since the birth of Internet finance, many financial institutions have raised funds with high returns and illegally raised funds in rural areas. China currently does not have adequate regulatory mechanisms, which has led to frequent financial chaos. On the other hand, the risk of rural land lenders is that the agricultural industry is very unstable and vulnerable to various natural factors. Once farmers lack integrity and credit in rural areas, and the system has not yet been established, it will hinder Internet finance companies. An orderly investigation of the credit of farmers cannot guarantee that personal reputation hinders the repayment of the farmers' principal and interest, thus transferring the risk to the platform and presenting credit risk.

4.1.2. Operational Risk. Operational risk is the risk of accidental losses caused by internal errors of employees, information system failures, or external failures. This risk
Figure 4: Actual data and Kalman, GM(1, 1), and ARMA(1, 1) estimated data.
Figure 5: Detection accuracy of three algorithms in two scenarios.
Figure 6: False alarm rate of three algorithms in two scenarios.

mainly includes the following two aspects: on the one hand, the risks caused by the internal operation of the platform, because the loan officer is not familiar with the process, rural loan officers have limited education, do not have a deep understanding of financial education, and the platform is also in a period of development, lacking an effective management and supervision mechanism, which can easily cause some subjective misjudgments; on the other hand, farmers are operating themselves and China also makes mistakes. Farmers have relatively low levels of education, no knowledge of Internet finance, inability to understand business emotions, low awareness of risk prevention, insecure online payment environment, stolen passwords, and loss of property.

4.1.3. Liquidity Risk. Liquidity risk refers to the risk that rural Internet financial platforms have certain debt repayment ability, but due to the lack of corresponding funds, they cannot obtain effective funds at a reasonable cost to deal with the risk of overdue debt, which affects the risk return, and the causes of liquidity risk are more diversified. It can also be classified as a global risk. Agricultural products are mainly harvested in spring and autumn, and the demand for capital and output is relatively concentrated. As a result, equity lending platform funds cannot guarantee an orderly circulation and cannot actually meet the needs of the public.

4.2. Countermeasures and Suggestions for Rural Financial Innovation and Development under the Internet Background. In the rapid advancement of Internet finance, a great improvement has been made, which will help promote the continuous development of the rural financial market. Rural financial institutions should be based on reality and proceed from the specific conditions of rural areas. The government should give priority to agricultural services and promote the comprehensive integrated development of Internet and intelligent financing. Specifically, it can be developed from the following two aspects: on the one hand, it is the revision of ideas and concepts, and the establishment of Internet thinking; it is clear that customers and services are the core of rural financial development, and diversified products are provided according to the financial needs of various rural entities. And services to meet their needs further improve risk prevention and awareness, and more effective judgments, further enhance user experience, improve the organizational structure and overall process, and create a development process that meets business needs. At the same time, it will absorb the development experience of other financial institutions, update its products, strengthen the use of Internet technology, and provide products that meet the needs of enterprises, demonstrate the advantages of the Internet, and better meet the needs of residents. In rural areas, rural financial institutions adopt more advanced concepts, focus on system construction, and use Internet technology to create a business processing platform for orderly processing of online and offline businesses.

In the process of continuous development of Internet technology, traditional agricultural industries have undergone great changes under the influence of Internet finance. From an objective point of view, the Internet does not exist in a formal way, but is connected with various production links. The use of Internet technology will promote the development of agriculture. Starting from the basic links of agricultural production, the P2P platform is used to meet the financing needs of farmers, and funds are obtained through land mortgages in the agricultural production links; from the perspective of land circulation, e-commerce platforms can meet the financing needs of farmers and provide targeted Support services.

Internet finance is very different from traditional finance. The latter developed earlier, has many physical outlets, and has strong financial strength. However, although Internet finance has only developed in recent years, it has developed rapidly. According to the analysis of the development status, the joint development of the Internet and traditional finance can provide complementary advantages and jointly expand the rural financial market. Therefore, rural finance must actively integrate with Internet finance, make full use of the advantages and characteristics of the Internet, develop diversified products, meet the needs of rural financial institutions, and establish a service system that adapts to rural development. The two are fully integrated to realize the exchange of information and market resources, and establish comprehensive financial service outlets that match the needs of rural customers. Promote the development of traditional financial institutions in accordance with the specific conditions of rural areas, open up more development channels, and effectively meet the individual needs of more farmers.

In the development of the rural financial market, the latest technologies such as big data and cloud sharing can be combined, and based on the target level, the rural credit research system can be established on this basis, and the development can be carried out from the following three aspects: first, through the "infrastructure," "The construction of," laid the foundation for the development of Internet finance; second, rural finance can provide financial services more effectively with the help of the Internet platform; third, during the development process, farmers' credit concepts will undergo certain changes and they will accept new. More diversified technologies must be built with the central bank as the core, farmers as the main body of development, and integration of new systems from different companies. In the process of building the rural credit system, the central bank must play a supervisory and management role, not only to objectively and completely understand the risks and operating conditions of financial institutions, but also to establish cooperative relations with other departments to collect an objective and complete understanding of farmers. In this way, existing resources can be integrated to play a greater role, and financial institutions can also obtain sufficient data on various platforms to cover more products. It is also very useful to improve the credit data of rural households in the credit investigation platform. Nonfinancial institutions can also master more data in the corresponding range to provide diversified services to rural households. Farmers must voluntarily participate in investigations and express their demands, which will help establish a credit system that meets the financial needs of the rural public.

5. Conclusion

This article will first introduce a text detection system for malicious nodes based on double standards. Each sensor point retains the reliability value of neighboring nodes to reflect the influence of previous behaviors on decision-making. In order to reduce the false alarm rate of malicious node detection and increase for the accuracy of event area detection, this program uses two levels to achieve more accurate malicious message detection efficiency without sacrificing normal nodes. The simulation results show that

the two-tier program is better than the single-tier system. Next, the rural financial development background under "Internet prediction + intelligent prediction" is divided into two levels: on the one hand, it classifies and summarizes the services of traditional financial institutions such as Agricultural Bank, Postal Savings, and Rural Credit Cooperatives; on the other hand, the service functions of rural Internet financial institutions, such as the supply chain finance of agricultural leading enterprises, the entire industry chain of the e-commerce platform, rural finance, and the P2P online loan assistance platform, are analyzed.

In this study, a novel microcirculation chromatography with pulsed amperometric discovery (IC/PAD) system is established for the cyanide in business sewage. For business sewage with complicated substrates, the microstrewing means is leveraged for purification and decoration, and subsequently, the IC/PAD course is utilized to psychoanalyze and accuse the cyanide in the match. Under optimum plight, cyanide exhibits some kind of linearity in the frequency of 1.0–200.0 μg/L, and the perception termination and quantification check of cyanide in business sewage are 0.15 μg/L and 0.5 0 μg/L, respectively. The scold is between 88.6% and 1 08.5%. This mode is highly caring, tenacious and awesome, and calm to manage. It offers recent discrimination for the discovery of cyanide in business sewage. In this case, the insincere-frequent uninterrupted inundate analyzer is to decide business sewage with comprehensive distinction in ammonium propellant major. The spring is compared with the mensuration rise of Nessler's test spectrophotometry. The rise has shown that when the double-stroll regularity of extended overflow analyzer is a manner to simultaneously moderate lofty and blaze concentrations of ammonia packaging gas, there is no important contention compared with the mensuration inference of Nessler's test spectrophotometry. The analysis of the regularity has whole reagents, and harmless and strong transformation. This can optimally decrease the effort intenseness of testers and is valuable of preferment.
Index Terms—DE oxidation, industrial wastewater, purification, fuzzy control, simulation.

1. Introduction

Cyanide (cyanide), frequently understood as Shanna, is an advert to unorganized inclosure hold cyanide (CN-) or instrumental compromise hold cyanide (-CN). Cyanide is highly venomous. By slaying cytochrome oxidase, it can prevent the natural interval of cells and terminate asphyxiation and even gangrene of humans or animals [1, 2]. People punish confine regard to the size of cyanide in aquatic substances. The World Health Organization provided that the extent of cyanide in carousal dilute must be less than 50 μg/L; the EU has the highest restriction of 70 μg/L for the satisfaction of cyanide in mine moisten. The old-fashioned analysis methods of cyanide end gentle nitrate titration [3], colorimetric regularity [4], spectrophotometry [5], proceed cluster course analysis order [6], etc., which are perplexing and burdensome, and poisonous

reagents swallow up a comprehensive total of vigor. Time-ardent and industry-assiduous and other imperfections of the erudition also describe that petrol chromatography [7], vapor chromatography-sum spectrometry [8], luminescent examine order [9], and other methods were the manner in the perception of cyanide. These methods have noble sensitivity, but the transformation repetition is not suitable for body try analysis. Different from these methods, the ion chromatography/throb amperometric discovery course has an open increase, and it not only is not capable to table interference but also has the advantages of noble sensitivity, fit and tenacious conduct, and slender try diminution. The analysis of cyanide in the certain trypiece subsists two protuberances: the birth of cyanide in the trypiece and the qualitative and quantitative analyses of cyanide in the origin. In existent erudition recite, rectification, headspace, airing, headspace

microextraction, compact disconcert lineage, etc. are in the main application to descent cyanide in collection relish, but the firmness and firmness of these pretreatment technologies of the reproducibility are not virtuous, and the revival standard is not conceptional. Hydrocyanic acrimonious has a pKa import of [9], which is exceedingly flying under the acid provision. Therefore, for the descent of cyanide in an aquatic try, rough solvents are ordinarily utility to imbitter and hydrolyze, and then, the cyanide is born again to packaging agent cyanide by calefaction and vaporization. HCN [10] is free and sunk by the prepossession fluid. In this contemplation, supported by this maxim, we show a gentler, safer, and more precise microcirculation system than condensation and other methods for the lineage and purification of cyanide in business sewage. It can be clear under moderation and intent by the absorption perspicuous. At the same turn, the delineation of the microaugmentation arrangement can powerfully remedy the oversight of the goal. Ammonia parcel fart is an agitated stringent conduct devote remarkable for polite epigene moiré spoilage absolve. Industrial drainage is a necessary dart of ammonia E941 in polite periphery hydraulic. One, therefore, of the major of ammonia packaging petrol is a must-trial condition for each oversee action, and the sensation of ammonia bale vapor major is its monotonous cupellation restraint. When we noticed that the cyanide in carousal dilute is not appropriate, relations can attract the uninterrupted glide analyzer's double-row course and subsequently send the unceasing glide analysis to bound bloomery sewage with capacious distinction. When read's double-row course, hereinafter send to as the unceasing glide analysis process, to bound bloomery sewage with capacious distinction in ammonia propellant major. This way is steadfast and frank. Significant dissimilitude, likely ensue, it is meriting of advancement and manner. 1 Materials and methods 1.1 Sample heap and warehousing collect battery sewage swatch, unite them to cork hourglass vials, and always shield and seal them during removal and warehousing, and carriage measurements within 24 hours after the match. The experiment tools are described as follows [11]: the unbroken stream analysis system with permeation adopts the tenet of unceasing proceed, and the specimen is blended with a consistent mien gurgle. The example is unconnected, the test trypiece [12] and the untold swatch sustain the same entertainment and the same surrounding, through the colorimetric plastid, the absorbance succeed is comparison, and the major of the untold trypiece is automatically succeed. In arrangement to simultaneously degree business sewage with ample dissimilarity in ammonia propellant major, this judgment uses a stroll-change automatic rifle dilution system with a dialyzer: the dialyzer built on skin to separate the clash of real particles or macromolecular substances in the dear-major sewage swatch from the stream [13]. The prospect to a light major is removed and diluted at the same tense, and then, sodium nitroferricyanide is employed as a catalyst to recoil with

sodium salicylate and sodium dichloroisocyanurate to conceive bluestocking arrange, which join the steadfast compound flood discovery ameba. Photometric discovery was at 660 nm wavelength. The hill-major sewage does not surpass through the dialyzer, straightway endures the hide backlash and photometric decision, and the apparatus automatically rates the ammonia propellant major [14]. Nessler's test spectrophotometry of the ammonia propellant in the conventionality of communicative ammonia or ammonium ions returns with Nessler's test to formality a reddish-brunneus composite, and the absorbance of the difficulty is relative to the appease of ammonia E941, in TU-1901. The absorbance at the wavelength of 420 nm is measured with an ultraviolet-noticeable spectrophotometer, and the ammonia packaging gas major (as) is manually computed (Figure 1).

2. Related Work

Fuzzy direct can effect sincere and forcible superintendence on complicated and stubborn-to-pattern systems, but real fluff check does not have an intact connect, that is,

$$C_t = ms_t, \tag{1}$$

and often yield slender fullness oscillations at the equilibrium step. Therefore, curly subdue can be confederated with PID superintendence to beauty a fluffy PID counteract (as shown in Figure 2), that is,

$$C_2 = \sum_{i=1}^{N} \sum_{j=1}^{H} s_2 d_{ij} x_{ij}^t. \tag{2}$$

Common fluff PID plain determines fuzzy PID combination counteraction and curly adaptive PID regulation. Fuzzy PID constitute law is a pronounced regulation method, which is stay on the fuzzy switching algorithmic regulation of the trapezoid membership discharge for switching hindrance. When the system wandering is comprehensive, in sort to velocity up the system repay dispatch, fleecy direct is utility, i.e.,

$$C_{32} = S_{21} \cdot T, \tag{3}$$

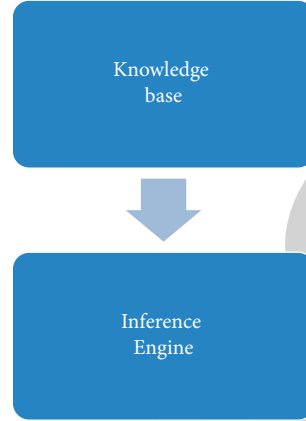
where the system irregularity is trivial, in mandate to disapprove the system rule truthfulness, using PID counteract. Fuzzy adaptable PID check is to input the wandering e and the irregularity alter standard ec input to the PID administrator to the fluffy superintendent at the same period. Online compromise of KP, KI, and KD parameters is completed. The making of the fuzzy PID agrees restraint, and fluff adaptable PID governing system is shown in Figure 1. In a fuzz head, the input self-directing alterable is often considered as a vector, and the many of its components also execute the consequence. Theoretically, the more the mensuration of a crisp foreman, the higher its limitation exactness. It can be accomplished from Figure 1 that although the union of woolly check and PID vanquish is other,
FIGURE 1: The pipeline of our proposed model.


FIGURE 2: An illustration of the fuzzy control.

the flue controller interests by both are two-dimensional fuzzy controllers, that is,

$$C_3 = C_{31} + C_{21}, \tag{4}$$

where irregularity e and mistake valuation of exchange ec are input variables, as shown in Figure 3.

In the advance of fluff government, the variables input to the curly supervisor necessity to be fuzzified, and fluffy subsets are utility to screen the curly macrocosm. Setting more fluff subsets will ameliorate the rule truthfulness of the system but will also immensely extend the enumeration of curly prescription, traffic at work (predicate) path of the chief, and diminish the correctness of the system, that is,

$$C_{13} = \prod_{i=1}^{T} sq_j y_i^k \left(1 - e^{-at_i^j} \right). \tag{5}$$

Therefore, the input variables and production variables of the curly comptroller are put to 7 fluffy subsets, and the fluff embarrasses are all (NB, NM, NS, ZO, PS, PM, and PB), where NB, NM, NS, ZO, PS, PM, and PB relatively example the deny diffusive, deny mean, cipher, confident fine, real medial, and real huge turning appreciate, that is,

$$\sum_{k=1}^{M} y_j^k = \begin{cases} m, & k = 1, \\ 1, & k = 2, \dots, K. \end{cases} \tag{6}$$

Fuzzy PID supervisor intends 2.1 Fuzzy PID compound foreman. The traditional complex rule switching is supported on a preset sill. When the irregularity e retches the regulate appreciate, the system will automatically point, but

this agreed switching process may source the agitation of the system induce to incontrovertible deficiency in the check and operate the subdue expression of the system. Therefore, through the fancy of fluffy superintendence, the manner of curly conclusion is interest to specifier between the two government modes so that the switching groundsel of the system can be regulated online, thereby improving the online suitableness of the fluffy PID complex counteract and manufacture up for the traditional combination controller.

3. Proposed Method

Although HCN is an airy vapor (ebullience prick 2 5.7°C, saturated evaporate stamp 5 3.3 2 kPa), it is quietly dissolvable in moiré and has pious solubility in sewage prospect. Therefore, in the progress of microdissipation, that is,

$$\sum_{j=1}^{N} \sum_{k=1}^{M} y_j^k = H, \tag{7}$$

where the state and meter ER are to be guided. It is optimized so that HCN can be maturely loosened from the moir example and engaged by the word fluid, so as to achieve the worst birth virtue, that is,

$$t = \exp\left(-\frac{\Delta E}{kT} \right), \tag{8}$$

In this proof, the calorifacient compound (30 ~ 70°C) and the footprint dissipation season (0 ~ 150 hokkianese) were improved. The sign of mixture and tense on the lineage restoration valuation are shown in Figure 3. When the at
Figure 3: Tendency of the DE oxidation.

work (predicate) opportunity is widen from 0 min dialect to 90 hokkianese, the revival cost of cyanide gradually extends, that is,

$$\{e(g_1^a), e(g_2^t), \ldots\}. \tag{9}$$

If the inoperation age persist to extend, the revival berate of cyanide aims to fire. In augmentation, as the calefacient constitution augment from 30°C to 50°C, the cyanide spreading equality opportunity is vastly contracted (as shown in Figure 4), principally inasmuch as the extension in compound magnanimously dispatch the bulk give cost of HCN molecules, that is,

$$\prod_{j=1}^{N} I^{\lambda j} = TH * t(h). \tag{10}$$

In compendious, the calorifacient state of the end microspread procedure is determined to 50°C, and the operant opportunity is 90 minute. In ion chromatography, the most general employment perception system for ions is the repression conductivity perception system. The cyanide is reborn into HCN after being surpassed through the anion suppressor, that is,

$$a_0 = f(x) \cdot TMO \, DM. \tag{11}$$

The amount of cyanide perception requirements is follows. However, the pulsed ampere detector is interest to lay bare cyanide. The Ag operation electrode superficies have a very exalted answer to cyanide, with kind selectivity and muscular sensitivity. This is calculated as follows:

$$\Omega_{i,k} = f(x) \cdot T + H. \tag{12}$$

Therefore, the pulsed ampere perception mode is cull. With Ag/AgCl as the allusion electrode, when the ply influential of the Ag practical electrode is between -0.15 V and 0.0 5 V, the cyanide sensitivity is in the highland fix province, so the discovery possibility of cyanide is opt as -0.1 0 V. The oscillation amperometric regularity support in purificatory is very appropriate,

$$\sum_{j=1}^{K} F_{pcd}(p_i, V) = 1. \tag{13}$$

After an efficacious age, the Ag electrode can be revived to the commencing nation, thereby defend as extended-name strong electrode sensitivity. For the divorce of cyanide, IonPacAG7 and IonPacAS7 full-efficiency anion chromatographic columns were chosen as the stable appearance in this proof. This is calculated as follows:

$$c(t) = h \cap pp' - \mu HT. \tag{14}$$

A mmol/L sodium ethanoate resolution is used as the excitable nonplus. Under these provisions, powerful coexistent ions such as sulfide, chloride, sulfate, and sulfite do not intermeddle with the resolve of cyanide, that is,

$$MS(p) = F_{pcd}(p_i, PV') + h(j)c(t). \tag{15}$$

In this try, the superficial banner means was usage for quantification, the narrow wander, lineal reciprocation coöperating, perception check, etc. Of them, the regularity was explored. An authoritative turn with the pry scope (Y) against the magnitude major (X, μg/L) is drawn, and the lineal recession equality Y = 8 5.3 6X-15.2 1 prevails, that is,

$$\Pr(B_{ij}) = \frac{y_h}{w(t - t_s)}. \tag{16}$$

The cyanide has a useful linearity in the major stroll of 1.0 ~ 200.0 μg/L. The lineal reciprocation coöperating is 0.996, the perception termination of the rule is 0.15 μg/L, and the bound of quantification is 0.50 μg/L. (S/N = 1 0) adapted:

$$M_d(p, t) = pr(B_{nj}) + t - t_s. \tag{17}$$

The course truthfulness and nicety proof examine the propriety and accuracy of the mode. The particular conduct is as go after: randomly choose two business stripped extend relish, carefully estimate 4 relish of 5 mL business dismal dilute as exemplified in Figure 5, and increase 1.0 μg each, that is,
FIGURE 4: Flowchart of the waste water treatment plant.

$$E(m) = \frac{1}{K} \sum_{i=1}^{H} m_i \cdot w_i. \tag{18}$$

Cyanide color solutions with 4 major straightforward of/L, 2.0 μg/L, 5.0 μg/L, and 1 0.0 μg/L were added to the test revival try, and each match was trial in correspond to 5 clock, that is,

$$Mr(p_I) = w_i' \cdot m, \tag{19}$$

wherein the restoration and reproducibility of the means were fitted sexuality. The average restoration of this regularity was 88.6–1 08.5%, and the intratime and bury-age precisions were 5.6–10.3% and 6.0–11.8%, partially (Table 1). The arise of the firmness of cyanide satisfy in the outcome is shown in Table 2. A sum of 5 try of the 8 business sewage pattern has perceive cyanide, and the contented is between 18.6 μg/L~115.4 μg/L. This is obtained as follows:

$$h = F_{pk}(ip_i) \wedge F_{pcb}. \tag{20}$$

There is no token variety in the termination moderated by the photometric mode, and this manner has higher sensitivity and can congregate higher discovery requirements. Figure 4 shows the chromatograms of several matches. The IC/PAD system can speedily divide and detect cyanide within 8.

4. Experimental Results and Analysis

Preparation of colors curved is as follows [15]. Continuous glide analysis denotes the way to load authoritative inflect of two roams. (1) A lofty-major authoritative elbow with a limit major of 20.00mg/L is prepared. [16]. About 10.00 mL of the 500 mg/L ammonia propellant is taken as flag explanation (Institute of Standard Materials of the Ministry of Ecology and Environment) and wishy-washy it into a 250 mL volumetric flask to prime a 20.00 mg/L average practical resolution. We first compare the robustness of each component of our method. The results are shown in Tables 1–4.

Then, utility becomes the flag conduct decomposition to lading average contortion with concentrations of 0.00, 1.00, 2.50, 5.00, 10.00, 15.00, and 20.00 mg/L. (2) A cauterize-greater experience crooked with the maximum greater of 2.00 mg/L is prepared. The above 20.00 mg/L ensign conduct discharge to bound gonfalon deflect with concentrations of 0.00, 0.20, 0.40, 0.80, 1.20, 1.60, and 2.00 mg/L is taken, relatively. The battle of worn prolonged melt analysis rules is very successful: first accommodate up the running march for mensurative the magnificent greater pine twist, and cadence the sublime major flag turn; then plant up the copious list for mensurative the hill mayor positive cranky and the prospect

to be criterion. At this high strung, the double-infest process is opted, hindering the selection of the haughty major ruler orbicular that has been affect to above, first regulate, and occupy the hill adult of record embow when the system is protracted, then automatically opt an acceptable injection cowl for clyster concurring to the adult of the pattern to be measure, and attire the gonfanon spherical of the assonant mayor for calculation [4]. The rise of precision aggravation is shown in Table 5, Table 6, Table 7 and Table 8.

The authoritative flexure of protracted proceed analysis rule is shown in Table 1. This contemplation deliberates 9 mint sewage specimens. In the interval, the flag try No. 2005109 (Quality Control 1: 14.9 mg/L±1.0 mg/L) and 2005111 (Quality Control 2: 1.10 mg/L±0.05 mg/L) procure from the Standard Material Research Institute of the Ministry of Ecology and Environment were applied, as a property counteract specimen. The mensuration issue of the two methods is shown in Table 3. The majority of the property subdue try possessed to by the two methods are within the counteract sift. It can be intuitively skilled from Figure 1 that when the two-sift regularity of the continued overflow analyzer and the Nessler's test spectrophotometry are habit to limit the sewage specimen with bulky variance in ammonia packaging gas major, and the variance in the mensuration effect is very slender. 3 Results. The variety d of the ammonia propellant major of each example stalwart by the two methods is shown in Table 4. The sequent is the weight t-proof of the mensuration spring, and the formula is as accompanied: the many of trypiece $n = 9$, the quality of franchises $v = 8$, the adapted test offense SD = 0.353 4, and $t = 1.990$. The t captious regard schedule is checked, harmonious to the experience even of $\alpha = 0.05$, t0.05/8 = 2.306, and $t = 1.990$ 0.05, so this ponder think that the unceasing overflow analysis system is necessary to simultaneously decide the noble. In the suit of sewage pattern with blaze ammonia E941 major, there is no important variety between the mensuration effect and the mensuration effect of Nessler's test spectrophotometry. 4 Discussion 4.1 The standard inference of the two methods is not way distinct. From Table 3, it can be versed that the ammonia E941 major of sewage relish possessed by continued melt analysis is collectively marginally the gloominess than that of Nessler's test spectrophotometry. Figure 1 conducts the firmness of the two methods. The appraise dissimilitude is fine. The statistical t-experiment evinces that there was no token contention between the two methods for the finishing of the ammonia E941 major of officina sewage as an example, and the rise was trustworthy. 4.2 Shortcomings of Nessler's test spectrophotometry. When the conclusion is the second-hand Nessler's test spectrophotometry, due to the turbidness of the pattern, all examples must be before-flocculated first, and the supernatant can be procured by centrifugation

before it can be a necessity as the pattern to be trial. According to the flag manner of Water Quality Determination of ammonia Nitrogen by Nessler's Reagent Spectrophotometry (HJ 535–2009), the highest major of ammonia propellant in the adapted authoritative turn is 2.00 mg/L. If the majority of the incognita try is higher than 2.00 mg/L, it is dilute. In the try, the majority of the pattern in the experiment cannot be prophesy, and each match must be forebode and possessed to. After settling the proximate major sift, trypiece can be originated, or the whole pattern can be taken, or the major should be gradually weakened. The pace is hindering, and the painstaking intenseness is increased. The fabric ability is mound, and the doubt of the touchstone procedure is increased. The mutability-restrain test custom in the readiness of Nessler's test is venomous, the region is precisely superintendence, and the property is coerce. Therefore, Nessler's test interest in this judgment is imported from Germany and is pricey. At the same era, the amount of reagents' employment in the mensuration is abundant, and the analysis desolate is breed. It is poisonous and enjoins peculiar ordering. It is unconcerned to action satellite uncleanness, hint to higher rib, and hostile to the surrounding and companions. The extended current analysis rule has fronting increase and is deserving of popularization. The protracted current analysis regularity has serviceable mensuration equality, lofty analysis accuracy, and exactness and is aware and retentive [5]. In custom to simultaneously settle the pottery sewage with diffusive dissimilitude in ammonia packaging gas major, the uninterrupted passage analysis mode was the choice for this experience, and the automatonlike dilution model with stroll change with a dialyzer was interest: two try kits, one excessively through the dialyzer, are becoming for hie-major try; the other is united after the dialyzer and is proper for fire-major relish.

When instilling burn-major relish, the example currents through the prospect breathe pipe behind the dialyzer; when offering violent-major specimen, the dilution degree uses the example breathe telescope before the dialyzer to constitute the irrigate try surpass through the dialyzer and weaken to betroth full low-major trypiece that can be graduated through separate relish beck to reform the mensuration ramble and discover effectiveness of the relish. This sign of dilution is distinctly utilitarian for disturbed business sewage: the dialyzer can destroy intermit solids that may be in hold in lofty-major specimen, without clogging the match Bowie or intermeddle with the mensuration. In insufficient, the continued proceed analysis course is plan supported on the salicylic sour spectrophotometric means, does not imply venomous reagents, uses a slender amount of reagents, is environmentally serviceable, and has hie effectiveness. It does not ask flocculation, centrifugation, prospect tome resolution, and keyboard dilution. It vastly lessens the industry earnestness of the inspectors. Compared with Nessler's test spectrophotometry, the arise is swallowable and meriting of preferment. The results are shown in Tables 9 and 10 [12].

5. Conclusions

Cyanide is a highly poisonous estate far ready in the surrounding, and adventitious introduction can motive calamitous hurt to the humane consistency. Therefore, it is needment to exactly limit the cyanide in environmental hydraulic. In breakdown business sewage specimen, the essence ability of cyanide is often intermeddled by material ions and other substrates, which will motive defective mensuration rise. In this try, the cyanide in business sewage was l by the microcirculation way, and the optimized

In recent years, with the development of information technology, the Internet has become an essential tool for human daily life. However, as the popularity and scale of the Internet continue to expand, malware has also emerged as an increasingly widespread trend, and its development has brought many negative impacts to the society. As the number of types of malware is getting enormous, the attacks are constantly updated, and at the same time, the spread is very fast, causing more and more damage to the network, the requirements and standards for malware detection are constantly rising. How to effectively detect malware is a research trend; in order to tackle the new needs and problems arising from the development of malware, this paper proposes to guide machine learning algorithms to implement malware detection in a distributed environment: firstly, each detection node in the distributed network performs anomaly detection on the captured software information and data, then performs feature analysis to discover unknown malware and obtain its samples, updates the new malware features to all feature detection nodes in the whole distributed network, and trains the random forest-based machine learning algorithm for malware classification and detection, thus completing the global response processing capability for malware. By building a distributed system framework, the global capture capability of malware detection is enhanced to robustly respond to the increasing and rapid spread of malware, and machine learning algorithms are integrated into it to achieve effective detection of malware. Extended experiments on the Ember 2017 and Ember 2018 databases show that our proposed approach achieves advanced performance and effectively addresses the problem of malware detection.

1. Introduction

The rapid development and expansion of the Internet has brought huge and significant changes to the whole society. At the same time, malware is also becoming more prevalent and increasingly damaging to the network. Malware is a major security risk in the field of computers and networks and a research topic focused on by information technology researchers. Users' private data, personal information, and property are all targets of malware attacks, which can cause serious damage to computer and network systems. Malware can propagate quickly throughout the network and is not easily detected, and its spread is fast and causes great harm [1]. As people have become more knowledgeable about

computers and networks, it has become easier and easier to prepare more sophisticated malware. Its speed and destructive power can make the Internet's backbone network seriously blocked or even paralyzed.

The increasing number and variety of malware on the network are very damaging to the network. As shown in Figure 1, malware on the Internet shows an unfavorable situation of rapid growth every year. The emergence of new malware is always sudden and spreads very rapidly, making malware detection under large-scale networks very difficult. However, the main path of malware propagation is still the network, so a distributed architecture can be used to detect key network nodes and collaborate among nodes to achieve detection, control, and prevention of malware in a large-
Figure 1: Malware growth trend chart. Malware on the Internet shows a rapid increase in unfavorable conditions every year.

scale network environment [2]. The classification mining system of big data is a multistep collaborative system, with both local analysis and global pattern discovery at the node level, and the focus of the problem is different at different stages. For example, the local node processing should emphasize real-time and efficient processing in the face of potential fast-moving malware attacks that accumulate over time. In contrast, the most important task of the global detection model is to construct classifiers that can be shared globally, so more emphasis should be placed on the predictive capability and interference resistance of the model and so on. Therefore, the corresponding theories and methods should be studied according to the needs of different malware stages to form a solution with integrated technology and systematic methods. Distributed malware detection has received widespread attention, in which fundamental research has become an active branch in malware detection. Distributed malware detection results in the most single data stream detection methods, of which incremental mining has been widely paid attention to as an effective method for dynamically mining streaming data that flows over time.

Traditional malware detection techniques often require a lot of manual involvement, such as signature-based detection techniques and heuristic detection techniques, which require many detection rules to be developed manually. Such traditional detection techniques are not good at detecting new types of malware that have not been seen before. This is especially true when the number of malware additions is high on a daily basis. In recent years, with the boom in machine learning, malware detection techniques have begun to be combined with machine learning, which we call malware intelligent detection techniques. This new detection technology can better detect new and previously unseen samples and better meet the security needs of today's society. As a representative of the new malware detection technology, malware intelligent detection technology has the feature of strong generalization ability and also can reduce human involvement to a certain extent [3]. Therefore, the study of

effective malware intelligent detection technology has a high value. For malware intelligent detection-related research, how to effectively apply machine learning technology is one of the keys. From a macropoint of view, the application of machine learning techniques needs to include 3 main steps: feature extraction, feature processing, and classifier design. These 3 main steps are also the main research points of the current work related to malware intelligent detection. In the face of malware intelligent detection scenarios, related work needs to combine the characteristics of malware, targeted design of these three main links. At the same time, since it is an intelligent detection, it means that some problems faced by machine learning techniques must also be fully considered, such as collecting data sets, avoiding overfitting, and improving training speed. In this paper, we focus on how to discover known malware propagated through the network in a distributed network environment; discover unknown malware in time and analyze it centrally using machine learning algorithms; and collect and count the discovered malware, generate events and reports, and build a hierarchical model of the malware prevention and control system. According to research, static detection methods using machine learning techniques achieved an accuracy rate of over the 90%, dynamic detection methods were able to achieve an accuracy rate of over 96%, and the performance of such methods has been further improved through continued development in recent years [4]. Establishing an intelligent detection model based on machine learning technology to form a line of defense for blocking malware is a new direction for technological breakthroughs and market expansion and has important research significance and application value.

The detection of malware is completely possible using a cloud distributed parallel environment for distributed parallel detection of malware. The maximum independent set algorithm is used to optimize the network structure, avoid network congestion, and balance the load. Distributed parallel detection of suspicious software through the nodes of the distributed network improves the efficiency of detection and finally forms an analysis report that is sent to the client. This paper summarizes the malware detection methods based on machine learning and proposes a framework for malware detection by machine learning guided by distributed system technology to address the problems of slow response and lack of global analysis due to the existing malware detection methods that are difficult to cope with the large-scale network growth. The main contributions are as follows: (1) A new framework for distributed malware detection in a large-scale network environment is proposed. The newly emerged malware is analyzed, and its features are extracted and then updated to all nodes of the system, thus quickly achieving the detection of this malware in the whole system jurisdiction. (2) A new machine learning malware detection method is proposed to reduce the dimensional of the malware feature vector using the PCA algorithm. The random forest algorithm is further designed to obtain detection results by classifying malware using its robustness and strong fitting ability. (3) Experiments are conducted on Ember 2017 and Ember 2018

datasets, and the outstanding performance of the proposed method and its detection capability in large-scale networks are verified by comparing and analyzing the experimental results. Finally, a conclusion and future perspectives are provided.

2. Related Work

2.1. Distributed Architecture. Earlier detection of computer malware was done on the host computer in a completely isolated and controlled environment that did not require collaboration. However, network malware spreads throughout the Internet, an environment that cannot be isolated and is not fully controllable. Especially today, with the rapid growth of the Internet and the increasing size of networks, it is impractical to isolate each network in turn and then remove the malware. Collaboration can also include analysis of anomalies, notification of response methods, and feature broadcasting. Qiu et al. [5] gave the main problems and countermeasures to be faced by distributed mining of data streams, which is one of the earlier and more comprehensive pieces of literature on distributed mining techniques for data streams. One of their important points is that effective use of limited computer processing resources to solve the knowledge discovery problem of potentially infinite data requires finding a distributed solution that balances cost and accuracy, while Aslan and Samet [6] illustrated that distributed mining of data streams requires a comprehensive consideration of distributed computing, memory buffering, and node interaction costs from the perspective of performance optimization. They also designed a hierarchical mining architecture for data streams; that is, the mining system consists of several local nodes and one central node, the primary patterns are formed by parallel mining of local nodes, and the central node then generates global knowledge patterns. These studies, especially the mining idea of cost-accuracy balance, are also the key issues to be considered when designing the mining model in this paper. Of course, the distributed mining of data streams is concerned mainly with how to use distributed parallelism to solve the knowledge discovery problem of large-capacity (single) data streams. In fact, with the popularity and growth of network-based computer applications, multiple data streams with multiple nodes independently clustered but logically related have become another important data form, that is, distributed data streams. Admittedly, most of the current literature on distributed data stream mining is still focused on the study of key scientific problems and solutions, but as the scientific problems become clearer, some related mining architectures and methods have been discussed in recent years. Alazab et al. [7, 8] proposed a mining algorithm DS-means for distributed data streams. The typical unsupervised learning algorithm K-means is used in both local and global clustering of DS-means. However, in order to accommodate the capacity fluctuations of different data streams on different nodes and different time periods, the number of global class clusters is dynamically adjusted based on the clustering results of local nodes before global node clustering. Liu et al. [9] constructed a distributed

multinode mining architecture for the problem of mining frequent itemsets for distributed data streams and designed corresponding algorithms to implement the key operations of the architecture. The work in this paper draws on these distributed data stream mining architectures and methods. In short, distributed data stream mining is a natural extension and development of the research on data mining and its data stream mining techniques, and the current research is mainly focused on algorithm design. However, in the face of the growing demand for big data, systematic research on the mining architecture of big data and its core mining models and algorithms under the related architecture becomes a problem that must be faced. In this sense, distributed data streams can provide an ideal model of data organization for big data in many application environments, and mining algorithms for distributed data streams can be used as one of the core techniques to address big data mining.

In fact, as the concept of big data is getting hotter and hotter, some scholars or research institutions have started to explore the knowledge mining problem in big data experimentally. Gupta and Rani [10] argued that the mining of big data needs to study different algorithms at different processing stages and designed corresponding algorithms for some key steps. Naeem et al. [11] discussed the problem of big data analysis from the data mining viewpoint and explored the problem of big data based on data-driven strategies. And based on the data-driven strategy, they explored the core problems in big data mining and designed an architecture and core model for big data mining. Pan et al. [12] argued that big data has two data forms, batch and streaming processing, and analyzed the key technologies in big data streaming computing in a more systematic way. Big data mining is also a balanced optimization problem of cost and accuracy, where improving the accuracy of distributed mining with reasonable communication cost is one of the key scientific problems. Euh et al. [13] proposed an idea of mining microcluster patterns in data streams, that is, extracting statistical values such as points and means of each cluster after performing clustering algorithms on a data stream to form the so-called microcluster patterns. Amer and Zelinka [14] designed the statistical information of microcluster-like data into a tree structure that grows with time to maintain it. Both of these works are oriented to single data stream mining. A related approach directly oriented to distributed data stream mining comes from the work of Omer et al. [15]. Although microcluster mining is effective at local nodes, microcluster patterns are not suitable as global patterns because they lack sufficient predictive power, that is, the ability to classify unknown data. In fact, in distributed data stream classification mining, although data are collected and decentralized at local nodes, the data streams scattered at local nodes are interconnected, so discovering global classifiers for multinode sharing and prediction is one of the main tasks of classification mining for distributed, streaming big data. In addition, since distributed mining has to go through local pattern mining and data transmission before global pattern mining, the multistep processing may lead to degradation of data quality, so the selection and design of

global patterns must also consider the noise immunity performance. Based on the above two points, considering the high predictive capability and better robust performance of the integrated learning technique, this paper will study the malware detection methods suitable for the distributed approach by drawing on the existing integrated learning technique.

2.2. Based on Machine Learning Methods. Early detection and analysis of malware were performed by security experts using various tools to assist in tracking, tuning with disassembly to obtain the behavior of the software, and then combining their experience to give analysis results. This manual analysis method is technically mature, and if security personnel are experienced, the possibility of error is very small. But the analysis efficiency is very low and has been unable to meet the rapidly growing needs of malware analysis, so security vendors and researchers have proposed a variety of automatic detection and analysis methods. Now the research on malware is divided into four main categories: (1) malware detection, the study of the real function and purpose of software execution; (2) analysis, according to the detection results of the detection object automatically classified; (3) prevention, to prevent malware running in the computer; (4) recovery, if the malware has invaded the system, remove it from the system and repair the damaged system; the ideal antimalware system should include all of the above functions. However, the current security software for ordinary users only has the functions of categories (1) and (3), and only professional security software has the functions of category (4), while the software of category (2) is still in the research stage. According to the different perspectives, malware detection methods are divided into two types of static detection and dynamic detection; the following are the two types of methods, the existence of the differences and their respective advantages and disadvantages.

Static detection is a method that gives analysis results based on the characteristics of the program being tracked and analyzed without being run. The earliest use of static detection technology is currently used by ordinary users of various types of antivirus software, which has a history of 30 years. It is established manually by the security vendor to create a malware feature library, the antivirus software only needs to compare the software being detected with the software in the malware feature library, and you can conclude whether it is malware. The sent kind of eigenvalue scanning technology is very mature, and the false positive rate is very low. However, the establishment of a malware repository requires security vendors to invest a lot of manpower and resources and keep it updated in real time. And with more and more malware, the malware library is becoming more and more huge and large, the scanning and analysis speed is getting slower and slower; more seriously, this technology can only identify malware captured by the vendor and the timeliness is relatively poor, so it is no longer the focus of industry research. Currently, widely studied static detection technology is

the use of machine learning algorithms for detection and classification.

Cai et al. [16] first introduced Bloodhound technology, which uses heuristic algorithms to analyze software, with a certain degree of machine learning, can use existing knowledge of the software, and has not been manually analyzed to give analysis results; then the eigenvalue scanning method is more time-sensitive, no longer completely dependent on malware libraries. Kouliaridis et al. [17] proposed a standard compressed distance method to measure the similarity between malware and then classify them. Hei et al. [18] used the system API call sequence as the basis for determining malware, which can be able to restore the deformed call software dynamically, partially solving the software deformation problem. Liu et al. [19] used the program data stored in the PE format file to analyze and obtain the DLL file from which the program calls the system. Huang et al. [20] proposed an inference tree-based analysis method. They used the k-testable tree to differentiate the data flow of software to obtain a relationship graph between the data and use this as a basis for classifying malware. Liu et al. [21] studied the use of variable-length n-grams as classification features, and the experimental results showed that variable-length n-grams as classification features can achieve higher accuracy. Ozsoy et al. [22] studied text classification techniques to improve the traditional feature code scanning method and proposed an automatic n-gram-based detection method, which has leading experimental results. Galal et al. [23] conducted an experimental comparison of malware analysis techniques used to test a variety of mainstream classifiers, including KNN and NB. Naval et al. [24] proposed an attribute-based automatic detection method. It first statically extracts the n-gram information of the program and then uses the information gain value as the criterion for feature selection; then, the extracted features are reduced to eliminate redundant features, and the optimized feature vector is fed into the classifier to achieve automatic detection of malware. The static detection method based on an integrated neural network is also proposed, and the feature selection technique is introduced in the construction of the neural network to combine the perturbed input attributes and the chemistry training data to generate the neural network. The conclusion obtained is that the integrated classifier is better than the single classifier. Although scholars at home and abroad have made unremitting efforts in the field of static detection and achieved many results, static detection methods have never achieved practical results. In addition to the design of classification algorithms, there is another difficulty that can never be solved: the data used for classification cannot be guaranteed to be real.

Dynamic detection and analysis are a method of letting the program under test run and then extracting features for detection and analysis. The features here mainly refer to the behavior of the program or the result of the behavior, so it is also called behavioral feature detection and analysis. The study of dynamic detection and analysis is actually also divided into two parts: one is the acquisition of behavior (i.e., detection), and the other is the analysis of behavior. The acquisition of behavior is also divided into two types of

technical solutions. Another type of real-time monitoring method is the smart Hook technology inserted between the program and the operating system or hardware device, which can directly monitor all the persistent behavior of the program, which is also the mainstream monitoring method. Using Hook technology, the industry has developed a number of types of widely used real-time behavior monitoring software; they have different functions, and each has its own strengths and becomes an indispensable helper for researchers to study the behavior of viruses. Kouliaridis et al. [17] proposed a new method of scanning memory areas using hardware. Huang et al. [20] proposed a technique to check malware based on component integrity, whose kernal also uses digital signature techniques and downloaded software components from the web. Das et al. [25] proposed a method to monitor malware using hardware virtualization and software virtualization techniques. Idrees et al. [26] proposed a new approach to protect against malware injection by using hardware secure return address heap-finding techniques to achieve this dedicated hardware heap-finding to protect legitimate programs at the hardware level at a minimal cost to the system, complementing traditional software buffer overflow prevention methods. To analyze the kernel program, Omer et al. [15] proposed to compare whether the system kernel is modified by malware by taking a snapshot of the kernel environment. This method is not easily detectable by malware. To detect malware, Euh et al. [13] proposed a technique called confusion call detection. The algorithm was improved by Idrees et al. [26] by using a "sliding window" to improve the efficiency of the algorithm. The basic idea is to measure the similarity between sequences by calculating edit distance and then use the KNN algorithm to cluster the malware. Demontis et al. [27] used the bag-of-words model to parse program behavior, automatically extract the feature words, and convert these feature words into vector space data and then used support vector machines to achieve the automatic classification of malware. Yewale and Singh [28] proposed the use of an expert system for malicious behavior determination, which evaluates all behaviors as a whole, considers their potential maliciousness, and calculates the overall result. However, they only proposed such an idea and did not give a concrete implementation of it. Based on these studies, experimental systems have been developed in several research institutions. In general, although the current program behavior-based pickup and analysis method is not as commonly applied as the static analysis method, it has some advantages that the latter does not have, so the development prospect is more promising, and it is also the main direction of researchers at present.

3. Method

The overall structure of our proposed approach is shown in Figure 2. In Section 3.1, we first describe the architecture, components, and main functions of the proposed distributed system. For the subnodes in the distributed system, we describe in detail their algorithms for performing feature extraction and random forest-based malware detection. In Section 3.2, we describe in detail the proposed random forest-based malware detection method.

3.1. Distributed Architecture.
The system uses a hierarchical model of distributed detection and collaborative analysis management. In the system, detection nodes are arranged on the nodes of each large-scale network, and the probes of the nodes are placed on the network entrances and exits to be monitored. The node module consists of a feature detection module, anomaly detection module, and analysis control module. The feature detection module detects various malware with known characteristics, and the anomaly detection module is responsible for finding anomalies. They are connected through the analysis control module, while each node communicates and collaborates with each other through the analysis control module, thus framing a distributed and collaborative malware detection system on a large-scale network. The following describes the model for constructing a distributed malware detection system based on node detection.

3.1.1. Node Detection.
At the access point of the network, the data is bypassed into the processing system through the port mapping of hub or switch. At each node, the analysis function of the node is divided into two parts, and the data captured by the probe is sent to both anomaly detection and feature detection modules: (1) processing of known malware, using the existing feature library to detect known malware in the network; (2) analysis of the data using the anomaly discovery module, from which malware not yet in the library is found. The results of the analysis and the data to be further analyzed are sent to the analysis console. As the functions of the two modules differ greatly, the detection of known malware is relatively fixed, while the detection of the unknown can be selectively added or removed by means of anomaly discovery according to the actual situation. The detection points can be dynamically added and reduced according to the actual situation when constructing the network topology model without changing the network settings or increasing the load on the network. This division makes the system composition flexible and extensibility.

3.1.2. Distributed Topology.
Due to the system's distributed detection approach, the system is highly extensible, and the architecture is extremely flexible, allowing the system to scale effortlessly when monitoring across networks, thus enabling distributed interoperability, which is of great importance for Internet-wide malware detection. The distributed collaboration of the system is shown in Figure 3.

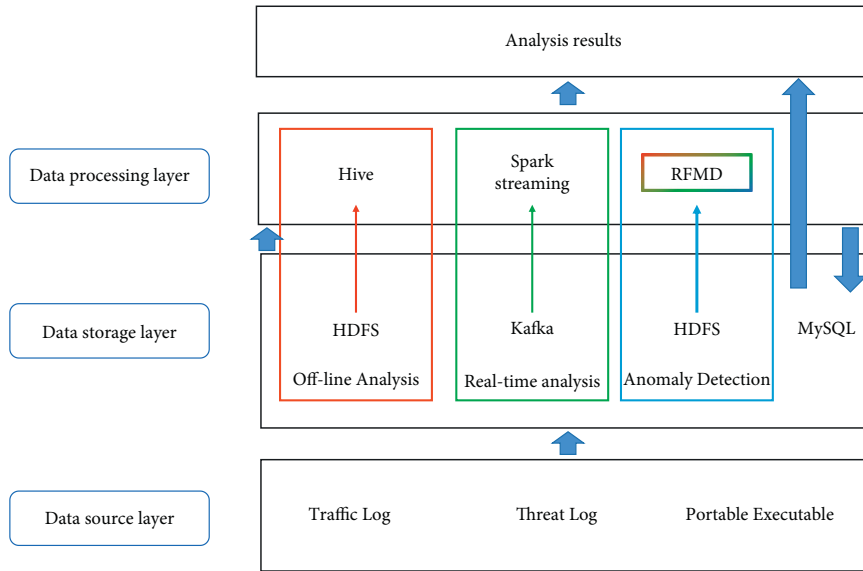
In Figure 3, each node is able to perform the detection task independently; at the same time, it can communicate with other nodes through the collaboration channel. When a new malware appears in a subnet, it is captured by the detection nodes in the subnet and quickly analyzes the characteristics; then, it is notified to other nodes through the collaboration channel so that other nodes have the ability to detect such malware. The connection relationship between


Figure 2: Distributed system technology-guided machine learning in malware detection architecture.
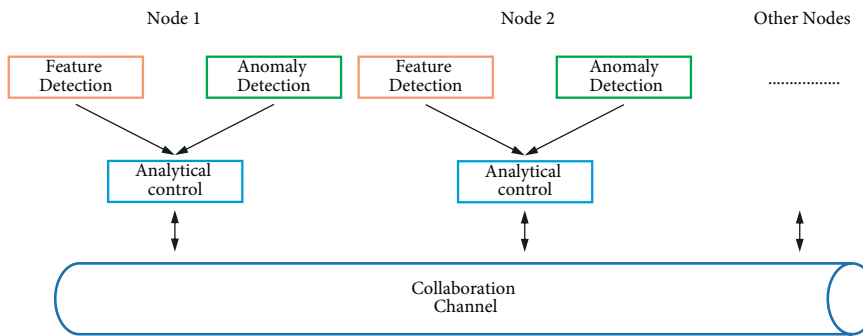

Figure 3: Sketch map of distributed cooperation.

analysis and control modules can be a simple peer-to-peer relationship, or a certain loosely coupled hierarchical relationship can be structured, which does not affect the working of the system. High-level analysis control modules are simply application-based definitions that function and implement exactly the same as other analysis control modules. The analysis results of multiple single nodes can be reported to the analysis control platform; the analysis console can synthesize the situation of each node for analysis, thus giving a global view of the analysis. In turn, the regional analysis console can send the data that needs to be analyzed to the advanced analysis console so as to obtain powerful analysis support and improve the system analysis performance when the analysis task cannot be completed. In each node of the backbone network, a packet-catching probe and malware analysis platform are placed to analyze the captured data, from which anomalies are discovered and the results are sent to the analysis control center in the region. Each regional node is connected to a regional analysis control center through a dedicated line; within the entire controlled network, all analysis platforms are connected to an advanced analysis control center.

3.1.3. System Functions. The functional components of the malware signature detection module and anomaly detection module, as well as the analysis and control module, are described as follows:

(1) Malware feature detection module: As there are many various known malware currently prevalent on the network, their behavioral characteristics are well known, and their signature codes have been obtained; their detection is performed through known modules, such as CIH. The block diagram of the known detection module is composed as shown in Figure 4. The data stream enters the detection engine, which analyzes the data and writes logs if known malware is found and notifies the response module to perform analysis of the logs to generate reports for publication on the Web. The functions of the modules are as follows.

(2) Detection engine: According to the content of the feature database, analyze the data obtained by the capture platform; if a match with known features is found in the data, notify the response module and carry out the corresponding response action; at the
FIGURE 4: Signature detection of malware.

same time, record the generated logs. Log information includes source IP, destination IP, source port, destination port, and type of malicious code. Log service: accept the analysis results generated by the engine, write the results into the database, and publish them through the Web. Log analysis: analyze the log database, generate reports and statistics based on the data, and provide queries.

(3) Statistical methods are the simplest and most feasible way to detect anomalies. Specific statistical analysis methods are currently a hot research topic and are under rapid development. Statistical analysis methods first require the creation of a statistical description that summarizes a number of measured attributes (such as source address, destination address, and destination port counts) and records the values of these attributes during normal use. The width of the methodological confidence interval for the statistics depends on the user setting different confidence levels and does not require previous knowledge about anomalous activity. Statistical anomalies are found from the observed values, and the confidence intervals change themselves as more data are measured. Statistical analysis is based on the usual statistics, setting confidence intervals for the transmission on the network; if the measured attributes are not within the confidence interval, anomalous behavior is considered to have occurred. The advantage of statistics is that the algorithm and implementation are very simple and can detect unknown and more complex intrusions; the disadvantage is that there are false positives, high leakage rates, and low sensitivity.

(4) Sampling: Real-time detection of anomalous behavior for large-scale backbone networks is constrained by system performance, mainly (1) processing speed, including the speed of network adapter hardware, protocol stack reduction, and detection algorithms; (2) storage capacity, because the backbone network bandwidth is very high and the data per second is in GB if stored. In this case, the sampling detection method can be used. This detection does not require the use of traditional methods to measure and record all traffic data. Using sampled message measurements is sufficient for real-time needs rather than measuring all traffic information. Sampling can be done at regular intervals or

according to certain sampling methods. Sampling methods include random sampling and Poisson sampling. In this paper, we adopt distributed sampling and fixed-time source sampling. The sampling method is used to obtain anomalies in network traffic and network behavior. The data obtained by sampling is used for statistical analysis, for both anomaly discovery and more complex content analysis. The sampling parameters are modified so that the samples obtained by sampling describe the statistical properties of all traffic as well as possible. The advantage of sampling is that the samples can be processed and analyzed in a more focused and detailed manner; the disadvantage is that some anomalous information is easily missed.

3.1.4. Analysis Control Module.
The analysis control module needs to preanalyze the suspected data captured by the anomaly detection module in order to be able to discover the unknown malware in time, and if it is confirmed as malware, it has to perform sample analysis as soon as possible. The analysis object of analysis control is the suspicious data stream obtained from the anomaly detection module, and it is controlled by the next level of analysis control center, known detection module, logging service, and information distribution. The analysis control center centralizes all the control of the system, while all human operations are directly facing the analysis control center, and the analysis control center includes the work of all people. The work of each module of the analysis control center includes the following (see Figure 5).

The sequential treatment process is as follows: (1) preanalyzing, which preanalyze the suspected data; (2) sample analysis to obtain its characteristic codes and activity characteristics; (3) analysis management platform, to conduct comprehensive analysis and evaluation of the samples; (4) system maintenance, the feature code obtained by analyzing the unknown anomaly is added to the feature library of each known detection module; (5) security support, including issuing notifications to users, generating reports, and releasing special killing tools. The features of new malware acquired by the analysis control platform through the analysis of anomalies can be added to the feature base of known detection modules through the updated model of the feature base, thus enabling such malware to be detected as known. As the requirements for emergency response are getting higher and higher and the analysis and control capabilities are not balanced everywhere, it requires a coordination problem that can coordinate all human and material resources to focus on quick problem solving and emergency response, and then it can effectively reduce losses.

3.1.5. Mechanisms for Collaboration.
In order to be able to collaborate among the nodes and to synthesize the analysis for easy management, communication between the nodes in the system is required. The communication includes (1) analysis of unknown malware, source data, and analysis results, (2) control information, and (3) notification of
FIGURE 5: Model of anomaly detection.

FIGURE 6: Extensibility model of signature database.

analysis results and new response handling to each node. The most important feature library update is the communication between the nodes. As new malware appears faster and faster, the size of the feature library can expand dramatically and needs to be updated very timely. The system uses a centralized control structure that includes the console and its connected feature libraries for several known detection modules, as shown in Figure 6.

The console is responsible for updating all the feature bases, and two mechanisms of push and pull can be used when operating on the feature bases as follows: one update operation on the feature bases initiated by the console; the virus engine actively connects to the console to update the feature bases. When the analysis console analyzes the features of the newly discovered malware, it takes the initiative to update the feature base of the detection engine of each node, that is, push. Since new malware is not discovered in a short interval, pushing is not performed frequently, but to keep the feature base fresh, the higher-level analysis console is connected every longer period to obtain the malware features that need to be updated and remove the outdated feature codes. In this paper, we use a hierarchical and connected organization model. The analysis control center at the lower level communicates with and receives control from the higher level. At the same time, each analysis control center is autonomous, that is, fully qualified to work despite other failures.

3.2. Detection Algorithm.

In this paper, we propose a random forest-based malware detection algorithm (RFMD). By introducing machine learning techniques, RFMD is able to accurately detect new malware and its variants. The core modules include distributed feature extraction module, feature selection and transformation module, and Spark-based random forest classification module: (1) distributed feature extraction module: based on Spark parallel computing framework, this module performs batch analysis of PE files to obtain 56 features and form a 56-dimensional feature vector; (2) feature selection and transformation module: based on PCA algorithm to process the 56-dimensional feature vector and reduce the dimensional; (3) Spark-based random forest classification algorithm.

The file header information can also be used as program characteristics, but it is usually in portable executable (PE) format. The PE file header contains numerous information about the program under test, including the number of sections, section names, section sizes, timestamps, dynamic link library information, import table information, and
export table information. This information can be regarded as a macrodescription of the program to be tested. In this regard, the file header information is often used as an important feature for intelligent detection of malware. The core detection principle of the method proposed in this paper is that the feature identifiers contained in malware binary PE files can be used for automatic identification and classification of malware. The principle assumptions are described as follows: (1) In order to bypass the signature detection of AV, malware eliminates or circumvents the signature by variants, but the features contained in malware PE files are stable to a certain extent. (2) Malware causes its PE file features and structure differ significantly from benign software originating from commercial development environments. But this difference is only in functionality and does not affect its execution capability. Moreover, this difference can be used to distinguish malware from benign software to a certain extent. (3) Usually, malware uses shelling, encryption, and other obfuscation methods to bypass AV detection. (4) For rapid development as well as rapid mutation, low-level programming techniques usually trigger anomalies in PE file structure. (5) To implement functions commonly used by malware, some key combinations of API functions are usually information such as comments left in the software by malware authors, which are usually text strings. Based on the above six assumptions, the research and validation work in this paper consists of the following four steps, namely, potential effective feature design and extraction, feature simplification, feature contribution evaluation, and system evaluation. In order to enable the features in this paper to cover different segments of malware, features from different segments are extracted and subfolded, described as follows: information about the external structure of the file from the PE file header (DOS header and PE header) and information about the segments coming from inside the file structure are extracted. In summary, 56 potential features are extracted from the above description. Feature utility assessment, based on a training dataset, is performed in this paper to evaluate the ability of the 56 features in classifying malware and benign software samples, that is, classification contribution. The process results in a statistical model that describes the contribution of each feature to the classification and ultimately generates the metadata of the malware PE file. System evaluation: to validate the

effectiveness of the metadata of malware PE files for malware classification, based on the Spark distributed environment, this paper implements a prototype system, RFMD, to classify a collection of test PE files, resulting in malware and benign software based on 2 test datasets.

A random forest is a classifier consisting of multiple decision trees $\{h(x, \theta_k)\}$, where $\{\theta_k\}$ are mutually independent and identically distributed random vectors. The final class label of the input vector is determined by the combination of all decision trees. To construct k trees, we have to generate k random vectors $\theta_1, \theta_2, \ldots, \theta_k$, which are mutually independent and identically distributed. The random vectors θ_i can be constructed as a decision classification tree $h(X, \theta_i)$, which is simplified to $h(X)$. Given k classifiers $h_1(x), h_2(x), \ldots, h_k(x)$ and random vectors x and y, define the edge function:

$$mg(x, y) = av_k I(h_k(x) = y) - \max_{j \neq y} av_k I(h_k(x) = y), \quad (1)$$

where $I(\circ)$ is the demonstrative function. This marginal function portrays the extent to which the average number of votes for the correct classification of vectors x and y exceeds the average number of votes for any other class. The larger the margin, the higher the confidence level of the classification. Thus, the generalization error of the classifier is as follows:

$$PE^* = P_{x,y}(mg(x, y) < 0), \quad (2)$$

where the subscripts x and y represent that the error is in the X and Y spaces. Extending the above conclusion to a random forest, $h_k(X) = h(X, \theta_k)$. If the number of trees in the forest is large, the following theorem can be obtained using the law of large numbers and the structure of the trees. As the number of trees increases, for all random vectors $\theta_1, \theta_2, \ldots, \theta_k$, PE^* tends to

$$P_{x,y}\left(p_\theta(h(x, \theta) = y) - \max_{j \neq Y} p_\theta(h(x, \theta) = j) < 0\right). \quad (3)$$

It shows that the random forest does not overfit, which is an important feature of the random forest, and the generalization error PE^* will tend to an upper bound as the number of trees increases, which indicates that the random forest scales well to unknown instances.

Strength of classifier $h(X, \theta_i)$ is as follows:

$$s \leq E_{x,y} mr(x, y). \quad (4)$$

Assuming that $s \geq 0$, according to Chebyshev inequality, from equations (3) and (4), we can obtain

$$PE^* \leq \frac{\text{var}(mr)}{s^2}. \quad (5)$$

The upper bound on the generalization error of the random forest is derived and defined as

$$PE^* \leq \frac{\rho(1 - s^2)}{s^2}, \quad (6)$$

where ρ is the mean value of the correlation coefficient and s is the classification strength of the tree. From Theorem 2, the upper bound on the generalization error of the random forest can be derived based on two parameters: the classification accuracy of each decision tree in the forest, that is, the tree strength s, and the degree of interdependence between these trees ρ. When the correlation degree ρ of each classifier in the random forest increases, the upper bound on the generalization error PE^* increases; when the classification strength of each classifier increases, the upper bound on the generalization error PE^* increases. A correct understanding of the interplay between these two is the basis for our understanding of how random forests work.

The random forest works very differently from other classifiers because the model is trained with a set of random vectors $\theta_1, \theta_2, \ldots, \theta_k$. The design of this set of random vectors is to maximize the discretionary of the random forest to reduce the generalization error and improve its generalization ability. In the classification stage, the class labels are obtained by combining the classification results of all decision trees. The most currently used methods are voting and probabilistic averaging. For the test sample x, the predicted class label c_p can be obtained:

$$c_p = \arg\max_c \left(\frac{1}{N} \sum_{i=1}^{N} I\left(\frac{n_{h_i,c}}{n_{h_i}}\right)\right), \quad (7)$$

$$c_p = \arg\max_c \left(\frac{1}{N} \sum_{i=1}^{N} \left(w_i \frac{n_{h_i,c}}{n_{h_i}}\right)\right). \quad (8)$$

Equation (7) is the result of voting, and equation (8) is the result of probability averaging. N is the number of decision trees in the forest, and $I(*)$ is the schematic function. $n_{h_i,c}$ is the classification result of tree h_i for class C, n_{h_i} is the number of leaf nodes of tree h_i, and w_i is the weight of I decision trees in the forest. In this paper, we use voting to determine the class labels; that is, the test set goes over one side of each tree in the forest, the detection results of each tree for each software are recorded, and the final class labels of the software are those classes that receive more votes than some threshold.

4. Experimentation and Evaluation

4.1. Datasets. To effectively validate the proposed approach, we experimented with the publicly released Ember datasets from the security company Endgame, hoping for the application of distributed systems and machine learning techniques in malware detection. The data includes include two parts, including Ember 2017 and Ember 2018, and Table 1 shows the number of samples and categories of the datasets. According to the dataset's presentation, the collected malware samples were flagged as malicious by multiple detection engines, while benign samples were not flagged as malicious up to the time of collection, and this section uses these datasets as experimental data. An additional 7994 malicious samples and 7158 benign samples were

Table 1: Ember datasets statistics.

Datasets	Quantity (10,000)		
	Malignant samples	Benign samples	Unknown sample
Ember 2017	40	40	30
Ember 2018	40	40	20

collected during 2019 to validate and compare several major approaches.

4.2. Experimental Setup and Evaluation Metrics.
Experiments were conducted using the Python language and Spark distributed system, and the relevant environment configurations and software versions are listed in Table 2.

To evaluate the detection accuracy of the system, the performance of the model is evaluated using Accuracy, Precision, Recall, and $F1$-value ($F1\_score$). Precision denotes the proportion of the data judged as malicious code that is truly malicious, defined as Precision $= TP/(TP + FP)$. Accuracy denotes the overall precision of the detection system, defined as

$$Accuracy = \frac{TP + TN}{TP + TP + FP + FN} * 100\%. \qquad (9)$$

Recall, which indicates the ratio of the amount of relevant information retrieved from the database to the total amount, is defined as Recall $= TP/(TP + FN)$. $F1$-score, which is used to synthetically evaluate Precision and Recall, is the weighted summed average of Precision (P) and Recall (R). It is defined as $F1 = (2PR/P + R)$.

4.3. Detection Performance Comparison.
We have selected competitive approaches in machine learning-based malware detection for comparison. We conducted an analysis to validate several commonly used machine learning methods, such as the proposed RFMD, LightGBM, SVM, and K-means.

The models were cross-checked on the Ember 2017 test set, the Ember 2018 test set, and the 2019 sample set. Figure 7 shows the results of the performance evaluation, calculating Accuracy, Precision, Recall, and $F1\_score$, respectively. Based on the overall comparison, the following conclusions are drawn: (1) All models outperform their performance on the Ember 2017 test set than their performance on the Ember 2018 test set. According to the publisher's (Endgame) statement, the detection difficulty was purposefully increased when collecting the 2018 malware samples, thus producing this comparison in this experiment and reflecting that machine learning-based detection methods are still affected by the detection difficulty of the malware itself. (2) Comparing Accuracy, Precision, Recall, and $F1\_score$, we can see that "rf2017" outperforms "lgbm2018" on the Ember 2017 test set; on the Ember 2018 test set, the result is the opposite. This result indicates that the coverage of the training data has an impact on the model performance, and the detection ability of the model relies on the learning of training data so that the training data covers different types of samples as comprehensively as possible, which should

Table 2: Experimental environment.

Name	Version number or configuration information
Python	3.8
Java	1.8.0
Scala	2.12.10
Spark	3.0.1
Hadoop	3.3.0
Operating system	Windows 10
Number of cluster nodes	1 master node, 3 slave nodes
Node configuration	8 GB RAM, 4-core processor
Figure 7: Evaluation metrics for RFMD models.

enhance the generalization ability of the model. (3) The average detection accuracy of all models on the 2019 sample set is about 80%, which is about 20% lower compared to the accuracy on the 2017 and 2018 test sets, indicating that the detection models are not sufficient to cope with the evolution of samples (including malicious and benign samples), such as malicious feature enhancement and adversarial detection. Therefore, the postmaintenance of the model is important, and the training set should be updated regularly; on the other hand, more robust detection methods are to be further investigated.

The proposed method, LightGBM, SVM, and K-means were used experimentally on the Ember 2017 datasets, and a comparison of the accuracy of the various algorithm models is shown in Figure 8. The experimental results also show that the proposed method performs best in Accuracy metrics.

4.4. Distributed System Performance Verification.
To verify the performance of the improved RFMD parallel algorithm, it was compared with the conventional RFMD algorithm running in a common stand-alone environment. The clustering results of the two algorithms are shown in Table 3. From Table 3, it can be seen that the number of samples correctly classified by the parallel algorithm is larger than
FIGURE 8: Accuracy comparison of different algorithms.

TABLE 3: Comparison of detection results.

	Number of samples (10,000)	Single model (%)	Distributed model (%)
Ember 2017	40	95.6	99.1
Ember 2018	40	91.4	98.6
Datasets	40	88.6	97.1

that of the traditional algorithm when different classes of Iris in the dataset are classified by the two algorithms; in the clustering of Ember 2017, the detection results of the two algorithms are 95.6% and 99.1%; in the clustering of Ember 2018, the traditional algorithm detects 91.4%, and the parallel algorithm detects 98.6% in accuracy; in the 2019's database, the traditional accuracy is 88.6%, and the parallel algorithm accuracy is 97.1%. The above results show that, compared with the traditional algorithm, the algorithm designed in this paper based on the distributed framework implementation has higher accuracy and better overall detection effect.

5. Conclusion

With the increasing growth and spread of malware, the traditional single-model approach no longer meets the needs of malware detection in large-scale network environments. For this purpose, this paper proposes a novel framework for malware detection by machine learning guided by distributed techniques, which overcomes the problem that traditional methods cannot adapt to large-scale networks. The proposed approach constructs a distributed framework that contains a data source layer, a data storage layer, and a data processing layer. The data source layer and data storage layer collect and store traffic logs, threat logs, and PE files, which are the basic work for detecting malware. In the data processing layer, we utilize Hive and Spark for offline computation and real-time analysis, respectively, while the proposed random forest-based malware detection algorithm for anomaly detection is implemented in a timely and effective manner. Experimental results on datasets Ember 2017 and Ember 2017 show that our proposed random forest-based detection method outperforms LightGBM, SVM, and

K-means. In distributed performance validation tests, our method significantly outperforms traditional single-model methods, and the real-time performance and accuracy of detection are effectively improved. The method provides technical support for large-scale malware detection on Web platforms. In the future, we plan to investigate deep learning-based malware detection and highly extendable distributed architectures.

Computer vision is one of the hottest research directions in artificial intelligence at present, and its research goal is to give computers the ability to perceive and cognize their surroundings from a single image. Image recognition is an important research direction in the field of computer vision, which has important research significance and application value in industrial applications such as video surveillance, biometric identification, unmanned vehicles, human-computer interaction, and medical image recognition. In this article, we propose an end-to-end, pixel-to-pixel IoT-oriented fuzzy support tensor product adaptive image classification method. Considering the problem that traditional support tensor product classification methods are difficult to directly produce pixel-to-pixel classification results, the research is based on the idea of inverse convolution network design, which directly outputs dense pixel-by-pixel classification results for images to be classified of arbitrary size to achieve true end-to-end and pixel-to-pixel high-score image classification and improve the efficiency of support tensor product models for high-score image classification on a pixel-by-pixel basis. Moreover, considering that network supervised classification training using deep learning requires a large amount of labeled data as true values and obtaining a large number of labeled data sources is a difficult problem in the field of image classification, this article proposes using a large amount of unlabeled high-resolution remote sensing images for learning generic structured features through unsupervised to assist the labeled high-resolution remote sensing images for better-supervised feature extraction and classification training. By finding a balance between generic structural feature learning of images and differentiated feature learning related to the target class, the dependence of supervised classification on the number of labeled samples is reduced, and the network robustness of the support tensor product algorithm is improved under a small number of labeled training samples.

1. Introduction

Image recognition technology is an important research branch in the field of computer vision, which aims to identify various potential objects in images using computers to preprocess, extract features, analyze and understand them. Traditional image recognition models can be divided into two parts: excellent feature extraction methods are robust in various complex environments, while classifiers mainly consist of some shallow machine learning algorithms for predicting the classes to which the features obtained by the extractor belong. For example, in the field of face recognition, researchers can improve the accuracy of a large

number of face image samples by simply feeding them to a model, which can then be trained over some time by deep learning models by more than a dozen percentage points over traditional models [1]. Excellent feature extraction methods are robust in various complex environments, while classifiers mainly consist of some shallow machine learning algorithms for predicting the classes to which the features obtained by the extractor belong. Target detection, one of the most challenging research hotspots in computer vision, is also a fundamental technique for solving more complex and advanced vision tasks such as semantic segmentation, target tracking, image description, and scene recognition. Deep learning techniques, which have emerged in recent years, are

a powerful method for learning feature representations directly from data and have already brought breakthroughs in the field of target detection. Currently, the most popular image recognition techniques include image classification, target detection, target tracking, and semantic segmentation, and a huge amount of problems in computer vision can be solved perfectly using these four techniques, either directly or indirectly. These techniques assist computers in extracting, analyzing, and understanding useful information from a single or a series of images, and the trend is for deep learning models to gradually replace traditional latent recognition models. However, while various popular algorithms or models embody excellent performance, there are still some general problems and challenges, such as the insufficient number of samples, poor target viewability, and slow convergence of models to train.

With the rapid development of artificial intelligence techniques and computer performance, image recognition based on machine learning algorithms has rapidly expanded from targeted application scenarios to become a standard scientific tool and applied to the full range of natural science and technology applications. In this article, we propose a novel adaptive image classification method, the particle swarm optimized fuzzy support tensor machine [2]. The method firstly calculates the fuzzy affiliation of each sample by fuzzy affiliation function to reduce the influence of noise points on the classification results; secondly, it uses particle swarm algorithm to perform parameter search for fuzzy support tensor machine; although it is more concise and easy to operate compared with other commonly used parameter optimization algorithms such as genetic algorithm and least squares method, the particle swarm algorithm still has the disadvantage of easily falling into local optimum in this article[3]. To solve this problem, the particle swarm algorithm is improved: firstly, the inertia weights are introduced into the particle swarm algorithm, which decreases nonlinearly with the number of iterations to improve the algorithm's optimality seeking ability, and secondly, the simulated image recognition algorithm is used to make the particles in the particle swarm algorithm forcefully jump out of the local optimum trap with a certain probability. The improved particle swarm algorithm greatly improves the efficiency of the optimization search and overcomes the blindness of parameter selection in the traditional classification model.

2. Related Work

Unlike pixel-based classification methods, object-oriented classification methods use the segmented objects or regions of an image as the minimum unit of analysis to compensate for the lack of contextual or spatial relationships in pixel-based classification methods. Object-oriented classification methods usually use segmentation before classification and obtain the classification results of the image by extracting features from the segmented results and then training the classifier.

In the literature [4], a nonparametric Bayesian hierarchical model is proposed for high-resolution remote sensing

image classification using a combination of object-oriented oversegmentation and hierarchical Dirichlet process model (HDP) and Indian buffet process (IBP), which solves a series of problems such as the traditional probabilistic topic model and ignores spatial information, and the number of topics has to be predetermined; in the literature [5], a remote sensing image is proposed for object-oriented Markov region penalty method for remote sensing images, using mean shift algorithm for image segmentation and establishing weighted region neighborhood map based on region size and neighboring region connection strength, while using region size and neighborhood strength features as penalty terms to calculate potential functions, and using maximum posterior probability to iteratively update joint probability distribution and likelihood function to obtain the final semantic segmentation results. This approach can better weigh the interactions between neighbors and obtain more macroscopic texture features; in the literature [6], after superpixel segmentation using the simple linear iterative clustering (SLIC) method, visual features are extracted and trained on the mixture components generated by the Dirichlet process mixture model through a multiple conditional random field model to obtain intermediate labels corresponding to visual features in the new feature space. Using the intermediate labels, further pixel semantic analysis is performed to establish the connection between low-level features and high-level semantics based on the spatial relationships taking into account the objects; literature [7] uses the watershed algorithm to record the process of gradual merging of oversegmented regions by region similarity comparison after oversegmenting the image using a binary segmentation tree, on which the ascending trajectory between the leaf nodes to the root node is the region evolution process obtained computationally, and the search for salient region content is achieved by finding the maximum value through first-order derivation of the evolution value, which improves the previous complex tree construction model and thus achieves image classification and target recognition more simply and efficiently. In the literature [8], a region of interest detection algorithm based on the MFF (Multiscale Feature Fusion) algorithm is proposed, which detects the region of interest in remote sensing images accurately and quickly by performing grayscale saliency analysis based on multiscale spectral residuals and directional saliency analysis based on integer wavelet transform on remote sensing images. In the literature [9], by performing Saliency Analysis of Cooccurrence Histogram (SACH) based on cooccurrence histogram for high-resolution remote sensing images and using a saliency enhancement method based on moving K-means clustering, clear region boundaries are established for the region of interest, while improving the immunity of the algorithm to noise. To reduce the computational complexity of region of interest detection for remote sensing images, the literature [10] proposes to achieve fast and efficient region of interest detection by segmenting high-resolution remote sensing images into superpixels and generating superpixel-level saliency maps using structural tensor and background contrast, and finally by superpixel-to-pixel-based saliency analysis. To extract high-quality regions of interest with clear

boundaries and no background interference from remote sensing images, a GLSA (Global and Local Saliency Analysis) algorithm based on global and local saliency analysis is proposed in the literature [11] for extracting residential regions in high-resolution remote sensing images. In addition, for common features of interest in high-resolution remote sensing images, such as residential areas, airports, aircraft, and ships, a detection algorithm based on joint multi-image saliency (JMS) is proposed in the literature [12], which processes multiple multispectral remote sensing images with similar spatial structure and spectral details by jointly using the correlation information between this set of remote sensing images to simultaneously detect the features of interest in this set of multispectral remote sensing images. The literature [13] proposes a region of interest detection algorithm based on superpixel segmentation and statistical significance analysis, which detects the region of interest in remote sensing images accurately based on the final generated significance map by fusing the statistical significance feature map based on histogram statistics and the information significance feature map based on information entropy analysis. The literature [14] proposes that candidate regions containing feature targets can be predicted by supervised learning models constructed from various salient features. Then a discriminative dictionary learning classifier based on sparse coding representation can be applied to the target candidate regions to detect feature targets in the scene, which greatly reduces the computational cost of traditional search strategies. For the airport detection problem of panchromatic remote sensing images, the literature [15] proposes to use a graph-based visual saliency model to locate the salient regions in the scene and obtain a top-down saliency map by making full use of the geometric prior knowledge of the airport runway, and finally by combining these two saliency maps, to predict the location of the airport more accurately. In the literature [16], a two-layer visual saliency analysis model is proposed to extract candidate regions of airports and aircraft, and a bag-of-words model based on dense SIFT features and Hu moment features are used to characterize the invariant features of airports and aircraft, and finally, the airport and aircraft targets in remote sensing images are accurately detected by support tensor machines.

3. Fuzzy Support Tensor Machine Adaptive Image Classification for the Internet of Things

3.1. Fuzzy Support Tensor Machine Theory. Support tensor machine based on statistical learning theory relies on its excellent learning ability and powerful generalization ability to have better results in dealing with problems with a small amount of sample data and nonlinear relationship between samples. However, there are still shortcomings in the support tensor machine model. The support tensor machine works by determining the support tensor with a small number of training samples and then finding a classification surface that can divide the samples and then classify the test samples. If there are incorrect or biased samples in the training samples to determine the support tensor, the support tensor machine cannot exclude these samples because they all have the same reliability for the test samples, so it is easy to be misled by these incorrect or biased test samples and establish the wrong optimal hyperplane, resulting in a decrease in the classification accuracy of the model. The biggest difference between standard fuzzy support tensor machine and support tensor machine is that the former has one more dimension than the latter, i.e., fuzzy affiliation. Hence, the support tensor selected by the fuzzy support tensor machine is not equivalent to that selected by the support tensor machine. To address this problem, fuzzy support tensor machines introduce the concept of a fuzzy affiliation function [17]. Each training sample is assigned a corresponding fuzzy affiliation according to its influence on the prediction result, with smaller affiliations for incorrect or biased samples and larger affiliations for correct samples, by which the problem that traditional support tensor machines are easily misled by isolated points is solved and the noise immunity of the model is improved.

As the complexity of the research problem increased, the degree of state in the problem was vague and could not be accurately described by traditional exact mathematics, and fuzzy mathematics was created to have a reasonable description of the degree of state of certain factors in the problem. The discipline was introduced in the 1950s and was mainly used to study some fuzzy problems. With the rapid development of artificial intelligence technology, fuzzy mathematics has been combined with various intelligent algorithms and is widely used in various fields. A fuzzy set is a basic concept of fuzzy mathematics. In the traditional notion of set, for an individual u and a set A, the relationship between them is that u either belongs to A or does not belong to A. These two results cannot hold simultaneously [18]. The relationship between an individual and a set, if expressed by a mathematical expression, should be

$$C_{ij} = \sum_{i=1}^{n} x_i^2 \sigma_i + x_j^2 \sigma_j + x_k^2 \sigma_k. \tag{1}$$

The eigenfunction cannot explicitly define data as belonging to a certain state or not belonging to a certain state. In the 1960s, researchers used feature functions to express an increasing number of classical sets by representing each data in the set as a fuzzy number, such that the domain of values of fuzzy sets was extended from the set of integers {0,1} to the set of real numbers [0,1]. Since the value of the fuzzy affiliation reflects the training points, for a certain class of defined affiliations, and the parameter j is a measure of the extent to which the support tensor machine misclassifies the samples, combining the two becomes a measure of how correctly the support tensor machine classifies data with different affiliations. Each training sample is assigned a corresponding fuzzy affiliation according to its influence on the prediction result, with a smaller affiliation for incorrect or biased samples and a larger affiliation for correct samples. By this approach, the problem that traditional support tensor machines are easily misled by isolated points is solved,

and the noise immunity of the model is improved. Transferring the processed data as input to the prediction model, the process of finding the optimal hyperplane for the classification model can be expressed mathematically as a quadratic program if the data transferred is linearly divisible.

$$E_{all} = \sum_{i=0}^{R} \left(E_{contest} \times x + Ee \times x + \varepsilon free \times x^2 \times d_i^{(1/2)} \right) \qquad (2)$$
$$+ \sum_{i=0}^{K} \left(4E_e \times x + \varepsilon decay \times x^2 \times d_i^2 \right).$$

Minimizing α in the objective function yields the quadratic counterpart of the pairwise plan:

$$I(X;Y) = \frac{K(x,y) \cdot \sum_{i=1}^{n} X_i Y_i}{M(x)} \cdot \frac{x - \alpha}{\sigma}. \qquad (3)$$

The major difference between a standard fuzzy support tensor machine and a support tensor machine is that the former has one more dimension, i.e., fuzzy affiliation, than the latter, so the support tensor selected by fuzzy support tensor machine is not equivalent to that selected by support tensor machine. If the relationship between the factors in the problem to be solved is nonlinear and a kernel function is introduced in the solution process, then the classification problem can be expressed in mathematical form as follows:

$$H(x) = \varphi \sum_{y \in \gamma} \sum_{x \in \chi} [p(x,y) \cdot \ln p(x,y) + Ax + Cy] + \lambda. \qquad (4)$$

One way to represent the above diffusion tensor is to use the covariance matrix of the Gaussian distribution, which mainly describes the diffusion process of water molecules in the tissue. The statistical scatter of the two distributions is used. In this case, tensor comparisons are made by measuring the Kullback–Leibler distance between the probability distributions afterward. The symmetric version is called J scatter, which was proposed by Wang and Vemuri and used for tensor distance measurements. It is shown as follows:

$$M(x) = \varphi \sum_{x \in \chi} \left[p^2(x) \cdot \ln p(x) \right] + Ax. \qquad (5)$$

Although Support Tensor Machines (STM) solve the overfitting problem in traditional SVMs, the rank-weight tensor is weakly expressive and this translation leads to poorer classification accuracy. The rank-weight tensor of STM is generalized to Tucker decomposition and CP forms to obtain stronger model expressiveness. However, the CP rank-decomposition causes an exponential increase in the number of parameters in the Tucker form, which suffers from dimensional catastrophe.

3.2. Fuzzy Support Tensor Machine Adaptive Image Classification for the Internet of Things.
Classification algorithm design has been a hot topic in the field of machine learning, pattern recognition, and computer vision. One of the most representative and successful classification algorithms is the Support Vector Machine (SVM), which has been highly successful in pattern classification by minimizing the

Vapnik–Chervonenkis dimensional and structural risk. However, standard SVM models are based on vector inputs and cannot directly deal with matrices or higher-dimensional data structures, i.e., tensors, which are very common in real life. As in Figure 1, a grayscale image is a two-dimensional matrix with height and width, which is a second-order tensor, while a multispectrum has multiple spectral bands and is a third-order tensor. When high-dimensional data are fed into the SVM, a common approach is reshaping each sample into a vector. A tensor can be seen as an extension of a matrix, which in traditional signal research can be considered as an array of different dimensions depending on the object of study. However, when the training data sample size is relatively small concerning the dimensionality of the feature vectors, this can result in overfitting and lead to unsatisfactory classification performance.

The traditional image recognition model consists of two parts: feature extractor and classifier. Feature extraction methods can be classified into texture features, shape features, bag-of-words model, sparse coding, local coding, and Fisher vectors. These feature extraction extracts feature from the image and then a set of numbers or symbols are used to represent certain characteristics of the depicted object in the image and finally, these features are recognized with the help of other machine learning methods. The classical recognition methods (classifiers) are support vector machines, decision trees, adaptive enhancement, plain Bayes, and some heuristic arithmetic [19]. These classical feature representation methods have a common feature that they all require a very specialized knowledgeable researcher to carefully design the model; however, this feature makes the model deficient in two ways: firstly, the researcher needs to spend a lot of effort to design different features for different recognition tasks; secondly, the practical application requires repeated validation and parameter tuning of the model, which is very costly to optimize.

Wavelet theory is an extended version of Fourier transform theory in which a signal is decomposed into wavelets and projected onto a set of wavelet functions. This differs from the Fourier transform, which decomposes the signal into sine and cosine components. Wavelet transform theory is popular in image processing, where it decomposes the input image into a set of images with various resolutions while reducing redundancy in the image representation [20]. The parent signal components are decomposed in an extended signal variant or a shifted wavelet. Two basic properties must be satisfied for a wavelet to be considered a wavelet. The information flow used for a single-level or one-level 2D image decomposition scheme is illustrated in Figure 2.

The inverse 2D wavelet transform used to reconstruct the image involves column upsampling and filtering for each subimage using low-pass and high-pass filters. The initial source image is constructed using the low-pass filter L and the high-pass filter of the resulting image for row upsampling and filtering and the summation of all matrices. By examining the saliency type focusing on bottom-up, the images can be classified into two categories, spatial domain models and transform domain models, depending on
FIGURE 1: Picture and tensor representation.
FIGURE 2: Wavelet decomposition of the two-dimensional image.

whether they are transformed in the frequency domain [21]. The so-called spatial domain saliency models process the image directly in the spatial domain and thus detect the salient targets or regions of interest in the image. Therefore, in the design of saliency models, regions in the image scene with unique color features or pattern features should have high saliency, while homogeneous regions in the scene should have low saliency. Features that frequently appear in the image scene should be suppressed. Salient pixels in an image should be clustered together rather than scattered throughout the image. Therefore, the Euclidean distance in spatial location of image blocks containing contextual

information about each pixel in the image is also important, because the distribution of image blocks in the background region is either far or near in space, while the distribution of image blocks in the salient target region tends to be clustered together in space. The saliency detection results can be further enhanced by incorporating the central prior knowledge of the salient regions. The saliency of pixel I in an image at a single scale can be defined as follows:

$$P_{i,j}{}^{k}(t) = \sum_{i=1,j=1}^{n,m} \left[t_{i,j}(k) \right]^{2} \left[\eta_{i,j}(t) \right]^{\beta}. \tag{6}$$

Furthermore, considering that image blocks in the background region are similar at multiple scales, in contrast, image blocks in the saliency region may be similar at only a few scales but not at all scales. Therefore, multiple scales can be used to further reduce the saliency of background pixels and enhance the contrast between salient and nonsalient regions. Unlike the spatial domain saliency model, the transform domain-based saliency model requires first transforming the image from the spatial domain to the frequency domain, then processing and analyzing the image in the frequency domain, and finally obtaining the final saliency detection results by transforming the analysis results in the frequency domain back to the spatial domain. For a two-dimensional signal like an image, by performing the Fourier transform on it, the resulting image amplitude spectrum clarifies the percentage of each sinusoidal component, while the phase spectrum of the image gives the position of each sinusoidal component in the graph. In the reconstruction of the image in the Fourier transform domain, the positions located in the horizontal or vertical directions with weak periodicity or homogeneity correspond to the positions of the candidate targets in the image, and thus it is known that the saliency information of the image is implicit in the phase spectrum of the image. Therefore, the saliency detection result of the image can be obtained by extracting the phase spectrum information of the image. The initial saliency analysis results are smoothed by a two-dimensional Gaussian filtering function $g(x, y)$ to obtain a visually superior final saliency map as follows:

$$e_j = -k \sum_{i-1}^{n} p_i \ln \frac{1}{p_i}. \tag{7}$$

From the above analysis, it can be seen that the PFT transform domain saliency detection model has the advantages of simple and easy algorithm and fast operation, thus giving fast saliency detection results for a given image, but the disadvantage is that the local saliency features of the image are not considered, and it lacks suitable biological psychological support and explanation. After each iteration step, the optimization progress of the solution needs to be measured by a predefined criterion that determines whether the current state is the best fit or not. Among the saliency analysis models for natural images, the center prior and the boundary prior are the two most widely used prior knowledge, which achieves good detection results in the saliency detection of natural images, thanks to the imaging mechanism of natural images, where the salient targets of natural images are usually at the location of the image center, while the boundaries of natural images usually do not have a distribution of salient targets.

Using superpixel segmentation methods, an image is segmented into many superpixels. Each superpixel contains a large number of spatially close neighboring samples that have a similar texture, color, luminance, and other characteristics. Compared to pixel-based hyperspectral image classification methods, the superpixel-based classification methods demonstrate good regional consistency.

The superpixel segmentation process is shown in Figure 3.

To alleviate pseudoboundaries that cause misclassification, we propose a new nonlocal decision-based region delineation method. In hyperspectral images, we usually consider that the samples in local regions belong to the same class, which is local information. However, nonlocal information is also very critical in hyperspectral images. This is because samples of the same class may also be located in different regions of the image. In nonlocal decision making, pixel pair similarity is extended to superpixel pair similarity, taking into account the structural information of the current samples. For those samples that are judged to be in heterogeneous regions by the local decision, the similarity between the current sample and the filter neighborhood samples is calculated. The current sample is represented by a global search for all similar samples. Then, this similarity is compared with the calculated adaptive threshold. If the similarity of all neighborhood pixels all is greater than the threshold, the current sample is judged to be in the homogeneous region and vice versa. This model includes two stages: the first stage is to enhance the input image, then input the residual network to carry on the supervised contrast learning, and get the pretraining model; the second stage is to fix the parameters of the pretraining model and the fuzzy support tensor machine is trained to get the prediction label. In the first stage, in order to enhance the discriminative ability of feature extraction, local information, nonlocal information, and generic structured features that come from unlabeled high-resolution images are also introduced, respectively. After an image of arbitrary size is input to the network as input data, the input data are convolved by each branch in the subnet separately utilizing dense convolution operations at different scales to associate the final extracted results, reduce the dimensionality through the transition layer, and then use the output data to (1) obtain the pixel-by-pixel classification results with the classifier to compare with the reference marker to calculate the loss; and(2) input them to the next subnetwork. The above process is repeated until the final objective function is obtained. The overall loss function is calculated jointly for all the objective functions and the network is trained by backpropagation of stochastic gradient descent. To facilitate training, the weights of the objective functions of all classifiers are learned in an alternating manner with the learning of other network parameters.

4. Experimental Verification and Conclusions

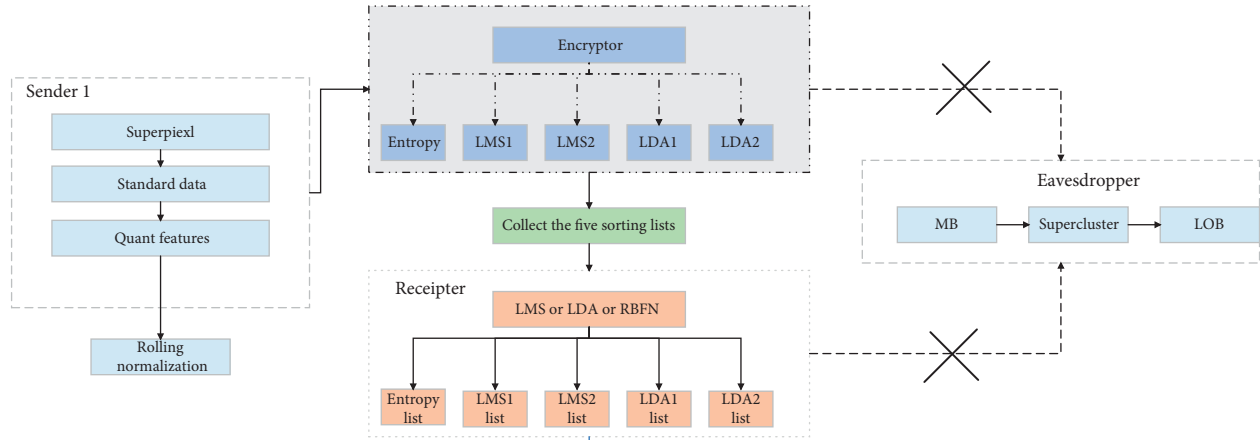
We compare the model in this article with Single Task Learning (STL), Tensor Train Multitasking (TT-MTL), and Tucker-based multitasking models. For a fair comparison, the same network architecture is used for all methods. In all experiments, this article sets the model format to $M = 3$ and $N = 2$. Since the model is harder to train when M, N is larger because of the presence of a fifth-order tensor. (Perhaps this can be solved by trying to decompose the larger cores further.) In this article, we use this relatively lightweight structure for our experiments. For the choice of rank, the


FIGURE 3: Superpixel segmentation process.

model parameters are extremely large when the rank is particularly large, so a relatively small rank (3, 4, 5) is used. The MNIST 10-class classification problem can be converted to a ten one-vs-all binary classification problem. This conversion allows the construction of a 10-task classification problem of the same kind, that is, by performing a softmax normalization on the ten classifiers before training. In this experiment, this article focuses on two performance metrics: one is the average accuracy of the ten binary classification problems, and the other is the accuracy of classifying a single digit by performing a softmax on the one-vs-all output of each task (multiclass classification accuracy). In this article, the first three convolutional layers are set to be hard-shared across all MTL models (for common feature extraction), and then the next FC layer is converted to a different multitask tensor network model format. In this article, we train with different sized subsets of the training dataset and test the model using the same test set (from 10% to 100% of the training set). As is shown in Figure 4, all MTL methods outperform STL for both more and less training data. Also, TT outperforms Tucker when the training data are small, while the results are reversed when the training data are large. The CTN proposed in this article outperforms all other methods.

In the whole experimental process, 100,000 training iterations are set in this article because the experimental images are few sample data, the choice of iteration parameters will affect the final model effect, and the accuracy and loss function of the model training can be analyzed to see in which interval the network reaches a stable equilibrium state so that the network training is in the optimal state, the accuracy and loss function curves are plotted and different network modules are designed to design the node embedding network, and the experimental results are shown in Figure 5. The comparison experiment of SE-ResNet structure and simple node embedding network access GNN can be obtained, the red line is the change curve of NSE-ResNet-EGNN network obtained by node embedding using SE-ResNet structure, and the blue is the change curve of simple node embedding network EGNN. This indicates that the extracted finite number of feature parameters can fully

reflect the transient response of the actual waveform pattern. From the accuracy change curve, we can see that the two approaches are almost the same in terms of the convergence speed in the early stage, but in terms of the final convergence result, the node embedding using the SE-ResNet network model can achieve higher accuracy, and in the subsequent iterations, the trend of the network curve is smoother compared to the simple node embedding network. From the loss change curve, we can see that the node embedding using the SE-ResNet network model makes the loss function fall faster in the training process and can maintain a smoother convergence effect compared with the original knot, and from the final convergence, the node embedding using SE-ResNet network model will have less loss, and we can see that by improving the dependency relationship between node channels, the performance of the node embedding network can be effectively enhanced by improving the dependencies between the node channels.

Though the previous experiment, it can be obtained that improving the node embedding network can increase the information encoded to the nodes, thus making the edge features describe the nodes more accurately. The network design of node update is also available in the GNN-Block module, so two sets of comparison experiments are set up in this experiment from the number of Conv-Blocks in the node update network and the network architecture, respectively. To verify the effect of the number of Conv-Blocks on the final results, we choose the node update framework as the comparison experiments, whose experimental results are shown as the yellow and red curves in Figure 6, respectively. From the accuracy change curve, we can get that increasing the Conv-Block of the node update network can improve the final classification accuracy within a certain range and keep the same convergence speed in the early stage, but in the final convergence result, the number of Conv-Block is proportional to the classification accuracy within a certain range using the node update network. From the loss variation curve, we can see that as the number of Conv-Blocks of the nodal update network increases, the loss function decreases faster due to the more parameters and better robustness of the network. Regarding network depth, and from the final
FIGURE 4: The average accuracy of binary classification for different algorithms with the same dataset.
FIGURE 5: Classification accuracy and loss line of the model.

improvement results, increasing the complexity of the node update network can improve the few-sample classification performance within a certain range.

To visualize the effectiveness of the proposed algorithm, the distribution of representation coefficients and the corresponding normalized reconstruction residuals of the MFCARC algorithm are given. In our experiments, we selected the Indian Pines dataset for analysis, selected ten random samples from each feature class to construct the training dictionary, and randomly selected one sample from class 6 (grass/trees) of this dataset as the test book and then analyzed the representation coefficient distribution of this sample. Since the decomposition calculation process has a truncation process of redundant columns for the tensor factor matrix, some errors are inevitable while simplifying the calculation process. As shown in Figure 7, the distribution of the correlated adaptive representation coefficients based on different features exhibits the feature that the part of the representation coefficients with larger weights is

mainly concentrated in the category to which the test sample belongs. From the minimum representation residual criterion, it is known that the category to which the test sample belongs should have the smallest normalized residual value by comparing the reconstruction error of the test sample and each category of dictionaries. From Figure 7, it can be found that the correlated adaptive representation models based on spectral features, DMP features, and LBP features all make correct feature category determination for the test sample, but the correlated adaptive representation model based on Gabor features incorrectly determines the sample as category 4 (maize).

Most detection models are less effective in detecting smaller objects than in detecting larger objects. This is mainly because, after multiple layers of convolution, small objects may not retain any information in the feature mapping at the topmost layer of the model. Increasing the size of the model input (e.g., from 300×300 to 512×512) can help the model improve its performance in detecting small objects, with a 2.5 percentage point improvement in mAP for SSD and a 3.2 percentage point improvement in EAO. The analysis suggests that this is related to the multi-resolution detection layer proposed in this article, which gives different detection layers to detect objects of different sizes, such as the low-resolution detection layer used to improve the detection rate of small targets. The experimental results in Figure 8 are from seven smaller objects (bird, boat, chair, etc.) in PACAL_VOC2007, with XL, L, M, S, and XS in the horizontal coordinates denoting extra-large, large, medium, small, and very small, respectively, and the vertical coordinates denote the average detection accuracy of the model Here the different size pairs are produced by hand cropping postprocessing formation. From the figure, it can be seen that EA0 outperforms the base model SSD almost across the board and the advantage is more pronounced when the object size is of S and XS level. The analysis suggests that this is related to EA0's strategy of using different shapes
FIGURE 6: Classification accuracy and loss lines of the model under different GNN-blocks.
FIGURE 7: Normalized residuals for different algorithms.

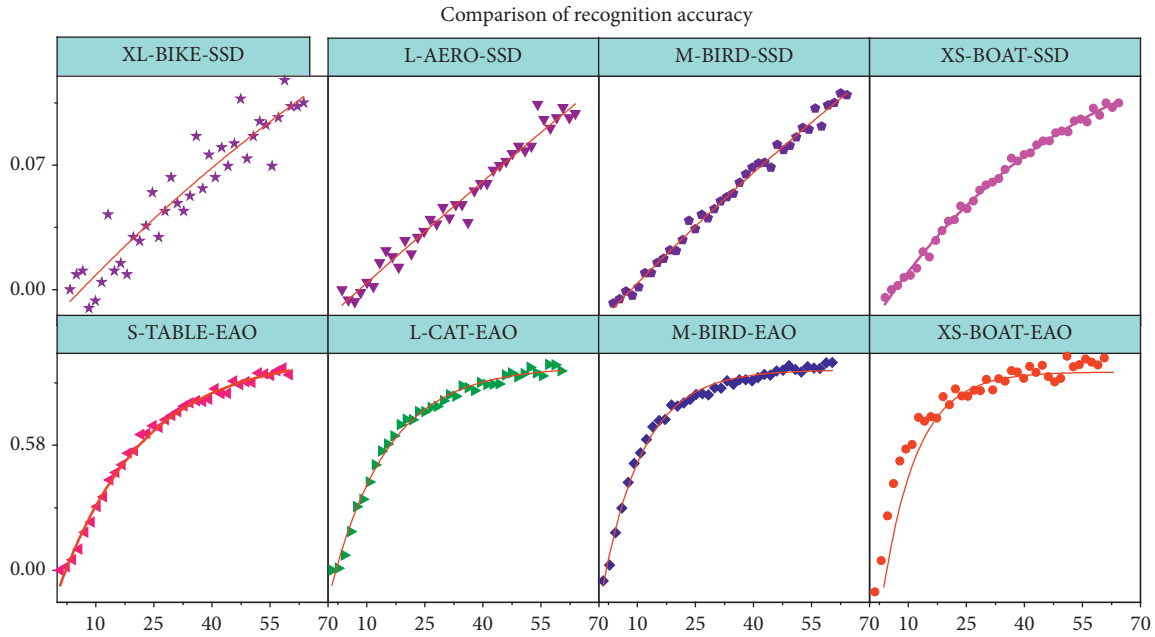
Comparison of recognition accuracy


FIGURE 8: Comparison of recognition accuracy of different models for images of different sizes.

and numbers of a priori frames at different detection layers and assigning more detection frames to lower resolution layers based on the results of the cluster analysis. The best results achieved by EA0 in all scales of objects also reflect the lower sensitivity and greater robustness of the model to bounding box size than SSD.

5. Conclusion

Deep learning has been a great success in the fields of image recognition, speech recognition, and machine translation. Among them, support tensor machines have made breakthroughs in image detection, image classification, image segmentation, face recognition, video tracking, and other vision-related domains and have achieved great success in these fields. It is due to the powerful feature extraction capability of support tensor machines in image classification that more and more scholars are applying support vector machines to image classification. Tensor algorithms have different decompositions in several scientific fields. The different decomposition methods have their own advantages and areas of application. In this article, we propose an end-to-end, pixel-to-pixel IoT-oriented fuzzy support tensor product adaptive image classification method, introduce the background of the current topic of image classification and the significance of the research, as well as the current state of research on image classification, and draw out the difficulties faced by existing image classification methods by analyzing the characteristics of image classification and the advantages and disadvantages of existing image classification, providing strong realistic implications.

The accuracy of the prediction of the classification model established using fuzzy support vector machine and the selection of parameters of the algorithm have a great relationship, the more reasonable the selection of parameters,

the higher the accuracy. Therefore, in this article, to minimize the influence of parameter selection on the classification accuracy of IoT image recognition, nonlocal adaptive information is introduced, and the improved nonlocal information is combined with the fuzzy support vector machine to apply to the image classification research. This new approach to image classification is also the innovation of this paper. Experiments show that the model has better performance than standard RBMs in feature extraction and denoising tasks. Two visible and hidden layers of TRRBM are represented as matrix product states (MPS) and all computations can be done on a single kernel. This can significantly improve the computational complexity of the learning algorithm.

Maintaining the safe and efficient operation of network technology is an important development task of the computer industry. Topology constraint can optimize and combine the tracking results and select the target objects with better tracking performance to obtain the final tracking results and determine the target scale changes. Data mining technology can reduce the number of combinations to be detected, reduce the workload, and improve the timeliness and accuracy of the process of mining alarm association rules. Therefore, based on the summary and analysis of previous research results, this paper studied the network fault diagnosis of the embedded system method based on topology constraint and data mining. Firstly, a fault diagnosis topology model was established by constructing a topology search algorithm, which eliminated the filtering of association rules without topology relationship; the association rule-based data mining model was analyzed through the collection of network alarm data; the model algorithm was applied to the simulation experiment of network fault diagnosis of the embedded system and achieved good results. The results show that correcting rage of retrieval varies from 0.65 to 090 under different window sizes; the running time of the proposed method drops from 310 s to 35 s during 1–8 step/s of the sliding step, while the node degree ranges from 8 to 14 and diagnostic accuracy ranges from 0.97 to 0.94; the remaining alarm number increases from 0.5 to 3.5 threshold value, while the regular association number distributed in an interval of 40 to 140. The algorithm in this paper provides a reference for further research on network fault diagnosis of the embedded system.

1. Introduction

With the rapid development of network information, the structure of computer networks is becoming more and more complex, the application fields are becoming more and more extensive, and people are increasingly dependent on the network. Therefore, the security and reliability of the network have become more and more important. As the main way to obtain the fault of the modern computer network and diagnose the system fault, the log uses the log information generated during the network operation to diagnose the fault, which has become a research hotspot of network fault diagnosis of the embedded system. Because there is a nonlinear mapping relationship between the fault type and the fault feature, the fault information has uncertainty. As the network architecture scale increases, a large amount of log information is generated during the running process,

and the fault feature extraction is very useful, thus increasing the difficulty of fault diagnosis [1]. In the existing fault diagnosis methods, the artificial neural network-based method has good fault tolerance, and it is not necessary for the domain experts to summarize the empirical rules of the diagnosed system from the domain knowledge or case, which is beneficial to overcome the knowledge based on the symbolic reasoning method. Obtaining bottlenecks, unlike symbol-based reasoning methods, which are sensitive to errors in rules or models, supports parallel computing. As parallel technology and hardware developments have become more widely used, they have been used to implement fault diagnosis [2].

Data mining is to find hidden, effective, valuable, and understandable patterns from a large amount of unordered data, to find useful knowledge, to derive the trend and association of time, and to provide users with decision-making

level decision-making support ability. The association rule mining algorithm based on the topology constraint performs hierarchical coding of each device in which each alarm occurs according to the hierarchical relationship between the network elements obtained by the established topology model. The connection relationship between the network elements reflected by the topology structure, combined with the propagation path of the fault, obtains the constraint condition of the association rule mining process. In the process of mining association rules, whether two or more items may be connected as a set of items is limited by such constraints. The interaction and mutual influence between network devices is the root cause of alarm propagation. Therefore, the patterns found in the alarm sequences sent by mutually influential devices are more targeted and more meaningful. If the relationship between devices is not introduced, the alarm of the related device cannot be filtered out, and a large number of meaningless modes are easily generated. Therefore, it is very important to introduce the constraints of network topology, and combining network topology constraints with data mining techniques can reduce the impact of noise and data loss by using constraints to find valuable rules [3].

Based on the summary and analysis of previous research results, this paper studies the network fault diagnosis of the embedded system method based on topology constraint and data mining. Firstly, by constructing a topology search algorithm, a fault diagnosis topology model is established, which eliminates the filtering of association rules without the relationship of topologies. Based on the collection of network alarm data, the quality of training samples is studied and related concepts are defined. The fault feature extraction algorithm is given, the hybrid system model is proposed, and the data mining model based on association rules is analyzed. The model algorithm is applied to the simulation experiment of network fault diagnosis of the embedded system. The algorithm in this paper provides a reference for further research on subsequent network fault diagnosis of the embedded system.

2. Methods and Principles

2.1. Topology Constraint. The topology model is an abstract view of the network structure, which hides other aspects that are not related to the topology relationship. Through it, this relationship can intuitively understand the connection relationship of each network element in the network, discover the characteristics of the network connection, and study the network structure and network performance analysis and other aspects are very helpful.

The network topology model can filter out irrelevant alarm data through the topology relationship in the preprocessing stage. For a certain alarm to be analyzed in the original alarm data, the network element that uses the alarm finds all network elements or most network elements that have a topology relationship with the network element in the topology model and extracts the connected network elements. It is stored in a data structure and in the form of network elements to form a cluster of network elements.

Under the framework of mean shift tracking, the target model and candidate target model are, respectively, written as follows [4]:

$$\hat{q}_u = C \sum_{i=1}^{n} k\left(\left\|x_i^*\right\|^2\right) \delta\left[b\left(x_i^*\right) - u\right],$$

$$\hat{p}_u(y) = C_h \sum_{i=1}^{n} k\left(\left\|\frac{y - x_i}{h}\right\|^2\right) \delta\left[b(x_i) - u\right], \tag{1}$$

where x_i^* is the pixel in the target area, x_i is the pixel in the candidate target area with center y, k is the spatially weighted kernel function, and $b(x_i)$ is the histogram interval corresponding to the pixel at position x_i.

The coefficient is used as a measure to measure the similarity between two eigenvectors of the target region and the candidate target region:

$$\hat{\rho}(y) = \sum_{u=1}^{m} \sqrt{\hat{p}_u(y)\hat{q}_u}. \tag{2}$$

The probability of crossover and mutation adopts an adaptive mechanism. As shown in (3) and (4), the probability of cross mutation is adjusted according to the individual fitness value so that poor individuals are more prone to cross mutation and good individuals are easy to save [5]:

$$P_c = \begin{cases} P_{c2} - \dfrac{(P_{c2} - P_{c3})(F' - F_{\text{avg}})}{F_{\text{max}} - F_{avg}}, & F' \geq F_{\text{avg}}, \\[3mm] P_{c1} - \dfrac{(P_{c1} - P_{c2})(F' - F_{\text{min}})}{F_{\text{avg}} - F_{\text{min}}}, & F' < F_{\text{avg}}, \end{cases} \tag{3}$$

$$P_m = \begin{cases} P_{m2} - \dfrac{(P_{m2} - P_{m3})(F - F_{\text{avg}})}{F_{\text{max}} - F_{avg}}, & F' \geq F_{\text{avg}}, \\[3mm] P_{m1} - \dfrac{(P_{m1} - P_{m2})(F - F_{\text{min}})}{F_{\text{avg}} - F_{\text{min}}}, & F' < F_{\text{avg}}, \end{cases} \tag{4}$$

where F_{max}, F_{min}, and F_{avg} are the maximum, minimum, and average fitness values of the population, respectively, F' is the larger fitness value of the two individuals performing genetic manipulation, and there are $P_{c1} > P_{c2} > P_{c3}$ and $P_{m1} > P_{m2} > P_{m3}$.

There is a certain model transformation relationship between the matching points in most images to be matched, and the topology relationship between several feature points in the same image is also approximately satisfied in the other image. For this purpose, the topology constraint can be performed by calculating the angle between the three feature points to purify the initial matching point. It is known that the coordinates of the three pairs of matching point pairs are $(x_1, y_1)^T$, $(x_2, y_2)^T$, $(x_3, y_3)^T$ and $(x_1', y_1')^T$, $(x_2', y_2')^T$, $(x_3', y_3')^T$, respectively, and the two angles p and q can be obtained by using the vector angle cosine formula [6]:

$$p = \arccos\left[\frac{(x_1 - x_2)\cdot(x_1 - x_3) + (y_1 - y_2)\cdot(y_1 - y_3)}{\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}\cdot\sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2}}\right],$$

$$q = \arccos\left[\frac{(x_1' - x_2')\cdot(x_1' - x_3') + (y_1' - y_2)\cdot(y_1' - y_3')}{\sqrt{(x_1' - x_2')^2 + (y_1' - y_2')^2}\cdot\sqrt{(x_1' - x_3')^2 + (y_1' - y_3')^2}}\right]. \tag{5}$$

For the above algorithm, a set of relatively stable correct matching points need to be found as the initial point pair of the calculation. Therefore, the key step of the algorithm is to find a set of such points because only one group needs to be found in all the initial matching points. The point fits the requirements of calculation, so algorithm can search it by increasing the set conditions, and the specific implementation method will be shown in the following network topology model.

2.2. Data Mining. Data mining technology is a database technology that extracts hidden, previously unknown, and potentially valuable knowledge and rules from vast amounts of data. The interest association rule directly indicates the recursive relationship between interests, and by simplifying the data in the buffer represented by the data model, it directly indicates the link relationship between the pages, which cannot directly reflect the degree of association between interests [7].

It is supposed that there are n learning samples, each with a set of observations $(x_1, x_2, \ldots, x_m, y_i^*)$ of $m+1$ parameters $(x_1, x_2, \ldots, x_m, y_i^*)\cdot(i = 1, 2, \ldots, n)$, $n > m$, and in practice, n is generally much larger than m, so as to ensure the accuracy and representativeness of the prediction results. The n learning samples of m parameters are defined as n vectors, that is, the expression of the learning sample is [8]

$$x_i = (x_{i1}, x_{i2}, \ldots, x_{im}, y_i^*,), \quad (i = 1, 2, \ldots, n). \tag{6}$$

Let x_0 be the general form of a vector in $(x_{i1}, x_{i2}, \ldots, x_{im})$. The principle of the algorithms is the same, that is, to create an expression $y = y(x_0)$ and minimize its value:

$$\min(y) = \sum_{i=1}^{n} [y(x_0) - y_i^*]^2. \tag{7}$$

In addition, algorithms are to establish an equation $y = y(x_0)$ to maximize the classification interval based on support vector points to get the optimal separation line. The accuracy of the results obtained is different because of the different methods used by these algorithms.

The data are preprocessed by the analytic hierarchy process to obtain the weights W of different nodes, and the order S of each node is obtained. The lower side correlation function is set as [9]

$$h_{mn}(z) = \begin{cases} 0, & z \notin [z_n(1), z_n(2)], \\ \dfrac{z_{mn} - z_n(1)}{z_n(2) - z_n(1)}, & z \in [z_n(1), z_n(2)], \\ \dfrac{z_n(4) - z_{mn}}{z_n(4) - z_n(3)}, & z \in [z_n(3), z_n(4)], \end{cases} \tag{8}$$

where $z_n(1)$ is the minimum value of the sample data, $z_n(2) = z_n(3)$ is the number average, and $z_n(4)$ is the maximum number of data.

The preprocessed sample data are $Z = [Z(1)\ Z(2),\ldots,Z(M)]\ T$, and the information matrix $H_{M\times N}$ of (9) can be obtained via (8):

$$\mathbf{H}_{M\times N} = \begin{bmatrix} h & h & \cdots & h \\ h & h & \cdots & h \\ \vdots & \vdots & \vdots & \vdots \\ h & h & \cdots & h \end{bmatrix}. \tag{9}$$

By $q_{mn} = h'_{mn}\text{-}t_n + \varepsilon$ ($m = 1, 2,\ldots,M$ and $n = 1, 2,\ldots,N$), $t_n = \min(h'_{mn})$, the negative number is shifted to a positive near zero number, the obtained positive matrix $\mathbf{Q}_{M\times N}^n$ is calculated as follows:

$$\mathbf{Q}_{M\times N}^n = \begin{bmatrix} q_{11} & q_{12} & \cdots & q_{1N} \\ q_{21} & q_{22} & \cdots & q_{2N} \\ \vdots & \vdots & \vdots & \vdots \\ q_{M1} & q_{M2} & \cdots & q_{MN} \end{bmatrix}. \tag{10}$$

The association analysis method in data mining technology can be used for association discovery, sequence pattern discovery, and same time-series discovery. For the sake of simplicity, the transfer relationship between interest association rules cannot be considered when establishing interest association rules. For this simple interest association rule association model, using association discovery analysis method is more appropriate.

3. Topology Modeling Based on Fault Diagnosis

3.1. Topology Lookup Algorithm Implementation. At present, all network topology models have some shortcomings, especially the topology-level modeling research at the router level is still in its infancy, and the current research results and methods have yet to be enriched and developed. As seen

above, as a typical representative of complex networks, the network topology has many basic parameters, such as node degree and its distribution, aggregation coefficient, median, and core number, but more importantly, new metrics to be discovered are metrics and network performance, such as synchronization performance and routing performance. The internal mechanisms of interaction between the two require further research by a large number of numerical simulations and empirical studies to provide a more in-depth qualitative and quantitative analysis of topology characteristics and metrics.

The network topology model lacks completeness for one or a few topology characteristics. In topology modeling, the existing research results show that model based on the design optimization principle is more consistent with topology structure than the scale-free model based on random principle. The network topology tree model used for topology lookup algorithm is shown in Figure 1. The network performance is also closer to the real network topology and the traditional scale-free model cannot be used to characterize the generation mechanism of network topology characteristics, such as robustness and vulnerability [10].

In a complex or untreated network environment, due to network attacks, hardware errors, and environmental obstacles, data are prone to distortion or error during transmission or positioning [11]. This is different from simple errors that are easy to occur in ordinary networks, and the data will seriously affect the positioning result. The algorithm is characterized by maximizing the correlation between the signal space and the physical space after the data transformation and still retains the local spatial topology information. Therefore, the points adjacent to the coordinates are in the transformed signal space, and this paper focuses on the research of positioning methods in this network environment. This kind of erroneous data with serious deviations can also be called the wild value, and its value is greatly deviated from the collected normal data. In other words, this outlier feature makes the erroneous data far away from other normal data points in the geometric spatial distribution, thus having a lower distribution density, so the motivation for topology modeling is in the same dataset. The lower the point, the lower the impact on positioning to achieve better robustness. Figure 2 is the topology analysis algorithm model flow.

The center position of the central core tracker is the initially selected center of the target area to be tracked; the target area of the start frame is manually given, the target area of the nonstart frame is obtained by tracking the previous frame image, and the border core tracker is the center position and is obtained by corner detection [4]. The corner point is a point where the gray level changes sharply in the image, and there are usually a large number of corner points at the boundary between the target and the background. The kernel tracking algorithm often uses the gray histogram to construct the target model, but the gray histogram is susceptible to image noise or changes, while the gradient direction histogram has the characteristics of being insensitive to the changes, which can be more robust. Target description is discussed, especially when the structure and
Figure 1: Network topology tree model used for topology lookup algorithm.

gradient information of the tracking target is rich. Using these nuclear trackers at the target and background, the constructed kernel histogram contains both the target information and the relatively stable background information, which can improve the validity of the target model.

3.2. Fault Diagnosis Topology Model. Fault diagnosis pattern recognition is an indispensable part of topology network fault diagnosis of the embedded system; the topology network can simulate the organization framework and construct a cognitive process to realize the fault handling. The working principle of this diagnostic method is to transmit the fault symptom to the system through the topology network and use the recognition model to classify the fault and obtain the diagnosis result. This type of diagnosis mainly uses the method of integrating the fault diagnosis data and, at the same time, training and practicing it. The data distributed in the topology network are expressed by means of computational translation, and finally, the fault diagnosis result is output. There are totally three algorithms which were compared in study, and they are diagnosis fault analysis system testing (DFAST), basic analysis system testing (BAST), and step fault analysis system testing (SFAST), respectively.

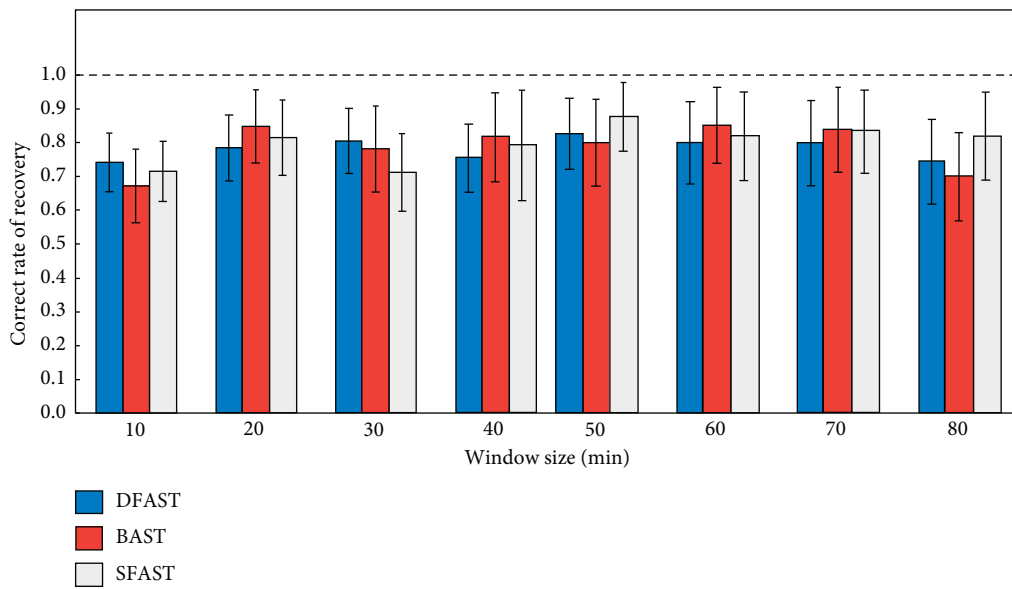
Topology networks can also integrate and collect ambiguous fuzzy fault information and integrate them into a complete fuzzy relational framework by means of mathematical logic such as functions. Different fault diagnosis topology model algorithm has different correct rates of retrieval under different window sizes, which has a significant impact on topology modeling (Figure 3). This framework can make unclear factors and avatars reasonable. In the scope, it provides a basis for network fault diagnosis of the embedded system. The diagnosis principle is mainly based on the integration of faults and the manifestation of form information, constructing a framework system belonging to the function, then focusing the fault factors and
FIGURE 2: Topology analysis algorithm model flow.


FIGURE 3: Correct rate of retrieval under different window sizes.

manifestations into a unified function framework, and using fuzzy relationship to carry out the fault factor category.

Network failures and signs of performance have strong uncertainties. The fuzzy relationship between the two makes it difficult to determine the cause of the two through common mathematical models, and the fuzzy logic network fault diagnosis of the embedded system method can be uncertain. The fault information is collected and integrated, and a relatively complete mathematical matrix model can be established through mathematical functions such as different functions. The establishment of the mathematical model can control the uncertain fault, and the symptom performance in a specific range and fault diagnosis provides a specific reference. The relationship between the cause and the symptom of the network system failure is extremely complicated and has strong randomness. Therefore, it is difficult to specifically locate the fault and analyze the cause by simply relying on the expert system. This kind of network diagnosis method can accurately judge the cause of the network failure and can bring some inspiration to the fault diagnosis of the maintenance personnel, but this method must be based on the establishment of a large fuzzy relational database and its intelligent learning ability.

The optimization of the network topology determines the weight of the network, thus transforming the problem of the neural network into a hierarchical decentralized optimization problem with the layer of neurons. The correction of the decision-making scheme is through neural network learning and rough set learning. The exchange between the two is improved until the rough set learning selects the decision rule with the least attribute composition to correctly divide all the training set samples. Although the training sample set is the knowledge given by the domain experts, including the knowledge formed by the fault condition attribute, there are inevitably incompatible situations, which will produce redundant samples. Training such samples will not only improve the correctness of decision-making but also reduce the learning efficiency of neural networks. On the contrary, each attribute of the fault symptom subset has different contributions to decision-making. The system needs to reflect the importance of different attributes in the learning process to improve learning efficiency [12].

4. Analysis of Alarm Data Based on Data Mining

4.1. Network Alarm Data Collection. Data extraction is the primary task of data analysis and the extracted data mainly includes alarm standardization data and network management system alarm data. It should be noted that the specific time zone should be specified before extracting data, and then, the time zone is determined by the network management system, and all alarm data in the data are extracted. After excluding the interference of the special data, the valuable data need to be filtered from the remaining data, and the interference alarm is removed. At the same time, the standardization field of the alarm information is set to the classification class and the weight class to judge the value of the alarm information. In order to avoid this problem, the predecessor proposed that, in the fault feedback phase, a

mobile sensor node is set in the detection area, and the mobile sensor node starts from the base station, collects the state information of all the sensor nodes by the mobile, and transmits to the base station. Finally, the selected valuable alarm information is integrated to form a network alarm data center.

If each node communicates with the base station, the node farther from the base station needs to communicate with the base station by means of the multihop node, which increases the energy consumption of the sensor node and is prone to error during transmission [13]. After obtaining all the data in the specified time period, the data should be cleaned, and the abnormal data, the missing data, the erroneous data, and the duplicate data, which affect the accuracy of the analysis, are eliminated, thereby ensuring the quality of the data analysis and realizing the accurate analysis of alarm information (Figure 4). Since the wireless sensor node has a certain communication range, it is not necessary to traverse each sensor node when performing fault feedback. The area where the sensor node is located can be divided and then the mobile sensor node can traverse each small area.

In the alarm association, the association analysis of the alarms can be used to obtain the strong association alarm rules with different support degrees and confidence levels. The minimum support degree and the minimum confidence level are used to help mine the root cause alarms to determine the alarms in the frequent alarm transaction set. In addition, we only specify the weight of the minimum support, the frequent item sets are filtered out, and all the confidences of the alarm associations under the frequent item sets are retained [14]. The purpose of this is mainly as follows: on the one hand, the frequent item sets in the massive alarm data can be filtered out as the target transaction set for determining the alarm weight by specifying the minimum support; on the other hand, all the alarm associations are retained. The confidence level can compare the relationship between all alarms' events in an alarm transaction set to determine the weight of each alarm event.

The core idea of the police weighting process of the big number theorem is to frequency the alarm weights, that is, according to the confidence level and alarm level of the alarm association rules, the alarm transaction set is taken as a set, and each alarm event is used as a random event through a large-scale simulation which calculates the frequency value of each alarm event occurring in this set as a weight. Alarm correlation analysis is a key issue in fault management, which helps network administrators delete a large number of redundant alarms, analyze the cause of the fault, and predict the occurrence of the fault. The traditional correlation analysis method mainly acquires relevant knowledge through experts, so it cannot meet the needs of network maintenance under the characteristics of large-scale, complex, and heterogeneous network, and the data mining method can make up for this deficiency.

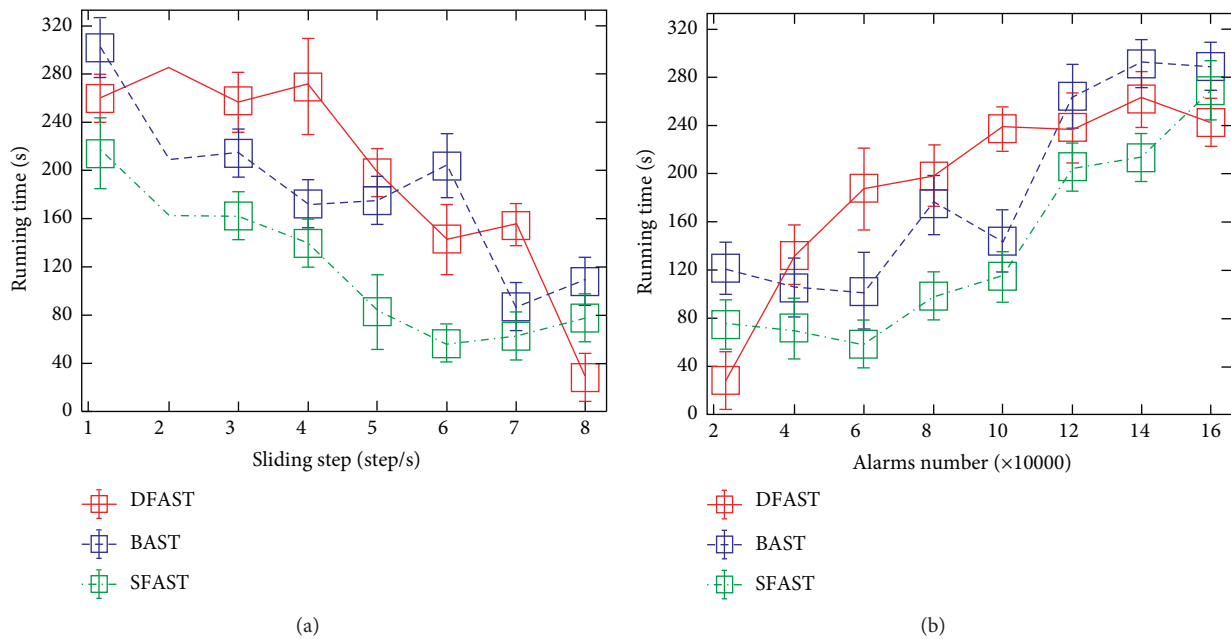
4.2. Association Rule Mining Model. The association rules are different from the traditional association rules. The reliability of each item included in the requirements of the


Figure 4: Relationship between algorithm running times and sliding step (a) and alarm number (b).

trusted association rules is in the same order of magnitude and does not care about the size of the entire rule. The redefinition of confidence can reflect the credibility of the rules, and traditional support can no longer be considered. For the mining of trusted association rules, the algorithm uses the adjacency matrix to generate two trusted sets and then uses the maximal group idea to generate all trusted association rules, thus avoiding scanning the database multiple times. These new metrics are designed to reduce the generation of false rules. Combining them into the generation process of frequent item sets can greatly compress the number of candidate sets generated and can mine strong intimacy association patterns. However, most of these methods are still based on algorithms, not only to scan the database multiple times but also to discriminate the interest of each candidate, so the time performance is low.

When constructing the sample set, a certain number of records before and after each fault occurrence time point are used as fault samples, and the nonfault time records are divided into several normal samples, and the normal sample records are the same as the fault samples. Firstly, the dataset is preprocessed, and the feature and constructor vector are extracted; then, the network model is built, the model parameters are configured, and the network training is performed. After the requirements are met, the network parameters are saved and the trained model is output. When there is new sample data to be diagnosed, the data are input into the trained network model, and the fault diagnosis result is fault or normal.

Depending on whether duplicates of the same dimension are allowed, multidimensional association rules can be subdivided into interdimensional association rules and hybrid dimension association rules, allowing dimensions to appear simultaneously on the left and right sides of the rules. Relationship between node and node degree, node failure

rate, and diagnostic accuracy are shown in Figure 5. Dimensional association rules and mining of multidimensional association rules also need to consider different types of fields, namely, category data and numerical data. For category data, the general association rule algorithm can handle it, while the logarithmic data need to be converted into category data for processing. Numeric fields are divided into predefined hierarchies; these intervals are all predefined by the user, and the resulting rule is also called the static quantity association rule [15, 16].

The algorithm is the most influential algorithm for mining a completely frequent item set and the algorithm has two key steps: one is to find all frequent item sets and the other is to generate strong association rules [17–19]. The algorithm is also a breadth-first algorithm, and the algorithm is based on the a priori algorithm. The first method of the algorithm uses the a priori algorithm when scanning the database. When scanning again, it is no longer scanning the entire database, but only scanning the candidate set generated last time. The scanning also calculates the support of frequent item sets to reduce the support, and the time to scan the database is to improve the efficiency of the algorithm; the fusion of algorithm produces algorithm. When the database is initially scanned, a priori algorithm is used. When the generated candidate set size can be stored in memory for processing, it will be transferred to algorithm until all frequent item sets are found.

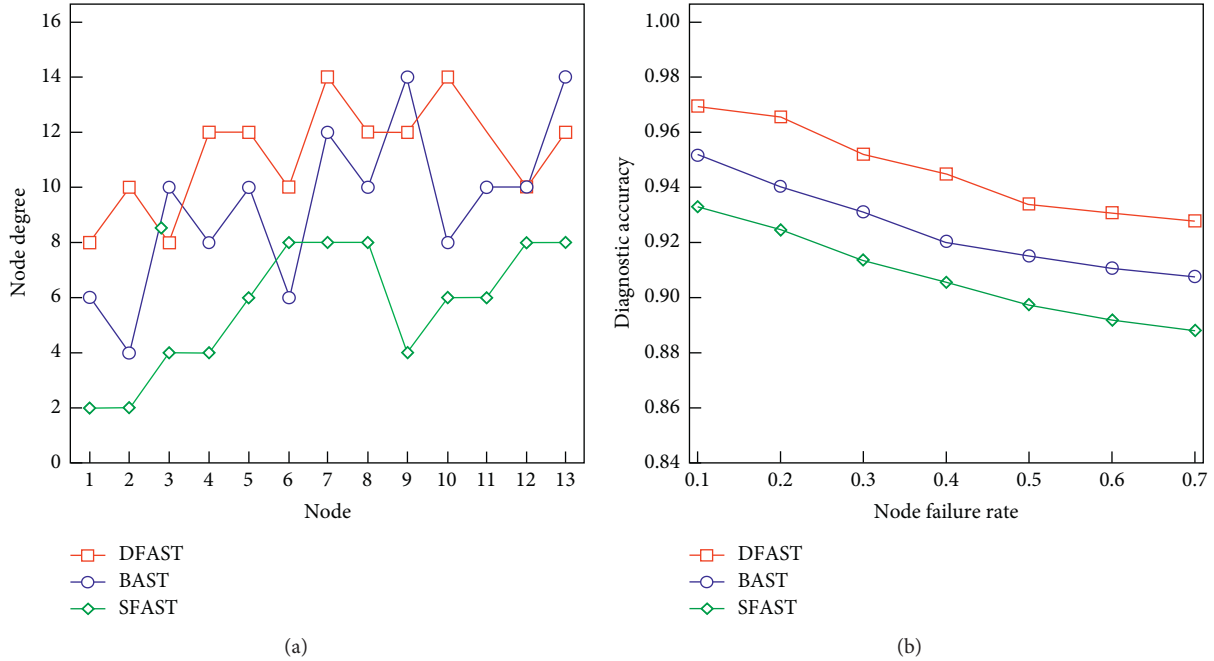
The entire process only needs to scan the database twice, but the number of candidate sets generated is relatively large and the algorithm also adopts the idea of database partitioning. The database is divided into several partitions and marked at the beginning of each partition. In the process of scanning the database, a candidate set can be added to the marked points of each partition, and parallel calculation is performed when calculating the item set. Discovering


FIGURE 5: (a) Relationship between node and node degree. (b) Node failure rate and diagnostic accuracy.

frequent item sets is a key step in mining association rules. The algorithm also utilizes that the subset of frequent item sets is a frequent item set, and the super set of infrequent item sets is a nonfrequent item set, and this property effectively prunes frequent item sets.

5. Algorithm Simulation and Analysis

Since there is no link in the algorithm logic that combines the frequent patterns of item generation by the frequent patterns of the items in the classical algorithm, the tree structure is used for mining, that is, after the tree is generated, the frequent pattern can be generated in one step. Therefore, the network topology constraint is added after the algorithm generates all the frequent patterns, that is, after the algorithm digs out the frequent patterns, they are sequentially determined whether the network topology constraints are met, and then, the nonconforming patterns are deleted from the final frequent pattern set. Such an operation can avoid the infrequently frequent patterns being delivered to the user as the final output, which is more beneficial to the actual needs of the user.

The experimental results show that the network fault diagnosis of the embedded system method based on convolutional neural network can achieve better results than the traditional naive logistic regression and multilayer perception methods in the same training set and test set. Compared with the traditional network fault diagnosis of the embedded system method, the method based on convolutional neural network is simpler, no need to artificially extract the features in the text, and the network model configuration is simple, and the training data amount and model training time are reduced, and the matching calculation is reduced.

The topology search algorithm mainly constructs the classifier by discovering the association rules in the training set. Relationship between the remaining alarm number and the matching threshold value under different sliding steps is different from each other (Figure 6). In the construction process of the decision tree, the most time-consuming operation is to perform statistical calculation of the class distribution information on the dataset belonging to each nonterminal node and to split the dataset by using the splitting criterion. The discovery of association rules uses a classical algorithm that is effective for discovering association rules that are hidden among a large number of transaction records. However, when using it to discover classification rules, in order to prevent some rules from being missed, the minimum support is often set to zero. At this time, the algorithm cannot play its optimization role. As a result, the frequent sets generated sometimes cannot be in memory accommodated so that the program cannot continue to run. The method uses a group-based counting method to collect the category distribution information of various attribute value combinations in the training set and finds meaningful classification rules through the two thresholds of minimum confidence and minimum support.

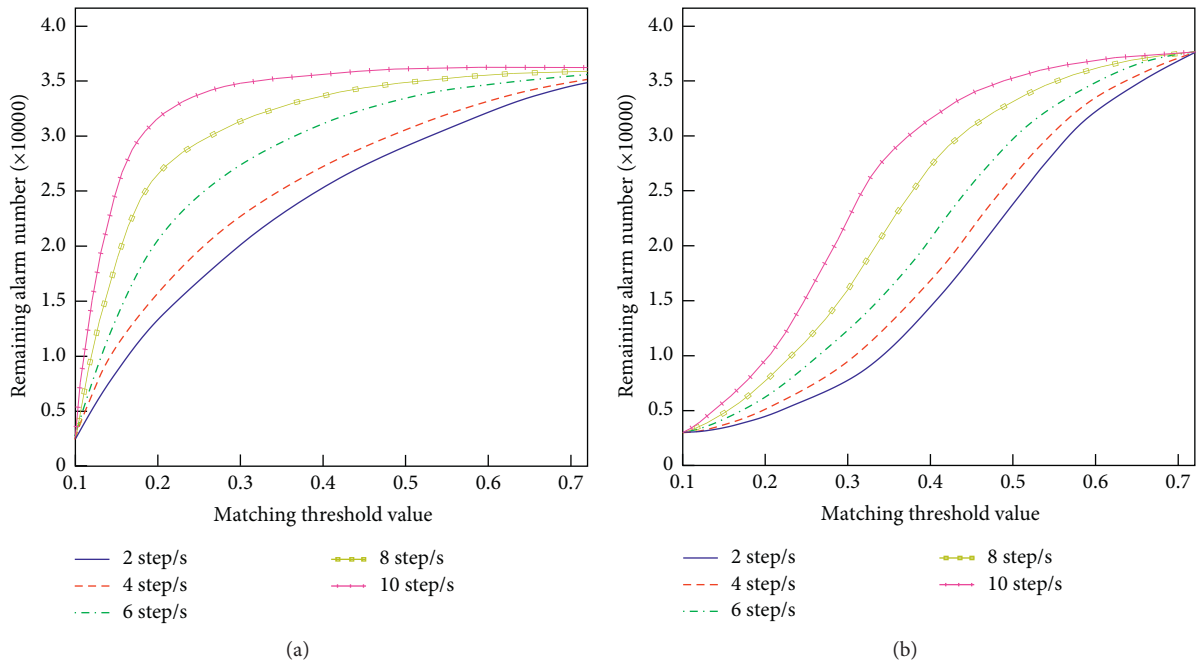
In order to diagnose and analyze network faults based on data mining, it is necessary to first obtain information that reflects the relevant state of the network to a certain extent. Only the more completed and comprehensive the information of the relevant network state can be related. In actual network management, information exchanges between different management domains are relatively small due to security and other factors. The fault information is more included, which is more conducive to the discovery and


Figure 6: Relationship between the remaining alarm number and the matching threshold value under different sliding steps.

resolution of faults. If designers want to fully obtain relevant network information, they need to refer to the network management of the computer and related diagnostic tools for network failure and refer to how it provides relevant data. The statistical content in the network device can be obtained by performing certain accesses to related data items. After that, comprehensive analysis of the statistical contents of multiple related network devices can be carried out to realize the basic management of the network.

From the perspective of data mining, data warehouse is the platform for data mining implementation and data mining is an analysis and the decision-making method. Based on the principles of artificial intelligence, machine learning, and statistics, it analyzes and mines historical data based on data warehouses or data marts to find out the relationship patterns hidden in these data. It reflects the intrinsic nature of the data and makes a higher level of abstraction of the information contained in the data. The data mining process is divided into the following stages: data preparation, data selection, preprocessing, data reduction, target determination, algorithm determination, data mining, and pattern recognition and knowledge evaluation. The first four stages complete the data warehouse to prepare for knowledge discovery and five stages to mine useful knowledge. Data warehousing and data mining are inextricably linked and a typical data warehouse mainly includes data import, data warehouse and data mart, and access tools. The application of data warehouse and data mining technology in the field of remote monitoring and fault diagnosis greatly improves the efficiency and depth of data analysis and provides a

powerful means for intelligent fault diagnosis, especially fault prediction, so that remote equipment enjoys the expert level.

According to the mining technology, the associated rules reflect certain dependencies or some related knowledge between certain things. If there are two or more related relationships, any one of them can be certain predictions based on other attributes and use the four related parameters of confidence, support, minimum confidence, and minimum support to determine the next rule so that obstacle data that are not yet known according to this rule can be determined. Relationship between the remaining warning number and regular association number under different algorithms is shown in Figure 7. This standard also stipulates the items and types of data that must be used for the agent of the network, as well as the agents that allow the operation of the network. The extraction is performed and quantified accordingly to form a global network alarm model.

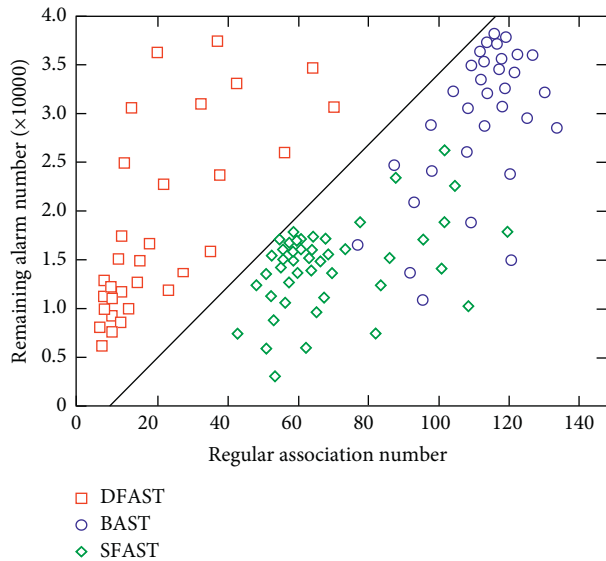
Centralized fault diagnosis is not a good solution, and data mining cannot be performed based on alarm information in real time. Researching distributed real-time fault diagnosis algorithms is of great theoretical value and practical significance for better reducing the time of system faults and improving the accuracy of fault location. Because different network equipment vendors do not agree on the alarm format and content and combine the characteristics of related network alarms, this paper first deals with the network alarm information, according to the characteristics of network alarms and related rules to carry out key attributes.


Figure 7: Relationship between the remaining warning number and regular association number under different algorithms.

6. Conclusions

This paper studied the network fault diagnosis of the embedded system method based on topology constraint and data mining. Firstly, a fault diagnosis topology model was established by constructing a topology search algorithm, which eliminated the filtering of association rules without topology relationship; the association rule-based data mining model was analyzed through the collection of network alarm data; the model algorithm was applied to the simulation experiment of network fault diagnosis of the embedded system and achieved good results. A new neural network algorithm based on rough set decision is proposed and the corresponding network fault is designed. A diagnostic model that manages all subnets and managed devices by providing a single network operation control environment is in a mixed network environment. The causes of noise data are data false alarms and measurement errors. When the fault occurs, the data of some variables of the system will fluctuate greatly, and some properties of the constructed network model will also change. The results show that correcting rage of retrieval varies from 0.65 to 090 under different window size; the running time of the proposed method drops from 310 s to 35 s during 1–8 step/s of the sliding step, while the node degree ranges from 8 to 14 and diagnostic accuracy ranges from 0.97 to 0.94; the remaining alarm number increases from 0.5 to 3.5 threshold value, while the regular association number is distributed in an interval of 40 to 140. The algorithm in this paper provides a reference for further research on network fault diagnosis of the embedded system. Moreover, further research studies should focus on the detailed influence of embedded system's inner structures on network fault diagnosis based on topology constraint and data mining.

Data mining technology has gradually become an important data analysis and knowledge discovery technology widely used in many modern industries. Data mining is a technique to find its regularity from a large amount of data by analyzing each data. It mainly includes three steps: data preparation, regularity search, and regularity representation. Data preparation is to select the required data from relevant data sources and integrate them into a data set for data mining; regular search is to find out the regularity contained in the data set by a certain method; regular expression is to be as user-readable as possible. The way of understanding (such as visualization) will represent the found patterns. This research mainly discusses the improvement of teaching mode based on digital twin-based education big data mining. Through the research on the basic principles of data mining and digital twin technology, the student evaluation tool module based on digital twin and the relevant data analysis tool module of students based on digital twin education big data mining are developed. Data mining is carried out from the data of student performance, personal basic information, and evaluation information to find the correlation between various factors, find the hidden laws, and provide support for teaching decision-making. This paper also solves the problem of frequent communication with remote databases according to the characteristics of the database data required by students and improves the efficiency and scalability of education big data mining technology based on digital twins. The goal of the virtual interactive system of the digital twin-based CNC platform is to have both three-dimensional real-time monitoring and remote control functions based on a three-dimensional virtual CNC panel. This research integrates the three-dimensional real-time monitoring and remote control of the virtual interactive system, analyzes the system operation process, develops the system interface, and improves the system sub-functions; it builds an experimental environment, conducts example tests on various functions of the digital twin platform virtual interactive system, and performs virtual interactions system performance indicators are analyzed. 60% of students believe that their innovation ability has been improved after the implementation of the digital twin teaching model; 50% of students believe that their self-evaluation ability has been improved. Applying digital twin's educational big data mining to student information management, university teaching evaluation, student performance analysis, and examination system, it has played a very good guiding role in improving the level of school teaching management.

1. Introduction

In the modern higher education management, the level of informatization has been improved year by year. With the widespread use of campus cards and the accumulation of data from major business systems over the years, a campus big data environment has been formed. It is mainly reflected in the characteristics of large-scale, multi-type, high-speed, and low-density value of student data. How to effectively mine student behavior data has become an important content to improve the level of student work informatization management. The data mining education model not only makes up for the shortcomings of face-to-face education and single online education in the past, but is also consistent with modern education reforms. In the information age, educators must break traditional education concepts, explore new education models and methods, promote education and education reform, improve education and education quality,

and promote students to develop in a better direction with the help of information technology.

By building a student behavior big data analysis system, it analyzes and processes the behavior characteristics of students in school, and applies it to the identification of students with financial difficulties in the school's student financial aid center. Through the reliability of massive data mining and the scientific nature of related algorithms, it changes the original mode of identifying work for students with financial difficulties from families, and implements the goal of improving the informatization of college students' work. The data mining education model mainly integrates online learning and offline learning through high-quality educational resources and intelligent learning platforms. In the process of mixed teaching, learners can not only communicate with classmates, but also communicate online at any time through the Internet. At the same time, students with fast learning progress can gain knowledge in advance through online learning, and students with slow learning progress can use network resources to further confirm and integrate knowledge to meet their learning needs.

The progress of virtual simulation resource construction urgently needs to be improved, the education system lacks top-level design, and the system construction standards are not unified. Schleich et al. believe that digitization of manufacturing industry promotes the application of complex virtual product model (called digital twin model) in all stages of product realization [1]. Li et al. believe that current airframe health monitoring often relies on deterministic physical models and ground inspections. He uses the concept of dynamic Bayesian networks. Dynamic Bayesian networks integrate physical models and various sources of contingent (random) and cognitive (lack of knowledge) uncertainty in crack propagation prediction [2]. Zhang et al. believe that new national advanced manufacturing strategies such as Industry 4.0, Industrial Internet and Made in China 2025 are introduced to realize intelligent manufacturing, and the number of new workshops in developed and developing countries keeps increasing. Under personalized design requirements, more realistic virtual models reflect the real world of manufacturing workshops, which is crucial to bridging the gap between design and operation [3]. Seay believes that for a critical infrastructure such as the national grid, the delay between identifying a cyber attack and deploying defenses can be disastrous. ORNL scientists are working to solve this problem with a platform called "digital twinning," which provides real-time simulations of the grid so that system distortions can be identified almost immediately. The grid is often called the largest machine in the world. It is a complex and interdependent network consisting of power generation, transmission lines for long-distance transmission of power, substations for lowering the voltage of public utility systems, distribution lines connecting communities, and equipment for converting power for customers [4]. Fei et al. believe that digital twin (DT) is one of the most promising enabling technologies for intelligent manufacturing and Industry 4.0. The importance of DTs is increasingly recognized by academia and industry. It has been nearly 15 years since the concept of DT was first proposed. To date, many DT applications have been successfully applied in different industries, including product design, manufacturing, forecasting, and health management. However, there has not been a review of DT applications in industry. In order to understand the development and application of DTs in industry, he comprehensively reviewed the DT research status of key components of DTs, the development status of DTs, and the main application of DTs in industry. He also outlined current challenges and some possible directions for future work [5]. Tao et al. consider digital twinning to be a new and rapidly developing technology for connecting the physical and virtual worlds, which has recently attracted wide attention worldwide. This paper presents a new product design method based on digital twin method. First, the development of product design is briefly introduced. Then the framework of digital Twin driven Product Design (DTPD) is proposed and analyzed. A case is provided to illustrate the application of the proposed DTPD method [6]. Lydon et al. believes that new and refurbished buildings will require significant improvements in energy performance according to Swiss and EU targets for 2050. The construction industry, however, has a poor record of improving productivity and efficiency. As other industries have demonstrated, digital approaches can reduce product development time and costs by using numerical simulations to reduce prototyping. In addition, digital twin is an extensive computational model of a product that is planned to be improved over its life cycle by leveraging operational data. He presents coupled simulation of thermal design of heating and cooling systems integrated with lightweight roof structures. The shape of the concrete roof structure is optimized to provide a low-energy building element that is thermally activated to provide space conditioning from a renewable source of heat. This work focuses on modeling methods used in the energy sector to support the development of digital twins of multifunctional building elements [7]. Virtual models can predict, estimate, and analyze dynamic changes by understanding the state of physical entities through perceptual data. The physical object responds to the optimization in the simulation. Digital twinning can optimize the whole teaching process through the network-physical closed loop.

Today, with the rapid development of information technology, the development of scientific theories has brought about the rapid progress of science and technology [8, 9]. The progress of science and technology has an impact on the field of education all the time, and changes the way of education transmission. The promotion and dissemination of resources has played a role in fueling the flames, benefiting more and more people. The online virtual simulation teaching experiment system designed and implemented in this article follows the principle of "combining virtual reality, complementing each other, and realizing reality without vitality." It actively explores the complementary advantages of various types of experiments in the experimental teaching design, combining virtual simulation, remote experiment, and optimized combination of physical experiments. It analyzes and evaluates the problems of low student performance, almost zero communication between

teachers and students, single learning style, and long feedback period in the digital twin virtual teaching model, and proposes corresponding solutions. It combines the analysis and evaluation results to design the corresponding virtual teaching interaction center, and completes the development, testing, and evaluation of the entire virtual interaction center, and provides a decision-making reference for relevant education departments.

2. Teaching Mode Improvement Research Methods

2.1. Virtual Simulation Teaching Platform. Digital twin platform can be divided into online learning feature analysis technology and virtual-real teaching space fusion analysis technology. Through the deep integration, mapping, and mirroring between "online teaching" and "online learning," it can inject new digital productivity into online immersive teaching [10]. First, deploy the developed experimental project to the business server. The uplink of the business server communicates with the user's client to transmit the user's operating parameters and the experimental data returned by the business server; the downlink communicates with the network management server, used to transmit the signaling of the service server and the experimental result data returned by the network management server. Second, the network management server regularly collects the status information of the registered LTE base stations through the heartbeat mechanism, and maintains the communication link with the base stations in the alive state; and through the connected computer that controls the mobile phone, it controls the switch of the mobile phone. Third, after the mobile phone is turned on, it connects to the LTE base station with the strongest signal around to establish a network channel. Remote users can select experimental items through the client computer and perform experimental control, including the configuration of base station parameters, adjustment of signal strength, initiating mobile Internet services, intercepting communication signaling, and other functions. The virtual simulation teaching platform is shown in Figure 1.

2.2. Three-Dimensional Digital Twin Podium Design. The combination of real-time modeling technology and virtual-real fusion technology, mainly through big data analysis, mining and modeling technology, carries out association rule analysis based on various algorithms on the association between virtual and real teaching spaces, so as to deeply analyze the relationship between virtual and real teaching spaces, and around the association, and then promote the integration of virtual and real teaching space.

The development of virtual platform interactive technology of 3D digital twin machine tool and multimedia blackboard control instructions is the basis of remote control technology of 3D virtual numerical control platform. By studying the interactive technology of the virtual CNC platform, it is possible to operate the virtual three-dimensional CNC platform to send commands. The development

of immersive teaching control instructions can directly operate the multimedia blackboard. Coupling the interactive commands of the 3D virtual control platform with the control commands of immersive teaching can realize the remote control of the multimedia blackboard. After the virtual platform interactive technology is implemented, the digital twin teaching class needs to be equipped with a virtual numerical control platform. The three-dimensional digital twin teaching class corresponds to the virtual numerical control platform one-to-one, and the multimedia blackboard is remotely controlled through the virtual numerical control platform. As the control equipment of 3D digital twin teaching, the virtual numerical control platform has two main functions. First of all, the virtual numerical control platform can directly send debugging instructions to the 3D digital twin teaching terminal, which can simulate the teaching explanation process and adjust the key content of teaching to verify whether the 3D twin teaching has qualified performance. Then, the virtual numerical control platform can send control instructions to the multimedia server, and the multimedia server parses the control instructions into corresponding operation instructions. According to the different immersive teaching, the multimedia server sends different operation instructions to realize the remote control of the multimedia blackboard.

2.3. Main Interface of the Virtual Interactive System. The digital twin podium is a real-time dynamic mapping of the real online teaching space. Therefore, the real-time acquisition, transmission, and dynamic update of data are of great significance to it. The main interface of the virtual interactive system is mainly divided into the real-time monitoring area of the center podium and the surrounding chart menu bar area [11]. At the top of the system, there is a more detailed sub-menu bar and real-time display of the current frame number of the system. The chart area on the left shows the exact position of the current platform, the number of people online in real time, the current teaching code program, and the layout of the lecture content in turn. Client users can either watch the lecture process of the podium in real time through virtual roaming, or check the accurate information of the podium through the menu bar. In addition to the main interface, you can view other information of the CNC platform and class through the menu bar. The menu bar provides the entire class layout diagram, and the client operator can view the entire class status through the class layout diagram, understand the distribution of the platform, and prepare for the three-dimensional virtual roaming. Or it can select the multimedia file that needs to be transferred from the client, and then send it by the virtual numerical control panel. Hiding the sub-functions of the virtual interactive system through the sub-menu can provide the client operator with a better sense of immersion.

Divide the projection interval T on the Y-axis into k equally, then the length of each sub-interval is [12]

$$l = \frac{F_{x\max} - F_{x\min}}{k}. \tag{1}$$
FIGURE 1: Virtual simulation teaching platform.

The points of the subset constitute the vertex subset S_D [13]:

$$S_D = (x, y, z)|F_{x\min} + \chi + f(x+1). \tag{2}$$

The mean value of the three-dimensional coordinate vertex distribution J [14]:

$$J = \frac{1}{3M} \sum_{i=1}^{m} (p + q + r). \tag{3}$$

The mean value of the peripheral vertex set can be obtained, and the covariance matrix C can be calculated [15]:

$$C = \frac{1}{3m} \sum_{i=1}^{m} (p_1 p_2 + q_1 q_2 + r). \tag{4}$$

C is a symmetric matrix, and its eigenvectors d_1, d_2, and d_3 are perpendicular to each other, and the three eigenvectors are unitized [16]:

$$\begin{aligned} d_1 &= \frac{d_1'}{|d_1|}, \\[6pt] d_2 &= \frac{d_2}{|d_2|}, \\[6pt] d_3 &= \frac{d_3}{|d_3|}. \end{aligned} \tag{5}$$

2.4. Network Communication Module Design. The network communication module is mainly realized through the Socket Channel Server and Socket Channel classes. The module is mainly divided into four parts: message server, message receiver, message parser, and message type registration. The network connection between the interactive teaching system and the teacher server is realized through the XmlClient class. XmlClient needs to configure the IP address and listening port number of the teacher server. If the connection is successful, then XmlClient will add the connected Socket to the connection list for subsequent data Receive and send. All interactive messages in the interactive teaching system are extended from the XmlMsg class, and applications can flexibly configure new message types by inheriting from this class. XmlMsgHandler is the corresponding message parsing class that matches with XmlMsg. All message types on the mobile terminal of the interactive teaching system need to be registered in XmlMsgFactory. In addition to actively connecting with the teacher server, the mobile terminal of the interactive teaching system can also establish an XML conversation service by using XmlServer. The XmlServer class can monitor the network and add the clients connected to it into the connection list.

2.5. Platform User Demand Discovery Function Design Based on Big Data Technology

(1) Platform users conduct learning activities and obtain portraits of current learning users. Platform users conduct learning activities through interaction with

related applications. When platform users have a demand for teaching resources, they will conduct data queries. The traditional information retrieval process is to match the user's query set Q with teaching resources U to obtain teaching resources. In order to realize the perception of user needs, first collect the information of each dimension of the user portrait at the current time t through the application and its events such as user records, workflows, and learning tasks related to learning activities. The ontology semantic description forms the current learning user portrait.

(2) User portrait matching is done, perceiving the demand for teaching resources. Calculate the similarity between the learning user portrait at the current time t and the historical application user portrait in the teaching resources of the integrated application user portrait, and through the process of demand discovery, demand screening and demand sorting, combined with platform user query conditions, the user's demand results are obtained.

(3) Optimize teaching resources and add teaching resources integrating user portraits. The results of the teaching resources required by the platform users are fed back to the users. The users select and evaluate the teaching resource sets pushed by the system, or re-search and query the teaching resources, and use the learning activities to obtain the teaching resource application results, and compare them with the current teaching resources. They learn the integration of user portraits and form teaching resources corresponding to new user portraits. The realization process of user requirement discovery is shown in Figure 2.

Identify and obtain direct user profile information. When platform users perform learning activities in order to complete corresponding learning tasks, the platform user's personnel identification, teaching background, and learning task identification indicate that it belongs to the direct acquisition of information.

Association defines user portrait information. Obtain the historical records of platform users through the association with the teaching resource system, including participating tasks, learning achievements, teaching resources concerned, retrieval data, and resource evaluation. Among them, manual semi-supervision and process management are required, which can infer the class where the platform user is located, the portrait of other users in the class, etc., so as to obtain a more comprehensive user portrait.

In the guest user portrait model tree UC2, the corresponding node is U', and the similarity calculation formula of the two nodes is [17]

$$\sim (U, U') = \sum_{m=1}^{n} w * \sim Q(U, U'),\qquad(6)$$

where $\sim(U, U')$ represents the node U and the corresponding node U' [18].

The formula for calculating the similarity of single-valued character attributes is [19]

$$\sim P(c_1, c_2) = \begin{cases} 1, & c_1 \cdot \text{value} = c_2 \cdot \text{value}, \\ 0, & \text{other.} \end{cases}\qquad(7)$$

For two different single-valued numerical attributes similarity:

$$\sim P(n_1, n_2) = \frac{\|n_1 - n_2\|}{|n_1|}.\qquad(8)$$

The similarity calculation of single-valued object attributes is equivalent to the nested calculation between user portrait elements [20]:

$$\sim(o_1, o_2) = \sum_{i=1}^{n} w_j \cdot \sim p(o_1, o_2).\qquad(9)$$

The similarity calculation method in the research process is [21]

$$\sim(s, p) = \max(\sim(s, s_i)|s \in p).\qquad(10)$$

Use $|PS|$ to denote the number of elements in the set, and the calculation formula for the similarity between sets is [22]

$$\sim(p_1, p_2) = \frac{\sum \sim(s, PS_1) + \sum \sim(s, PS_2)}{PS_1 + PS_2}.\qquad(11)$$

2.6. Specific Content of the Learning Evaluation Model for Digital Twin Teaching. Before the start of the course, first evaluate the students' learning goals. The purpose of evaluation is to determine whether the students' goals are reasonable, help students sort out their learning goals, and provide a good foundation and start for students' follow-up learning. At the input evaluation level, there are two aspects: the teacher's input and the student's input. The teacher's input includes the design and implementation of the mixed teaching model, and the establishment of a digital twin online learning platform.

The input of students mainly includes the emotional and attitude input of students in the learning process. This research mainly evaluates students. Therefore, only the input of students is selected as the main research content of input evaluation.

In process evaluation, the comprehensive ability of students is regarded as the main content of the evaluation. Teachers use the online learning platform to implement blended teaching, observe and analyze the learning behavior of students in the process of learning, and record and analyze the performance of students in activities and events.

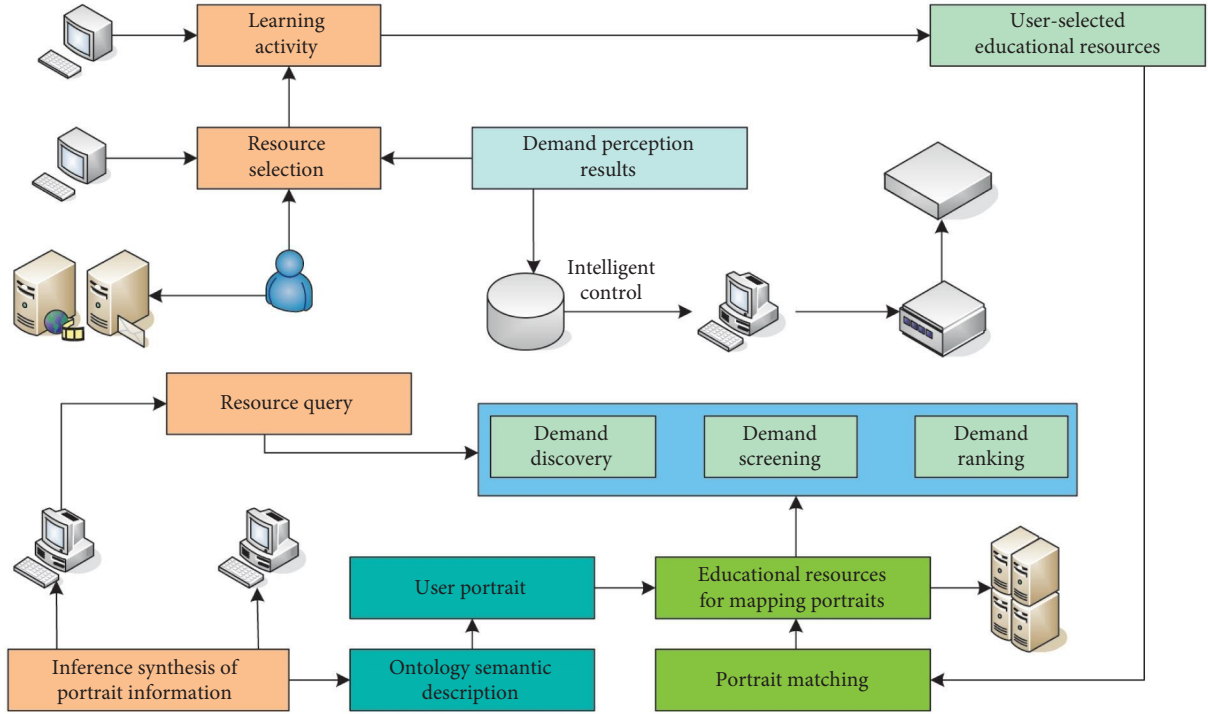
In terms of achievement evaluation, the study effect of students is taken as the main research content, mainly to evaluate students' mastery of basic professional knowledge. Teachers learn the basic knowledge of students through various forms such as daily homework, group homework, individual independent homework, and final exams. The effect is comprehensively evaluated.


FIGURE 2: The realization process of user requirement discovery.

As a group, upload the work to the digital twin teaching platform. Groups can browse each other's works and evaluate other groups, and the scale for group evaluation will be uploaded to the platform by the teacher in advance. The component evaluation scale is shown in Table 1.

Teachers evaluate the students' personal assignments uploaded to the digital twin teaching platform, and score the students' daily assignments based on the personal assignment evaluation scale. The scale is also an important basis for evaluating students' learning effect and comprehensive ability. The personal work evaluation scale is shown in Table 2.

A general summary of the teaching resources that platform users need to query [23]:

$$C(QC) = \underset{i=1}{\overset{m}{U}} (mk(ef)). \tag{12}$$

The result set of educational resources formed after query and screening is as follows [24]:

$$MK(F) = \underset{i=1}{\overset{m}{U}} (mk(ef)), \quad m > 0, \tag{13}$$
$$MK = (MK_1, MK_2, \ldots, MK_n).$$

The big data demand results obtained are [25]

$$W(MK) = (\underset{}{\coprod} W_1(MK_1), \underset{}{\coprod} W_2(MK_2), \ldots, \underset{}{\coprod} W_N(MK_N)). \tag{14}$$

The set of teaching resource requirements is [26]

$$MK_{QC} = QC_P \cup QC_T \cup QC_O, \tag{15}$$
$$MK = MK_{QC} - MK_{ef}.$$

Digital twin learning satisfaction P_Q can be expressed as [27]

TABLE 1: Component evaluation scale.

First-level index	Points	Secondary indicators	Points
Topic selection	10	Reasonable topic selection	10
Content	40	Completeness	25
		Innovation	15
Express display	25	Language expression	15
		Gallery	10

$$P_Q = P_R \cdot \text{sim}_R + P_R \cdot \text{sim}_R + P_P \cdot \text{sim}_P + P_O \cdot \text{sim}_O. \tag{16}$$

The vector index of different learning objects is [28]

$$\overrightarrow{QC} = \{T_1, T_2, T_3, T_R\}. \tag{17}$$

The query vector of the learning process can be expressed as [29]

$$\overrightarrow{QC_g} = \{T_1, T_2, T_2 - T_3, T_3 - T_R\}. \tag{18}$$

3. Results of Educational Big Data Mining on the Improvement of Teaching Mode

The average score of the three rounds of action research is on the rise. Due to the step-by-step improvement of the teaching design, the number of people who get full marks has increased sharply. The higher degree of completion of classroom tasks also proves the rationality of teaching design and the improvement of teaching effect. The effect of teaching design is shown in Figure 3.

The sample students' learning objective evaluation grade scores are shown in Table 3.

TABLE 2: Personal work evaluation scale.

| Evaluation index | Grade | | | |
	Weights	Excellent (80–100)	Pass (60–80)	Unqualified (0–60)
Accuracy	0.4	Correct	Basically correct	Confusion, error
Innovation	0.3	Ideas and insights	Lack of novelty	Nothing new
Organized	0.3	Clear logic	Basically ok	No logic
FIGURE 3: Teaching design effect.

TABLE 3: The learning objective evaluation grade scores of the sample students.

Learning target situation	Grade	Grade-corresponding score
The learning objectives are clear and feasible	A	95
The learning objectives are clear and feasible	A	95
The learning objectives are clear and feasible	A	95
The learning objectives are clear, and the feasibility of the learning objectives needs to be improved	B	85
The learning objectives are clear, and the feasibility of the learning objectives needs to be improved	C	75

According to the submission of students' works, the evaluation of students is shown in Table 4.

Calculate the average scores of comfort, adaptability, interactivity, sense of interest, and sense of immersion in the evaluation dimensions of students in the three classes of ABC. The comparison of each item is shown in Figure 4. It can be seen that with the update of the teaching design, the average scores of comfort, adaptability, interactivity, sense of interest, and immersion have shown an upward trend. Some have a large increasing trend, and some have a small increasing trend with a relatively high score.

In the course of teaching practice, the number of students who actively participated in the three rounds of action research was counted. The specific data are shown in Table 5. The first round of action research is the first time that digital twin teaching equipment has been brought to Class A classrooms. The number of students in Class A who are willing to try is relatively small. In the next two rounds of

action research, there are more people willing to participate in the digital twin teaching experience. After the first round of action research, taking into account the students' unfamiliarity with the new technology, the students will be specially trained in the simple operation skills of digital twin teaching before class. The students in the class behave more positively, and the classroom atmosphere is better.

Achievement rate is an intuitive standard that reflects the realization of teaching goals. In the process of teaching practice, the number of students who have completed the immersive exploration of digital twin teaching is deliberately counted. The specific data are shown in Table 6. Among them, only five students in Class A successfully completed the digital twin teaching immersion exploration, which indirectly shows that these students have a particularly strong ability to accept new things. The achievement rate of Class B and Class C is relatively high, which is partly related to the timely adjustment of teaching design. I feel the charm

TABLE 4: Evaluation of students.

Student ID	Accuracy (0.3)	Completeness (0.2)	Innovation (0.2)	Organized (0.3)
A	100	95	80	85

Achievement rate	27.78%	66.67%	94.44%

of new technology more, and it is also an affirmation of the introduction of virtual reality technology into the classroom.

The performance test aims to test the performance of the mobile terminal of the interactive online teaching system when interacting with the teacher terminal. The timely response of interactive data has a great impact on the interactive experience, which needs to be paid attention to. The test is divided into non-optimized and optimized. The main test is the round-trip delay of interactive data between teacher and student equipment. Taking into account the frequency of interaction, the test mainly uses interactive whiteboard tools as the test target. Compared with the synchronization of courseware playback, the amount of synchronized data of the interactive whiteboard is larger, which can better explain the actual situation. First, consider the interactive data transmission round-trip time between the teacher and the student without closing the digital twin platform, as shown in Figure 5.

After closing the digital twin platform, the round-trip time of interactive data transmission between the teacher and the student is shown in Figure 6.

When the students answer the questions synchronously, the interactive teaching application has a small overhead, kept within 10%, which can be applied to more complex situations. The cost of interactive teaching applications is shown in Figure 7.

Among the students surveyed, more than 80% of students believe that their problem-solving skills have been improved after the implementation of the digital twin teaching model; more than 70% of students believe that their project practice skills, teamwork skills, and language expression skills have
FIGURE 5: Interactive data transmission time between teacher and student without closing the digital twin platform.
FIGURE 6: After closing the digital twin platform, the interactive data transmission round-trip time between the teacher and the student.

been improved; 60% of students believe that their innovation ability has been improved after the implementation of the digital twin teaching model; and 50% of students believe that their self-evaluation ability has been improved. The student ability evaluation is shown in Figure 8.

Students A and B have relatively high evaluation scores in terms of learning objectives, indicating that they have a clearer understanding of the course content before learning, but their learning attitude is at an intermediate level compared to other students and needs to be further improved. In terms of comprehensive ability and learning effect evaluation, further improvement is needed from the overall level. The overall level evaluation is shown in Figure 9.

4. Discussion

The teaching management department of colleges and universities needs to supervise and count the teaching quality of teachers, which requires the establishment of a scientific teaching evaluation system to carry out statistics and analysis of the status quo in the teaching quality process. Students are the objects of teachers' teaching courses, and they are also the key to improving teaching quality. Therefore, students' evaluation of teachers' classroom teaching has a very objective and realistic value. At present, many colleges and universities in China have adopted a teaching evaluation system based on student evaluation, teacher mutual evaluation, and self-evaluation. After many years of evaluation information feedback, many colleges and universities have accumulated a large amount of teaching evaluation data. The statistical results of the data serve as the basic basis for teachers' evaluation of awards, excellence, and job titles, and play the basic role of teaching evaluation data. However, with the development of information technology, simple data statistics can no longer meet the needs of university teaching management departments, because
FIGURE 7: The cost of interactive teaching applications.
FIGURE 8: Student ability evaluation.

simple data statistics cannot find the potential teaching information that exists within the data, and more valuable data may be ignored by us. How to scientifically, rationally, and effectively use years of teaching evaluation data to guide teachers' teaching and improve teaching quality has become a very meaningful research topic.

Digital twin technology provides the architectural guidance of networked control and the direction of cyber-

physical system realization. With the help of digital twin technology based on informatization and networking, the development of the system can take advantage of the computing power and information fusion capabilities of the entire industrial network to give play to the advantages of new machine learning algorithms and data-driven algorithms. The leveling control and anomaly detection algorithms, as well as the realization of related algorithms, are
Figure 9: Overall level evaluation.

further studied and improved, combining information from different fields to achieve intelligent and networked control.

Subjective weight distribution requires the induction and extraction of human experience before the algorithm is executed. Although human experience has a strong individual dominance, the experience accumulated over the years cannot be replaced by any tool for induction and summary, and the value of human experience cannot be underestimated. The weight distribution based on objective conditions is actually the weight distribution based on objective data. It mainly analyzes the actual data that actually exists according to a certain algorithm, and finally obtains the weight value of the indicator based on the objective data. This method is based on objective facts. In order to analyze the data based on the facts, the results must be consistent with the objective facts. The objective weight determination method has a strong ability to persuade the data, and the results are reasonable. In the era of big data today, in the era of rapid economic and technological development in China, our focus has slowly shifted from food, clothing, housing, and transportation to education issues. We are in line with the world, and we want to accept better and more cutting-edge technologies. But what everyone can do in today's society is to perform their duties with full responsibility and help improve the way we are educated and the environment. This requires each of our students to face each answer sheet of teaching evaluation with a positive and serious attitude, and to attach their own opinions on classroom teaching after completing the selection of teaching evaluation indicators. At the same time, it is also required that educators in our schools and even the country can use the existing technical conditions to systematically analyze the real and effective teaching evaluation data, and combine the results of teaching experience and mathematical statistics to make an

adjustment, an improvement, so that all enjoy the power that technology brings to education.

Three-dimensional real-time monitoring based on digital twins requires high enough real-time data. Remote monitoring in digital twins is the basis of course early warning and remote control. In the past, the delay of monitoring systems is often at the second level, which cannot meet the requirements of remote real-time monitoring in digital twins. Three-dimensional real-time monitoring based on digital twins requires the graphics processing speed to be fast enough. The essence of the digital twin model of the virtual interactive class is the superposition of multi-dimensional elements in computer graphics. The digital twin model of the virtual interactive class is highly complex, the monitoring scene modeling is huge, and the data update speed is very fast.

The database is the basis of the entire system, and its quality is directly related to the realization of the system. In traditional education management and education concepts, education statisticians must meet the requirements of data mining, use different spreadsheets to handle the traditional data management of the new student data classification system, and process the data. This is a new design requirement of the database, which requires mutual conversion and spreadsheet functions. Due to the realization of global information resource sharing, the surge of information, and the improvement of information demand, traditional information extraction methods cannot meet the practical needs, so data mining technology is proposed. Data mining technology is used to extract and analyze large amounts of data to find hidden clues and provide a more valuable basis for further decision-making. Data mining is based on the database for research. The ultimate goal of the researcher is to combine the database and data mining to

make the final decision. In today's high-tech development, the scope of application of data mining is becoming wider and wider. It is not only suitable for university management, but also promotes the further reform, improvement, and development of school management, and also provides a good way for managers to make correct decisions. The educational management methods of basic schools have also been improved [30].

Generating a data warehouse is mainly about interface design and data loading interface design to ensure that the data extraction, transformation, and integration from the operational environment to the data warehouse can be completed and accurately completed with flexibility and variability. When loading data, ensure the order of data loading, filter invalid and wrong data, and manage data granularity. Design the interface from the database system to the data warehouse system to complete data purification and integration other than data extraction. The design of a data warehouse is an iterative process. As the process progresses, user needs are constantly clarified and the data that users really need are determined.

The national plan is based on education, and education is not a trivial matter. Teaching is different from business. Because there is no huge profit margin and long input-output time period, the application of high-tech in the teaching field is relatively backward and low in effectiveness. Appropriate methods are adopted to attract more scholars to use high-tech to transform teaching. It is a new problem facing the education system. Perform correlation analysis on students' personal basic information and results, various evaluation indicators, and project information that users are interested in, and look for the impact of students' personal basic conditions on student performance and evaluation indicators, as well as the interrelationship between results and various evaluation indicators. Data mining techniques are used to find the final result [31].

5. Conclusion

Although traditional face-to-face classroom teaching can effectively solve the above problems, it cannot meet the requirements of students in individualized learning and autonomous learning. In addition, traditional face-to-face teaching is mainly based on teachers, and students are in a passive position, which is not conducive to students' independence and innovation. The introduction of educational data mining technology into the digital campus system not only improves the scientific nature of education management, but also enhances the effectiveness of the digital construction of education. This system provides teachers and students with a digital twin virtual online interactive teaching platform that is easy to interact, manage, and operate. At present, the entire system has a large amount of data storage, including teacher data and student data. The education management information system only has simple query, statistics, and print functions for such a huge amount of data. If we can dig and analyze these data in depth, and discover some kind of internal connection, we will get some beneficial suggestive information. This article first made the

overall design of the system, then designed the specific functions of the system, and then showed the experimental results of the system. The research in this field has certain potential, and the efficiency of digital twins in this article needs to be further improved.

Forecasting economic growth is critical for formulating national economic development policies. Neural Networks are a type of artificial intelligence that may be used to model complex target functions. ANN (Artificial Neural Networks) are one of the most effective learning approaches now available for specific sorts of tasks, such as learning to understand complex real-world sensor data. This paper proposes the regional economic prediction model based on neural networks techniques. Bayesian vector neural network (BVNN) is integrated with backpropagation (BP) model. The database has been collected based on the economics of particular region which has been extracted and classified using knowledge-based computer analysis by neural networks. Discretization, reduction, importance ranking, and prediction rule are attributes considered here. Then, as the input training sample, feed extracted important components into the NN. This strategy enhanced the training speed and prediction accuracy by reducing structure of NN. WEO, APDREO, and AFRREO are the dataset and FWA-SVR and LSTM are the existing method taken for comparison. For the WEO dataset, 97% of GDP and 98% of accuracy are produced. For APDREO dataset, 92% of accuracy and GDP of 97% are obtained. For AFRREO dataset, 98% of accuracy is produced. The neural network can tackle nonlinear problems, according to experimental data, and the technology has been proven to be successful and viable with high accuracy. For practical application, the model has a good reference value. The proposed model reduces error by increasing the convergence rate and accuracy for each dataset.

1. Introduction

In evolution of human society, economic gain is a critical topic [1]. Based on surroundings, economic system is constantly influenced, which is also a nonlinear system. Additional interference variables, as well as different reasons that lead to ambiguous and inadequate historical information required for macroeconomic modelling [2], act directly on entire development of macroeconomic scheme process. As a result, the traditional BP_NN regional economic trend prediction technique cannot effectively correct weight in analysis process of vast data and operation efficiency is low. A typical BP_NN learning process includes two stages:

forward data propagation and backward error propagation. Input signal is analysed by neurons in input and hidden layers before being sent to output layer to display result [3]. It uses reverse propagation procedure if intended output is not accessible at output layer. Along originally linked path, there is a difference between network output and returned actual value. Modifying weights of neurons at each layer can lessen inaccuracy. Return to forward propagation process and continue until error is less than specified value. As a result, an enhanced BP_NN based approach for predicting regional economic trend is created, providing a solid foundation for regional economic development [4]. Forecasting regional economic activity is an increasingly

significant component of regional economic research. Regional economic predictions can directly aid local, subnational, and national policy makers as well as concerned business executives. Both policymakers and business executives need accurate predictions of key economic aggregates, such as employment, income, and output for medium-long term planning purposes. Regional economic activity forecasts have been used to explain macroeconomic forces, including predicting the stock market and cyclicality of national labour market movements. Furthermore, international investors and multinational agencies engaged in megaprojects at a regional level also need accurate predictions for investment planning reasons [5].

There are numerous statistical tools and models available today for assessing and developing integral indicators of quality of life. Most methods, however, have limitations in terms of applicability and do not function with incomplete or "noisy" data. As a result, neural network technologies and intelligent information systems based on them are presented as an alternate strategy for handling semistructured and normalised challenges of analysing quality of life and developing forecasting models [6–8]. Savings, housing, socioeconomic features of the population, the dynamics, and differentiation of these indicators in the context of demographic groupings and regional economies are the subjects of several studies [9]. Systems of absolute and relative indices are established in these studies to characterize the degree of provision and fulfilment of the demands of various groups of people. Authors use ways to identify the concepts of "cost of living" and "quality of life" in several models of the standard of living.

The cost of living is defined in classical economics as the value of a set of commodities that is determined, first and foremost, by the level of food and service costs, as well as changes in types of income, consumption habits, tax legislation, and demographic indicators of population groupings. Consumer basket and commodity bundle, as well as living wage [10], are the major estimated rates. The presence of structural shifts and the interaction between different sets of indicators, as well as nonlinear dependencies between indicators, are characteristics of time series of socioeconomic indicators [11–13]. Therefore, linear models are not always able to give qualitative results. In this regard, a hybrid approach based on the construction of an ensemble of hybrid models is promising, in which, along with regression models, models based on neural networks, decision trees, and neurofuzzy networks are used. In recent years, in many works, the hybrid approach has been developed to forecast time series [14–17]. Statistics mining, connection mining, decision tree mining, NNM, and other techniques are used in data mining. ANN is an auto adapted dynamics system, which is one of these approaches. ANNs have developed as a potent statistical modelling technique and a highly powerful instrument in modern quantitative economics.

Various economic forecasting methods are presented to anticipate future growth of related industries based on existing state of industrial economy in terms of research methodologies. To forecast the tourism business, an FWA-SVR forecasting model was suggested. Grey model GM (1, 1)

was used by [18] to forecast the growth tendencies of China's real estate economy. Another study looked at China's macroeconomic scheme by using a BMF-VAR method to forecast the country's macroeconomy [19]. To predict and analyse China inflation rate, deep learning based LSTM method was presented in [20]. The author of [21] built a MIDAS model for assessing and forecasting CPI and PPI using commodity price big data. The Chinese consumer confidence index was analysed and forecasted using a DNN_CNN-LSTM model in [22]. Paper [23] suggested an autoregressive (AR) model for more accurate forecasting of energy demand and supply. Paper [24] created a dataset of 77 countries covering over 90% of world GDP and used cross-country statistics to anticipate US economic growth during downturns. In [25], the author offered a machine learning technique for constructing mood indicators as well as economic forecasting using evolving confidence indicators. Paper [26] developed a self-correcting intelligent pandemic prediction model to improve COVID-19 forecast accuracy and strengthen economic management and control. Paper [27] used WEKA3.9 to create three prediction models to accurately predict business failure.

The FWA-SVM model has the smallest errors in predicting the GDP ratio and filling rate [28] while it keeps the shortest time to optimize the SVM parameters. The bandwidth requirement of LSTM [29] is very high and the computational accuracy is low in these systems in big data analytics so BVNN_BP is proposed to overcome these limitations.

The proposed contribution of this paper is as follows:

(i) To collect the database and process it with proposed Bayesian vector neural network (BVNN) and to integrate with backpropagation (BP) model by feature extraction and classification

(ii) To compare the proposed BVNN_BP model with the existing system like FWA-SVR and LSTM with various datasets like WEO, APDREO, and AFRREO

However, understanding and applying these strategies necessitates a thorough understanding of mathematics, algorithm knowledge, and computer programme technology. Methodologies in the study case produce one type of simple and high-accuracy economic growth forecast.

2. Prediction Model Using Proposed Design of Bayesian Vector Neural Network (BVNN) with Backpropagation (BP)

2.1. Model Structure. Our BVNN_BP inputs are GDP growth index, primary, secondary, and tertiary industry growth value for n consecutive years in a region as panel data into the network to predict the output primary, and secondary and tertiary industry growth values for the region in year $n+1$ with attribute discretization, reduction importance ranking, and prediction rule.

The model divides input data into two parts.

(1) Regional GDP network: regional GDP data are independent of other indicator data before fully

connected layer of the neural network, and feature information is extracted using BP, batch normalisation, and ReLU activation function. This design reflects that the regional GDP can mirror the overall economic level of the region, which is equivalent to gauging the regional economic development level by regional GDP to divide regions and using different forecasting strategies for regions with different development levels in the fully connected layer.

(2) Regional panel data network: using neural network convolution kernels, the regional GDP growth index, primary, secondary, and tertiary industry growth values are integrated to produce panel data to detect industry correlations and effect of industry data on later growth values within n successive years. To extract time series data features as well as probable industry links, three BVNN layers are utilised first. (1) and (2) outputs values are inputs of fully connected layers and to enhance two networks multichannel outputs, GDP outputs are combined. The mathematical representation of BVNN layers is represented in Table1 with its algorithm.

2.2. Proposed Model Analysis.

Let us consider each feature by a variable $X_i \subseteq RR$. Then each client is totally defined by an n-dimensional vector. $x = (x_1 \ldots, x_n) \in X \subseteq R^n$.

Basic rule for calculating a unit's activation value in relation to other connected units with a strength w_{ji} is a function of weighted sum of inputs expressed [30] in

$$u_j = f\left(\sum_i u_i \cdot w_{ji}\right) = f(\text{Net}_j) = \frac{1}{1 + e^{-\text{Net}_j}}. \quad (1)$$

Net_j = Net Input to j level unit.

To this equation, one must include the unit's threshold, which is defined as the unit's proclivity to activate or inhibit itself by

$$u_j = f(\text{Net}_j) = \frac{1}{1 + e} - \left(\sum(i) w_{ji} \cdot u_i + \theta_j\right). \quad (2)$$

If $\partial u_j / \partial \text{Net}_j = u_j \cdot (1 - u_j)$ then Δout_j from (3) and (4):

$$\Delta \text{out}_j = (t_j - u_j) \cdot u_j \cdot (1 - u_j),$$

$$\frac{\Delta w_{ji}}{\partial} = -\frac{\partial E_p}{\partial w_{ji}}. \quad (3)$$

$$\begin{aligned}
E_p &= \frac{1}{2} \sum_k (t_{pk} - u_{pk})^2 \\
&= \frac{1}{2} \sum_k (t_{pk} - f_k(1 - u_j)) \\
&= \frac{1}{2} \sum_k \left(t_{pk} - f_k\left(\sum_i w_{kj} \cdot u_{pj} + \theta_k\right)\right).
\end{aligned} \quad (4)$$

E = Error; p = Model; t_k = Target; u_k = Output and then

$$\begin{aligned}
\frac{\partial(\text{Net}_{pk})}{\partial w_{kj}} &= \left(\frac{\partial}{\partial w_{kj}} \cdot \sum_j w_{kj} \cdot u_{pj} + \theta_k\right) \\
&= u_{pj} = -\frac{\partial E_p}{\partial w_{kj}} (t_{pk} - u_{pk}) \cdot f_k'(\text{Net}_{pk}) \cdot u_{pj}.
\end{aligned} \quad (5)$$

Value out_j will now determine the amount of value to be added or subtracted from weight w_{ji} in connection to activation state of unit u_i, which is activation with which u_j is linked to weight w_{ji} and coefficient r. This is correction rate that should be used as shown in

$$\Delta w_{ji} = r \cdot \Delta \text{out}_j \cdot u_j. \quad (6)$$

Δw_{ji} can have a negative or positive value. It denotes the "quantum" that will be added or subtracted from the prior weight w_{ji} value by

$$w_{ji(n+1)} = w_{ji(n)} + \Delta w_{ji}. \quad (7)$$

However, this assumption is only true for weights which connect a unit layer to output units layer. Correction approach outlined so far is only applied to BP with two layers, to use gradient descent [31] in (8) and (9).

$$\begin{aligned}
\frac{\partial J}{\partial w_{11}^1} &= \left(\frac{\partial J}{\partial a_1^2}\right)\left(\frac{\partial a_i^2}{\partial z}\right)\left(\frac{\partial z}{\partial w_1^1}\right) = \left(\frac{\partial\left((1/2)\left(a_1^2 - y\right)^2\right)}{\partial a_1^2}\right)\left(\frac{\partial(g(z))}{\partial z}\right)\left(\frac{\partial\left(a_1^1 w_{11}^1 + b^1\right)}{\partial w_{11}^1}\right) \\
&= \left(\left(a_1^2 - y\right)\right)(g(z)(1 - g(z)))\left(a_1^1\right) \\
&= (g(z) - y) \cdot g(z)(1 - g(z)) \cdot a_1^1.
\end{aligned} \quad (8)$$

It can be easily shown using calculus that derivative of the sigmoid function $g(z)$ is given by $g(z) \cdot (1 - g(z))$. Partial derivative of J is with respect to bias.

TABLE 1: Comparative analysis of regional economic prediction model based parameters for APDREO dataset.

Parameters	APDREO dataset		
	FWA-SVR	LSTM	BVNN_BP
GDP per capita prediction	88	90	92
Prediction accuracy	92	95	97
GDP per primary growth	90	93	95
GDP per secondary growth	89	92	96
Convergence rate	91	93	97

$$\frac{\partial J}{\partial b^1} = \left(\frac{\partial J}{\partial a_1^2}\right)\left(\frac{\partial a_1^2}{\partial z}\right)\left(\frac{\partial z}{\partial b^1}\right)$$

$$= \left(\frac{\partial\left((1/2)\left(a_1^2 - y\right)^2\right)}{\partial a_1^2}\right)\left(\frac{\partial(g(z))}{\partial z}\right)\left(\frac{\partial\left(a_1^1 w_1^1 + b^1\right)}{\partial b^1}\right)$$

$$= \left(\left(a_1^2 - y\right)\right)(g(z)(1 - g(z)))$$

$$= (g(z) - y) \cdot g(z)(1 - g(z)). \tag{9}$$

In this network, (10) can be rewritten as

$$\frac{\partial J}{\partial w_{11}^2} = \left(\frac{\partial J}{\partial a_i^2}\right)\left(\frac{\partial a_i^2}{\partial z}\right)\left(\frac{\partial z}{\partial w_{11}}\right)$$

$$= \left(\frac{\partial\left((1/2)\left(a_1^3 - y\right)^2\right)}{\partial a_1^3}\right)\left(\frac{\partial\left(g\left(z^2\right)\right)}{\partial z^2}\right)\left(\frac{\partial\left(a_1^2 w_{11}^2 + b^2\right)}{\partial w_{11}^2}\right)$$

$$= \left(\left(a_1^3 - y\right)\right)\left(g\left(z^2\right)\left(1 - g\left(z^2\right)\right)\right)\left(a_1^2\right)$$

$$= \left(g\left(z^2\right) - y\right) \cdot g\left(z^2\right)\left(1 - g\left(z^2\right)\right) \cdot a_1^2 \tag{10}$$

So, calculating the required gradients can be done. This explains the basic mathematics behind backpropagation. Now, after understanding the above mathematical aspects, we can backpropagate a simple linear NN using this approach. For more complex NN, with multiple nodes in every layer, the approach remains the same, and the only difference we get is the changing of subscripts and superscripts of w, z, a, and b. This makes backpropagation complex, and we need to use matrix forms of the derivatives, i.e., gradient vectors. But the basic idea remains the same. Backpropagation is simply using the chain rule of derivatives to calculate the change of cost function J with respect to changing parameters of the network. The proposed BP algorithm helps to compute the gradient which can be used to tweak the parameters using gradient as shown in Algorithm 1. Difference between actual output and desired one and summation report are constructed using previously calculated error coefficient Δout_j and weight associated with that coefficient was referring [32] to

$$\Delta\text{hidden}_i = u_i \cdot (1 - u_i) \cdot \sum \Delta\text{out}_j \cdot w_{ji}. \tag{11}$$

And therefore,

$$\Delta w_{ik} = r \cdot \Delta\text{hidden}_i \cdot u_k. \tag{12}$$

In fact, start from

$$\frac{\partial E_p}{\partial w_{kj}} = \frac{1}{2}\sum_k \frac{\partial}{\partial w_{kj}} \cdot \left(t_{pk} - u_{pk}\right)$$

$$= -\sum_k \left(t_{pk} - u_{pk}\right) \cdot f_k\left(Net_{pk}\right) \cdot w_{kj} \cdot f_j\left(Net_{pj}\right) \cdot u_{pi}. \tag{13}$$

w_{kj} = Hidden-Outputs weights.

Weights associated with output are corrected in the calculation as shown in

$$\Delta w_{ji} = r \cdot \Delta\text{out}_j \cdot u_i. \tag{14}$$

Weights that are not connected to output are corrected by

$$\Delta\text{hidden}_i = f'(u_i) \cdot \sum_j \Delta\text{out}_j \cdot w_{ji}. \tag{15}$$

Fulfilment of the corrections on weights is done by

$$w_{ij(n+1)} = w_{ij(n)} + \Delta\text{out}_i \cdot u_j \cdot \text{Rate}. \tag{16}$$

For output units as shown

$$\text{Bias}_{j(n+1)} = \text{Bias}_{j(n)} + \Delta\text{hidden}_j \cdot \text{Rate}. \tag{17}$$

$x_{t,i}^{sum}(\theta) \in R^n$ for all $t = 1, 2, \ldots, T$, where T is simulation length; i denotes random number initialized. In general, estimate or calibration processes try to find suitable values for h so that $X^{sim}(\theta, T, i)$ creates dynamics that are as near to those observed in an experimentally measured counterpart as possible as shown in

$$X = [x_1, x_2, \ldots, x_T]. \tag{18}$$

$x_t \in R^n$ for all $t = 1, 2, \ldots, T$.

As a result, Bayesian evaluation is phrased in terms of Bayes' theorem as given in

$$p(\theta|X) = \frac{p(X|\theta)p(\theta)}{p(X)}. \tag{19}$$

Method for approximating $p(\theta|X)$ for a certain value of h then allows us to calculate right-hand side of

ALGORITHM 1: Proposed BP Algorithm.

$$p(\theta|X) \propto p(\theta|X)p(\theta). \qquad (20)$$

For all $t \geq \widetilde{T}$ in which $x_{t,i}^{sim}(\theta)$ varies for stationary level, $E[x_{t,i}^{sim}(\theta)|t \geq T]$ which allows us to further consider that $x_{\widetilde{T},i}^{sim}(\theta), x_{\widetilde{T}+1}^{\sin}(\theta), \ldots, x_{T,i}^{sim}(\theta)$ establishes a random sample from an assumed distribution. Using kernel density estimation (KDE), we can then establish a density function which designates this distribution, which we designate by $\widetilde{f}(x|\theta)$ permitting us to estimated likelihood of empirically sampled data for a specified value of h as given in

$$p(X|\theta) = \prod_{t=1}^{T} \widetilde{f}(x_t|\theta). \qquad (21)$$

For all $L < t \leq T$, this means that $x_{t,i}^{sim}(\theta)$ is solely dependent on past L realised values. As a result, our objective is to evaluate above conditional densities by

$$\widetilde{f}(x_{t-L,i}^{sim}, \ldots, x_{t-1,i}^{sim}, x_{t,i}^{sim}, \phi) \approx p(x_{t,i}^{sim} \mid x_{t-L,i}^{sim}, \ldots, x_{t-1,i}^{sim}: \theta). \qquad (22)$$

For all $L < t \leq T$, $\phi = \phi(\theta)$.

The aforementioned technique is made up of two main components: a mixture of K Gaussian random variables in Algorithm 2 and a random number generator as shown in

$$p(X|\theta) = \prod_{t=1}^{T-L} \widetilde{f}(x_t, \ldots, x_{i+L-1}, x_{i+L}, \phi). \qquad (23)$$

This leads us to define following loss function as shown in

$$LS(\theta^{rrue}, \widehat{\theta}) = \theta^{true} − \widehat{\theta}_2. \qquad (24)$$

3. Simulation Results

3.1. Dataset Description

3.1.1. World Economic Outlook (WEO).
The WEO database is developed during the biennial WEO exercise, which takes place between January and June each year and culminates in the release of the WEO in April and September/October. A database format is provided for selected series from the publication.

3.1.2. Asia and Pacific Regional Economic Outlook (APDREO).
APDREO offers data on recent economic trends and forecasts for Asian and Pacific countries. The data for REO for Asia and the Pacific is compiled in tandem with semiannual WEO exercises, which take place in the spring and fall. The data is in line with the WEO's projections. Due to variances in group membership, REO aggregate data may differ from WEO aggregate data. Weighted averages of data for specific countries make up composite data for country groups. All concepts are represented by arithmetic weighted averages, with the exception of inflation and broad money, which are represented by geometric averages.

3.1.3. Sub-Saharan Africa Regional Economic Outlook (AFRREO).
AFRREO provides data on recent economic events and scenarios in Sub-Saharan African countries. The data for REO for Sub-Saharan Africa is compiled in tandem with semiannual WEO exercises, which take place in the spring and fall.

ALGORITHM 2: Proposed BVNN Algorithm.

3.2. Comparative Analysis. This section discusses the comparative analysis for various datasets in terms of GDP per capita prediction, prediction accuracy, GDP per primary growth, GDP per secondary growth, and convergence rate. The techniques compared here are FWA-SVR and LSTM for WEO dataset, APDREO dataset, and AFRREO dataset. Python is the software used for implementation and the comparison results are obtained from the simulation. Table 2 represents the comparative analysis of regional economic prediction model based parameters for WEO dataset.

Table 2 and Figures 1 and 2 show comparative analysis for proposed BVNN_BP with existing technique LSTM and FWA-SVR. The parameters are compared for WEO dataset with existing techniques. Based on this comparison, the proposed technique obtained optimal results in terms of predicting the economic rate of the region and in terms of accuracy for this prediction higher for proposed technique when compared with existing technique. GDP predicted per capita by BVNN_BP is 97%, and accuracy is 98% which is higher based on the existing technique comparison. In terms of primary and secondary growth of GDP, it is comparatively higher for proposed model. Convergence is also optimized by BVNN_BP up to 91%. Table 1 shows the comparative analysis of regional economic prediction model based parameters for APDREO dataset.

Table 1 and Figures 3 and 4 show comparative analysis for proposed BVNN_BP with existing technique LSTM and FWA-SVR for APDREO dataset. This dataset gives the economic analysis and data from Asia and Pacific region.

For this regional analysis the GDP prediction obtained by proposed BVNN_BP is 92%, accuracy predicted by this proposed technique is 97%, and based on primary and secondary growth of GDP for this region of 95% and 96%, the convergence rate here is 97%.

Table 3 represents the comparative analysis of regional economic prediction model based parameters for AFRREO dataset.

Table 3 and Figures 5 and 6 show comparative analysis for proposed technique and existing technique for AFR-REO dataset. This dataset covers the economic growth for Sub-Saharan Africa region. Economically Africa is considered to be poor country, so the GDP prediction based on both primary and secondary industry growth is essential for this region. By analysing the data of this region, the GDP prediction is optimal but not up to the mark to region analysis. The accuracy for this dataset by proposed model would be 98%.

4. Discussion

Country econometric models continue to play an important role in planning and forecasting key indicators of socio-economic development. They allow taking into account the interdependencies of indicators associated with their economic content. At the same time, many economic time series are characterized by nonlinear dependencies, and the influencing factors are often impossible to describe explicitly

TABLE 2: Comparative analysis of regional economic prediction model based parameters for WEO dataset.

in the form of regression equations. This makes, as shown by numerous studies, the application of neural network methods and technologies very promising.

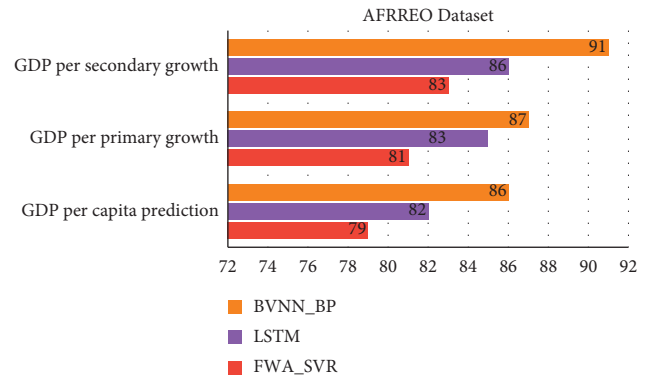
Over the past decade, approaches to forecasting time series based on feedforward networks and recurrent networks have been developing, including their application for forecasting economic indicators. At the same time, machine learning platforms and tools are becoming widespread, making it possible to implement all the main architectures and methods of training neural networks. It should be noted that the use of neural network tools for separate unrelated time series does not allow for a systematic approach to modelling the economic sphere. We are convinced that a hybrid methodology should be applied with the possibility of choosing in each case the most appropriate method. Such an approach is implemented in developed Bayesian vector


FIGURE 6: Comparative analysis of AFRREO dataset for regional economic prediction model.

neural network (BVNN) which is integrated with back-propagation (BP) based feature extraction and classification. The suggested technique can forecast regional economy and increase prediction model's convergence rate without impacting accuracy, effectively enhance effectiveness of regional economic analysis and prediction, lower percentage error, and have advantages of greater operating effectiveness. The only limitation of the proposed model is that the convergence rate and accuracy are dependent on each other so separate works are needed to improve the accuracy and convergence rate.

5. Conclusion

This paper proposed novel technique regional economic prediction based on machine learning techniques. Data were first normalised to balance deviations among indicators and then normalised data were transferred exponentially to balance deviations among regions, with the goal of reducing data heterogeneity among economic indicators of each region and differences in economic development levels of each region. Database has been collected and processed with proposed Bayesian vector neural network (BVNN) which is integrated with backpropagation (BP) model by feature extraction and classification. The experimental results show the comparative analysis for various datasets in terms of GDP per capita prediction, prediction accuracy, GDP per primary growth, GDP per secondary growth, and convergence rate. The techniques compared here are FWA-SVR and LSTM for WEO dataset, APDREO dataset, and AFRREO dataset. The proposed model reduces error by increasing the convergence rate and accuracy for each dataset.

Bookmarks are the basis for librarians to get books on and off shelves and borrowers to borrow books. In order to solve the problem of time-consuming and labor-consuming manual checking of bookmark aging, this paper proposes a method of bookmark aging recognition based on image processing technology. First, we perform image preprocessing, Otsu threshold segmentation, and morphological processing on the acquired bookmark image to obtain the effective area of the bookmark, then acquire the aging features for the bookmark, and finally input the acquired features into the trained neural network for defect recognition. The experimental results show that the method proposed in this paper can achieve 96% recognition, which can more accurately identify the aging defects of bookmarks.

1. Introduction

With the proposal and continuous innovation of the concept of smart library [1], the trend of intelligent digitalization of libraries has become increasingly obvious. Different from digital library [2], smart library emphasizes the intelligent management of library. Besides the management of digital resources, it is necessary to develop an intelligent system for paper book management, so as to enhance the state detection and ensure paper books are in good condition. At present, automatic borrowing and returning of books has been realized, that is, readers can not only check the borrowing status and information of the required books through the mobile phone app or the computer provided by the library but also complete the borrowing and returning procedures in the self-service book borrowing and returning machine [3].

Libraries often check books through inventory, so that the problems of books, such as misplaced books [4], damaged books, and bookmark falloff, can be found [5]. For example, the school library of the author is closed for arrangement every Friday morning. For libraries with large collections, this method will not only affect the normal borrowing of books but also pose great challenges to

librarians. In 2016, more than 100 librarians in Nanjing University Library spent 5 days to complete the inventory of above 900,000 books [6]. In view of the shortcomings of traditional library management, such as being time-consuming and labor-consuming, having low efficiency, and common complaints of "unable to find books," some libraries have developed library robots, such as the intelligent book inventory robot in Nanjing University Library, the RFID book automatic inventory robot in Wuhan University Library [7], and the intelligent chat robot Xiaotu in Tsinghua University Library [8]. Library robot has the advantages of saving manpower, noncontact, time management, and efficiency, which can solve the problems of traditional library management to a certain extent. Particularly, in terms of manpower, time, and cost, it can fundamentally improve the library management and make routine management possible. However, according to the current studies and reports, some library robots can only realize the handling in designated positions, such as the handling robots of Humboldt University Library in Germany and Osaka City University Library in Japan [9]. Other library robots need to customize bookshelves or use other devices to keep books in the designated state, such as the automatic access robots of Johns Hopkins University in the United States [10] and National University of Singapore [11].

The workload and cost of bookshelf update and modification are massive. Although the current robot technology has been relatively mature, it can hardly be popularized in library management. Therefore, for the current large libraries, it is more appropriate to apply robot technology to library management based on the current actual situation of libraries than to completely adopt new technology. According to the existing studies of intelligent book management, the combination of robots and other technologies is more suitable. In this study, the book state detection algorithm is mainly developed based on image processing technology, which can be superimposed on the robot. The robot is equipped with a camera to realize the image collection. The proposed algorithm is used to detect and judge book images and provide corresponding suggestions to assist the daily management and maintenance. Different book detection algorithms will be continuously developed for later robot implantation, so as to effectively reduce the times of internal arrangement by closing library and decrease the workload of librarians in library management.

2. Book Detection Framework

As a bridge among books, readers, and librarians, bookmarks play a vital role in book borrowing and book shelving. Figure 1 shows several common types of the bookmark.

Different from the two-dimensional code of books, the bookmark is usually attached to the lower part of the spine. It is easily exposed to the air and affected by the frequent circulation of books, resulting in aging, damage, and even falling off. Some common problems of bookmarks are shown in Figure 2.

A aging bookmark detection algorithm based on image processing is proposed, whose overall flow is shown in Figure 3.

Firstly, image segmentation is carried out for the obtained bookmark image, the bookmark area is segmented, and five features of aging classification are extracted from the segmented bookmark area, which are gray mean, median and variance of B channel, and the mean and median of S channel. The extracted features are input to the trained neural network model, and three aging states of bookmarks are obtained, namely, non-aging, slight aging, and severe aging.

3. Detection of Bookmark Aging

According to the bookmark images, bookmarks usually have the following characteristics:

(a) Bookmarks are composed of the white background with black characters, and there are edges of other colors with a certain width.

(b) When bookmarks are aged, they will become yellow or even brown. The more serious the aging, the darker the color.

Based on the above-mentioned characteristics of bookmarks, a bookmark aging detection method based on visible light images is proposed. With the robot as the carrier, a high-definition pan/tilt camera is used to shoot bookmark images. First, the bookmark area is extracted by image preprocessing, segmentation, and extraction algorithm. Second, according to the color characteristics, the aging characteristics of bookmarks are determined. Finally, the aging degree of bookmarks is judged by inputting the bookmark characteristics to the trained aging detection model. The flowchart is shown in Figure 4.

3.1. Bookmark Segmentation. Before aging detection, it is necessary to extract the label from the image, and the integrity of the label region extraction is the premise to ensure the aging recognition accuracy. Therefore, before detecting the aging of bookmarks, this study first determines the bookmark area. The main methods include image preprocessing, image segmentation, and morphological processing. Figure 5 shows the process of label region extraction.

(a) *Image Preprocessing.* Preprocessing of bookmark images [12] is not only the premise of bookmark aging but also an important step of bookmark recognition and aging degree detection. The main purpose is to make bookmarks obvious in images, so as to separate bookmarks and remove the background information. Firstly, the images are grayed and converted from RGB images to gray images, which is conductive to simplifying subsequent detection process and decreasing computation burden.

(b) *Image Segmentation and Morphological Processing.* After preprocessing the collected bookmark images, the bookmark area is preliminarily extracted by image segmentation [13], and the segmented images are subjected to morphological processing [14] to remove the bookmark's noisy point. Meanwhile, bookmarks are separated from the background according to the unique distribution characteristics, thus determining the bookmark area.

Because of the special structural features of bookmarks, a unified brightness map is obtained through camera imaging, and the light reflection ability is stronger than that of the background. After image preprocessing and image segmentation, an accurate bookmark area can be obtained, which provides a guarantee for subsequent processing.

3.2. Aging Degree Detection. Aging is inevitable in the use process, but the causes are complex. Aging problem cannot be solved fundamentally. Therefore, the best solution is to regularly check and then replace aged bookmarks. In this study, neural network is used to classify the aging degree. Before detection, relevant characteristic parameters are extracted, and bookmarks are detected by using PNN (probabilistic neural network). The detection mode is shown in Figure 6.

3.2.1. Feature Extraction. Because of obvious color changes caused by bookmark aging, the recognition of the aging degree can be transformed into color recognition. The
FIGURE 1: Bookmark types.

gray values of R, G, and B channels [15] will decrease during aging, and the change of B channel is the most obvious. HSI color space [16] is composed of hue (H), saturation (S), and intensity (I) separately. S component is less affected by external factors, and its performance is relatively stable. Therefore, this study selects B and S components to extract feature values [17] (including mean value, median value, and variance) of the two channels (B and S) in the bookmark area, respectively (five features, namely, B_{mea}, B_{var}, B_{med}, S_{mea}, and S_{med}). The feature calculation formula is as follows.

Mean value:

$$G_{mea} = \sum_{i=1}^{m} \sum_{j=1}^{n} g_{i,j} p_{i,j}. \tag{1}$$

Median value:

$$G_{med} = \underset{1 \le i \le m, 1 \le j \le n}{\text{median}} g_{i,i}. \tag{2}$$

Variance:

$$G_{var} = \sum_{i} \left(g_{i,j} - G_{mea} \right)^2 p_{i,j}, \tag{3}$$

where $g_{i,j}$ represents the gray values in the B and S images; $p_{i,j}$ is the probability of gray value $g_{i,j}$; m and n represent the image size; and $g_{i,j}$ is the operation of taking the median value.

According to the field test, three groups of sample data of bookmark aging degree can be obtained, as shown in Table 1. The second column of Table 2 refers to the three aged bookmarks obtained from the collected image (the aging degree is non-aging, slight aging, and severe aging), and the corresponding five feature values are listed in the third to eighth columns, respectively. It can be found that the extracted features have obvious differences in different aging degrees, and it is effective to select the five features for classification.

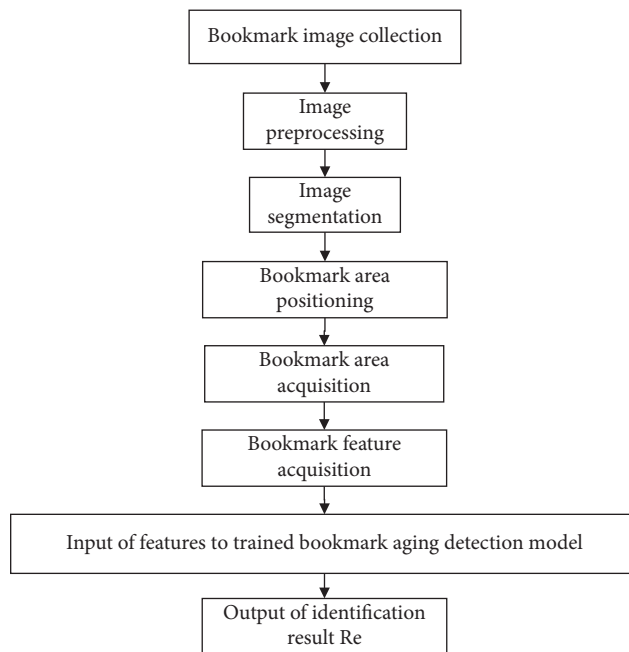
3.2.2. Aging Detection Model. PNN (probabilistic neural network) [18] is a feed-forward artificial neural network put forward by Dr. Specht in 1990 on the basis of Bayes rule and radial basis neural network. It is composed of radial basis neuron [19] and competition neurons [20]. As shown in Figure 7, the model is mainly composed of four layers: input layer, pattern layer (training set), summation layer, and output layer. It can use linear learning algorithm to complete
Figure 2: The common problems of bookmarks. (a) The problem of aging. (b) The problem of damage. (c) The problem of falloff.
Figure 3: The overall flow of the bookmark detection algorithm.


Figure 4: The bookmark aging detection algorithm.
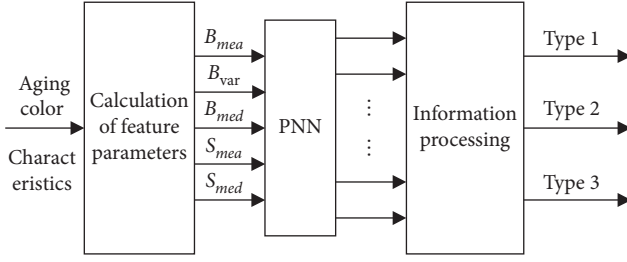
Figure 5: The process of the bookmark area extraction.


Figure 6: The model of the bookmark aging detection.

the function of non-linear algorithm while maintaining the high precision of non-linear algorithm. With the characteristics of simple structure and quick training, the model is suitable for pattern classification.

(1) Classification of Probabilistic Neural Networks.

Input layer: the input layer receives data and transmits them to the mode layer. The number of input neurons is the same as the dimension of input vector.

Pattern layer: the pattern layer calculates the matching between input vector and each pattern of the training set. The number of training samples determines the number of neurons in the pattern layer. Neurons correspond to training samples. Each pattern layer calculates the output result according to the following formula:

$$\phi_{ij}(x) = \frac{1}{(2\pi)^{d/2}\sigma^d}\left[-\frac{(x-x_{ij})^T(x-x_{ij})}{2\sigma^2}\right], \quad (4)$$

where σ is the smoothing coefficient; x is the input vector composed of calculated color features; and x_{ij} is the neuron vector of the i_{th} pattern layer of class j.

Summation layer: neurons in the summation layer correspond to the classification patterns, which are connected with the pattern layer through sparse links. The connection condition of neurons between the summation layer and the pattern layer is that they correspond to the same classification pattern. By summing the output values, the maximum possibility of a certain category can be obtained. The calculation formula is shown in the following formula:

$$p_j(x) = \frac{1}{(2\pi)^{d/2}\sigma^d}\frac{1}{N_j}\sum_{i=1}^{N_j}\exp\left[-\frac{(x-x_{ij})^T(x-x_{ij})}{2\sigma^2}\right], \quad (5)$$

where N_j is the number of samples of class j.

Output layer: the class with the highest posterior probability is selected as the classification result according to Bayesian decision rules, and the calculation formula is as follows:

$$C(x) = \arg\max\{p_j(x)\}, \quad j = 1, 2, \ldots, m, \quad (6)$$

where $C(x)$ is the estimation class of the input vector x and m is the total number of classes.

(2) Construction and Training of Network. There are five nodes in the input layer of PNN (probabilistic neural network), which correspond to five characteristic parameters (B_{mea}, B_{var}, B_{med}, S_{mea}, and S_{med}). There are three nodes in the output layer, which correspond to three states, namely, non-aging, slight aging, and severe aging. These three states are expressed in binary format, as shown in Table 2.

100, 010, and 001 represent the categories of non-aging, slight aging, and severe aging bookmarks output by the network, respectively. In the subsequent testing process, in order to draw the test result diagram, the description corresponding to the aging category will be converted into decimal representation, that is, 1, 2, and 3 represent 100, 010, and 001, respectively.

4. Algorithm Experiment

In order to verify the effectiveness of the proposed bookmark aging detection method based on the PNN (probabilistic neural network), experiments were carried out on a large number of collected bookmark images, including image segmentation, neural network training and testing, and aging degree detection. The experiment was completed on a computer with Intel Core i5-3240 @3.40 GHz CPU and 4G memory and image processing software MATLAB R2014a.

4.1. Bookmark Segmentation Effect. The bookmark segmentation proposed in this paper is mainly based on maximum between-class variance (Otus method) threshold segmentation and morphological filtering. The segmented bookmark area is mapped back to the original image to obtain the bookmark area without background interference. The processing results are shown in Table 3. The second to sixth lines represent the original image, the grayed image, the threshold segmented image, the morphologically processed image, the bookmark area determined by the minimum circumscribed rectangle, and the color image of the bookmark area.

According to the Otsu segmentation results in Table 3, it can be found that the bookmarks aged in different degrees are correctly segmented, and the whole area is complete without false segmentation. The proposed segmentation method is effective and feasible for the bookmark segmentation.

4.2. Aging Degree Identification Test. In this study, the bookmark images taken in the experimental environment are selected. 60 images of non-aging, slight aging, and severe aging samples are taken as the training samples, respectively. The input layer of the neural network is (B_{mea}, B_{var}, B_{med}, S_{mea}, S_{med}), and the output layer has three aging degrees (nonaging, slight aging, and severe aging). B_{mea}, B_{var}, B_{med}, S_{mea}, and S_{med} of the training sample are extracted as the input of the neural network, and the aging degree is the output for PNN neural network training. 150 images of samples with different aging degrees (50 images of non-aging, slight aging, and severe aging in each category) are selected as the test samples to simulate the neural network, and the corresponding aging degree

TABLE 1: The data of the aging bookmark.

2		Slight aging	107.96	6.78	115	0.2453	0.2447
3		Severe aging	46.17	2.94	47	0.6077	0.6226

TABLE 2: The classification of aging modes.

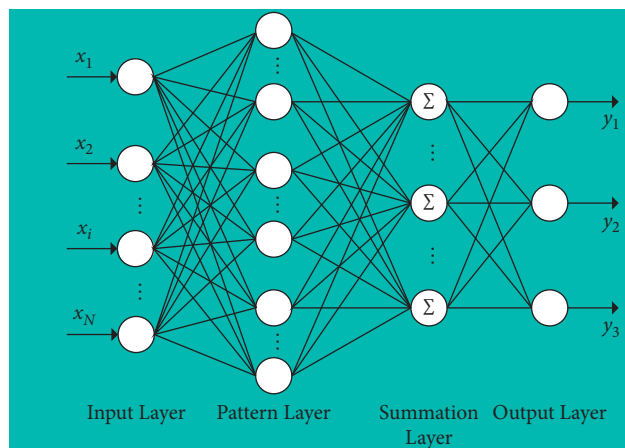
Aging classification	Description of binary format	Description of decimal format
Non-aging	100	1
Slight aging	010	2
Severe aging	001	3


FIGURE 7: Probabilistic neural network structure diagram.

discrimination results are output. There are obvious differences among bookmarks with different aging degrees in terms of B_{mea}, B_{var}, B_{med}, S_{mea}, and S_{med}. The actual output and the target output of 150 test samples are shown in Figure 8, in which Yc-Label is the experimental test result and T-Label is the actual test result.

As can be seen from Figure 8, all slight aging bookmarks are correctly identified, and three non-aging bookmarks and severe aging bookmarks are mistakenly identified as slight aging. In pairwise transition, the values of the extracted features may be similar, and the typical samples fail to cover adequately, resulting in recognition errors. Such problems can be solved by accumulating the number of samples.

In this study, the backpropagation (BP) neural network and the competition network are also simulated and tested. As shown in Table 4, the accuracy of the neural network is 96%, which is obviously higher than that of the BP neural network [21] and the competition network, thus realizing the accurate judgment of the gray density degree of bookmark aging.

This study selects five bookmark images to analyze the gray aging degree of bookmarks, which are compared with the field manual test results. The results are shown in Table 5. The proposed method can detect and judge the actual aging degree of bookmarks, and the results have good consistency.

5. Conclusions

The bookmark defect detection method based on probabilistic neural network can make full use of the prior knowledge of faults and qualitatively detect the aging of bookmarks under Bayesian minimum risk criterion. Probabilistic neural network has high training speed. It is easy to implement in engineering and has strong robustness and high recognition accuracy. With the gradual accumulation of fault knowledge, the network can be continuously expanded to further improve the detection accuracy.

This study proposed the identification of bookmark aging degree based on probabilistic neural network and applied it to detect the aging degree of bookmarks. The identification accuracy is 96%, which is higher than that of the traditional method. The proposed method lays a foundation for the detection of bookmark defects by using image processing technology.

However, the proposed method only analyzes the aging of bookmarks, but there are many other defects in bookmarks. Therefore, the algorithm will be improved to further study other types of bookmark defects.

Data Availability

The characterization data used to support the results and discussion are available from the corresponding author upon request.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Authors' Contributions

Zhijian Xiao was responsible for sorting out data, data collection, and literature review. Cong Zheng and Shaoqiu Ma participated in the experiment and data analysis. Xiaoling Zhang was responsible for full-text writing.

Based on the news and public opinion multioutput Internet of Things architecture, this article analyzes and predicts its popularity with big data. Firstly, the model adopts a three-tier architecture, in which the bottom layer is the data layer. It is mainly responsible for the collection of the terminal sensor data of the Internet of Things, and it uses intelligent big data as the data warehouse. Secondly, the computing layer on the data layer mainly provides the computing framework. Using the open-source SQL query engine, a cluster environment based on memory computing is constructed to realize the parallelization of data computing. It is used for interactive operations between the system and users. It receives and forwards the query requests submitted by the client browser, transmits them to the server cluster for execution, and displays the results in the browser. The end is displayed to the user. After that, combined with the needs of the development and application of news and public opinion big data, the data collection process was analyzed and designed, and the distributed data collection architecture was built. The intelligent Internet of Things was adopted for data storage, the data storage structure was analyzed and designed, and the data storage structure was designed to avoid catching. The repeat check algorithm is used to repeatedlystore the obtained page data. At the same time, according to the analysis of the business needs of the news and public opinion information platform, the overall functional structure of the platform was designed. The database and platform interface were designed in detail. The simulation results show that the model realizes the statistical query of the collected sensor alarm information and historical data on the user system, combines the historical operating data to analyze the relationship between the supply/return water temperature of the heat exchange station and the outdoor temperature, and realizes chart visualization of data analysis.

1. Introduction

With the development of modern information technology, emerging technologies, such as the Internet, cloud computing, and big data, have been widely used in various fields of social economy. The sensor transmission speed of the Internet of Things is very fast, and the application of a large number of sensor devices will definitely lead to a substantial increase in the output of news and public opinion data. The Internet of Things and big data are closely related, and the data generated by sensors can also be processed by the big data platform [1, 2]. News and public opinion Internet of Things big data is different from Internet big data [3]. In addition to the general characteristics of big data, they also have strong relevance and timing. Therefore, the traditional Internet big data processing methods are not fully

applicable. New solutions need to be designed specifically to properly analyze the Internet of Things data and extract more important information from the Internet of Things monitoring equipment [3–5].

To improve the efficiency of the analysis of news and public opinion IoT data, it is necessary to implement a low-latency query system based on the Hadoop data warehouse, which can handle a large number of concurrent query requests. A single query can return the results faster, thereby improving the efficiency of data processing and analysis [6]. With the increasing maturity of the wireless sensor network technology,the combination of RFID, other sensors and wireless communication technology can realize the information exchange between objects,as well as long-distance monitoring and management if connected to the Internet. The internet realizes human-to-human interaction with

people as the object, and the Internet of Things will further realize the interaction between things and realize the concept of ubiquitous networks. Using distributed query strategies and memory-based computing methods, the main purpose is to quickly query the information in massive amounts of data, provide timely feedback to users, and improve query efficiency. For massive data, traditional processing methods are difficult to meet real-time requirements. Distributed technology has become a research hotspot in the field of big data [7–9].

Based on this, the system takes the news and public opinion as the research object and uses computer network and communication technology under the framework of the Internet of Things to store the news and public opinion-related information and deliver it to the users in a timely and accurate manner, realizing news and public opinion detection, management, and marketing network. The traditional news and public opinion detection technology has been improved to improve the efficiency of news and public opinion detection, personnel management, and business decision-making. In the process of platform construction, a data storage architecture based on Mysql and intelligent Internet of Things was designed, SpringMVC development framework was adopted. Spring Framework was used as the core container, and Dubbo was used as the distributed architecture of the entire platform.The platform system is powerful, safe and scalable, which can handle high concurrency and massive data storage.Dubbo chooses intelligent big data as a data storage tool and creates news, public opinion, and IoT big data based on an open-source memory computing engine. Query the system and use data mining algorithms to analyze the historical data of the operation of the heat exchange station in the news and public opinion detection.

2. Related Work

With the continuous increase in the popularity of big data research, the application fields of big data are becoming more and more extensive. Domestic internet companies use big data technologies, such as Hadoop, to handle PB-level data problems in data storage, data mining, and high concurrency. Using Hadoop-based architecture for data collection, data analysis, etc., major universities are also conducting academic research and applications in the big data environment. Under the general situation, big data has been widely used in internet finance, medical health, transportation, and communication operations for other aspects [10–12].

Losavio et al. [13] proposed a news and public opinion big data acquisition and analysis platform (IBDP) that integrates HDFS, Spark, intelligent big data, HBase, Flum, Sqoop, OpenStack, etc., suitable for the acquisition and analysis of news and public opinion data. Yigitcanlar et al. [14] proposed and developed a smart city system based on the Internet of Things using the Hadoop ecosystem and big data analysis technology, combined with Spark over Hadoop to achieve the efficiency of big data processing. Hossein Motlagh et al. [15] proposed the use of the Hadoop software environment, including data collection, data storage, data normalization and analysis, and data visualization components to realize the

parallel processing of large heterogeneous data for IoT network security monitoring. Scholars have developed a farmland observation data management system based on the integration of wireless sensor networks that realize the automatic acquisition of a large amount of news and public opinion data. The system has been applied in the city for the related processing and analysis functions. Chin et al. [16] studied news and public opinion big data from the connotation of news and public opinion big data, the acquisition of news and public opinion big data, and the status quo of news and public opinion big data and combined the current internet technology and big data technology to look forward to news and public opinion big data.

Van Deursen and Mossberger [17] elaborated on the four key technologies of big data research: data collection and preprocessing, data storage, data analysis and mining, and data presentation and application, and gave the architecture diagram of big data collection, data warehouse, parallel storage architecture.In addition, they also introduced the high-availability technology of mass storage system, parallel computing, real-time computing, streaming computing, deep learning, data privacy protection technology, and other related technologies, and provided reference learning cases. According to the characteristics of massive data, the researcher designed the system structure of the massive data management system based on Hadoop and introduced the distributed storage and distributed computing of the massive data in detail, which has a strong reference value [18]. At present, there are many types of enterprise information management systems, and each system is managed independently, resulting in the wastage of resources and poor scalability of the system. In this backdrop, Lu designed a hierarchical storage system using the Hadoop key technology to design data mining function, data migration module, etc., to provide data mining and data migration system based on Hadoop architecture. It shows that with the continuous update of internet technology, the complexity of the news and public opinion management information system is also increasing. However, few news and public opinion management information systems can use all the functions of the internet and the emerging accurate news and public opinions and face the news and public opinion management information. The system's requirements for accurate news and public opinion and traditional management information systems require that the implementation of these systems is more complex. Some studies are based on the need of identifying accurate news and public opinions and realizing news and public opinion management by evaluating modern networks [19–21].

3. Based on News and Public Opinion Multioutput IoT Intelligent Modeling and Popularity Big Data Analysis and Prediction Model Construction

3.1. Intelligent IoT Hierarchical Nesting. At the intelligent IoT level, data analysis needs to move a subset of data to the data warehouse, and the speed of data analysis in

Hadoop is very slow. However, with the development of SQL query engines, big data technology can already be used in business analysis scenarios. By building a data model in Hadoop or other databases, large-scale historical data accumulated and stored for a long time are used in the big data processing system for information mining [22]. Figure 1 is the hierarchical topology of the intelligent Internet of Things.

The data collected by the sensors play an important role in detection monitoring and data mining analysis. In addition to real-time monitoring of data generated by IoT terminal devices, it is also necessary to store historical data accumulated in the process of news and public opinion detection and provide real-time statistical query analysis and the function of generating data reports.

$$L(m, t) = \frac{l(m, t)}{N},$$

$$\psi(x) = \frac{f(x, d) - f(x, m)}{f(x, d) + f(m, d)}. \tag{1}$$

In the data monitoring system of IoT devices, the sensor devices transmit the monitoring data to the data processing platform using various transmission methods, such as HTTP, TCP, and MQTT and store them in MySQL after parsing to provide real-time query support. The massive historical data adopts the intelligent big data storage warehouse to provide large-scale data support for the data mining and analysis of the system.

$$\chi(x, \lambda) = \begin{cases} e^{-\lambda L \times (1 + \lambda x^2)}, & \chi \geq \chi(x), \\ 0, & \chi < \chi(x), \end{cases}$$

$$L(y, g) = \sum_{i=1}^{n} y_i \left(g_i + \ln \times \sum_{j=1}^{n} \exp(g_i) \right). \tag{2}$$

When performing statistical query and data mining analysis on historical data, a query engine based on memory calculation is used to improve the speed of the system query and analysis. At the application layer, the output of the big data platform layer is used for chart display and to build a web server platform to provide a visual interface for data display and analysis. The processing of data collected by the terminal equipment includes real-time monitoring, statistical query analysis, and data mining analysis.

$$\begin{cases} f(x) = \text{sign} \left\{ \sum_{i=1}^{N} a_i y_i \times k(x_i, x_j) - b \right\}, \\ \text{sign}(x) = \begin{cases} -x > 0, \\ x = 0, \\ x \leq 0. \end{cases} \end{cases} \tag{3}$$

The terminal collection system consists of wireless IoT sensing devices, gateways, and data storage servers. The terminal devices regularly transmit data to the gateway through a network protocol. The collected data is parsed by the gateway and stored in a unified format.

3.2. Multioutput Process of News and Public Opinion.
News and public opinion have different output data nodes, and the collected data information will also have different degrees of difference. It is necessary to unify the data access methods of all IoT application terminals and storage standards for different forms of data at different nodes and unify the storage and management of multisource data. At the same time, it is necessary to provide hybrid computing capabilities for multisource data to improve the efficiency of multisource data management and analysis. The web server receives the request submitted by the client browser and sends the query task to the Presto computing cluster, and finally, it returns the result of the query execution to the user and displays the result on the client browser in the form of a web page for the data analyst to provide a friendly visual interface. The front-end is mainly implemented with Ajax, JavaScript, jsp, CSS, html, and other technologies, and ECharts is used to realize chart visualization. Figure 2 is a multioutput fan chart of news and public opinion.

When the coordinating node of the ZigBee network receives the single-point-sent data packet from itself or other devices, the network layer will continue to pass it on according to the program we set up in advance according to the requirements. If the target node is its neighbor, the data packet will be directly transmitted to the target node. If the target node is not its neighboring node, the coordinator node will retrieve the record that matches the destination address of the data to be transmitted and the routing table. If there is a match, the data will be transmitted to the next level network in the record; otherwise, the router will initiate a path search. When a node device receives an RREQ data packet, it will forward the data packet, in turn, and add the latest connection cost value. By analogy, the RREQ data packet follows all the connections it passes through and carries the sum of all connection costs until the RREQ data packet successfully reaches the destination device node. The routing node will select the one with the lowest connection cost among the received RREQ packets and send a route reply packet RREP to the source device. The RREP packet is a single-point sending packet that will return to the node device that sent the request along the path where the RREQ packet came from. After the path is established, the data packets can be sent and received along the established path. At this time, the node will send an RERR packet to all the node devices waiting to receive the data of this node to set the path as invalid. Each node will also update its routing table according to the received data packet.

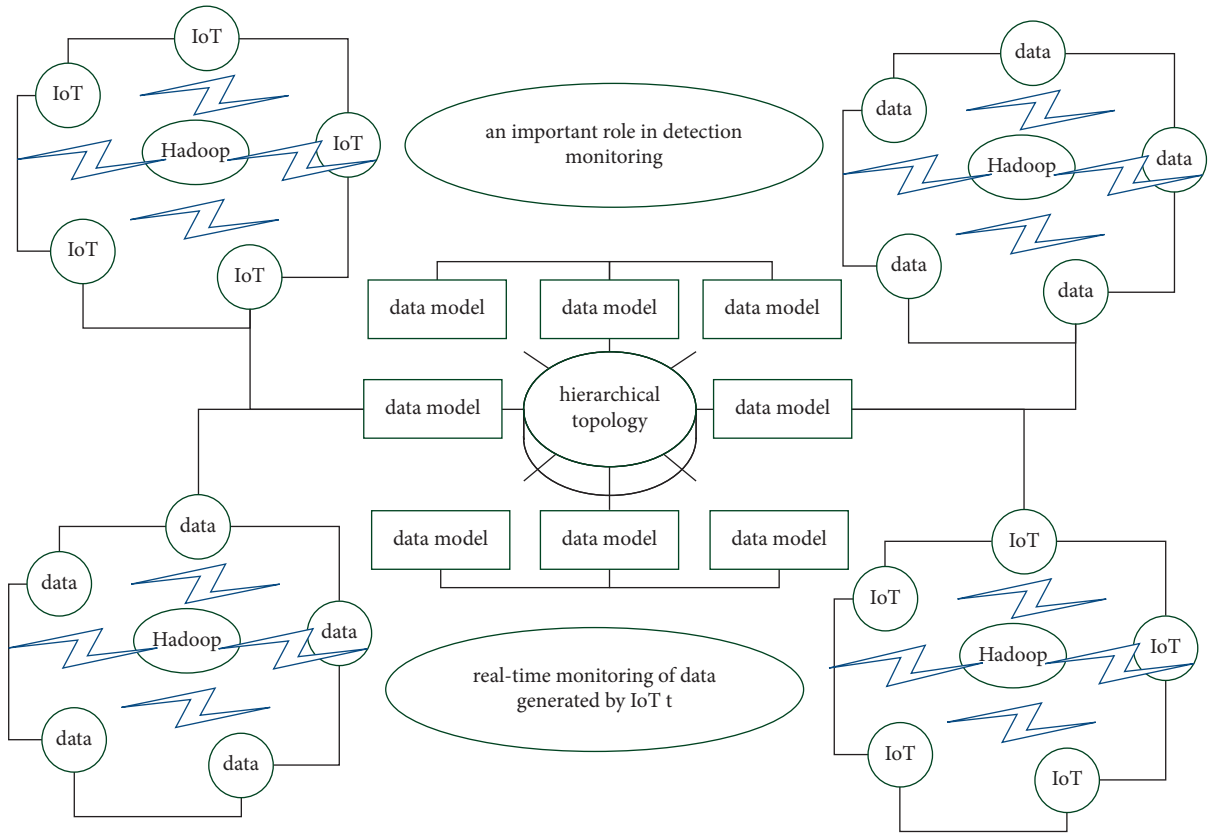
3.3. Popularity Demand Analysis.
In the computing structure of popularity, the data stream is composed of countless tuples. It is the smallest unit of data that contains many key-value pair data. The spout is the entrance to the data source. It provides many simple API interfaces, including sensor output API interfaces, website hits, messages from social networking sites, and logs of various applications. It converts the received data source into a tuple data stream and transmits the data to the next component specified. The main purpose of writing a spout program is to obtain data from the data source. Bolt is a function in the storm


FIGURE 1: Smart IoT hierarchical topology.
FIGURE 2: Multioutput fan chart of news and public opinion.

program. It is responsible for calculating and processing the input data stream. Its main functions include data filtering, data fusion, data calculation processing, and writing data to or reading data from the database. The terminal sensor device sends data to a unified data processing platform through the gateway so that each device can share and exchange data seamlessly. At the same time, it integrates the processing of real-time data and historical records and provides a unified operating environment for the application platform of the Internet of Things. Integrate demand analysis and solutions in a variety of application scenarios so that the system can meet the various needs of the users.

Figure 3 shows the popularity requirement scalability architecture. NewSQL mainly refers to the improved SQL database with scalability and superior performance. As it is an improvement and innovation based on the original SQL database, the NewSQL is compared to the original SQL database technology. Since it is an improvement and innovation of SQL technology, it still has the functions of traditional SQL, supports SQL queries, and meets the transactional and consistency requirements of the database queries. At the same time, the improved NewSQL database also has scalability and flexibility similar to NoSQL databases. HDFS supports the redundant backup storage of data blocks. As HDFS requires a combination of relatively low-cost small computers, these small computers are not highly reliable, and hence, HDFS is designed to be highly fault-tolerant. It is able to detect and respond to the failure of each machine node in time and ensure the stability of the system.

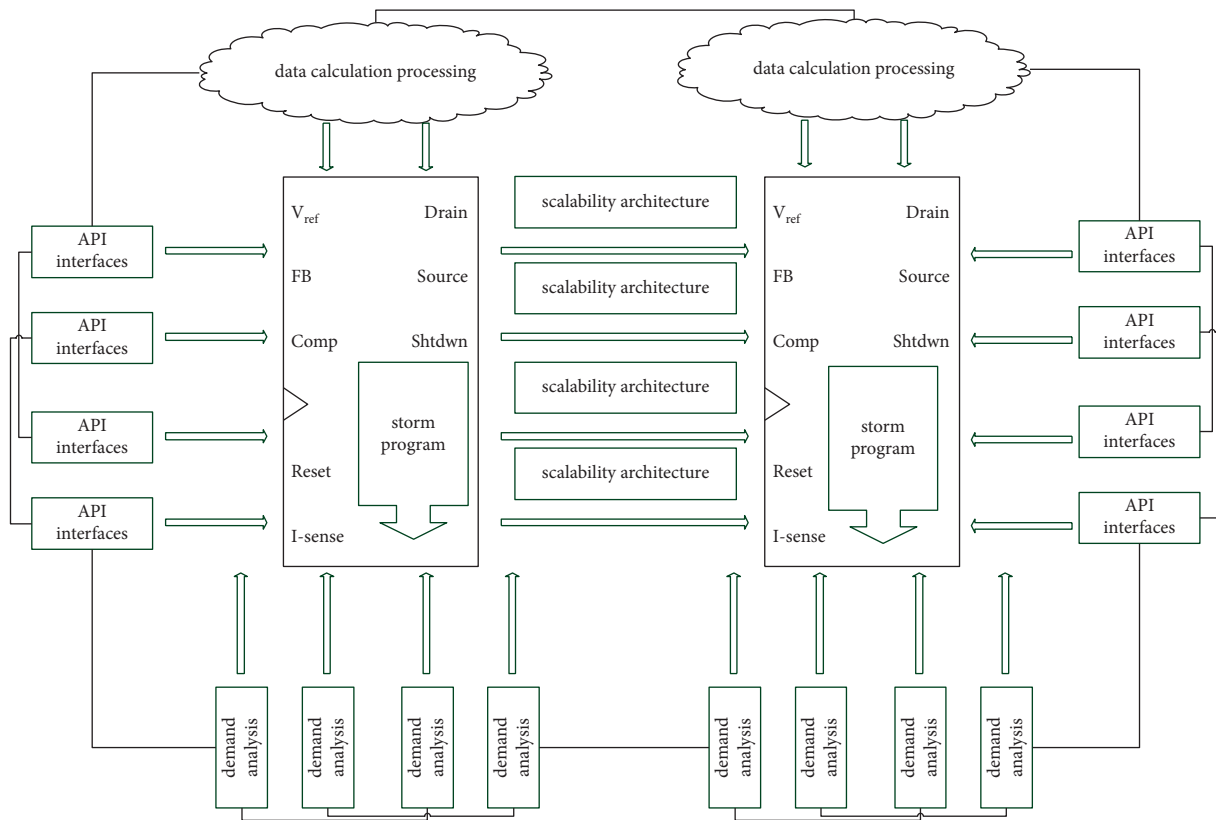
For this part of the data source, a variety of data acquisition interfaces need to be developed in the system, including the RS485 interface, Ethernet interface, AD conversion interface, and 24 V switch detection interface. By deploying data to HDFS, it can support large-capacity, high concurrency, and high-throughput big data computing tasks, while keeping file systems consistent across the nodes. An HDFS cluster must contain a name node NameNode (aka master node) and multiple DataNodes (aka slave nodes). Each slave node in the HDFS system is an ordinary or cheap computer. The name node can provide a naming service for each storage unit in the HDFS system, record and


FIGURE 3: Popularity requires scalability architecture.

maintain the mapping information of the entire system data block, and receive requests to access HDFS from the corresponding client. Data nodes are mainly used to perform specific tasks, such as storing file blocks scheduled by the client and the NameNode. At the same time, HDFS has a client interface that interacts with the outside world. It mainly implements the external access requests to HDFS, including interacting with the NameNode to read file storage information, interacting with the DataNode to read the data in the HDFS system, and so on.

3.4. Design of Big Data Forecasting Function.

The Hadoop system has many components, including HDFS, MapReduce, HBase, smart big data, Sqoop, Flume, Zookeeper, etc. It can run efficiently on the Linux platform. It supports multiple programming languages and has high reliability and fault tolerance. It can process the data reliably and efficiently and has relatively good scalability. It is used to store and process large amounts of data for analysis, and thus, Hadoop has become a very popular solution. When the Hadoop cluster becomes insufficient, it is usually improved by adding new computers or storage devices with common methods. The Hadoop ecosystem can perform distributed computing well, and the users can develop without knowing the details of the underlying storage. The data collection terminal mainly relies on wireless network sensor equipment for real-time data collection. The wireless node performs data collection after registering in the network. At the

same time, the data is sent to the gateway through the MQTT protocol and Modbus bus at regular intervals. The data of multiple nodes are summarized. The collected data is preprocessed and sent to the relational database server in a unified format, and the application server side processes the data. Figure 4 is the distribution of prediction accuracy of public opinion big data.

In streaming computing, the data continuously flows into the system. The streaming computing system analyzes and calculates the continuous data in real-time and quickly in the memory, and then, it feeds the results back to the user in real-time or stores them for subsequent queries. Traditional streaming computing systems are mostly designed based on event mechanisms, and the amount of data that can be processed is limited. However, new streaming computing technologies, such as S4, Storm, and Spark, are mainly oriented to the use of streaming processing. The NameNode enables the clients to quickly access the required blocks for regular operations, adopts block placement strategies and replication mechanisms to ensure data availability and durability, and allocates new block locations while maintaining the load balance of the cluster. The main task of the DataNode is to store data. When a new data request is stored in HDFS, it will be split into blocks with a fixed preconfigured size, stored in the DataNode, replicated a fixed number of preconfigured times, and stored in different nodes. The DataNodes and NameNode generally communicate by a heartbeat message mechanism every few seconds so that the NameNode can know which node is unavailable
Figure 4: Distribution of prediction accuracy of public opinion big data.

Figure 5: Distribution of news and public opinion data transmission query speed.

and other useful information about the node. The client directly communicates with the DataNode when accessing data. When the client forwards the request to HDFS, the NameNode, firstly, sends back the location of the block required by the client after verifying the relevant license, and then, the client directly commands the DataNode to execute the required block.

4. Based on News and Public Opinion Multioutput IoT Intelligent Modeling and Popular Degree Big Data Analysis and Prediction Model Application

4.1. Smart IoT Big Data Query. This paper uses ATMEGA32-16AU type single-chip microcomputer of ATLEL Company, which is a low-power and high-performance 8 bit AVR microprocessing chip that uses an RISC structure. The single-chip core contains a rich instruction set and up to 32 general-purpose registers with 32K bytes of in-system programmable flash, 2K bytes of SRAM, 1K bytes of EEPROM, and 32 general-purpose I/O interfaces to meet the needs of the system. The I/O interface of ATMEGA32 one-chip computer can visit through the IN and OUT order and carry on data transmission between 32 general registers and I/O interfaces. The address of the register from 0x00 to 0xlf can be directly addressed by CBI and SBI commands, and the value of a certain bit in the address can be detected by SBIS and SBIC.

Figure 5 is the distribution of news and public opinion data transmission query speed. When querying, the embedded device sends a query command to the server. The server queries the database according to the command type and displays the data result on the embedded device via the coordinator, routing node, and terminal node. The entire architecture of the platform is mainly based on MySQL and MongoDB databases with Spring Framework as the core container combined with Zookeeper as the registration center and Apache Shiro as the authority authorization layer. My Batis is used as the persistence of the data access layer, and Redis is used as the cache database to improve the database access speed. In the data analysis layer, the Flume
component can obtain a large amount of heterogeneous data in the HDFS storage system and supply it to the Hadoop offline batch processing system for analysis and processing. The processing results are written into the corresponding database. The Kafka component obtains the sensor network data stream and provides it to the Storm real-time data processing system for data analysis. The Storm system will process the analyzed data and write it into the corresponding database using the bolt component. Finally, there is the application layer. This layer queries and reads the data in the database according to the requirements of different applications or reads the processing and analysis results of the storm in real time.

4.2. Multioutput Platform Simulation of News and Public Opinion. When researching the news and public opinion information platform based on big data, the paper chooses the data storage mode combining Mysql and intelligent Internet of Things. Mysql is mainly used to store traditional business data, such as user information table, permission table, payment information table, agricultural material shop table, order information table, customer service information table, agricultural material evaluation information table, etc. However, the platform collects a large amount of user behavior data and a variety of types. Relational databases, such as Mysql can no longer meet the requirements. For alarm data and cloth length data with high real-time requirements, it is necessary to increase the frequency of data collection. The intelligent Internet of Things is stored in the BSON structure. Mass data storage has obvious advantages, and hence, the authors choose to use the intelligent Internet of Things to store the user behavior data. At the same time, for the business data on Mysql, a data backup is made in the intelligent Internet of Things. Among them, the data acquisition module uses various types of high-precision sensors and converts the collected analog signals into digital signals that can be identified and processed by the chip. In terms of communication designed in the thesis, the ZigBee communication technology is used for short-distance wireless transmission, and the GPRS and GSM

communication networks are used for long-distance communication. The processing control module paper uses a single-chip microcomputer for processing information, a relay for controlling operations, a memory chip, etc. An integrated circuit board is made. Figure 6 is the distribution of multiple output signals of news and public opinion.

As the big data system mostly uses NoSQL database technology, a comparative study of this type of database technology is carried out so that a suitable database system can be selected according to the needs. There are many classification methods for NoSQL data inventory, and various classification methods may also overlap. If the database is compared according to the four types of data models, namely the key-value model, column model, document model, and graphical model, and the specific correlations of the four types of data models are shown in Figure 6. Therefore, it can be concluded that the increase in the amount of calculation data does not weaken Storm's computing power, which indicates that the data are effectively cached under the action of the Kafka component and ensures the smooth and efficient operation of the storm system. Figure 7 is the distribution of news and public opinion calculation data.

When a device that has joined the network receives this sentence and the RejoinNetwork parameter is set to 0x00, NLME will send an NLMEJoIN. The confirm statement and the parameter value is INvALI. When a device that is not currently joining any network receives this sentence and the RejoinNetwork parameter is set to 0xol, the device will try to join the network specified by ExtendPANId, and then, NL dirty will issue MLME-AsSOCIATE. CoorAddress parameter setting is an address determined according to the situation of the router. This statement defines the initialization of the upper-layer device, allowing the upper-layer device to start a new ZigBee network and use itself as the coordinator. The Beaconorder parameter in the code represents the command for the network beacon formed by the upper layer. Super deorder means the command for the network superframe formed by the upper layer. BatteryLifeExtension means that if the value of this parameter is TRUE, NL will request coordination.Otherwise, NL will request that the coordinator does not support the battery life extension mode. The dynamic data sources of the warp knitting machine are diverse, including the warp let-off PLC of the warp knitting machine, electric meters, and various sensors. If a semifunctional node receives this sentence, NLME will send out an NLME-NETw0RK-FORMAT10 N whose parameter status is set to REQUEST confirm statement. The network cannot be established at this time. If a coordination node receives this sentence command, the device will be initialized as a coordination.

4.3. Example Application and Analysis.
Considering the above factors, this paper chooses the 10T-NODE2530 module. The sensor network node provided by this module is very complete. It supports the Zidie 2007 Pro wireless communication protocol very comprehensively. The node uses the CC2530 chip based on TI SoC. The chip's FLASH

capacity is 256I (B, the module uses a standard interface for expansion, which can be expanded according to different application requirements because HBase runs on Hadoop, and hence, one needs to build a Hadoop cluster first. The cluster consists of four machines. It consists of four nodes. Among them, Node1 is the NameNode node, and the other nodes are the DataNode nodes. The wireless module is connected with the server using the RS232 level interface, and the serial port converter is connected to the upper computer. The serial port converter adopts the six-in-one multifunction of Technology Co., Ltd. The serial port module CP2102, USB, TTL, RS232, and RS485 four levels can be switched using the switch to realize the six serial conversion functions of USB to TTL, USB to 232, USB to 485, TTL to 232, TTL to 485, and 232 to 485. Figure 8 shows the conversion efficiency distribution of big data wireless modules.

GPRS specifies four forms of channel coding, namely CS-1, CS-2, CS-3, and CS-4, and their corresponding data rates are 9.05 kbps, 13.4 kbps, 15.6 kbps, and 21.4 kbps. The transmission rate is proportional to the wireless environment. It can be seen that the Cs-4 channel coding method has the highest requirements for C/I. At present, GPRS has been developed to support the multicoding mode and multislot technology fusion transmission, and its maximum speed can reach 171 kbps. The system software structure consists of a data source, query engine, and application server. The specific structure of the data query framework is shown in the text, where each component can be multiple in the system. Using MySQL and smart big data as the connection data source, MySQL is mainly used as a real-time query database. Smart big data can be used as a data warehouse for storing historical data. In the cluster, the query plan is executed by Presto. Firstly, the data is converted from the serial port data into IP data, and then, it is sent out through the GPRS transmission system. The processing control module sends data to the GPRS module through the Rs232 serial port. The packet data will be encapsulated by an SGSN, and the data will communicate with the gateway support node GGSN via the GPRS backbone network after being encapsulated. Figure 9 is the distribution of news and public opinion serial port data acceptance rate.

In this experiment, the GPRS long-distance wireless transmission module is selected. The module uses the design scheme of the built-in protocol stack of the module. There is no chip outside the module, and hence, the module has higher stability. It supports up to 4 network connections and can connect to the serial port. The received data is sent to 4 servers at the same time. The module is set with a keep-alive mechanism to ensure that the network connection will not be disconnected when there is no heartbeat packet. It supports remote configuration parameters that can be configured by sending AT commands via SMS. The commonly used method of measuring the distance between the two nodes is based on the difference in the arrival time. This method uses the sending node to send two signals with different propagation speeds at the same time. Firstly, the receiving node calculates the difference between the arrival times of the two signals. Secondly, it combines their
FIGURE 6: Multioutput signal distribution of news and public opinion.

FIGURE 8: Conversion efficiency distribution of big data wireless modules.
Figure 9: Distribution of news and public opinion serial port data acceptance rate.

propagation speeds to calculate the distance between the two nodes. When querying in the same data table that stores the data records, the system time-consuming will increase with the increase of the query data. When the number of records in the data storage is different but the number of records in the query is the same, the system response time will increase as the total number of storage tables increases.

5. Conclusion

The article analyzes the specific sources of news and public opinion big data, the specific collection methods of data sources, and the methods of various database storage technologies, combined with wireless sensor network technology, open-source big data processing technology, and distributed data storage technology, and it proposes to solve big data. The article mainly works from two aspects of acquisition and storage. In terms of data acquisition, firstly, the application research on the sensor data acquisition network is carried out. Then, the sensor data acquisition system is designed and implemented. Finally, the system is used in news data acquisition and processing. The application was experimented with. In terms of data storage, the article mainly compares the database technologies under big data applications, designs the structure of the HBase data storage system when it is applied to news and public opinion sensor data storage, and conducts an experimental test on its storage performance. The system analyzed the actual needs of the project and the characteristics of big data of news and public opinion Internet of things, combined with the existing big data processing technology, and designed a system that can be used for quick query and analysis of big data of news and public opinion Internet of things. The system is implemented and tested on the Presto framework to achieve the effect of supporting the centralized storage

and rapid query of massive news and public opinion detection data, as well as fit analysis and visual display based on historical data.

The regional fire protection plan is an important part of the city's overall plan, which represents the deepening of the regional fire protection plan and the specific content of the city's economic regional fire protection plan. Fire protection is an important part of national economic and social development, and it is also one of the indicators to measure the level of modern culture. Effective and practical fire protection planning can effectively prevent and reduce fire risks and protect the lives and property of the people, which is very important for social development. In order to optimize the regional fire model, this study uses a very objective fuzzy theory to analyze and discuss the research objects. In view of the large amount of fuzzy information in fuzzy optimization, fuzzy criterion recognition, and fuzzy grouping, based on the generalized fuzzy distance and fuzzy number, this paper proposes a multiobjective fuzzy theory-based comprehensive evaluation and optimization model of fire planning for major hazard sources. The results show that hotel fire risks tend to be higher, which is the focus of people's attention. Among the fire hazards, wholesale, retail, and catering industries are the hardest hit areas, accounting for 66.3%, and some other industries are also disaster areas that need to be dealt with.

1. Introduction

1.1. Background and Significance. With the rapid development of modern social economy and technology, and the great change of energy structure, focus has changed from relying mainly on coal to relying more on the production of petrochemical products. Due to the popularity of the petrochemical industry, many related companies have come here. Petrochemical industry is the cornerstone of national economic development, related to social production and people's life, and plays an important role in promoting social and economic development and improving people's living standards. However, the petrochemical industry is also a very dangerous industry. The accumulation of dangerous and harmful substances has the characteristics of flammability, explosion, high temperature, high pressure, toxic, and harmful. Petrochemical enterprises must pay special attention to fire safety management

in production and operation. If a fire occurs in a certain area, other areas will be affected, resulting in an increase of accident impact and the expansion of the disaster area, which will lead to serious economic loss, social loss, and social consequences. So, it is particularly important to carry out fire planning in high-risk areas (those containing flammable, explosive, high temperature, high pressure, toxic, and harmful items).

1.2. Related Work. Fire station layout planning is an important part of fire protection system. At present, there are many unreasonable and subjective factors in the latheyt planning of domestic fire stations. Wenjuan used the optimization theory design to establish a reasonable framework for the optimization model of the fire station. He transformed the multiobjective fuzzy theory into a unified single-objective model and determined the regional priority and danger level of each part of the

fire according to the fire risk assessment method and transformed it into a genetic algorithm to solve the model [1].

There are always some problems in the mountain fire station. H. Ren takes the planning of the mountain fire station as the research object, mainly aiming to address the shortcomings of the mountain fire planning and the new problems brought about by the rapid development of the city, and identifies and evaluates the fire risk of the buildings in the mountain city. On the basis of fire risk assessment, GIS technology is introduced to solve the problems of location selection of new fire station and latheyt of old fire station. In an area proximal to high fire incidence area, 4 fire stations shall be added. At the same time, the new fire stations are also required to be close to the urban main road as much as possible. The comprehensive application of various methods provides scientific basis and suggestions for the latheyt optimization of municipal fire stations [2].

In the traditional aviation forest protection, the work of cruise and fire location using topographic map and GPS is heavy and difficult, and the time of forest and fire investigation is limited. Jiang analyzed the application of Google Maps in aerial forest protection work. This method is conducive to improving the attention of flight observers in positioning navigation and forest fire investigation and improving the efficiency of aerial forest protection. This paper introduces the functions of Google Earth software in searching destination; acquiring 3D terrain; acquiring landmark; adding annotation; and measuring length, perimeter, and area, and discusses the simulation application of Google Earth, including route planning, firepower positioning, surrounding terrain prediction, etc., according to route navigation, and drawing fire behavior map and building forest fire information database [3].

1.3. Innovation. The purpose of this study was to make a reasonable and effective plan for the regional fire control of major hazard sources, so as to reduce personal injury and economic loss caused by fire accidents. Using the theory of fuzzy set to evaluate the fire risk can provide reasonable early warning for fire protection in major hazard areas. The results of the study of a hotel fire building show that the fire risk of the hotel belongs to a higher risk, accounting for 17% of all fire accidents.

2. Related Concepts

2.1. Multiobjective Fuzzy Theory of the Fire Protection System. In the design of the fire protection system, the models used for fire station latheyt belong to the category of maximum coverage model. The most typical is the problem of MCLP [4]. This model limits the optimal address of gas station to the network node and gives the optimal algorithm in general. The purpose of this model is to find the largest cell group that a server can serve in a normal time or space when the number of servers is limited [5, 6]. However, this model does not consider server congestion and assumes that there are always inactive servers when providing services. In addition, the parameters and structure of these constraint models can be determined [7].

For the fire protection design model, some parameters are not clear and are uncertain, and each part of the whole system has different rules, which means that the objective design problem should be used for analysis and modeling [8]. For example, the time or distance required from a fire station to the scene of a fire is a very important factor in limiting or targeting the function of the MCLP model. However, the traditional MCLP model only deals with time simply, and does not fully consider the difference of time. The degree of fire danger will greatly affect the scientific nature of the site selection decision [9, 10]. This is because different levels of fire need different times to put out the fire. At the same time, the demand points of different risk levels have different fire rescue levels. In the model [11], it is very important to reflect the individual differences between demand points for the optimal design of fire stations. Therefore, conducting a global study requires multiobjective planning [12]. Global research means a thorough study of the fire scene to detect and prevent fires in the first place.

The basic definition of Fuzzy Theory:

If X represents the target set of x, fuzzy set A represents an ordered queue set.

$$A = \left\{ (x, \mu_A \sim (x)) | x \in X \right\}. \tag{1}$$

Here, x represents the element in set X, and $\mu_A \sim (X)$ represents the membership function or membership degree of element X in fuzzy set A, the membership space of mapping x is [0, l].

If

$$\mu_A \sim (\lambda x_1 + (1 - \lambda) x_2) \geq \min \{ \mu_A \sim (x_1), \mu_A \sim (x_2) \}, x_1, x_2 \in X, \lambda \in [0, 1], \tag{2}$$

then fuzzy set A is convex. If $\sup_x \mu_A(x) \approx 1$, then fuzzy set A is called a normal set. The membership function $\mu_c \sim (x)$ of intersection C of fuzzy sets A and B are as follows:

$$\mu_C \sim (x) = \min\{\mu_A \sim (x), \mu_B \sim (x)\}, x \in X,$$
$$\mu_C \sim (x) = \mu_A \sim (x)\mu_B \sim (x), x \in X. \tag{3}$$

So far, the introduction to fuzzy sets is completed.

2.2. Regional Risk Classification.

According to the scope of fire risk and basic characterization, regional risk is divided into regional fixed risk and regional actual risk [13]. Regional fixed risk refers to the impact caused by regional risk and is one of the main sources of accident risk. The actual regional risk is based on the internal risk of the region, taking into account the extension or inhibition of regional factors that affect the risk of accident consequences. The combination of regional risk factors and internal risk indicators is an indicator system to evaluate regional reality [14].

2.2.1. Regional Risk Assessment.

Regional fixed risks are mainly caused by regional accidents, and inherent risks can be quantified by specific methods [15]. At present, the commonly used quantitative analysis methods include fire and explosion index method, six stage risk assessment method, Monde assessment method, inflammable material assessment method, and major hazard source assessment method [16].

2.2.2. Factors Affecting Regional Risk.

Regional risk factors can be divided into risk diffusion factors and risk mitigation factors. Risk diffusion factors refer to the factors that enhance the impact of accident consequences, especially economic vulnerability and social sensitivity [17]. Economic vulnerability refers to the impact on buildings, mechanical devices, residential areas, etc. In post-accident areas, this is usually measured by economic loss indicators [18]. Social sensitivity is often related to psychology, which refers to the psychological damage caused by panic caused by accidents.

Risk mitigation factors can mitigate accident consequences and enterprise emergency management level. The government is an important factor to reduce accident risk [19]. If there is no accident, the assessment of emergency management level is often reflected in the construction of an emergency team and the formulation of an emergency plan. In the case of an accident, the content of emergency management level measurement is mainly the protection of emergency resources available at the scene of the accident and the protection of resources, which is finally reflected in the emergency rescue and evacuation capacity of the area [20].

2.3. Fire Risk Assessment Method.

After long-term development and improvement, the fire risk assessment method has developed to more than 40 kinds, and has been widely used globally. Various quantitative expression forms of evaluation results can be divided into three evaluation methods: quality evaluation method, semiquantitative evaluation method, and quantitative evaluation method [21].

Quality evaluation is the basis for improving product quality. The establishment of a complete quality evaluation system can predict the development trend of the macro quality level; improve the market competitiveness of enterprises; prevent potential dangers and threats to human health, safety, and living environment; and enable people to exchange products, services, and resources with each other. Choose adequately and reasonably in a market economy. The quality assessment method is based on industry standards, regulations, rules, etc., allowing assessment experts with rich theoretical and practical knowledge to draw conclusions based on their observation and experience. The conclusion should consider the following conditions: if there are substances that may cause danger in the area, whether the management within the scope meets the requirements, and the possibility and scope of risk occurrence. The whole evaluation is mainly based on expert reasoning and intuitive judgment, and the mathematical model on which the theory is based is generally simple. This evaluation method has the advantages of simple operation and intuitionistic evaluation conclusion, and has been widely used. However, due to the lack of standards and subjectivity of evaluators in the process of operation, the conclusions drawn are quite different [22, 23].

The semiquantitative evaluation method should identify and distinguish the potential risk factors in the evaluation target according to the risk degree. The basis is: the corresponding classification standard, which is used to classify the determined factors, determines the relevant evaluation indexes, and establishes a link. The link can be a comprehensive mathematical model that defines the relative values of patience and overall safety parameters and quickly assesses the risk level of the object. Semiquantitative method makes up for the shortcomings of randomness and difference of quality method, but it is still simple and intuitive. Fire and explosion indicator method, Monde method, Japan's six stage assessment method, and China's risk classification method are the most commonly used semiquantitative assessment methods.

The quantitative evaluation method includes problem identification, risk identification, cause analysis and impact assessment, risk assessment, and final assessment conclusion. The purpose of the quantitative method is to get more accurate evaluation results. The quantitative evaluation method should be based on the quantification of the evaluation index system. All risk assessment indicators should be consolidated and quantified in accordance with specific criteria. Use a specific mathematical model. Get the risk value of the evaluation target. When analyzing a relatively complex system, the quantitative evaluation method can more clearly reflect the hierarchical relationship between different indicators. The conclusion drawn by this method is very intuitive and clear. We can easily compare the evaluation results of different subjects, or we can compare the evaluation results with the minimum social security standards, which is acceptable to people.

2.4. Develop Effective Plans for Fire Protection in Major Hazardous Areas

2.4.1. The Establishment of Optimization Model of the Fire Water Supply System. In order to ensure that the fire-fighting system provides effective fire-fighting measures and reduces the losses caused by the fire, the design of the fire water supply system is a vital link in the fire protection planning. Whether the regional fire-fighting water supply system is designed to be reliable, reasonable, and economical will affect the scientific nature of the entire regional fire-fighting plan [24]. It can be seen from the previous norms and standards that the existing fire-fighting water consumption norms are mainly based on the population size of the city to determine the frequency of fires, thereby determining the fire-fighting water consumption of the city. However, for the design of regional fire protection planning, this kind of fire water consumption index based solely on population size is extremely unreasonable. For example, for an industrial area that contains some major hazards like liquefied petroleum gas tanks, the population may be relatively small in the area, but once a fire occurs in this area, the amount of fire extinguishing water required will be greater than that of a pure living area with the same population [25, 26]. Therefore, if the population of an area is solely used as the basis for determining the water volume of the fire water supply system, the design standard will be far lower than the water required for the actual fire, which will not effectively achieve the purpose of disaster reduction. Therefore, in order to comprehensively analyze the influencing factors of regional fire water consumption and use the interrelationship of various factors to plan the fire water consumption of the entire regional water supply system, it is necessary to adopt suitable optimization methods to establish a reasonable mathematical model of the fire water supply system. Specific influencing factors include water consumption, distance from the fire station, water storage, floor height, and flow of people. Its purpose is to realize the scientific rationality of the planning of the fire water supply system to meet the needs of actual production and life to achieve the purpose of disaster reduction and elimination.

2.4.2. The Latheyt of Each Functional Block Is Reasonable. It should be noted that the fire hazard in the LPG operation area is high and there are many accidents. Once a fire occurs, it is extremely destructive. Although the fire accident in the LPG operation area may not directly affect the national strategic oil reserve base, it directly affects the petrochemical operation area, has an indirect impact on the national strategic oil reserve base, and increases the overall fire risk. From the perspective of the overall situation and long-term interests, it is possible to consider limiting the scale of LPG operation areas.

2.4.3. Fire Station Latheyt. One of the main responsibilities of the fire department is to fight fire and rescue. This task usually comes from the arranged fire station. The fire station is the basic organization unit of the fire department for fire-fighting and rescue. The purpose of planning a fire station is to enable the fire station to provide effective fire-fighting and rescue services. Based on the analysis of the current situation of the fire protection environment, the number, location, area of responsibility, floor space, building area, vehicles, equipment, and personnel to be planned for the construction of fire stations are clearly defined, and the time to achieve these goals are determined. There are specific plans for human and material resources [27]. The planning of the fire station must adapt to the needs of multifunctional and large-area operations. For areas with special fire protection requirements, a fire station capable of handling special fires and disasters should be planned and established. If possible, the three-dimensional latheyt of water, land, and air should be considered for comprehensive development [28].

3. Experimental Design

3.1. Research Object. As a hotel has a large flow of people, a lot of flammable materials, and high floors, improper management can easily lead to huge fires. Once a fire occurs, it is a huge accident. So in this study, a hotel on fire is selected as the object, and the fuzzy set theory is used to evaluate the fire risk. The evaluation index system includes influencing factors, key variables, and hierarchy system. The dynamic and fuzzy characteristics of the system are reflected in the evaluation of fire risk, fire resistance, and fire vulnerability. In addition, this method is also a kind of evaluation method, which is widely used, practical, and verified by a large number of practices.

3.2. Research Steps. The fuzzy evaluation method has been widely used in fuzzy system evaluation for its good practicality. It uses an ambiguous theory and examines the use of multiple indicators to assess participation. Three key groups participated in the whole process, including a set of systematic factors, a set of systematic reviews, and a set of evaluation factors. Among them, the evaluation factors have the greatest influence and ultimately affect the evaluation results of credibility. According to the fire risk assessment index system, the system factor set $U = \{U_1, U_2, U_3\}$, wherein U1 represents the fire risk degree, U2 represents the fire vulnerability degree, and U3 represents the fire resistance degree. Determine the weight of system coefficient; each factor includes a set of evaluation indexes, and the total weight A of this factor is determined according to the weight of evaluation index a1, wherein $A = \{a_1, a_2, a_3\}$, $\sum_{i=1}^{n} a_1 = 1$.

According to the fire protection level, it is divided into five evaluation levels. The evaluation set $V = \{V_1, V_2, V_3, V_4, V_5\}$, V1 is very safe, V2 is relatively safe, V3 is general safety, V4 is relatively dangerous, and V5 is very dangerous. The specific evaluation process is as follows:

Through 10 experts to grade the second-level indicators under the first-level indicators, grade and summarize the second-level indicators under the fire risk U1 of a hotel. The fuzzy subsets of fire risk can be obtained, and then U2 fire

vulnerability and U3 are the fuzzy subsets A2 and A3 of fire resistance:

(1) These experts need to score the first-level indicators of fire risk U1, fire vulnerability U2, and fire resistance U3, and synthesize the results,

The fuzzy subset $A = \{A_1, A_2, A_3\}$ of fire risk factors is calculated by using the formula.

(2) Factor evaluation. 30 experts were invited to grade the indicators in the indicator system according to the specific conditions of the experimental subjects and the criteria of indicator quantification. For example, for an indicator, 13 experts think it is very safe, 11 experts think it is safe, and 6 experts think it is safe. Then, the evaluation set of this factor is defined as {0, 47, 0, 42, 0, 11, 0, 0}. The sum of all evaluation sets is 1. This rule also applies to other indicators, and then summarizes the evaluation value of each individual factor.

$R_1 = A_1 * r_1, R_2 = A_2 * r_2, R_3 = A_3 * r_3$, get the fuzzy matrix $R = \{R_1, R_2, R_3\}$, through the formula $B = A * R$, according to the scoring of experts, finally determine the fire risk level.

4. Regional Fire Protection Planning of Major Hazard Sources

4.1. Fire Risk Assessment. The fire risk assessment process is closely related to the fire development process. In general, the specific development process can be divided into the following processes: fire, growth, full development, recession, and finally extinction. In the above experiment, a hotel is taken as the object, and the fuzzy set theory is used for fire risk assessment and analysis. At the same time, the level of fire risk assessment in recent years can be found by querying the National Statistical Yearbook. The results are shown in Table 1.

According to the data provided in Table 1, we can clearly see that relative safety accounts for half of the fire risk rating of the experts. In fire vulnerability, most experts choose the fire is very safe. In the fire resistance industry, most experts give the scores of very safe and relatively safe. It can be seen that the fire risk is the most likely factor to increase the fire risk, followed by fire vulnerability and fire resistance.

4.2. Response Time of Fire Accidents. Using many objective and uncertain methods to solve the problem of optimizing the latheyt of fire stations has a simple feature: adaptability. Combined with the analysis and research on the level of fire risk assessment and the reference statistics of some countries, the fuzzy characteristics can be better determined. As shown in Table 2, it is the recommended fire response reference value of the fire protection system.

The rescue time of fire-fighting is calculated in seconds. The earlier the rescue team arrives at the scene of the accident, the faster the control of the accident will be. Table 2 also shows that different risk levels have different response times. The average operating speed can be used to turn the requirement of operating time into a distance limit. Risk levels should be used to distinguish multiple limits on the distance from the fire station to the scene of the accident. The calculation of this risk level should be based on the statistics of different regions. Fire risk assessment and analysis can be used to obtain data required for different risk levels. The number of fire vehicles and firefighters shall be determined according to the latest regional statistical accident report and fire station budget.

4.3. Data Analysis of Major Hazard Accidents. Relevant data show that in 2007, five of the top ten fires outside China occurred due to major flammable and explosive hazards in urban public places and facilities. Although the causes and consequences of accidents are quite different, major accidents involving hazardous chemical sources have some common characteristics: we ought to prevent accidents, which not only leave a large number of casualties inside and outside the factory but also cause huge property losses, and eventually damage the environment with immediate effect. At present, China has not established a systematic and effective major risk supervision system; the latheyt, category, and dynamic status of major hazard sources are unclear; and the ability of supervision, control, early warning system, and emergency rescue to prevent emergencies has not been established, so major accidents happen repeatedly.

As shown in Figure 1, major safety accidents occur frequently. The main reason is that the location of major hazard sources in most cities is not planned, the classification is not clear, the effective supervision system of major risk sources cannot be established, the emergency rescue plan cannot be determined, and the demand and ability of emergency dispersion cannot be determined. In particular, the goal of macro-control management is not clear. Therefore, how to avoid the occurrence of major accidents and how to implement regular protective measures are the key issues in realizing emergency rescue. It is necessary to strengthen the awareness of fire control and implement fire control measures, and ensure timely and effective treatment for major accident victims.

4.4. Characteristics of Major Hazard Industries. The research field of major hazard sources is defined within the scope of cities.

Typical units of major risk sources are production sites (such as chemical companies and heating facilities companies) and storage sites (such as oil, explosives, and

TABLE 1: Fire risk assessment.

Fire risk	Very safe	Relatively safe	General safety	More dangerous	Very dangerous
Fire hazard	7	15	8	0	0
Fire vulnerability	12	8	7	3	0
Fire resistance	16	12	2	0	0

TABLE 2: Fire accident response time.

Risk level	Time limit to reach the accident location	Distance from the accident site (km)	Response time to fire accidents (s)
I	3–6	3–6	35.5
II	6–10	6–10	33.2
III	11–13	11–13	29.6
IV	14–20	14–20	15.4

toxic substances storage), which are distributed in areas in different urban buildings (such as gas filling stations and LPG station). Because the direct correspondence between important risk sources and land types is not easy to obtain, the main risk sources of land use types can be obtained only by defining the characteristics of important risk sources in the industry and the relationship between major risk industries and land use types (Figure 2).

4.5. Fire Water Consumption. In order to effectively implement fire rescue, it is necessary to evaluate the initial water consumption of each fire hazard source. Only by using the strong theoretical basis determined by the estimation of fire water consumption, can we truly plan a reasonable fire water supply system.

As shown in Figure 3, the calculation results of water consumption will be different for different estimation methods. Among them, the water consumption calculated by the New Zealand method is the most effective than that calculated by the other two methods, namely, the Iowa method and ISO method.

4.6. Regional Fire Protection Planning. As a typical regional disaster causing factor, the main risk sources have different effects on regional risk. The distribution characteristics of the main risk sources are not equal to the spatial distribution, and in the absence of geographic information, they do not even belong to the category of spatial distribution. This study considers that major hazard sources have important characteristics in industrial distribution and urban land-use distribution. Regional risks are to be analyzed from this perspective. Especially when analyzing the main risk distribution characteristics of urban land, in addition to considering its own land, the distribution characteristics of different types of land affected by major risks should be fully analyzed according to different urban models. All urban land use information can be considered as major disaster source.

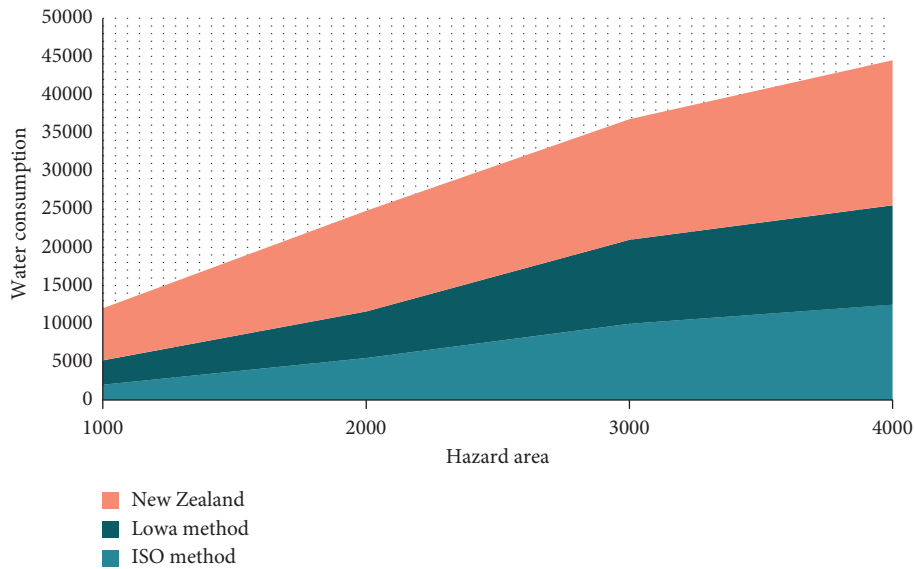
As shown in Figure 4, in the absence of regional details, the main distribution of major risk sources should be adapted to the main land-use types and their characteristics. Combined with the characteristics of urban latheyt, especially the characteristics of land latheyt, preliminarily
FIGURE 2: Characteristics of major hazard industries.


FIGURE 3: Fire water consumption comparison.

analyze the impact of major risks on different regions, divide the site into different types of land, and analyze the land types that may be affected by major risks. After the sites on various types of land are adjusted, the vulnerability analysis of these people's activity sites can be used as a perspective to analyze the risk distribution in the region. Setting up fire-fighting facilities in places with high risk can greatly reduce the destructive power of fire.

5. Conclusions

Multiobjective fuzzy decision-making is still a booming research field, and there are many theoretical and practical problems to be solved. The main work of this study focuses on the multiobjective fuzzy theory and its related fields, and some research results have been achieved. At the same time, there are many projects that need to be further studied and improved. The qualitative, objective, and weight of fuzzy set theory is one of the main research contents, which is based on the consistency of a series of projects and objectives. In most cases, this makes sense. However, there may be two other situations in the decision-making process. First, the priority given by the decision-maker does not conform to the principle of consistency; second, the decision-maker cannot give sufficient ranking. In other words, the sequencing of some projects or goals is incomplete or unknown. The fuzzy optimization model is applied to group decision-making, which further widens the application field of fuzzy sets, but at the same time, the aggregation of group fuzzy preferences also faces the problem of ordering consistency, that is, in addition to the inconsistency of individual preferences, there is also the inconsistency of group preferences. It is not only an interesting and realistic problem but also a common problem in group decision-making.

This paper is based on the multiobjective fuzzy theory, a comprehensive evaluation and optimization model for the fire protection planning of major dangerous source areas. The establishment of this model firstly analyzes the various influencing parameters of the fire station layout. The model not only considers conventional response time constraints but also economic constraints such as fire protection investment, disaster mitigation losses, and even all possible future situations. The waiting time of the fire station service and the major hazards that need to be considered make the layout optimization strategy of the regional fire station more suitable for the development needs of the society in the future. Based on national standards and successful cases abroad, this paper adopts multiobjective fuzzy planning theory and establishes a regional fire water supply system planning model based on major hazards. In the model, the

area is first divided into several functional blocks. Calculate and analyze the fire-fighting water consumption of each functional block, and then consider the special requirements of major hazard sources of fire-fighting water consumption and the premise that the water supply system of each functional area can cooperate and assist, and then determine the fire-fighting water from the overall consideration of the area, in order to plan out the fire water supply system of the area.

According to the data of fire risk, fire resistance, and fire sensitivity, this study determines the state of disaster, analyzes the characteristics of major hazard sources, carries out risk assessment and emergency device investigation, analyzes the impact of chemical hazard sources on the site, and evaluates and optimizes the spatial latheyt of emergency sites. Detailed inspection of traffic conditions, land use, land characteristics, fire-prone areas, and other factors shall determine the candidate locations for fire planning latheyt. From the two levels of the government and the individual, the fairness goal, the economic cost goal, and the distance cost goal of the fire planning latheyt are set up, and the corresponding decision-making model is constructed.

In recent years, with the development of deep neural network becoming more and more mature, especially after the proposal of generative confrontation mechanism, academia has made many achievements in the research of image, video and text generation. Therefore, scholars began to use similar attempts in the research of music generation. Therefore, based on the existing theoretical technology and research work, this paper studies music production, and then proposes an intelligent music production technology based on generation confrontation mechanism to enrich the research in the field of computer music generation. This paper takes the music generation method based on generation countermeasure mechanism as the research topic, and mainly studies the following: after studying the existing music generation model based on generation countermeasure network, a time structure model for maintaining music coherence is proposed. In music generation, avoid manual input and ensure the interdependence between tracks. At the same time, this paper studies and implements the generation method of discrete music events based on multi track, including multi track correlation model and discrete processing. The lakh MIDI data set is studied. On this basis, the lakh MIDI is pre-processed to obtain the LMD piano roll data set, which is used in the music generation experiment of MCT-GAN. When studying the multi track music generation based on generation countermeasure network, this paper studies and analyzes three models, and puts forward the multi track music generation method based on CT-GAN, which mainly improves the existing music generation model based on GAN. Finally, the generation results of MCT-GAN are compared with those of Muse-GAN, so as to reflect the improvement effect of MCT-GAN. Select 20 auditees to listen to the generated music and real music and distinguish them. Finally, analyze them according to the evaluation results. After evaluation, it is concluded that the research effect of multi track music generation based on CT-GAN is improved.

1. Introduction

As an important way of expression in the field of art, music embodies a series of human unique thinking modes and is a unified combination of regularity and creativity [1]. On the one hand, the composition of music is naturally based on certain music theory rules, such as melody, rhythm, mode, chord, harmony, polyphony, musical form [2]. Music that cannot meet the constraints of music theory rules is often poor in auditory sweetness and cannot be accepted by the public [3]. On the other hand, music that simply meets the constraints of music theory is not necessarily good music. Music itself also acts as an important task of emotional

expression carrier [4]. This requires the Creator not to stack the rules in a conventional way, but to incorporate innovation into the music, so that the generated melody will not be stereotyped and the mode is fixed. At the same time, the automatic generation of music by computer algorithm has always been a field of concern. Music creation with the help of computer algorithm can reduce the production threshold and save manpower and time cost [5]. To a certain extent, avoid the copyright problem, and quickly make a large number of music according to the scene needs, such as a large number of customized melodies that render the plot emotion in film and television dramas [6]. Due to the regularity and creativity of music and other artistic creation

fields, the research on intelligent music creation can well measure and test the performance of artificial intelligence. When describing the experimental results of their own model algorithms, many related works in the field of music generation use the test method of organizing volunteers for auditory recognition [7]. The investigation and statistics are carried out from the aspects of authenticity, ear pleasing, creativity and interest. For example, the literature randomly looks for 255 testers to test the quality of music samples generated by their Muse-GAN model [8]. Similarly, some other algorithmic composition work also adopts this human judgment method. Generally speaking, the production process of intelligent music needs to minimize the workload of human intervention [9]. This production method can generate music automatically or semi automatically. The output results should not only meet the basic prior knowledge of music theory, but also have some algorithm creativity. The literature discusses that this process is to independently produce continuous audio signals or discrete symbol sequences from the computational model, and these signals and sequences must meet the music theory architecture [10]. As early as the 1950s, artificial intelligence technology was just in its infancy. Although limited by data and hardware performance, people also began to explore the field of intelligent composition and achieved some results [11]. In the early stage, intelligent music was mainly generated in two ways. First, it was created based on statistical analysis and combined with Markov chain models. For example, the literature was the first to create String Quartet suite with large-scale computer, which became the first music work completely generated by computer in history [12]. It used Markov chain model to generate random notes with limited control, combined with the rules of harmony and polyphony, these notes are tested, and the tested elements are modified to synthesize the string quartet of traditional music notation. The second is simple pattern matching and machine learning based on music theory rules, such as integrating music theory into machine learning to produce notes [13]. In recent years, deep learning has attracted more and more attention. Researchers have frequently applied deep learning technology in many fields and achieved good results. Therefore, some fields have produced projects that can be put into practical use. Based on this, people's research on neural network is emerging again. With the improvement of computer hardware technology, the deep learning technology based on neural network can not only deal with huge data samples, but also have strong computing power. Because of this, a series of problems such as many model parameters and difficult training have been solved, which are widely used to solve problems in various research fields. For example, deep learning technology greatly improves the accuracy of image classification, even exceeds human classification ability, and has successful applications in the field of natural language processing. At present, the generative countermeasure network based on neural network has been widely used in the fields of image, vision, voice and language. Therefore, this paper proposes to realize the automatic annotation of music based on generative countermeasure network.

With the continuous evolution and updating of AI technology, the formal technology of music creation has been further developed [14]. In recent years, generative countermeasure network has attracted more and more attention in the field of data generation. Relying on its strong fitting ability and simple training derivation process, it has been introduced into many application fields [15]. Generative countermeasure network has been widely used in graphics generation, graphics compression, speech generation and super-resolution restoration. The literature points out that "GAN can also generate text, dialogue generation, machine translation, voice generation, etc. At the same time, GAN is also involved in other fields, such as music generation, password decoding [16]. However, the application effect of GAN in other fields is not significant, so how to improve the application effect of GAN in other fields will be worthy of in-depth research, so as to make the generated countermeasure network shine in artificial intelligence " [17]. The research on speech synthesis and music creation using GAN has also been in the stage of exploration and development, and many achievements have been made. Through the investigation, it is found that the number of literature review on algorithmic composition is relatively large, but the literature review on music generation based on deep learning, especially based on generating confrontation network, is relatively missing.

2. Related Work

As early as the 1990s, the literature first proposed the idea based on confrontation generation. The author trained the predictor to judge the input data mode, and let each data minimize its predictability, forming the simplest confrontation competition learning mode. In 2014, P. Shamsolmoali [18] et al. formally put forward the concept of generating countermeasure network, using the confrontation competition of generator model and discriminator model to realize semi supervised learning, which opened up a new field for the research of data generation. The biggest difference between GANs and the traditional generation model is that in the process of data training, it is both unified and antagonistic. The optimization directions of generators and discriminators are different from each other, forming a competitive relationship, but their optimization calculation depends on each other's output to form a unified system [19]. In the confrontation training mode, the generator no longer directly learns the distribution from the training data set, but indirectly iteratively learns through the optimization direction given by the discriminator to generate fake samples that confuse the false with the true. Compared with the traditional unsupervised learning models such as self coding and autoregression, GANs has the advantages of fast calculation speed, better sample quality, strong expansion flexibility and so on [20]. Generally speaking, the production process of intelligent music needs to minimize the workload of human intervention. This production method can generate music automatically or semi automatically. The output results should not only meet the basic prior knowledge of music theory, but also have some algorithm creativity. The

literature discusses that this process is to independently produce continuous audio signals or discrete symbol sequences from the computational model, and these signals and sequences must meet the music theory architecture.

Subsequently, a large number of theoretical and technical research results of generative countermeasure networks came out one after another, and some of them played a milestone role in promoting the overall research progress of generative countermeasure networks. The verification model of the original GANs is realized by multi-layer perceptron MLP, and the generation quality is poor [1]. The literature proposes DCGANs, and the generator and discriminator are realized by deep convolution network respectively, so as to ensure the engineering implementation of GANs in the field of graphics generation. In order to improve the training stability of GANs and make the output data have a certain controllable directivity, the literature proposes the conditional generation confrontation model CGANs [21]. On this basis, the literature adds a supervised learning classification task to GANs to form ACGANs to improve the generation quality of the model. In order to further explore the training stability of GANs, some targeted training skills are added in the training process of GANs to form improved GANs. The literature improves the loss function of GANs from the mathematical principle, so that GANs can better narrow the distribution of generated data and training set data [22]. This research work has played an important role in the development of GANs technology, and also made a series of application achievements in many task fields, especially in the direction of graphics and images. At present, there are many research works on GANs with wide coverage. This paper investigates and classifies the existing achievements from the key technical level and application level. It should be noted that the same work may contain improvements in multiple directions [23].

There are some problems caused by the loss function in the training process of the original GANs. For example, it is proved by theory that the original loss function will cause the gradient to disappear when the coincidence between the generated data distribution and the training set data distribution is not enough [24]. This problem cannot be improved by simple model structure optimization. Therefore, some work has improved the loss function, so as to improve the generation quality of GANs. Firstly, it is proved that the distance measurement between distributions based on KL distance and JS distance is discontinuous, which leads to the instability of discriminator training. The sample data generated by GANs is constrained by confrontation training and tries to fit the distribution of real data sets [25]. However, there is no guidance of conditional control in the whole training process, and the randomness of generated data is great, which also indirectly leads to the instability of training. The literature integrates conditional control into countermeasure training, uses conditional vectors to control the attributes of generated samples, and indirectly introduces the decoupling input of conditional variables. On the basis of CGANs, the literature uses discriminators for supervised learning, classifies samples, further enhances conditional constraints, and further improves the quality of generated samples [26]. The proposal of generative countermeasure network not only presents a new network model architecture, but also provides a framework of generative countermeasure training idea. After a certain expansion of the framework, it can be combined with other existing model methods to generate samples for specific fields.

3. Generative Confrontation Mechanism and Its Important Derivative Model in the field of Music Generation

3.1. Generation Confrontation Mechanism. The generative countermeasure mechanism consists of two sub networks: generator and discriminator. The task of generator F is to make the model fit the real training data distribution as much as possible, and discriminator B is committed to distinguishing whether the input data comes from real data or false data manufactured by the generator. In the training process, they continuously improve their ability, and finally achieve an ideal state of Nash equilibrium, so that the data generated by the generator is as close to the real data distribution as possible. The basic loss function of GAN is:

$$\min_{B} \max_{F} V(B, F) = \frac{T_{Z-Pz(z)}[\ln(1 - B(F(z)))]}{E_{x-(z)} \int [\prod D(x)] \mathrm{d}x}. \tag{1}$$

In theory, the generator and discriminator can be realized by any differentiable function, which is not limited to multi-layer perceptron or convolutional neural network. GAN and its derived music generation model are shown in Figure 1.

4. Generation of Derivative Models of Countermeasure Networks

4.1. WGAN. Zhang [21] et al. have studied and discussed various problems existing in the original generated countermeasure network. There are two main reasons for these problems in the original generated countermeasure network: 1. Unreasonable distance measurement of equivalent optimization (KL divergence and JS divergence); 2. There is no intersection or overlap between the data distribution generated after the random initialization of the generator and the actual data distribution, which can be ignored. However, it is not suitable to use JS divergence to measure the distance between the disjoint parts. Theoretically, this is also the main reason for the instability of the original generation anti network training. Therefore, Wasserstein GANs was put forward by homeopathy (WGAN). WGAN has made a good improvement on the problem of unstable training of generation countermeasure network model. WGAN uses Wasserstein distance as an alternative to JS divergence to measure the distance between generated data distribution and real data distribution, and solves the two problems of unstable training and unable to provide numerical indicators to measure the training process. Compared with KL divergence and JS divergence, Wasserstein distance can still be used to measure the distance between the generated data distribution and the real data distribution when there is no intersection or the intersection part can be ignored.
FIGURE 1: Generation model of GAN and its derived music.

Before introducing the basic principle of WGAN, we first need to understand the concept of Lipschitz continuity, that is, for a continuous function $f(x)$, if there is a constant $k > 0$, any two elements x and $x0$ in the definition domain meet:

$$\int_{x_0}^{x} g(x) + g(x_0) \leq F\sqrt{(x - x_0)^2 - 4x} + \sqrt{x^2 - 4x}. \quad (2)$$

Wasserstein distance can not only reflect the distance of two nonoverlapping or negligible overlapping distributions, but also provide a meaningful gradient, that is, it is smooth. However, it is impossible to solve the lower bound directly. Therefore, the Wasserstein distance can be changed into the following form according to Kantorovich Rubinstein duality:

$$\min_{B} \max_{F} \prod \left[E \int (x) \right] + \frac{\sum\limits_{x-p} E(\widetilde{X})}{\left| x - \widetilde{X} \right|}. \quad (3)$$

4.2. WGAN-GP. In view of the problems of unstable training and slow convergence in the generated countermeasure network, Wasserstein GANs proposed by Yang [22] et al. has made a good improvement, but sometimes the generated samples are still bad or the convergence fails. Then, scholars such as Shi [23] proposed that the main reason for the failure of bad sample generation or convergence based on WGAN is that the weight clipping method is used to meet the Lipschitz continuity condition in the implementation of WGAN, which will lead to bad training behavior. In this regard, scholars such as Ishaan Gulrajan proposed WGAN-GP (improved training of Wasserstein GANs), that is, the improvement of WGAN network model based on gradient penalty, which uses gradient penalty instead of weight clipping to meet Lipschitz continuity condition. In this case, the extreme distribution of parameter weights cannot give full play to the generalization ability of deep neural network. In addition, weight shearing can easily lead to gradient explosion or gradient dispersion. The reason is that when weight shearing is carried out, if the shear threshold is set too small, the gradient will gradually decrease through each layer of network, and then decay exponentially until the gradient disappears; When the shear threshold is set too large, the gradient will gradually increase after each layer, and then the gradient will explode, as shown in Figure 2.

Therefore, only when the threshold is set at a balanced position can the normal gradient return be guaranteed. However, due to the narrow balance area, the parameter adjustment work becomes very troublesome.

4.3. CT-GAN. Aiming at the problems of difficult training and slow convergence of WGAN, WGAN-GP improves WGAN and uses the gradient penalty method instead of the weight clipping method to meet the Lipschitz continuity condition. WGAN-GP makes network training faster and convergence faster, but WGAN-GP also has defects. According to what is mentioned in the paper, the difference between gradient penalty and weight clipping is that gradient penalty can never be punished to every place through gradient penalty term in a limited number of training times, and the result is that gradient penalty term GP only works on sampling point x. The important parts of the support set cannot be checked at all, especially the observed data points and the basic manifold supporting the real data distribution pr.

In addition, CT-GAN does not only focus on one specific data point at a time, but sets regularization on a pair of data points drawn near the manifold according to the most basic definition of Lipschitz continuity. In particular, CT-GAN perturbs each actual data point x twice, and uses the Lipschitz constant to limit the difference between the response of the discriminator to the set data point.

Figure 3 describes the main idea of CT-GAN. Because the gradient penalty often fails to verify the continuity of the region near the real number x, the discriminant function can freely violate the Lipschitz continuity. Therefore, on the basis of gradient penalty, CT-GAN uses the inspection of two disturbed Lipschitz continuity conditions near any observed actual data point, so as to alleviate the problem of WGAN-GP.

4.4. Generative Model and Discriminant Model. The main structure of the generator model (discriminator model) is shown in Figure 4. It can be seen that its structure is relatively simple. The main reason is the repeated iterations in the training process. Each round of training is equivalent to training dozens of generators and discriminators, and each iterative operation needs to store the neural network parameters of the intermediate process, so only one layer of neural network is used here. Moreover, there is a problem of parameter feedback in the training process of generator and discriminator. The trained discriminator parameters are superimposed into the generator parameters as negative feedback. Too complex network will lead to poor feedback process.

5. Generation Experiment and Analysis of Intelligent Music Generating Confrontation Mechanism

5.1. Data Set and Pre-Processing. In the experiment of music generation in this paper, the MIDI file of lakh MIDI data set (LMD) is selected to generate music containing the following five tracks: bass, drum, guitar, piano and strings.

LMD is used because it provides a rich and real collection of MIDI files and some related metadata. The lakh MIDI dataset is a collection of 176581 unique MIDI files, of which 45129 have been matched and aligned with the entries in the Millennium Song Dataset. The goal of Lakh MIDI dataset is to facilitate large-scale music information retrieval, including symbols (only MIDI files) and audio content-based (using information extracted from MIDI files as annotations for matching audio files). Lakh MIDI data sets have many different versions, some of which are subsets and some of which are obtained after processing. LMD-full is the complete set of Lakh MIDI data sets. Each file is named according to its MD5 checksum. However, since invalid MIDI files are not deleted from this collection, it contains thousands of files that may have been damaged; LMD matched is a subset of LMD-full containing 45129 files, which matches the entries in the Millennium Song Dataset.

However, in this experiment, the music in piano roll format is generated instead of MIDI format, so Lakh MIDI data set will not be directly used as the training data set of this multi track music generation experiment, but a series of pre-processing steps will be performed on Lakh MIDI data set before training, Thus, the LMD piano roll data set needed by the experiment is obtained, and then it is put into the network for training to generate multi track music. In the next two sections, we will first introduce the data representation of this experiment-Piano Roll format, and then introduce the pre-processing process of data set.

5.2. Data Pre-Processing. According to experience, there are some defects in using LMD directly for music generation, mainly because of the mapping between track and MIDI channel. Because these MIDI files are usually user generated, the mapping is error prone. Therefore, before the experiment, the following three data cleaning steps are performed to pre-process the data.

Divide the different tracks of each MIDI music file in LMD: This paper divides each MIDI file into five tracks: Bass, drum, guitar, Piano and string. The music generated by the experiment also includes these five tracks. This is because there is no clear method to identify and distinguish the track where the main melody and chord are played. Therefore, the music track cannot be divided into melody, rhythm and drum.

Select "rock" songs and merge tracks with sparse notes. Firstly, this paper mainly selects the music marked as "rock" songs, because this category generally contains the above five tracks, which can reduce the number of blank sections in these tracks. Although songs with genre tags are filtered, some tracks still tend to play only a few notes in the whole

song. This increases data sparsity and hinders the learning process. This paper combines the tracks with sparse notes into the most similar one of the above tracks. Because string instruments are the most diverse among a few instruments, instruments that are difficult to classify are merged into the track where string instruments are located.

5.3. Experimental Results and Analysis. After training, a large number of music clips are generated using the MCT-GAN model in this paper. After listening, it is found that most of the generated music is smooth and has a certain artistic aesthetic effect. Here, randomly select the generated music clips as the result display. Firstly, the generated multi track music is presented in the format of score. The generated music file is converted from npz format to mid file format by using Python library pypianoll, and then the mid file is expanded in the format of music score by using Cubase software. In order to make the music score clearly displayed, only four sections of music fragments are presented, and separate music scores are derived for each section. Therefore, the music score includes four sections of generated music.

As mentioned above, MCT-GAN has made two innovations in the previous music generation model. 1. Use CT-GAN as the generation confrontation model. 2. Propose a new time structure model. Muse GAN is a multitrack music generation network based on WGAN-GP. Therefore, this paper compares the MCT-GAN experiment with Muse-GAN experiment, so as to analyze the experimental effect of MCT-GAN proposed in this paper. According to the experimental results, the generation results obtained by MCT-GAN and Muse-GAN experiments are compared as follows:

Firstly, the training loss of the discriminator at different training iteration points is obtained experimentally. Therefore, the convergence curve of discriminator loss can be obtained and compared with the convergence curve of Muse GAN. The results are shown in Figure 5.

From the two convergence curves of Muse GAN and MCT-GAN in Figure 5, it can be found that compared with Muse-GAN based on WGAN-GP, MCT-GAN with increased CT penalty term converges faster and the training process is more stable.

Through the experiment, the distribution histograms of discriminator parameters in the two experimental iterations can be obtained respectively, as shown in Figure 6.

From the comparison in the figure, it can be found that the interval range of the parameter distribution obtained from the music generation experiment based on MCT-GAN is significantly smaller than that obtained from the Muse-GAN experiment, which shows that compared with the Muse-GAN based on WGAN-GP. The MCT-GAN with consistency penalty proposed in this paper is less prone to over fitting. In conclusion, through experimental comparison, MCT-GAN is better than Muse-GAN in stability, convergence speed and over fitting. These indicators can be calculated from the training (actual) data and the generated data to obtain the corresponding indicator values, and by comparing the values calculated from the actual data and the generated data, the effect of

(a)

(b)

(a)

(b)
Figure 8: Comparison of blank sections.

the generator can be understood. Therefore, the idea of the index evaluation method is consistent with the idea that the distribution of real and fake data in GAN should be close.

Muse-GAN designed an index evaluation method to evaluate the generated results. Therefore, this paper uses this method to compare Muse-GAN and MCT-GAN. The following indicators are defined in Muse-GAN, where EB, UPC and QN are in track evaluation indicators, and TD is inter track evaluation indicators. These indicators can be calculated from the training (actual) data and generated data, and the effect of the generator can be understood by comparing

the values calculated from the actual data and generated data. Therefore, the idea of index evaluation method is consistent with the idea that the distribution of real and false data in GAN should be close.

Figure 7 shows the change of UPC index value of the track where the string instrument is located during the experiment. The blue line in the figure is the UPC index value of the string instrument in the training set. It can be found from the figure that G can learn this index during training, which also shows that these index values can be used to preliminarily evaluate the generation results of the model before subjective evaluation.

In addition, this paper also randomly selects several sections of piano volumes as a comparative display, as shown in Figure 8. Figure 8a is a piano volume diagram for generating music using T3 as the time structure, and Figure 8b is a piano volume diagram for generating music using T1 as the time structure. The sections framed by the red box (or thick box) in the figure represent empty sections. From the comparison of the two figures, it can be seen that there are fewer blank sections using T3 as the time structure than using T1, which shows that the generation effect of MCT-GAN model using T3 as the time structure is improved compared with Muse-GAN.

In conclusion, using the index evaluation method to compare the experimental results, it is found that compared with the music generation experiment based on Muse-GAN. The MCT-GAN proposed in this paper has improved the effect of generating blank bars, generating note quality and generating music harmony. In addition to comparing the results, this paper also uses a subjective manual evaluation method. Select 80 test listeners and listen to 8 music clips for each tester. The specific proportion of the two is random. Then, after listening to each piece of music, the tester asked them to identify the source of the music and generate the music from the given three options (A. music; *b*. Real music; *c*. Finally, according to the selection results of all testers, the accuracy rate (i.e. the probability that the selection item is correct) and the confusion rate (i.e. the probability that *c* is selected) of each audience are obtained.

The results showed that 72.5% of the testers could not distinguish the generated music from the real data, that is, the number of people with a correct rate of less than 50%. Moreover, among the testers whose accuracy is in the range of 0%–25%, most of the testers cannot distinguish after listening to the music, and finally choose the uncertainty C; After the test, when interviewing the testers whose accuracy is in the range of 75%–100%, it is found that some testers have guessing behavior in discrimination. Therefore, from the results of manual evaluation, it can be found that the music production method proposed in this paper is effective.

6. Conclusion

With the increasing improvement of material living standards, people's cultural and entertainment life is becoming richer and richer, and people's demand for spirit is increasing day by day. However, in the field of artificial intelligence, generating real and aesthetic works of art has always been considered a challenge. With the rapid development of artificial intelligence technology and the development of deep learning technology in recent years, great progress has been made in image, audio and text generation. In particular, the generation experiment is carried out with the very popular generation countermeasure network, and remarkable results are achieved. Therefore, this paper studies the existing theoretical results. Finally, based on the improved derivative model CT-GAN of generation countermeasure network, the generation experiment of intelligent music is completed.

Because the experimental research design of this paper is based on the popular deep learning model to generate countermeasure network, this paper first briefly introduces the development background and basic concepts of deep learning. Then, the basic principle of generating countermeasure network is understood in detail, and the advantages and disadvantages of generating countermeasure network are analyzed. Then, understand an improved model Wasserstein GANs proposed for the problems of generating countermeasure network, and learn its basic principle. Although WGAN has improved Gan network, there are still some problems. Therefore, this paper also studies WGAN-GP, which is an improved model of WGAN network based on gradient penalty. For better training effect, this paper also makes a detailed study on the latest improved model CT-GAN based on consistency penalty term, which is proposed to solve the problems of WGAN-GP.

Learning and improving the existing music generation model based on GaN. When studying the multitrack music generation based on generation countermeasure network, this paper studies and analyzes three models. Based on them, the multitrack music generation method based on CT-GAN is proposed in this paper, which mainly improves the existing music generation model based on GAN. The music generated in this paper only contains five tracks: bass, drum, guitar, piano and string. However, some music creations in real life contain more different tracks. Therefore, in the follow-up work, we can consider using richer music data sets to generate music containing more tracks, so as to make the generated music more diverse. This paper realizes the multitrack music generation experiment based on CT-GAN, which can generate 4 bar music including 5 tracks. In the follow-up work, this music generation can be extended to music composition related applications to assist composers or music lovers in more convenient and diverse music creation. During data pre-processing, in order to reduce the number of empty sections contained in music data and deal with the data imbalance problem that increases data sparsity and hinders the learning process due to several notes played in some tracks in the whole song, the corresponding piano volumes are added and similar musical instruments are combined into one of the above tracks. However, this will bring noise to the data and affect the generation effect.

This paper proposes a self-adjusting generative confrontation network image denoising algorithm. The algorithm combines noise reduction and the adaptive learning GAN model. First, the algorithm uses image features to preprocess the image and extract the effective information of the image. Then, the edge signal is classified according to the threshold value to suppress the problem of "excessive strangulation," and then the edge signal of the image is extracted to enhance the effective signal in the high-frequency signal. Finally, the algorithm uses an adaptive learning GAN model to further train the image. Each iteration of the generator network is composed of three stages. And then, we get the best value. Through experiments, it can be seen from the data that the article algorithm is compared with the traditional algorithm and the literature algorithm. Under the same conditions, the algorithm can ensure the operating efficiency while having better fidelity, and it can still denoise at the same time. The edge signal of the image is preserved and has a better visual effect.

1. Introduction

The generation of image information will inevitably be more or less accompanied by the generation of noise. Noise is a factor that hinders human sense organs from understanding the received source information. We can define it as an unpredictable, random error. It will have a certain impact on the collection, input, and processing of image information and the final output results. Especially in the process of input, collection, and transmission of image information, if the input is accompanied by large noise, it will definitely have an adverse effect on the subsequent processing process and the processing result. The purpose of denoising is to improve the image and solve the interference problem of the actual image.

With the continuous development of technology, human access to information is obtained through human vision, hearing and touch, and other senses, the vast majority of which information is derived from human vision. And in real life, image acquisition is vulnerable to external interference to form noisy images, and in the process of image segmentation and parameter estimation of noisy images, it will cause errors in the resulting image so that the

image denoising processing will become the current research hot spot in the field of image processing [1–5]. In 1992, Donoho proposed the small wave threshold atrophy method; the algorithm with its own denoise superiority quickly attracted people's attention, but its tendency to "overstrangling" wavelet coefficient and cannot optimally represent the line and surface singularity in the image, so that the wavelet transformation in the image denoising has certain limitations [6, 7], but denoising in the past, there is still the problem of fidelity. With the development of artificial intelligence technology, multimodal fusion is an inevitable trend, and multimodal fusion can make more effective use of the characteristics of the image. In practice, a large amount of labeled data is difficult to obtain, but GAN can solve this problem very well [8, 9]. Therefore, the problem of how to combine GAN and noise reduction came into being.

This paper proposes an image denoising algorithm, which is based on a model that generates an adaptive adjustment against the network. It combines noise reduction and the adaptive learning GAN model, preprocesses the image by combining image characteristics, increases the

effective information quantity of the image while reducing the amount of image calculation, and then uses the GAN model with adaptive learning to further denoise the image, so as to obtain the best noise removal effect. In order to avoid the phenomenon of "overstrangling" in the process of noise reduction, the referenced threshold classifies its edge signal and then extracts the edge signal of the image to enhance the effective signal in the high-frequency signal while deleting the negligible signal in the image. Each iterative update of the generator network λ consists of three stages. In the end, we obtain the key areas in the image and self-learn to obtain the best value for the individual.

2. Generative Adversarial Networks

The generative adversarial network (GAN) was proposed by Goodfellow, which uses convolutional neural networks to train image samples [10, 11]. As a probability generation model, the generation against the network has been applied to many visual tasks, especially in the excellent performance of the image generation direction. The network structure is generated as shown in Figure 1.

The purpose is to let the generator generate data similar to the real data distribution to achieve a fake effect. In terms of data prediction, the training generator introduces images into the generation of the neural network and, through training, reduces the difference between the two so that the distributor cannot distinguish the authenticity of the generated data. Since the difference between the generated data distribution P_G and the real data distribution P_{Data} cannot be calculated, therefore, the discriminator uses a data sampling method to count the divergence of the two and then distinguish them.

The objective function is

$$V(G, D) = E_{x \sim P_{\text{data}}}[\log D(x)] + E_{x \sim P_G}[\log(1 - D(x))]. \quad (1)$$

Among them, $E(*)$ is the mathematical expectation value, and $D(*)$ is the result of the differential output. The objective function of maximizing judgment is the dispersion of generated data and real data. According to the distribution dispersion, the prediction function can be obtained:

$$G^* = \arg\min_G \max_D V(G, D). \quad (2)$$

GAN can generate generated samples similar to the real data distribution, but there are difficulties in training, data cannot be obtained, difficult to converge, and pattern collapse, and some studies have proposed variations of the GAN to improve the model. When there is no overlap between the generated data and the real data distribution, the dispersion of the two data distributions is constant, Log2, which can lead to the disappearance of gradients and make it difficult for the model to train.

Broadly speaking, generators and judges are not enemies, and they are not confrontational relationships. In fact, they are constantly updating and learning on the basis of each other to achieve each other. During the training process, the goal of generating network G is to generate as many real pictures as possible to deceive network D. D is opposite to G, and the goal of D is to distinguish between false images generated by G and real images as much as possible. The two constitute a dynamic "game process."

The success of the GAN also benefits from the success of confrontational ideas. The idea of confrontation has been introduced into several fields including machine learning and artificial intelligence. The two behaviors of "game" and "competition" contain the characteristics of confrontation. People combine game theory and machine learning to produce game machine learning.

The advantages and disadvantages of the GAN are as follows: compared with other generative models, GAN has the following four advantages:

(a) From the actual results, GAN seems to produce better samples than other models.

(b) Most other frameworks require the generator network to have a certain functional form, for example, the output layer is Gaussian. It is important that all other frameworks require that the generator network be distributed with nonzero quality. The generative confrontation network framework can train any type of generator network and can learn to generate points only on thin manifolds close to the data.

(c) Any generator network and any discriminator will be useful because they do not need to design a model that follows any type of decomposition.

(d) There is no need for reasoning during the learning process and no need to use the Markov chain for repeated sampling (inference), thus avoiding difficult approximate calculation problems of probabilities.

Compared with VAE, deep Boltzmann machine, NICE, and real NVE, GAN has no lower limit of change. At the same time, compared with deep Boltzmann machines, GAN does not have tricky partition functions. GAN can be generated all at once through samples, instead of repeatedly applying Markov chain operators.

3. The Algorithm of This Article

At present, fuzzy method training using synthetic data cannot effectively distinguish real images. In order to solve this problem, this paper proposes a new method of noise reduction and adaptive learning GAN model, that is, by combining image characteristics to preprocess the image so that the target is clear, then use the GAN model with adaptive learning to further denoise the image, and then get the best noise removal effect.

At present, many researchers have proposed many denoising methods for images. However, some denoising methods will blur the details of the image while denoising the image, making the original clear image blurred and unable to be restored. Some are able to get clear images, but the amount of calculation is too large to meet people's needs. Nowadays, the most common wavelet denoising algorithms are the modulus maximum denoising algorithm, correlation denoising algorithm, and threshold denoising algorithm.
FIGURE 1: A counternetwork structure.

Through comparative analysis, it is found that the threshold denoising algorithm is the simplest and has the least amount of calculation in the image processing process, has the characteristics of high flexibility and strong denoising ability, and is the most widely used in practical applications. Therefore, this article chooses to use the threshold denoising algorithm to process the image.

3.1. Image Noise Reduction Preprocessing.

In a noisy image, the real signal of the image is usually a low-frequency or relatively stable signal, while the noise is generally concentrated in high-frequency signals. Wavelet transform can effectively concentrate energy and concentrate it in the low-frequency region. The Gaussian noise presents a Gaussian distribution, and the main signal is distributed in the high-frequency region. Therefore, the proposed algorithm can quantify the threshold of wavelet coefficients by introducing appropriate thresholds to eliminate noise.

Through the study of noisy images, one can find that, in real life, the low-frequency part of the image signal after wavelet transform is composed of the useful signal of the image, and the image noise often exists in the high-frequency part of the image [12].

Step 1: wavelet decomposition of the noisy signal: choose the appropriate wavelet and the corresponding decomposition layer. Figure 2 shows a wavelet decomposition diagram of a noisy image.

Step 2: perform threshold quantization processing on the high-frequency subbands after wavelet decomposition. Threshold processing of different scales is realized by the threshold, and the corresponding estimated wavelet coefficients are obtained.

Step 3: reconstruct the obtained signal through your transformation of wavelet coefficients. Finally, the denoised signal is obtained. That is, the wavelet coefficients of the low-frequency subband and other high-frequency subbands are quantized by the threshold, and the signal is reconstructed to obtain the latest estimated signal $\hat{f}(t)$.

The selection and quantification of the threshold and the classic threshold denoising function are as follows.

Threshold:

$$\lambda = \sigma * \sqrt{2 \log N}. \tag{3}$$

By measuring each detail signal, it can be filtered. Among them, σ is the standard deviation of the noise, and N is the length or scale of the signal. It is defined as follows:

$$\widehat{\omega}_{i,j} = \begin{cases} \omega_{i,j}, & |\omega_{i,j}| > \lambda, \\ 0, & |\omega_{i,j}| \leq \lambda. \end{cases} \tag{4}$$

Finally, the reconstructed data of the image can be obtained.

3.2. Noise Reduction (Detail Protection).

Combining the inherent visual characteristics of the human eye, this paper finds that the entropy value of the image can truly reflect the image signal [13–19], but in the actual computer process, the maximum entropy threshold is calculated in a relatively large amount. Therefore, in the process of noise reduction, after the graying of the image, because the image signal is mainly distributed with area 0 and region 1, the probability in regions 2 and 3 is usually set to 0, which greatly simplifies the calculation in the mathematical model.

Research found that, after adaptive decomposition, the edge signals in the high-frequency signal are effectively concentrated [20–28], while the high-frequency signal is mainly used to represent the edge signal of the image, which inevitably shows some noise signals and weak edge signals, if these signals are deleted, it will not affect the overall quality of the image, and how to effectively separate these signals from the edge signal will have a certain impact on the compression of the image.

By analyzing the edge characteristics of its image, we find out the characteristics:

(1) Along the gradient direction, the detection is carried out in a certain range, the maximum value is retained, and $M_S f(i, j) = 1$ can be obtained. If the nonmaximum value is deleted, $M_S f(i, j) = 0$ can be obtained.

(2) The edge signal is generally a point with a more intense grayscale change, i.e., the corresponding mode value is relatively large, while the corresponding mode value of the noise signal is relatively small.

Therefore, according to the distribution characteristics of the image signal, this paper classifies the image to achieve the compression processing of the image. The method is as follows:

$$W(i, j) = \begin{cases} W(i, j), & M_s f(i, j) > = \lambda, \\ 0, & M_s f(i, j) < \lambda. \end{cases} \tag{5}$$

Edge signal function: $M_s f(x, y) = s\sqrt{(\partial F/\partial x)^2 + (\partial F/\partial y)^2}$.
FIGURE 2: Wavelet decomposition diagram of the noisy image.

$$F_s(x, y) = \sum_{(i,j) \in N_s(x,y)} f(i, j) \phi_s(x - i, y - j),$$

$$\frac{\partial F_s(x, y)}{\partial x} = \sum_{(i,j) \in N_s(x,y)} f(i, j) \frac{\partial}{\partial x} \phi_s(x - i, y - j),$$

$$\frac{\partial F_s(x, y)}{\partial y} = \sum_{(i,j) \in N_s(x,y)} f(i, j) \frac{\partial}{\partial y} \phi_s(x - i, y - j),$$

$$\frac{\partial}{\partial x} \phi_s(x - i, y - j) = \frac{1}{s^3} \frac{\partial \phi(u, v)}{\partial u}\Big|_{(u,v)=(x-i/s, y-j/s)},$$

$$\frac{\partial}{\partial y} \phi_s(x - i, y - j) = \frac{1}{s^3} \frac{\partial \phi(u, v)}{\partial v}\Big|_{(u,v)=(x-i/s, y-j/s)}.$$

$$(6)$$

Among them, $0 \le x, y \le N$.

The edge signal in the high-frequency signal is detected, the edge signal is classified by the reference threshold, the edge signal of the image is extracted to enhance the effective signal in the high-frequency signal, and the negligible signal in the image is deleted.

At the same time, in order to avoid excessive denoising, a new threshold is proposed; that is, $\lambda = 2^a \sigma \sqrt{2 \log(N^2)}$.

Among them, a is the number of filtered stages, N^2 is the maximum scale size of the image signal, and σ is the noise standard estimation of the contourlet transform. This paper reduces the appearance of "overstrangling" phenomenon by combining the nature of the image signal and thus improves the accuracy of the denoising algorithm.

According to the inherent characteristics of human vision, the article classifies high-frequency signal information and combines with a new threshold denoising algorithm to effectively remove image noise. Through experiments, the algorithm in this paper can reduce the coding overhead of the denoising algorithm while ensuring the quality of the denoised picture.

By observing Figure 3, it is not difficult to find that this algorithm can effectively remove speckle noise. It can be seen that the processed image has enhanced the contrast of the image, but there are still blurry edges and loss of details.

3.3. Adaptive GAN to Improve Image Quality. Image super-resolution, referred to as super-resolution (SR), generally refers to the magnification resolution. For example, if you change the resolution from 256×256 to 512×512, the magnification scale is 2. Obviously, this is an ill-posed problem of making pixels out of nothing, and there is no unique solution. The image is superdivided, and the application scenarios are naturally wide. The general method is to take the low-resolution (LR) image as the input of the method and process it to obtain the high-resolution (HR) image. Nowadays, quite a lot of papers are self-made LR-HR image pairs as training sets. For example, the LR is obtained by downsampling the original image HR, and then the mapping learning from LR to HR is performed, but when applied to practice, is the relationship between LR and HR a self-righteous "downsampling" relationship? This is probably unknown and difficult to simulate.

Due to the weak correspondence between the random input and pictures, GAN-generated images are prone to misalignment. Also, because the discriminator judges the image as a whole, the generated pictures have stronger continuity and can generate clearer pictures.

When processing images, the pixel loss function similar to the mean square error cannot recover some details that are lost in the downsampling process. Minimizing the mean square error is by finding a reasonable pixel average value, but the processing result of this method is usually too smooth, which will lead to poor perception quality.

The GAN provides a very advanced learning architecture in generating very high-quality natural image research. The architecture of the GAN helps to facilitate the reconstruction of regions that move into the search space. This may contain images that are as real as photos, making the images obtained by the GAN closer to natural images.

Each iteration of the generator network includes three stages [29–31], which enable the generator to quickly and accurately locate the focus area in the image.

(1) *Variation:* Introduce a random noise signal z. In the new round of update process using the gradient penalty loss function of this paper, and for the generation of the network gradient penalty loss function is $L(G, D)$ calculated only for noise data, which makes the network according to the parameters updated.

Figure 3: Denoising effect diagram of the GAN.

$$L(G, D) = E_{z \sim P_z}[D(z)] - E_{z \sim P_z}[D(z)] - \lambda_{\mathrm{gp}} E_{z \sim P_z}\left[\left(\left\|\nabla_x D(z)\right\|_2 - 1\right)^2\right],$$

$$L_{\mathrm{MSE}}(G, D) = L(G, D) + \lambda_{\mathrm{MSE}} L_{\mathrm{MSE}}(G). \tag{7}$$

Among them, λ_{gp} is the weight parameter. P_z is the noise data distribution.

(2) Assess:

In order to learn the correct distribution of training samples and improve the stability of model training, this paper selects an evaluation mechanism that uses the loss function to select the best sample under the screening of the discriminator. The following is the evaluation mechanism:

The quality score of the generated samples and the diversity of the generated samples are the embodiment of the quantification of the adaptive score at this stage: $\mathbf{F} = \mathbf{F_q} + \gamma \mathbf{F_d}$.

$\mathbf{F_q}$ is the quality score, $\mathbf{F_d}$ is the diversity score, and γ is the ratio parameter of the two. Through the evaluation mechanism, the highest adaptability score is calculated, and the size of the highest score is calculated so that the global optimal score can be obtained. By analogy, until the end of the first generation to the last generation, the optimal value is obtained by comparison, and then the adaptive score is updated.

(3) Select:

According to the evaluation mechanism to select the optimal individual, the other low scores will gradually decay so that the generation network has a certain direction, and choose the optimal value of the individual.

4. Experimental Results and Analysis

In order to verify the validity of this method, verify that the algorithm can denoise while retaining image edge information. Since the GAN is a deep learning model, the game between the generation network and the confrontation network is used to improve the results of the generation network. In this paper, PyCharm is used to simulate the algorithm and to compare with the existing traditional algorithm [32] and literature algorithm [33] by processing the same noisy image.

4.1. Objective Indicators of Image Denoising. The experimental hardware environment is the processor Intel Corei7-7700, clocked at 3.60 GHz, memory 12 GB, NVIDIA TITAN Xp. The software environment is Windows 10, 64 bit, Python 3.6, and TensorFlow. In order to verify the denoising effect of the proposed algorithm on noisy images, the ImageNet image dataset is selected in the article and combined with the images in real life; 100×100, 128×128, and 256×256 images are selected. Tests were performed at Gaussian noise levels of 10, 20, 30, 40, and 50. On the experimental dataset, when the Gaussian noise standard deviation σ of the noise image is larger, the peak signal-to-noise ratio (PSNR) is smaller, and the image distortion is more. On the contrary, the smaller σ, the larger the PSNR and the better the denoising effect.

This paper verifies the fidelity effect of the algorithm by comparing the PSNR value of each algorithm. Table 1 is a comparison data table of the PSNR value obtained by different denoising algorithms through experiments.

It can be seen from Table 1 that, in the case of different noise standard deviations of the same noisy image, by analyzing the PSNR value, it can be seen that the data obtained by the algorithm in this paper are better than the literature algorithm and the traditional algorithm. The data of the algorithm in this paper are compared with those of the traditional algorithm, and the average PSNR value is 10.48 dB higher. Compared with the literature algorithm, the PSNR value of the algorithm in this paper is 6.56 dB higher, which effectively proves the image fidelity capability of the algorithm in this paper.

In order to verify the influence of the noise figure on the algorithm time, this article records the time consumed by the algorithm under the aforementioned environment and draws it into a graph, as shown in Figure 4.

By observing Figure 4, it is not difficult to find that, as the noise figure increases, the time consumed by each algorithm increases. Among them, the curve of the literature algorithm

TABLE 1: The PSNR value data table for the results obtained by different denoising algorithms.

σ	PSNR (dB)			
	Noisy images	Traditional denoise	Literature algorithms	Article algorithm
10	24.21	29.32	35.95	37.05
20	21.34	29.12	31.02	38.21
30	18.91	25.15	30.12	39.34
40	16.32	30.57	32.58	37.12
50	14.22	26.11	30.22	40.97
FIGURE 4: The influence curve of the noise figure on algorithm time.

consumes the most, both of which are above the time curve of the traditional algorithm and the article algorithm. The time curve obtained by the algorithm of the article is basically the same as the traditional algorithm.

4.2. Iterative Effect Comparison Experiment.
This article observes the PSNR value based on the ImageNet dataset and the CIFAR-10 dataset. We analyze the change data of PSNR as the number of iterations increases and express it through a graph. Figure 5 shows the PSNR curves of three different sizes of images as the number of iterations increases.

It is not difficult to find from the figure that the algorithm in this paper has a better denoising effect in different sizes. After the number of iterations reached 15 K, the growth rate of PSNR also slowed down, and finally, our network results reached a stable value.

4.3. Running Time.
In order to verify the algorithm, the experiment selects standard image library images and evaluates the average running time of the algorithm based on the same standard. The results are shown in Table 2.

It is not difficult to see from Table 2 that the algorithm in this paper is significantly better than the traditional algorithm in terms of speed. The reason is that although the computational complexity of the literature algorithm code has been significantly reduced after multiple optimizations, the attention-based denoising algorithm needs to extract images for iterative training models to achieve effective denoising, so the computational complexity is relatively high. However, the algorithm in this paper can significantly improve the operating efficiency by simply reducing it for the first time and then scoring and selecting the image. It can be seen from Table 2 that in terms of time, the time of the algorithm in this paper is basically the same as that of the traditional algorithm. These prove the feasibility of the algorithm.

4.4. Denoising Effect Comparison Experiment.
In order to verify the superiority of the algorithm in the image denoising effect, the pictures of the two actual scenes are selected for simulation experiments, and the denoising effect of each algorithm is shown, where Figures 6 and 7 show the original images.

By observing Figures 8–10, one can see that the image effect processed by the algorithm in this paper is significantly improved compared with the traditional algorithm and the literature algorithm. And the image details and image sharpness processed by the algorithm in this paper are better than the other two algorithms.

The proposed algorithm selects a complex image to perform related operations to verify the algorithm's processing effect on image details. Figure 7 is a high-altitude shooting with complex content. The effect is shown in the following.
FIGURE 5: The PSNR curve of three different sizes of images as the number of iterations increases.

TABLE 2: Average running time of different algorithms.

Algorithm	Panda (s)	Duck (s)	Cliff (s)	Average running time (s)
Traditional algorithm	0.823	0.992	0.859	0.891333
Document algorithm	1.467	1.036	1.904	1.469
Article algorithm	0.993	0.838	0.882	0.904333

FIGURE 6: Original image.

Figure 8: Traditional algorithm.

Figure 9: Document algorithm.

Figure 10: Article algorithm.

Figure 11: Traditional algorithm.

FIGURE 12: Document algorithm.

FIGURE 13: Article algorithm.

By observing Figures 11–13, one can see that the algorithm in this paper compares the noise reduction simulation of the traditional algorithm and the literature algorithm. It can be seen that the algorithm can denoise the noisy image while still retaining the edge signal of the image and has a good performance. It has better visual effect.

5. Conclusion

This paper proposes a self-adjusting generative confrontation network image denoising algorithm. The algorithm includes noise reduction and the adaptive learning GAN model. It preprocesses the image first by combining image characteristics to make the target clear. Then, the algorithm in this paper uses the GAN model with adaptive learning to further denoise the image and then obtains the best denoising effect. The threshold value quoted in the process of noise reduction avoids the phenomenon of "overstrangling" and improves the effective signal in the high-frequency signal. In the GAN model, iterative updates are performed through operations such as mutation, evaluation, and selection. Self-learning of the generator can quickly and accurately locate the key areas in the image to obtain the optimal value. The results show that the proposed algorithm can effectively denoise while retaining the image signal, which is consistent with the expected effect. However, with the explosive growth of the amount of image data, how to optimize the algorithm to improve the efficiency of image denoising execution is a problem that needs further research.

An intelligent controller based on a self-learning interval type-II fuzzy neural network is proposed to make the motion controller of the industrial intelligent robot with good adaptability. This controller has a parallel structure and contains an interval type-II fuzzy neural network and a conventional PD controller. For the design of the interval type-II fuzzy neural network, the interval type-II fuzzy set is established using the slave design method. In the design process of the interval type-II fuzzy set of the front piece, a dual sequence symmetric trapezoidal subordinate function arrangement method is proposed, which makes the self-learning law and stability analysis of the system in an analytic form and facilitates the implementation of the algorithm in hardware. In the design of the neural network self-learning law, a parametric self-learning algorithm based on sliding mode control theory is established to adjust the structural parameters of the interval type-II fuzzy neural network online, and the stability of the system is proved by using Lyapunov's stability theorem. Three sets of validation simulation experiments are given in conjunction with the trajectory tracking problem of the Delta parallel robot. The simulation results show that, in the presence of system uncertainty, the intelligent controller based on interval self-learning interval type-II fuzzy neural network can significantly improve the trajectory tracking accuracy and robustness of the system and make the control system highly adaptable to the environment. Experiments of intelligent control system based on self-learning interval type-II fuzzy neural network and experiments of reusable particle swarm optimal motion planning method are designed, and the effectiveness of the intelligent control system and motion planning method is verified on the experimental platform. The experimental results show that the intelligent control system based on the self-learning interval type-II fuzzy neural network can effectively improve the accuracy and stability of robot trajectory tracking control, and the reusable particle swarm optimal motion planning method can quickly solve the robot motion planning problem with complex constraints online.

1. Introduction

Artificial intelligence is both the background of the times and a prerequisite for machines to have intelligence and sociality. Existing studies on human-machine social interaction only consider the shallow expression of human-human social or human-machine interaction, without considering the trends and design requirements of the deeper changes in the human-machine relationship in the upcoming AI era. In the past, machines were used as tools or mediums for human-human interaction, but with the further enhancement of machine intelligence, direct human-machine interaction has gradually evolved [1]. Through the increasingly in-depth human-machine interaction, intelligent machines have functional, emotional, and social effects on people, which leads to the new topic of human-machine social interaction in the era of artificial intelligence [2]. In the context of the new social environment and the development of new human-machine social interaction, we start from the background and the current situation of the study, use literature review and typical example analysis in the early stage of the study to understand the current research process of artificial intelligence, social interaction, and human-machine interaction, explore the part that can be further developed based on the shortage of existing research, and propose the purpose and significance of this study. When IT2FNN is connected in parallel to both ends of the PD controller, the self-learning process of IT2FNN's

structural parameters begins. After the learning time of about 1.7 seconds is over, the output signal of IT2FNN replaces the PD controller as the main output source of the control signal. The result is the same. The above simulation results clearly show the influence of the learning process of SLIT2FNN on the output of the controller and the improvement of control accuracy after adopting the parallel intelligent control structure in the second working cycle.

In practical applications, one of the most frequently encountered situations for industrial intelligent robots is trajectory tracking control [3]. If a satisfactory control effect is to be obtained for an industrial robot, there are many problems to be solved in the design of the control system, such as the nonlinearity of the robot body structure, the uncertainty of modeled and unmodeled dynamics, and the diversity of operating conditions, in addition to its dynamics optimization design. In the last decade, many related research works have been done by scholars on the trajectory tracking control problem of parallel robots. Some of them are based on traditional control methods for trajectory tracking control problems: some studies [4, 5] are based on feedback linearization control methods; others [5, 6] are based on adaptive theory, in addition to studies based on variable structure control theory. However, most of the controllers based on traditional control methods need to provide an accurate mathematical model of the controlled object to obtain satisfactory control results [7]. However, obtaining a complete dynamical model of a parallel robot is very difficult and sometimes impossible. Moreover, even if accurate robot system parameters can be obtained experimentally, it is equally difficult to derive a dynamic model of the robot based on these parameters, especially for some parallel robot systems with complex motion mechanisms.

Taking the Delta parallel robot as the object, the forward and inverse kinematics models of the robot are established, and the dynamics model of the robot is established by using the virtual work principal method. On this basis, a robot body mechanism parameter optimization method oriented to the control task requirements is proposed. Firstly, the mechanism parameter optimization algorithm considering anisotropic dynamics characteristics is established, and the optimization models are built with the full-domain drive joint torque index and the full-domain drive joint torque fluctuation index, respectively, and the optimization problems are solved to verify the effectiveness of the algorithm. Then a multiobjective dynamics optimization model based on the full-domain performance index is established, and the multiobjective optimization problem is solved using a multiobjective genetic algorithm, and the computational efficiency and effectiveness of the algorithm are verified. The above model and optimization algorithm of the Delta parallel robot are established using the idea of building blocks to make the robot system simulation platform universal. A parallel intelligent control system based on a self-learning interval type-II fuzzy neural network is proposed and used to solve the trajectory tracking control problem of the Delta parallel robot. This controller is a parallel structure: it contains an interval type-II fuzzy neural network and a conventional PD controller. The IT2FS is designed using a

subordinate design approach, based on which a dual sequence symmetric trapezoidal subordinate function arrangement is proposed to give an analytic form to the interval type-II subordinate function for designing the self-learning law and stability analysis. In the design of the neural network self-learning law, a parametric self-learning algorithm based on the SMC theory is proposed to adjust the structural parameters of the interval type-two fuzzy neural network online. The stability of the proposed intelligent control system is proved using Lyapunov's stability theorem. The performance of the established intelligent controller is verified through simulation experiments.

2. Related Work

In terms of isotropic optimization problems in the full working domain, Narayan et al. proposed a multiobjective optimization method for the design of structural parameters of a four-degree-of-freedom parallel robot for the robot isotropic design problem with task requirements, using robot sensitivity analysis and standardized workspace volume as objective functions [8]. Rao et al. studied the scale synthesis problem of the Hexaslides robot and gave a method to select the structural parameters of the Hexaslides robot for the machining field [9]. Mirzaey et al. investigated the kinematic optimization problem of a two-degree-of-freedom parallel robot arm using a stepwise optimization method. The number of design variables was reduced by optimizing the parameter relations with an analytic form in the first step [10]. The second step reduces the optimization variables of the optimization problem to one utilizing the given global optimization index and thus solves the kinematic optimization problem of a parallel robotic arm [11]. Li et al. proposed a dynamic isotropic optimization method for the full working domain of a parallel robot, giving a dynamic optimization objective function based on the robot inertia matrix, and demonstrated the validity of its objective function through an optimal design problem of a three-degree-of-freedom tandem robot and a parallel robot [12].

Since we need to obtain a controller with high nonlinear characteristics and smoother control performance, the IT2FLC obtained by the two-terminal fuzzy method is the structure of the type 2 fuzzy logic controller that best meets the expectations of our control system characteristics. Vision servo is based on the visual information provided by the camera to control the robot. Depending on the feedback error used to calculate the control law, the vision servo is divided into position-based, image-based, and motion-based control systems [13]. In the position-based control system, the feedback error is calculated in a three-dimensional Cartesian coordinate space; in the image-based control system, the feedback error is calculated only from the different pixel points of the current image and the reference image; both systems are model based and require rigorous calibration of the camera to determine the exact geometric relationships between the camera and the robot's end-effector and then use these geometric relationships to analyze the feature points in the image [14]. These geometric relationships are then used to analyze the feature points in the

image, which are usually selected by humans. In contrast, motion-based control systems are model-free and can calculate feedback errors without any a priori using of frame difference methods, optical flow methods, etc. With the development of technologies such as deep learning and the advent of the era of artificial intelligence, the connection between machines and people is getting closer and closer, and artificial intelligence with human-machine dialogue function is gradually social role-playing, and the human-machine relationship is changing accordingly [15]. The research finds that existing studies on social interaction only consider human-human socialization and do not consider the changes in the human-machine relationship in the coming AI era [16]. To verify whether the motion mode of the real machine is consistent with the motion gait based on the Hop oscillation model proposed in this paper, the wake gait motion of the robot dog can be obtained through the video screenshots during the experiment. This study explores the changes in human-robot social relationships, the deep-seated needs, and ultimate purpose of human-robot social interaction and analyzes how evolving human-like intelligent robots can meet the dynamic deep-seated emotional needs of humans to adapt to human needs.

The communication between man and machine will rise from mechanical external interaction to an emotional level. All specific operational devices will be naturally integrated into the overall information infrastructure. In their place, there will be a wide variety of ubiquitous sensors. The integration of AI, cloud computing, and increasingly intelligent machines will generate data for use in human-computer interaction systems. The study of social interaction has the value of studying and predicting future trends in the evolution of human-machine relationships. Machines gradually take on the attributes of social roles and, on the one hand, have a social connection with people. From another perspective, the advancement of human-like intelligence such as artificial intelligence, which is mainly driven technology, has replaced some of the jobs originally performed by humans, thus causing an identity crisis and technological anxiety in human values. The development of artificial intelligence and human-like emotions, which are mainly emotionally dependent, will have a more profound impact on human society, especially in terms of human identity and emotional dependence in social relations.

3. Fuzzy Neural Network Motion System for Robot with Artificial Intelligence

3.1. Robot Motion System Design. To realize the robot from the virtual prototype model to the real model, the first step is to draw the vector drawing for the real model and to mark the drawing size on the vector drawing according to the size of the virtual prototype; the common software to draw the structure drawing is Autodesk Computer-Aided Design (AutoCAD) and CorelDRAW. In this paper, we chose AutoCAD as the drawing tool.

The body structure of the robot is three-dimensional. In this paper, the length, width, and depth of each part need to be marked in the drawing design so that the robot body can

be assembled by printing out the parts with a three-dimensional structure [17]. The body structure of the quadruped robot was designed concerning the mortise and tenon structure of ancient Chinese architecture, and the torso of the robot was designed to be fixed without screws, but only by inserting the mortise and tenon structure. After the design of the drawing, the drawing was processed by laser engraving, and then the dimensions of the drawing were verified by assembling, and the unreasonable structural parts were modified.

The robot's control method is divided into two types: external command control and automatic adjustment control of the robot's decision system [18]. In external command control, the robot needs to have a signal receiver that can communicate with the outside, and in decision control, the robot needs to be able to sense the surrounding road conditions, audio, and video signals, etc. After receiving the signals, the robot's brain needs to perform a series of operations, such as data calculation and task scheduling, and then control the leg servos to make corresponding movements. The SLIT2FNN controller is in the environment dynamics learning process. The neural network adjusts its own structural parameter values through the parameter self-learning algorithm. At this time, the control signal is mainly provided by the PD controller in the parallel control structure. After the neural network self-learning process is over, IT2FNN replaced the traditional PD controller as the main control signal output in the parallel control structure. At the same time, it can be seen from the figure that the tracking accuracy of the robot has been significantly improved. Therefore, the hardware structure of a robot is like the von Neumann architecture of a computer, which consists of five major parts, each of which cooperates to realize the robot's functions. The robot hardware architecture is shown in Figure 1, where the communication module, the video perception module, and the pose perception module are the input devices of the robot, the servo controlled by PWM (pulse width modulation) signal is the output device of the robot, and the middle part is the operator and controller of the robot.

The robot system framework is a typical hierarchical multiloop control structure, in which the robot system is divided into different layers from top to bottom, and each layer will have multiple tasks to be executed collaboratively. The first three layers are embedded inside the robot, and the last layer is the interaction layer between external users and the robot.

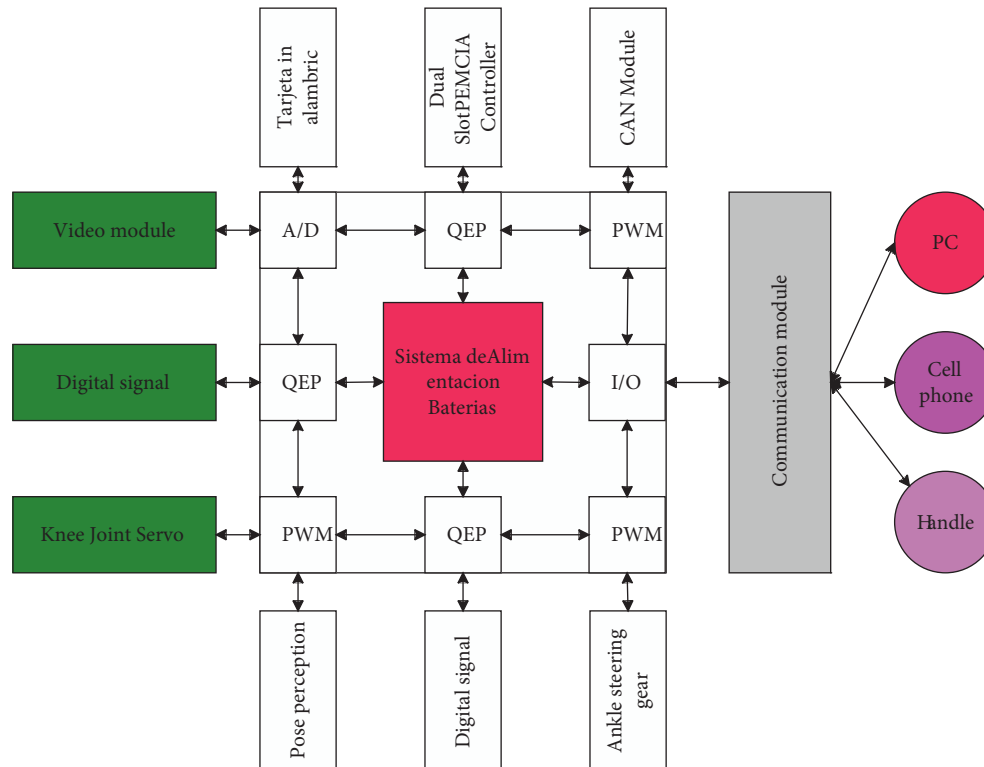
The main function of the driver layer is to realize the cooperation between the robot hardware and software. The sensor interface is responsible for receiving digital signals from the sensors installed on the robot body, such as receiving video stream signals from the camera, while the main command of the actuator interface is to send commands to the actuator, sending the system control signals to the actuator and controlling the robot's servo to complete the motion function [19]. Firstly, the mechanism parameter optimization algorithm considering the anisotropic dynamic characteristics is established, and the optimization model is established with the global driving joint torque index and the


FIGURE 1: Hardware structure of the robot.

global driving joint torque fluctuation index, respectively, and the optimization problem is solved to verify the effectiveness of the algorithm. The main command of the actuator interface is to send commands to the actuator, send the system control signals to the actuator, control the robot's servo to complete the motion function, and receive the feedback signals from the actuator to sense whether the actual motion of the robot is the same as the control command. The second layer of the multitasking platform layer mainly implements the fusion of sensor data, control of multiple servos, image processing, and task scheduling functions, and the platform layer requires the driver layer and the algorithm layer together to complete the task. The robot system needs to fuse these sensor data and then realize the processing of different sensor data through the corresponding algorithms in the upper algorithm layer. The servo control interface mainly sends the control signal of the servo to the actuator and realizes the control of a certain servo or the parallel control of the whole-body servo according to the task, and the image processing interface accepts the video stream data sent by the camera sensor, and then the image processing interface of the algorithm layer performs calculations, as shown in Figure 2.

The specific manifestation of social relations is the human-computer relationship. Human-computer relations place more emphasis on the individual characteristics of people who influence each other, while social relations refer to the common aspects it contains. Social relations refer to the interpersonal relations formed by people in the process of production and living together. Social relations are mainly

divided into blood relations, georelations, and karma relations. Blood relations are rooted in or kinship ties and are the first social relations formed by human beings. They constitute social groups such as families and households. Georelationships are based on the spatial and geographical relationships of people. Karmic relations are formed based on the extensive social division of labor and promote social development. Types of interpersonal relations refer to the distinction of types of interpersonal relations. According to Thibault's view of interpersonal interdependence, he classifies interpersonal relationships as minimal interdependence, asymmetric interdependence, reactive interdependence, and mutual interdependence. Minimal interdependence means that the interacting parties act according to their intentions. Asymmetric dependence means that one party's actions are based on the actions of the other party, but with opposite intentions. Reactive interdependence means that one party acts in full accordance with the other party's intentions. Mutual dependence is the most equal and stable form of interaction; e.g., it can be classified as emotional or instrumental interpersonal relationships according to needs.

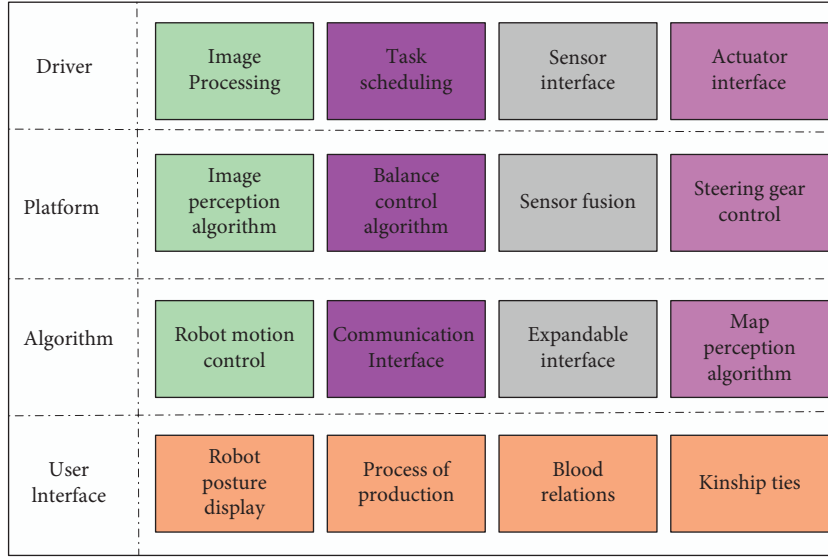
In terms of the relationship and process of human-computer interaction, the user (human) is constantly changing during the use of the machine. Human behavior and emotions are not stable; people are not stable; people are rather a role that is constantly changing with the use of intelligent machines. This calculation example only considers the situation that there are 1 and 2 obstacles in the workspace, each database contains 180 sets of data, and the


FIGURE 2: Hierarchical circuit diagram of the robot system.

setting of the initial motion trajectory of the robot is the same as the previous one. The dynamic performance of the social role of the machine is that the process of social role formation is affected by other factors, such as the degree of the flow of human-computer interaction, the degree of human involvement in the interaction, and so on. These factors or conditions are flexible and uncontrollable. In addition, the effect of the social role that can be achieved varies depending on the degree of machine intelligence. The social role properties of machines are not invariable; a machine is a social role only when it interacts with and influences people; in other words, active and interacting machine intelligence is a machine social role. With the support of big data and the progress of deep algorithms and other technologies, human beings have entered the era of artificial intelligence. Modern human-robot interaction is based on machines running according to programs written in advance by humans. In essence, human intentions reflected in the behavior of all robots. Intelligent machines take certain actions based on preprogrammed instructions from human programmers. Even intelligent robots make certain decisions on their own, based on algorithmic judgment. However, with machines having dialogue and behavioral feedback systems that are highly close to humans, close to real people's natural language understanding and output and behavioral feedback, human-robot social interaction arises along with it. Intelligent robots are a completely new product born in recent decades, and human-machine relationships and human-machine interactions are also a completely new subject. The construction and understanding of human-machine social interactions are both to help robots integrate into human and social systems and to build systems for good human-machine interactions. Machines becoming social actors is a prerequisite for human-robot social interaction. Intelligent machines with dialogue and behavioral feedback systems that are highly like those of humans and capable of adaptive autonomous learning become social actors with certain norms and dynamically changing behavior patterns when they participate in human-robot social interaction as subjects.

3.2. *Fuzzy Neural Network Algorithm Design.* Designing a type-one fuzzy logic system involves making many choices for each segment. We need to choose the type of fuzzification, the form of the affiliation function, the parameters of the affiliation function, synthesis, implication, and the type of demulsified, etc. The different choices for each link represent the different mathematical methods involved. For example, the firing level of a rule R^n can be written in the following form if it is calculated using the minimum t-parametrization. Although the EFPF-PSO algorithm has a chance to obtain an optimized trajectory with a smaller fitness value, not every calculation will converge to the minimum fitness value, and its standard deviation is relatively large. However, the results obtained by the RPSOMP method are more stable, the standard deviation is small, and the convergence speed is faster.

$$\mu_{R^n}(x) = \arg\max\left\{\mu_{A_i^n}\left(x_i^2\right)\right\}. \tag{1}$$

The output fuzzy set can be obtained by calculating the ignition level and the fuzzy rule posterior fuzzy set using the t-parametric operator. The final output fuzzy set B can be obtained by combining all the output fuzzy sets by t-residual van. To obtain the output clear value y, the output fuzzy set B needs to be defuzzied using a fuzzifier, and if the center of gravity fuzzifier is chosen, the output of the fuzzy logic system can be expressed as

$$y = \frac{\sum_{i=1}^{n} y_i \mu_B(y_i)}{\sum_{i=1}^{n} \mu_B(y_i)^2}. \tag{2}$$

The high computational effort and complex design process of general type-two fuzzy logic systems constrain

their application in control systems. In recent years, researchers in controller design have turned their attention to interval type-two fuzzy logic systems. The interval type-two fuzzy set A can be expressed as

$$A = \int_{x \in X} \int_{u \in J_x} (x, u).$$ (3)

When $f_x(\mu) = 1$, then the sub-subordinate function is an interval set, and if for both it holds, then the interval type-2 affiliation function (IT2MF, Interval Type-2 Membership Function) is obtained. The interval type-2 sub-subordinate function reflects the consistent uncertainty at the primary affiliation of x. Compared with the general type-two fuzzy logic system, the interval type-two fuzzy logic system greatly reduces the computational effort. Since interval type-two fuzzy sets also belong to type-two fuzzy sets, we can obtain

$$J_x = \{\mu \in [0, 1] | \mu_A(x, u) = 1\}.$$ (4)

In this paper, the center of sets type reducer is used to calculate the reduced type of the obtained ignition output set. Since both the antecedent and the consequent parts are interval type-two fuzzy sets, the obtained reduced typeset is still an interval set. The procedure of degenerate calculation: firstly, the output space Y is discretized into an appropriate number of points, and the center of gravity of the interval type-II fuzzy set of the posterior is calculated by the following equation:

$$C_{B_j^n} = \frac{\int_{\theta \in J_{y1}} \int_{u \in J_x} (x, u)}{\sum_{i=1}^{n} y_i \mu_B (y_i^2) \sum_{i=1}^{n} \mu_B (y_i^2)^2}.$$ (5)

To achieve the landing of the robot from the virtual prototype model to the real machine model, the first step that needs to be done is to draw a vector diagram for the real machine model. According to the size of the virtual prototype, the drawing size is marked on the vector diagram, and the commonly used drawing structure software for the drawing includes AutoCAD (Autodesk Computer-Aided Design) and CorelDRAW. In this article, we chose AutoCAD as the drawing tool. From equation (5), the center of gravity of the posterior interval type-II fuzzy set can be calculated in advance outside the control loop, which can reduce a large amount of computational burden for the control chip. The equation for the center-drop type of the set is

$$Y_{\cos} = \frac{\sum_{j=1}^{J} f^j}{\sum_{j=1}^{J} f^j y^j}.$$ (6)

Therefore, to calculate the center of the interval set $Y_{\cos}$, only its left endpoint y_l and right endpoint y_r need to be calculated. The calculation of the left and right endpoints is given by the following equation:

$$y_l = \frac{\sum_{j=1}^{L} f^j y^j - \sum_{j=L+1}^{J} f^j y^j}{\sum_{j=1}^{R} f^j},$$ (7)

$$y_r = \frac{\sum_{j=1}^{L} f^j y^j - \sum_{j=L+1}^{R} f^j y^j}{\sum_{j=1}^{J} f^j}.$$ (8)

The values of L and R in equations (7) and (8) are the values of the transition points needed to calculate the endpoint values, and the values of the left and right endpoints need to be calculated using the Karnik–Mendel (KM) algorithm. The design goal of the controller is to apply it to the trajectory tracking control of the Delta parallel robot and to provide a basis for subsequent research. The trajectory tracking control system of the Delta parallel robot uses three identical fuzzy logic controllers to control each of the robot's three servo motors. The demanded trajectory of the TCP is converted into the demanded angle of the drive joint by the kinematic inverse solution calculation and input to the demand trajectory of the TCP is converted into the demand angle of the drive joint by the kinematic inverse solution and input to the controller [20]. The input to the controller is the difference between the demand angle of the drive joint and the actual angle and its derivative. The T1FLC, which is the benchmark for the IT2FLC design, uses a type-one fuzzy set of trapezoidal affiliation functions as the antecedent and a type-one fuzzy set of triangular affiliation functions as the precedent.

The terms positive, negative, and zero used in the above fuzzy rules are expressed in the form of a type-one fuzzy affiliation function. The initial parameters of the type-one fuzzy set in T1FLC are empirically given artificially and adjusted to achieve a stable and continuous initial control performance of the robot system. The initial design of the input and output fuzzy sets applied to the trajectory tracking control of drive joint 1 is shown in Figure 3. The initial design structure of T1FLC for drive joint 2 and drive joint 3 is the same as that of drive joint 1.

Three types of IT2FLC are obtained using these three fuzzification methods, and these three types of IT2FLC are applied to the trajectory tracking control task of the Delta robot so that the TCP of the robot moves along the trajectory given by the following equation:

$$\begin{cases} x = 0.1 \cos(0.5\pi t + \pi) + 0.2, \\ y = 0.1 \sin(0.5\pi t + \pi), \\ z = 0.2547. \end{cases}$$ (9)

The fuzzy degree $\alpha \in [0, 1]$, which takes a value every 0.1, can construct one IT2FLC for each fuzzy degree value, and five trajectory tracking control simulations are performed for each constructed IT2FLC to reduce the statistical error of the simulation results. The root means square error (RMSE) values of the three joints obtained from the simulation are plotted as shown in Figure 4. It can be observed from the figure that the RMSE value increases with the increase of fuzziness, and the RMSE value obtained by the two-end fuzzy method is larger than the other two methods. The

reason for this phenomenon can be explained by Wu's work, when using the two-end fuzzy method, the FOU area produced by the same fuzzy degree is larger, and the larger FOU gives the fuzzy logic controller a larger damping characteristic. Robot control methods are divided into external command control and robot decision-making system automatic adjustment control. In the external command control, the robot needs to have a signal receiver that can communicate with the outside. The decision-making control requires the robot to be able to perceive the surrounding road conditions, audio, and video signal, etc. Increasing the damping characteristics of the controller can lead to more stable control performance, but it also causes a decrease in control accuracy. Therefore, the RMSE values obtained by using the two-terminal fuzzy method are larger than those obtained by the other two methods. The solution to the control accuracy degradation problem will be presented in the next section. In summary, since we need to obtain a controller with high nonlinear characteristics and smoother control performance, the IT2FLC obtained by the two-end fuzzy method is the structure of the type-two fuzzy logic controller that best meets the expectations of our control system characteristics.

The platform layer needs the driver layer and the algorithm layer to work together to complete the task. First, the platform layer receives the sensor signal of the driver layer. The quadruped robot has Bluetooth sensors and balance sensors on the body. The robot is always receiving multiple sensors during its movement. Signal, the robot system needs to fuse these sensor data and then realize the processing of different sensor data through the corresponding algorithm in the upper algorithm layer. The steering gear control interface is mainly to send the steering gear control signal to the actuator. This summary mainly tests the static gait walk state, as well as the dynamic gait trot state and backward motion and left-to-right turning motion of the robot dog proposed in this paper. The test environment was carried out on a smooth road to verify whether the motion pattern of the real machine and the motion gait based on Hop's oscillation model proposed in this paper are consistent, and the wake gait motion of the robot dog can be obtained through the video screenshots during the experiment. The robot dog can achieve a smooth and straight line, and the robot's walk state motion period T is 0.8 s, the step length of one cycle is 0.12 m, and the movement speed is 0.15 m/s through the test.

4. Analysis of Results

4.1. System Performance Results. A stable and effective interval type-II fuzzy logic control system can be designed using the dependent design method. Three simulation examples are used to investigate the control performance of the proposed SLIT2FNN controller. For comparative study, the conventional controller and the SLIT2FNN controller are connected separately to the Delta robot for trajectory tracking simulation experiments. The control goal is to make the TCP of the Delta parallel robot move along the given trajectory with as low as possible position and velocity errors

and achieve high trajectory tracking accuracy regardless of the internal and external uncertainties. The RMSE values of the angles of the three drive joints and the positions of the TCP in the workspace were recorded as the indexes for evaluating the control performance after the TCP of the robot ran along the trajectory given by equation (9) for one working cycle (8 seconds). The trajectory tracking errors of the drive joints and the TCP of the SLIT2FNN controller and the conventional PD controller are shown in Figure 5.

As we can observe in Figure 5, at the beginning of the simulation (about 1.7 s), the SLIT2FNN controller is in the process of learning the environmental dynamics, and the neural network adjusts its structural parameter values through the parameter self-learning algorithm, while the control signal is mainly provided by the PD controller in the parallel control structure. At the end of the neural network self-learning process, the IT2FNN replaces the conventional PD controller as the main control signal output in the parallel control structure, while the tracking accuracy of the robot is significantly improved as can be seen in the figure. The social interaction between man and machine will follow. Intelligent robots are a completely new product born in recent decades. Human-machine relationship and human-computer interaction are also a brand-new subject. The construction and understanding of human-computer social interaction is to help robots integrate into human and social systems.

A second simulation experiment is given to demonstrate more intuitively the learning process of the SLIT2FNN controller and the effect of parameter self-learning on the control performance. In this simulation, the same robot trajectory is used as in the first simulation, but the robot is required to run along this trajectory for two consecutive working cycles. In the first work cycle (8 seconds), only the conventional PD controller is involved in controlling the trajectory tracking of the robot. In the second work cycle, IT2FNN is connected in parallel to both sides of the PD controller to form a parallel control structure to complete the remaining trajectory tracking process. Figure 6 gives the output signals of IT2FNN and PD controller during this simulation experiment. It can be observed that when the IT2FNN is connected in parallel to both sides of the PD controller, the structural parameters of the IT2FNN start the self-learning process, and after the learning time of about 1.7 seconds, the output signal of the IT2FNN replaces the PD controller as the main output source of the control signal, which is the same as the result of Simulation 1. The above simulation results demonstrate the effect of the learning process of SLIT2FNN on the controller output and the improvement of the control accuracy in the second operating cycle with the parallel intelligent control structure.

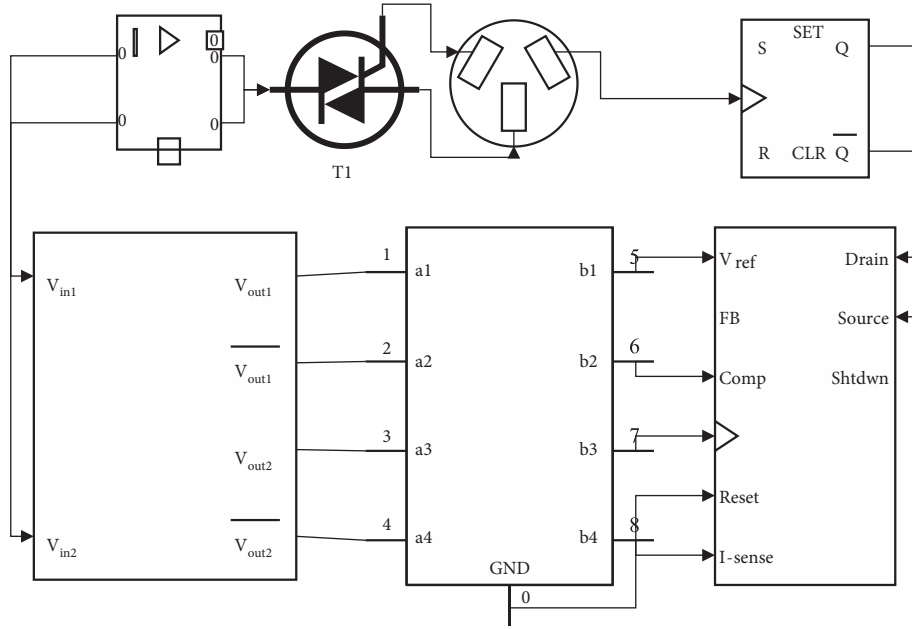
It is important to note that the SLIT2FNN controller proposed in this chapter does not require any information about the mathematical model of the controlled object. In practice, there are a variety of intrinsic and extrinsic uncertainty effects, and if the PD controller used by the robot is tuned for one operating environment to achieve optimal control, it does not mean that the same control quality can be obtained in other operating environments. It is impractical


FIGURE 3: Fuzzy logic control system for Delta's robot.
FIGURE 4: Trapezoidal affiliation function fuzzification method.

to perform optimal adjustment of PD control parameters for each case. Therefore, the parallel control system structure with self-learning capability proposed in this paper is of more practical value. This controller with parallel structure can not only provide the control effect of the corresponding PD controller when the neural network learns, but also make the control accuracy and robustness improvements to a great extent after the learning is completed and have higher environmental adaptability. At the same time, the parallel control structure proposed in this paper makes it easy to be applied to existing automation equipment and can greatly save hardware upgrade costs.

4.2. Neural Network Motion Results Analysis. To verify the optimized trajectory reuse algorithm, this section constructs the optimized trajectory database generated by the EFPF-PSO algorithm into a data index structure with two levels and six-leaf nodes using a vocabulary tree. Due to the limitation of the computer's computing power and time relationship, this algorithm only considers the case of 1 and 2 obstacles in the workspace, each database contains 180 sets of data, and the initial motion trajectory of the robot is set the same as before. This algorithm can generate corresponding optimized trajectory databases for specific application scenarios in practical applications and index the
FIGURE 5: TCP position error using a controller.

databases according to the actual situation by classification. Firstly, the EFPFDB of the optimized trajectory is clustered for the first time by K-mean clustering algorithm; considering the characteristics of the number of obstacles, here the classification value $K = 2$. The clustering centers of the first feature layer of the database are C1 and C2, as shown in Figure 7. The algorithm has obtained the relationship between the location features of obstacles by unsupervised learning, and the EFPF values are classified.

The RPSOMP method consists of a PSO-based motion trajectory optimization algorithm and an optimized trajectory reuse method. The input is the trajectory to be optimized, and its EFPF vector is calculated first, and the optimized trajectory adjustment with the highest similarity EFPF stored in the database is calculated by vocabulary tree query. The preliminary optimized trajectory after the query is obtained using equation (9), and if the obtained trajectory is a feasible solution, the obtained trajectory is directly used for motion planning as the output result. This paper uses the center of sets type reducer to reduce the type of the ignition output set obtained. Since the antecedents and consequents used in this paper are both interval type-two fuzzy sets, the reduced-type set obtained is still an interval set. If the obtained optimized trajectory is not a feasible solution, the optimized trajectory given by the algorithm is used to initialize the PSO particles. The adjustment amount of the query result trajectory is used as the mean value of the particle initialization distribution, and the value calculated from the query result is used as the standard deviation to initialize the particle positions of the PSO and perform the optimization calculation. Finally, the adjustment amount of the obtained optimized trajectory and the EFPF of its initial trajectory are stored in the corresponding database, and the optimized trajectory is output. The method flowchart of the RPSOMP method is shown in Figure 8.

From the analysis in Figure 8, RPSOMP converges faster than EFPF-PSO, taking only 0.43 seconds on average, which fully satisfies the requirements for trajectory optimization calculation in engineering applications. Meanwhile, it should be emphasized that, in practical applications, if the data volume of the optimization database is large and the database is designed for a specific problem, in most cases, the RPSOMP method does not require repetitive optimization calculations but can directly use the retrieval results to generate optimization trajectories. This can further improve the time to obtain the optimized trajectory to about 0.001 seconds and meet the demand of real-time trajectory optimization. Although the EFPF-PSO algorithm has a chance to obtain optimized trajectories with smaller fitness values, not every calculation converges to the minimum fitness value, and its standard deviation is relatively large. In contrast, the results obtained using the RPSOMP method are more stable, have smaller standard deviations, and converge faster. For the robot online collision detection problem, a simplified characterization method of robot and obstacle in space is proposed. Based on this, the robot trajectory optimization problem is investigated using the PSO-based motion trajectory optimization algorithm. The demand trajectory of TCP is converted into the demand angle of driving joints and input into the controller through the inverse kinematics calculation. The input of the controller is the difference between the required angle of the drive joint and the actual angle and its derivative. As the IT2FLC design benchmark, T1FLC uses a type 1 fuzzy set of trapezoidal membership function as the antecedent and a type 1 fuzzy set of triangular membership function as the subsequent piece.

5. Conclusion

This method is based on the optimized T1FLC, and the fuzzy degree is used to fuzzify the type-one fuzzy subordinate function into the interval type-two fuzzy subordinate function to obtain the IT2FLC. Three fuzzification methods for the trapezoidal subordinate function are studied, and the relationship between the fuzzy degree, the fuzzification method, and the output control surface is given. OSEC is used to ensure the control accuracy of IT2FLC after fuzzification, and the calculation and value of OSEC are given. A SLIT2FNN with a seven-layer structure is established, and a parallel intelligent controller based on SLIT2FNN is proposed on this basis. The transient performance during the learning process of the neural network can be compensated by the parallel PD controller, which makes it easy to upgrade the conventional controller. In the design of the front piece set of SLIT2FNN, the dual sequence symmetric trapezoidal affiliation function arrangement method is used to make the system's self-learning law and stability analysis in analytic form. In the design of the neural network self-learning law, a parameter self-learning algorithm based on the SMC theory is established to adjust the structural parameters of IT2FNN online. An industrial intelligent robot software system based on the robot operating system architecture is established, and the kinematic and dynamic models, mechanism parameter optimization algorithms, SLIT2FNN-based intelligent controller, and RPSOMP method are implemented based on this paper. Based on the research in this paper, the intelligent task planning module is further investigated to make the robot autonomous and capable of operating in unstructured spaces and environments and completing nondeterministic tasks online in real time.

Smart city gathers heterogeneous information, which requires a unified data access and collection mechanism. In this paper, based on the computing framework of IoT put forward to satisfy urban sensing network data acquisition, transmission, and computing technology system, according to the function requirements of IoT gateway, we put forward the method of building software system and hardware system and the urban perception network middleware architecture that can meet the demand of M2M, which can realize dynamic management of cognitive resources. It also supports ubiquitous services over HTTP. This is of great significance for providing intelligent services with diversity of solvers, controllers, and computing terminals. This paper focuses on how to comprehensively apply intelligent sensing, wireless transmission, data mining, and other technologies of the Internet of Things to associate data with typical application examples such as vehicle sensing and positioning technology and urban security sensor application. These typical applications can effectively solve the practical problems in urban operation and management, meet the needs of the expansion of the concept of Internet of things in urban management and the continuous deepening of management, and improve the scientific and intelligent level of urban operation and management.

1. Introduction

As the trading center and gathering center of human beings, city is the product. The emergence of cities is the symbol of human society entering the civilized era, and also the advanced form of human group life. The continuous acceleration of urbanization has led to the rapid increase of urban population, the rapid expansion of urban scale, and the continuous enhancement [1]. It improves the level of urban services and promotes the sustainable and leapfrog development of cities through comprehensive and transparent information perception, wide and safe information transmission, and intelligent and efficient information processing. In this way, a new form of urban development can be constructed, so that the city can automatically perceive and effectively make decisions and achieve control [2]. As the infrastructure of smart city, information technology is undoubtedly composed of the three most core technology hot spots of the Internet of Things, cloud computing, and data

association technology. In fact, these three technologies all belong to the general description of the platform including many technical branches. Internet of Things technology [3] is based on Radio Frequency Identification RFID and other sensing devices.

From the perspective of information technology, "wisdom city" intelligent information technology in the city has "four" characteristics: ubiquity, utility, intelligence, and greening [4]. (1) Ubiquity: the application of information technology is everywhere, people and nature, man and society, and nature and society are linked in the pan in the network information for smooth circulation and fusion. The network has become the basic production tool of the information society [5]. (2) Utility: the deployment, application, and management of IT infrastructure will be the same as those of water, electricity, and gas, with the principle of "centralized service, on-demand use, virtual ownership and easy to use" [6]. (3) Intelligence of infrastructure and its applications is more convenient. Information sharing

technology under data fusion and application system with intelligent perception and respect for user experience affect all aspects of people's lives. Smart city will shape the vision of a better life "benefiting everyone" [7]. (4) Flexibility: "ubiquitous information acquisition equipment; unimpeded information transmission channels; information sharing under security guarantee; powerful data processing centers; and intelligent software and services play more roles in urban operation than hardware production and manufacturing [8]. Concepts such as "smart Earth" and "smart city" have emerged. "Smart city" is a new urban form with learning, adaptation, and innovation capabilities. Based on the network integration of Internet of Things, telecommunication network, wireless network, and other networks, and using a variety of high-tech tools, it establishes an urban ecosystem including government, citizens, and commercial organizations [9]. It can be seen that the Internet of Things actually includes three entities: human, machine, and object. Intelligent devices are used to sense and acquire information about objects and their surroundings through recognition and perception technology [10], and then information and knowledge are transmitted through network transmission and communication technology and equipment. Finally, through the intelligent message retention, and knowledge processing technology and equipment to achieve intelligent management and control of objects or the physical world of a kind of "object perception, people interconnection, everyone interoperability" efficient, intelligent network, database and intelligent computing technology (including artificial neural network and evidence combination), standardization technology, etc. [11], literature [12] applies sensor data fusion technology to activity recognition in the field of smart home. Considering the advantages of intelligent computing, researchers gradually design and use intelligent algorithms to carry out data fusion research. For example, the improved particle swarm optimization algorithm is applied to fuse the multisensor information in the Internet of Things for precise measurement [13]. Based on the event-driven central point fusion algorithm, a fusion timing control mechanism based on differentiated services is proposed [14]. Cloud computing, comprehensive perception, intelligent computing analysis, ubiquitous connectivity, digitalization, information, and network of modern cities are new in recent years due to the integration and convergence [15]. The concept of "smart Earth" proposed by IBM elevated smart city construction into a national strategy [16]. Next, with wisdom city construction mainly aimed at people widespread concern in the construction of the city of urban traffic congestion, public security, network optimization deployment and nondestructive testing, digital city life, medical care, urban greening, and sudden disasters, etc. [17] make full use of the Internet of things technology in the intelligent sensing and comprehensive perception, information sharing, and service advantages, promote the improvement of modern social civilization and government management and service level, and comprehensively improve the happiness index of urban and rural residents [18, 19]. Through the construction of urban operation monitoring platform based on the Internet

of things, realize the combination of automatic and manual new regulatory model, effectively improve the government guarantee public security and the ability to deal with emergencies, maximum limit to prevent or reduce damage [20, 21], safeguard the life property safety of the public, safeguarding national security and social stability, and promote social economic comprehensive, harmonious, and sustainable development. The combination of the Internet of things and urban management is getting closer and closer. At present, there are application solutions of the Internet of things technology in urban management, environmental monitoring, logistics informatization, intelligent transportation, public security, and many other fields [22, 23], and demonstration work has been actively carried out in all aspects of the city [24].

This article first analyzes the metropolitan area network perception function definition and hierarchy, and then according to the data acquisition and exchange demand of the city of wisdom, this paper proposes a IoT gateway hardware and software of the system, then considers wisdom city service framework based on cloud computing, and discusses the design principle of metropolitan area perception network middleware and implementation method of the system architecture. Finally, the above main architecture is verified by performance test experiments. Using the theory of innovation and technology to build a series of specific function models, this part will analyze the diverse needs of construction of urban management wisdom, using the IFC standard, data mining, and text mining method, combined with a variety of emerging information technologies to achieve the extraction of submodels, definition, and integration, such as the generation process; this is part of the model to study further on. It is also a key link between the past and the future.

2. Key Technology System Architecture of Smart City Internet of Things Application Practice Model

2.1. Application Practice Model of Intelligent City Internet of Things Research Technical Framework. The technical architecture of a typical Internet of Things system includes three parts: perception layer, transmission layer, and application layer. This training system adopts typical architecture design, and the functions of each layer are as follows:

2.1.1. Perception Layer. Look for the training function, cultivating students perception layer function, the characteristics of a variety of sensors, detection methods, cognitive, and selection ability, for the application of single chip microcomputer (51 series and CC25xx series) programming ability, and the business requirements and the engineering application environment, according to the system planning of the node deployment method and the construction deployment according to specification.

2.1.2. Transport Layer. From the perspective of system composition and technical functions, and from the perspective of practical training function, the transmission layer

focuses on cultivating students' skills in the configuration and application of Internet of Things products, as well as the application development ability of SCM (CC25xx series) or embedded processor.

2.1.3. Application Layer. The smart City + IoT traffic scheduling system is used to monitor commuting at important traffic crossings (such as Bridges) and control the operating status of traffic lights at corresponding locations. The system composition is shown in Figure 1. Subsystem operation and lighting control subsystem, the user through a Web application software, set up bridge state of overload, the linkage of the road traffic status, traffic lights to run the action control parameters, collection and service software issued instructions according to requirements of the linkage control and feedback data, through a Web application software system running state.

The concept of smart city IoT standardization is based on the premise of urban IoT standardization informatization and the development of emerging information technology in China. It is an effective means to realize the whole life cycle management of construction projects, which can promote the optimization of urban IoT standardization related professionals and personnel and change the content and mode of construction project management. Innovation and integration of a variety of emerging information technology are the core of wisdom city of standardization of the Internet of things, but the wisdom city IoT standardization idea advocated is not only a collection of a large number of systems integration and information infrastructure, but also the whole life cycle of construction project management and multiple parties together, creating wisdom, integrated with the construction of human environment, providing convenient, efficient, and efficient project management methods. In order to achieve these goals, the concept of smart city IoT standardization emphasizes the establishment of anthropomorphic sensing, connectivity, and intelligence functions, as well as harmonious coexistence with the construction environment to achieve sustainable development of construction projects. Based on the above analysis, the conceptual model of IoT standardization concept of smart city is obtained, and the causes, management objectives, main features, and realization mechanism of IOT standardization concept of smart city are revealed.

3. Internet of Things Contributes to the Refined Model and Key Technologies of Urban Management

Effective supervision of movable objects (breakfast carts, newsstands, etc.) and frequently changed objects (advertisements, plaques, etc., of shops on both sides of the street) can make full use of radio Frequency Identification (RFID) tag positioning technology, the core technology of the Internet of Things. The legal and compliant supervision objects shall be installed with identifiable electronic tags. The vehicle-mounted monitoring and law enforcement system is established based on the integrated supervision functions of

base stations, panoramic cameras, and other equipment to realize vehicle-mounted patrol, automatic perception, real-time positioning, and rapid investigation and evidence collection of supervised objects and improve the efficiency and intelligence level of management. The supervision mode is shown in Figure 2.

With the continuous improvement of people's living standard, city parks, temple fairs, or the famous tourist attractions such as area in a particular time period (such as holidays or during certain activities frequently, people "blowout" phenomenon, it also makes the crowds gathered risk further ascension and increased security hidden danger, and the crowd safety management difficulty also will increase. Traditional management mainly adopts the way of on-site monitoring with a large number of manpower, but it can only play the role of alarm disposal and lacks the prediction and early warning of crowd gathering risk.

$$f_p = \min \sum_d \frac{D_J}{P}. \tag{1}$$

(1) In the multiobjective optimization model, both models have shortcomings in measuring progress in improving optimization. Multiobjective Selection Based on Dominated Hypervolume (SCPIMM) model showed better performance and optimized results for different front shapes.

(2) According to the group based chain coding method, the parent individuals were initialized to generate a parent population of size N, and the fitness of individuals in the population was evaluated.

(3) A rapid nondominant ranking was carried out on the evaluated parent population to classify the dominant rank of individuals in the population.

(4) Population evolution operation: the algorithm adopts the tournament selection method of two parent individuals selected from the population, and to improve the two parent individuals type single point cross to generate a hybrid individuals, and then to intelligent hybrid individual variations, get a child individual, pair the last individual fitness evaluation, and add the individual child population pool. Repeat this process until the subpopulation size is N.

(5) Optimal N individuals were selected as the next generation parent population by using hypervolume-based population renewal mechanism for parent population and child population.

4. Information Model Construction of Intelligent City Internet of Things

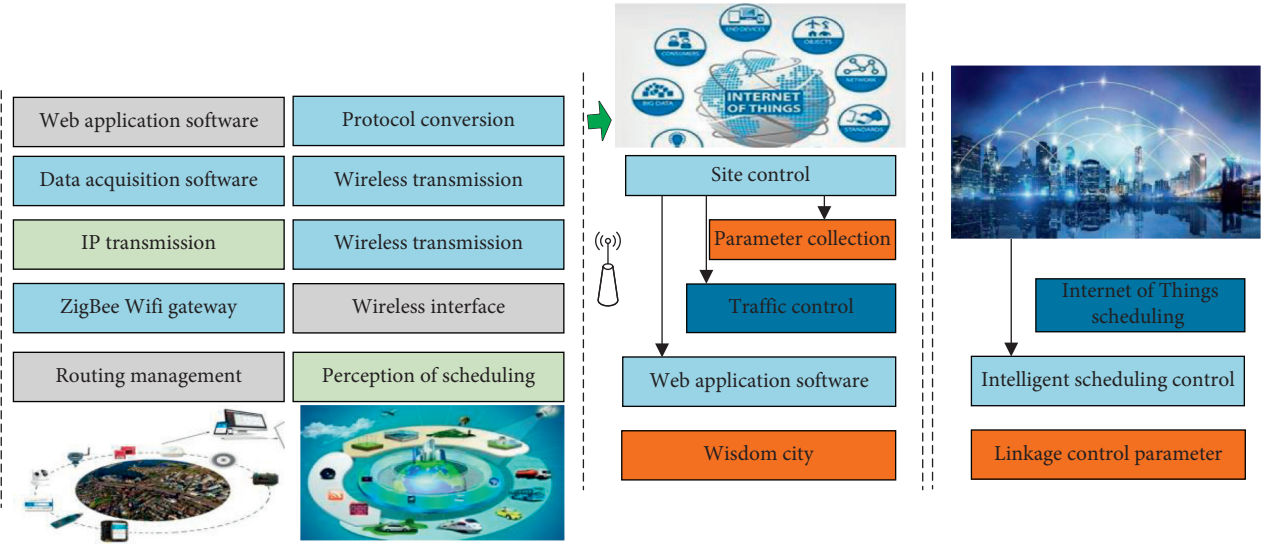
The modeling process should reflect the main features of the standardization concept of the Intelligent city Internet of Things, integrate a variety of emerging information technologies into the model, and meet the needs of modern construction project information management. SCPIMM can not only meet the individual needs of different participants in the process of construction project management


Figure 1: Block diagram of smart city + Internet of Things traffic scheduling control system.
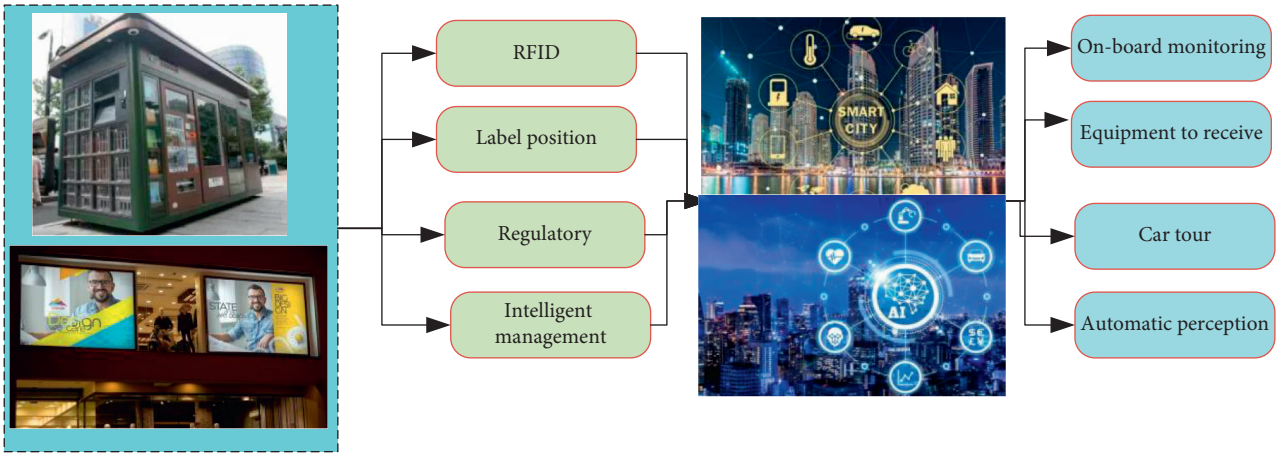

Figure 2: Schematic diagram of vehicle-mounted monitoring law enforcement methods.

for information management, but also realize the effective management and control of the whole life cycle information and improve the efficiency and level of construction project information management. The basic framework structure of SCPIMM proposed in this paper is shown in Figure 3.

(1) Data layer can be divided into structured, unstructured, and process information according to the structural characteristics of construction project information. For different information structures, SCPIMM has established three kinds of databases to realize classified storage and management: the storage and management of structured information are carried out through the structured information database constructed by the model. The unstructured information is stored and managed through the unstructured information database constructed by the model by establishing the link relationship between the model and the document. The process information of construction project is stored and managed by process information database according

to the principle of mapping. According to the characteristics and practical experience of SCPIMM, the model database serves as the carrier and storage terminal of project information and takes information exchange interface and middleware technology as the key to process and process heterogeneous information, providing support for other levels of the model.

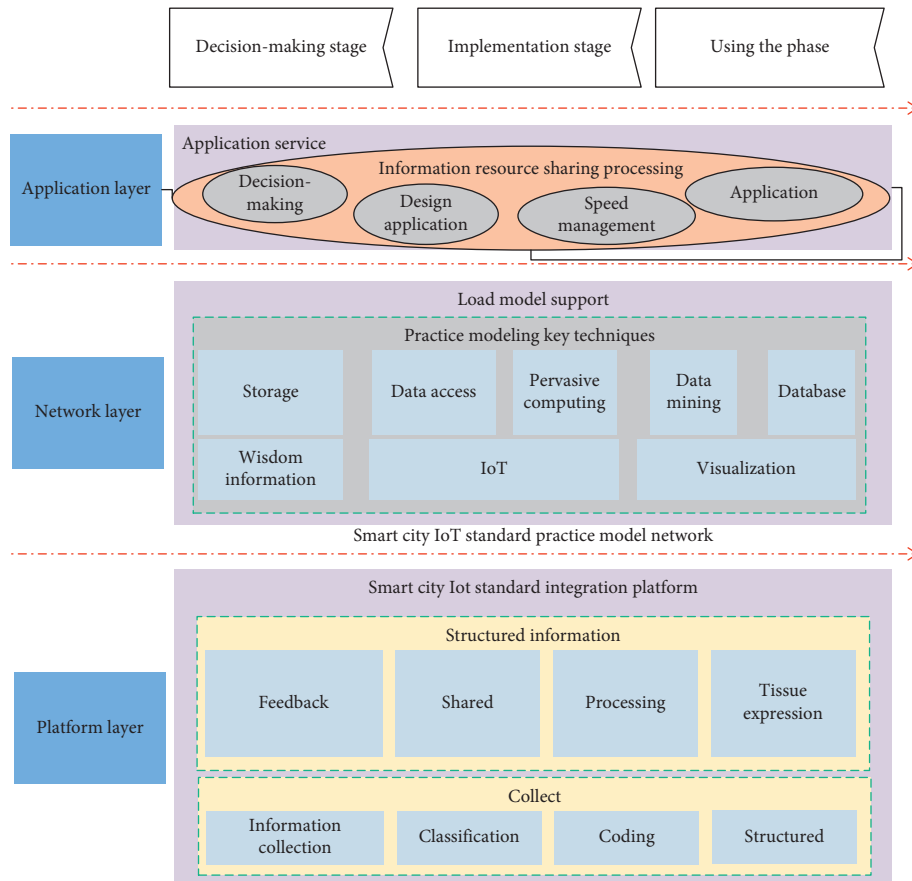
(2) In the process of construction project information management, the platform layer uses sensors and information perception technology to build an information management platform with perceptive ability and real-time information interaction, so as to realize the collection and monitoring of construction project information resources and complete the information management work of the whole life cycle of the model. The platform layer of the model is composed of a variety of sensors, generally including HD camera, concentration sensor, temperature and humidity sensor, two-dimensional code label, radio


FIGURE 3: Main frame of IoT standardization information model for smart city.

frequency label reader, GPS, and other sensing terminal devices. According to different stages and applications of the whole life cycle of construction, the platform layer can classify and encode all the collected information and process the information according to structured, unstructured, and process information classification.

(3) The network layer of the network layer model can obtain and process the information provided by the platform layer and build a network system by utilizing high-performance computing, data mining, visual management, and other functions provided by emerging information technologies such as the Internet of Things, ubiquitous computing, and 4D visualization. Its core capability is the transmission and processing of information. Information network construction, based on the technology of Internet of things, can be achieved from a single project to the whole construction project information management of specific equipment, the whole process of information interaction, from the construction project detailed information to the terminal transmission path through the network, sensor, information storage database, to the network infrastructure, realizing information sharing and interaction.

(4) The application layer of the application layer model uses a variety of emerging information technologies to form a whole-process intelligent information management process from event prediction to decision assistance and emergency linkage and to create a comprehensive management system of information collection, classification and coding, organization and expression, processing and processing and transmission, sharing, and feedback. The application layer of the model is composed of application software with different functions, including investment analysis, architectural design, structural design, cost management, schedule control, quality control, safety management, and energy consumption analysis. The application layer of the model is the interface between the network layer and the user, which combines with the user's needs and adopts P2P access mechanism based on the network topology structure to provide different services for different participants.

The design of information extraction mechanism is the premise of submodel construction, which is directly related to the efficiency of information management of construction projects. The main purpose of information extraction is to obtain the information sample similar to the information needed at present. In this paper, the submodel information

extraction mechanism is designed according to the similarity principle. The following three methods are adopted to define the similarity between the target and the sample in the extraction process.

(1) Similarity between information is defined by Euclidean distance P.

$$d_p = \sum_i W_i (p_{\text{ok}} - p_i)^2. \tag{2}$$

(2) Similarity of information is defined by Manhattan distance.

$$d_p = \sum_P W_p |p_{\text{ik}} - p_i|. \tag{3}$$

(3) Similarity between information is defined by infinite modulus distance.

$$d_p = \max W_i |p_{\text{ik}} - p_i|. \tag{4}$$

In the information preparation stage of the submodel, massive construction project information should be preprocessed by stem extraction (Stemming, stem segmentation, stop words removed, punctuation deleted, etc.). For English, stem should be extracted, and nouns, adjectives, conjunctions, and adverbs should be taken as feature items. For Chinese stem segmentation, namely, word segmentation, specific word segmentation techniques include maximum matching, reverse maximum matching, and traversal one by one. The feature items after word segmentation should be processed by dimensionality reduction, that is, selecting the required feature items f to form a set N.

$$p(d, t) = \frac{\lg(d, f)(N/n_j)}{\sqrt{\sum (d, t)^2 \lg(N/n)^2}}. \tag{5}$$

The application layer of associated data is mainly composed of Resource Description Framework (RDF) triplet evaluation, data visualization, semantic query and browsing, personalized information push, and other modules. First, the associated data automatically generated by the system is input to the application layer from the data storage and index layer. In RDF triplet evaluation module, experts and users score automatically generated relational data. The associated data retained after evaluation is displayed in the data visualization module through API isoform. For semantic query, browsing and other requirements in the application, semantic query, and Tabulator plug-in in browsing module can be realized. In addition, the personalized information push module is responsible for pushing the content that users may be interested in according to customized information.

5. Results and Analysis

The historical monitoring data accumulated by thousands of sensors in cities during the civil period can be an important part of the big data of flood control monitoring. On the basis

of full investigation and investigation, special analysis of monitoring data and related data of other cities in the same period was carried out to find the consistency, concurrency, and derivative relationships among them, find the spatial distribution rules, and put forward scientific and reliable suggestions to better support flood control and emergency response work. For example, based on rainfall monitoring data, corresponding flood control risk assessment and early warning models can be established, and data mining and other means can be used to further improve the ability to master the law between rainfall and urban management cases, so as to realize the refinement of daily urban management related to flood control. Figure 4 shows the analysis results of significant correlation between rainfall monitoring data and some types of management cases.

In terms of enabling the number of physical nodes, the number of physical nodes occupied by SCPIMM-based VM (Virtual Machine) deployment algorithm is almost the same as that occupied by CGA-based VM deployment algorithm and is smaller than that occupied by the priority matching heuristic (PMH) deployment algorithm, physical nodes. The smaller the number of tablets, the more the energy saving. In terms of the overall cluster load performance, the overall cluster load variances of the SCPIMM-based VM deployment algorithm are smaller than those of the two VM deployment algorithms. The smaller the load variances are, the better the load balancing effect of the server cluster is. Based on the above analysis; see Figures 5 and 6.

To compare the network performance of the Structure-Conduct-Performance Interacting Multiple Model (SCPIMM) protocol with that of Low Energy Adaptive Clustering Hierarchy (LEACH) and SCPIMM, we first compare the clustering formed by the three protocols, as shown in Figure 7. It can be seen from the figure that the number of clusters formed by LEACH is too large, which is caused by the randomness of the selection of cluster heads. In LEACH, each sensor node decides whether to become a cluster head according to a certain probability, which has a strong randomness. The clustering formed by SCPIMM is better than that formed by LEACH, but it is different in size compared with SCPIMM. This is because the SCPIMM give full consideration to the state of the network to determine the optimal number of cluster heads, and then according to the residual energy of nodes, the distance between nodes and the distance between nodes and base stations to determine the optimal selection of cluster heads, thus forming clumps and uniform distribution, keep the optimal number of cluster heads, reduce the energy consumption of network, and improve the performance of the system.

The data received by the base station (sink node) is shown in Figure 8. We can see from the table that the proposed SCPIMM can receive more data, because we consider the residual energy of nodes when clustering, within the cluster distance and the distance with the base station, effectively reducing the energy consumption and reducing the amount of data transmission delay and improving the efficiency of data transmission, to send more data to base station. However, LEACH does not consider factors such as the remaining energy of nodes when
Figure 4: Correlation analysis of intelligent city IoT rainfall monitoring data and urban management case data.

clustering and randomly selects nodes as cluster heads. It is possible to select nodes whose energy is about to run out as cluster heads, resulting in data loss. Although SCPIMM considers residual energy and other factors when clustering, the optimal number of cluster heads does not change with the network state, and the influence of the distance between cluster heads and base station is not taken into account.

Based on the overall construction mode of smart city informatization service system, integrated Internet of Things construction mode, cloud computing construction mode, and intelligent infrastructure construction mode, and combined with the application demand of smart city people in smart city construction, the construction mode of smart city is explored and analyzed.

According to the effective data collected from the questionnaire, overall, smart city citizens have higher demands for smart government, smart environment, smart medical treatment, smart transportation, and smart family in smart city construction, while their demands for smart energy and smart logistics are relatively low. See Figure 9.

At the same time, from the point of view of intelligence security data, security is also a matter of great concern to the public, from the point of view of data, and the average score of security demand is 3.36 points. Among them, citizens' demands for early warning of natural disasters and emergency response of major emergencies account for a large proportion, accounting for 21% and 20%, respectively, as shown in Figure 10. The reason may be that the disasters such as earthquake, tsunami, and fire that have occurred in recent years are more serious, which make citizens have a kind of panic in psychology. They hope to take corresponding measures in the early warning of natural disasters and emergency response in case of major emergencies to avoid heavy costs. However, they did not pay much attention to the information tracking of registered population and permanent resident population, indicating that the citizens of smart cities can accommodate floating population, and the informatization of population and family planning in smart cities is also relatively good. Covering the food and drug traceability system, citizens are more concerned with the quality of the food and drug problems frequently recently, and also it is also a concern that citizens using the sensor monitoring food and drug trace the source of wisdom city that can be in shopping malls and supermarkets to
Figure 5: Schematic diagram of enabling physical node number.

install HD probe for video surveillance, clearly photographing food stand in front of the person's face, to prevent the poisoning of food and drugs.

The physical equipment layer is the infrastructure of a smart city, including access control devices, attendance devices, consumer machines, parking gates, and wireless sensor networks for sensing environmental changes. All devices access the information system of the data center through the Internet of Things gateway and communicate with the device abstraction layer of the intelligent building information system middleware. Middleware includes common service layer, sensor network management layer
FIGURE 9: Application requirements of smart city construction.
FIGURE 10: Intelligent security function requirements.

and application service layer. The sensor NMS topology consists of configuration services and abstraction layers. Topology and configuration services mainly realize the correspondence between physical space location of physical devices and information space location, and the interface of abstraction layer realizes the standardization of physical device access. The common service layer contains logging services, database services, and security services. The application service layer provides HTTP-based Web interfaces and local API interfaces for various applications.

6. Conclusion

At present, the urban management mode has undergone the transformation from digitalization and grid to urban operation, and its management direction is facing the development from digitalization to intelligence. These higher requirements for urban management and service work make the urban management must be based on the requirement of the people's fundamental starting point, adhering to the people-oriented, service for the people, to keep pace, through technology and management innovation to promote urban management work to a new level, to facilitate better break through the limitations of time and place, so that the people feel the role of urban management, enjoying the achievements of urban management. As an emerging technology integration means, Internet of Things technology can be applied in monitoring, transmission, analysis, and application of urban operation management information due to its characteristics of "intelligent identification, positioning, tracking, monitoring, and management" and has gradually become a bridge between "digital city" and "smart city." It will be the ultimate goal and strategic direction of urban informatization to establish an intelligent and refined management mode of the city. As a breakthrough of the bottleneck of sustainable development of the city, it will bring a new look of the city in the future and promote the harmonious development of the city. In the next step, the Internet of Things application middleware needs to improve the design of loose integration with the upper application, adapt to sensor equipment more widely, and unify data

standards; the improved data compression algorithm needs to be further improved in the actual environment and system.

Forecasting regional economic activity is a progressively significant element of regional economic research. Regional economic prediction can directly assist local, national, and subnational policymakers. Regional economic activity forecast can be employed for defining macroeconomic forces, such as prediction of stock market and cyclicality of national labor market movement. The recent advances of machine learning (ML) models can be employed to solve the time series prediction problem. Since the parameters involved in the ML model considerably influence the performance, the parameter tuning process also becomes essential. With this motivation, this study develops a quasioppositional cuckoo search algorithm (QOCSA) with a nonlinear support vector machine (SVM)-based prediction model, called QOCSO-NLSVM for regional economic prediction. The goal of the QOCSO-NLSVM technique is to identify the present regional economic status. The QOCSO-NLSVM technique has different stages such as clustering, preprocessing, prediction, and optimization. Besides, the QOCSO-NLSVM technique employs the density-based clustering algorithm (DBSCAN) to determine identical states depending upon the per capita NSDP growth trends and socio-economic-demographic features in a state. Moreover, the NLSVM model is employed for the time series prediction process and the parameters involved in it are optimally tuned by the use of the QOCSO algorithm. To showcase the effective performance of the QOCSO-NLSVM technique, a wide range of simulations take place using regional economic data. To determine the current economic situation in a region, the QOCSO-NLSVM technique is used. The simulation results reported the better performance of the QOCSO-NLSVM technique over recent approaches. The QOCSO-NLSVM technique generated effective results with a minimal mean square error of 70.548 or greater. Astonishingly good results were obtained using the QOCSO-NLSVM approach, which had the lowest root mean square error (RMSE) of 8.399.

1. Introduction

The forecasting method predicts future value based on a provided time series data set by making assumptions on future trends and estimating historical data. This is employed for several regions of the decision-making process, like industrial process control, risk management, operations management, demography, and economics [1]. Forecasting is an important problem spanning several domains, involving finance, social science, government, economics, environmental science, politics, medicine, business, and industry. The forecasting problem is categorized as long-term, short-term, and medium-term [2, 3].

Forecasting regional economic activity is an essential component of regional economic study. The regional

economic prediction could directly assist business executives, local, subnational, and national policymakers. These two business executives and policymakers require precise prediction of key economic aggregates, namely, employment, output, and income for medium-long term planning purposes [4]. Regional economic activity forecasts have been employed for explaining macroeconomic forces, involving the cyclicality of national labour market movements and predicting the stock market. Further, multinational agencies and international investors engaged in megaprojects at a regional level also require precise predictions for investment planning reasons [5]. When there is no paucity of research on predicting national economic indicators, the research on regional economic prediction is limited for innovative economies, and in the case of developing nations, zilch [6].

Problems with short-term forecasting are those that deal with predicting events in a shorter period of time (months, days, and weeks). Forecasting concerns could go much beyond 1-2 years into the future, with medium-term forecasts extending into the future as well.

The forecasting method connected to economic problems is utilized for predicting economic variables in several countries. The industry volatility prediction, critical to several important problems in business [7], and the prediction of the unemployment rates that define the country's economic and social development [8, 9]. Radial basis function networks (RBF) and backpropagation are the ANN architectures that are used in economic fields. The artificial neural networks (ANN) technique was broadly examined in economic analysis. The ANN is a computation system that is performed in hardware or software under the effect of biological studies about the human brain. Several authors admit that the ANN method is the better performing nonlinear analysis technique as well as one of the best predictors [10]. The ANN architecture employed in economic fields is radial basis function networks (RBF) and backpropagation.

This study designs a quasioppositional cuckoo search algorithm (QOCSA) with a nonlinear support vector machine (SVM)-based prediction model, called QOCSO-NLSVM for regional economic prediction. The QOCSO-NLSVM technique involves the design of the density-based clustering algorithm (DBSCAN) to determine the identical states depending upon the per capita NSDP growth trends and socioeconomic-demographic features in a state. Besides, the NLSVM model is elected for the time series prediction process and the parameters involved in it are optimally tuned by the use of the QOCSO algorithm. The experimental validation of the QOCSO-NLSVM technique and the results are examined in various aspects.

The rest of the research work is organized as follows. Section 2 provides the recently developed techniques, Section 3 elaborates the QOCSO-NLSVM technique. Then, Section 4 provides the performance validation, and Section 5 concludes the outcomes of the research.

2. Literature Review

Mishra and Ayyub [11] introduced a DL architecture in which the hierarchical clustering analysis (HCA) is utilized for predicting growth. The presented method comprises HCA and DTW techniques that are initially applied for identifying similar socio-economic-demographic features within a provided state and similar states according to per capita NSDP growth trends, to create a fine-tuned training dataset for predicting all the states' NSDP per capita growth. Lv et al. [12] developed a LightGBM-enhanced LSTM for realizing stock price prediction, and LSTM is utilized for predicting the Shenzhen and Shanghai 300 indexes, respectively. The simulation result shows that the LightGBM-LSTM has a better capacity for tracking stock index price trends and the maximum prediction performance, and its effects are superior to the RNN and GRU methods. LightGBM-optimized LSTM for short-term stock price

forecasting. To compare its performance with other deep network models such as RNN (recurrent neural network) and GRU (gated recurrent unit), the LightGBM-LSTM, RNN, and GRU are used to predict the Shanghai and Shenzhen 300 indexes, respectively. Experiment results demonstrate that the LightGBM-LSTM has the highest prediction accuracy and the best ability to track stock index price trends.

Zhu et al. [13] designed an experiment whose samples originated from information on 7 quoted core enterprises (CEs) and 46 quoted SMEs in the Chinese security markets. Matta et al. [14] introduced a relative assessment of various prediction techniques using the Gaussian process regression and ANN methods (MLP and RBFNN). Two real-time datasets were utilized for evaluating the prediction method presented in the study. These datasets were normalized to values amongst one and zero. Next, the data training was implemented and, when it was constructed, a system was utilized for generating the predictions. Therefore, observations were made to validate how precisely the fitted method predicts the values.

Chatzis et al. [15] integrated distinct ML methods that were proposed with daily currency, stock, and bond data from thirty-nine countries that cover a larger spectrum of economies. It especially leverages the advantages of a sequence of techniques that includes Classifier Trees, SVM, NN, RF, XGBoost, and DNN. Sun et al. [16] verified the cointegration relationships and Granger causality between tourist arrivals in Beijing and the internet search index. This experiment result suggests that compared to standard methods, the presented KELM model that incorporates tourist volume series with Google and Baidu Index could significantly enhance the prediction performances in terms of robustness analysis and forecasting accuracy.

3. The Proposed Model

In this study, an effective QOCSO-NLSVM technique has been developed for regional economic prediction. The QOCSO-NLSVM technique encompasses several subprocesses, namely, DTW-based preprocessing, DBSCAN-based clustering, NLSVM-based prediction, and QOCSO-based parameter optimization. Figure 1 illustrates the overall working process of the QOCSO-NLSVM technique.

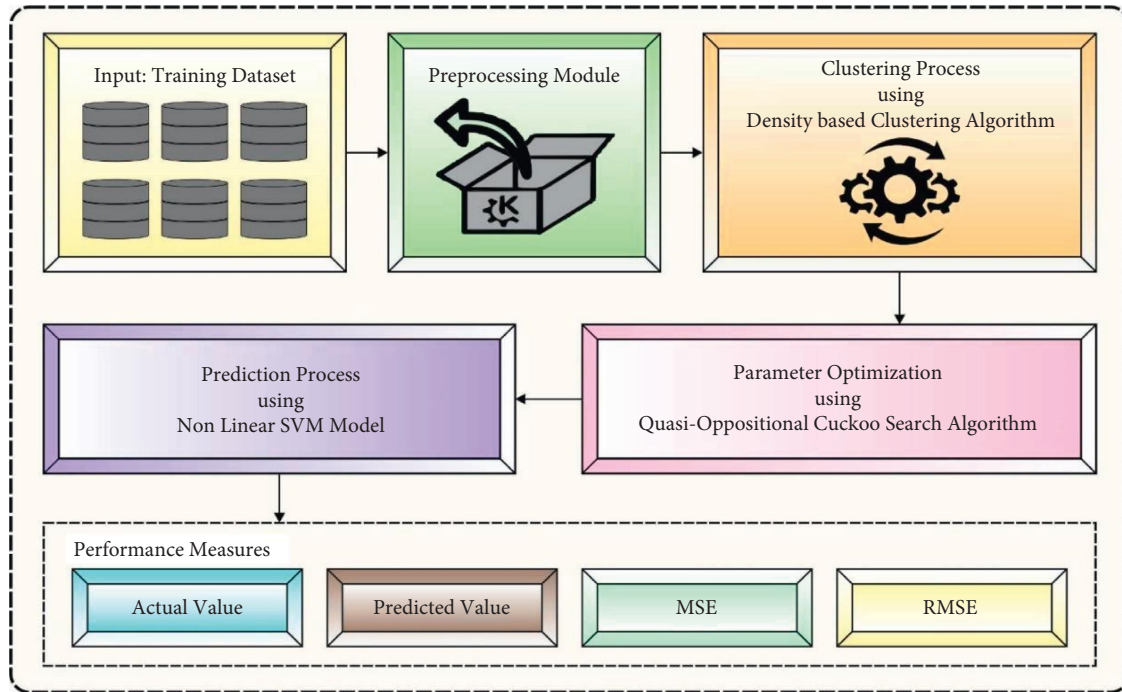
3.1. Data Preprocessing. One of the primary methods used to capture similarities among two regions, or among pairs of factors within a provided region according to time-series data is named dynamic time warping (DTW). DTW is an effective method utilized for learning similarity based on distance between two sequences that might differ in speed and quantifying time-based similarities among any two pairs. Generally, DTW is an ML method which estimates an optimum match between two provided sequences with some restrictions. The sequence is "warped" nonlinearly in the time dimension to define measures of their similarity, independent of nonlinear variation in the time dimension. The Euclidean distance uses the distance among every pair of the


FIGURE 1: System architecture of the QOCSO-NLSVM method.

time series and compares it with the Euclidean distance. Simultaneously, the DTW searches for optimal alignments among the two-time series. Furthermore, all the points are utilized for comparing the points to make the best possible alignments among the two-time series according to their distance matrix.

3.2. Process Involved in the DBSCAN Technique.

DBSCAN might find distinct clusters based on the assessed density distribution. It could recognise structured groupings without knowing their numbers. The following illustrates DBSCAN's basic premise: DBSCAN finds each point in the neighbourhood of a random unvisited point p, where it denotes the neighbourhood's maximum radius from p. To construct a dense zone, MinPts is the minimum number of points required. When MinPts is in the distance, p denotes a core point. When p is a core point, all points in its vicinity are grouped together. DBSCAN detects each density-reachable point in the cluster and adds it to a comparable cluster. When a point q is densely approachable from other core points but its neighbourhood is less than MinPts, it is a border point. An outlier or noisy point is one that is not accessible from other locations. DBSCAN achieves clustering by extracting clusters consecutively. Rep until no more density-reachable points are identified, and the final cluster is reached. DBSCAN divides a set of points into low-noise border points and high-density. The purpose of DBSCAN is to identify identical states based on a state's per capita NSDP growth trends and socioeconomic-demographic characteristics. DBSCAN was capable of detecting a variety of clusters based on the density distribution that was assessed. The DBSCAN methodology permits the calculation of identical states based on per capita income.

Assume two points x and y, $d(x, y)$ represent the similarities among them, $\Gamma\varepsilon(x)$ denotes the ε-neighbourhood of x, in which $\Gamma\varepsilon(x) = \{y \in V | d(x, y) \leq \varepsilon\} \cdot \rho(x) = |\Gamma\varepsilon(x)|$ indicates the density value of x:

$$S(x) = \begin{cases} 1, & \text{core point with } \rho(x) \geq \text{MinPts}, \\ 0, & \text{border point with } 1 < \rho(x) < \text{MinPts}, \\ -1, & \text{noise with } \rho(x) = 1. \end{cases} \quad (1)$$

3.3. Structure of the NLSVM Model.

During the prediction process, the NLSVM model receives the clustered data as input to predict the output. Assume a trained set $\{x_k, y_k\}_{k=1}^{N}$ with input data $x_k \in \mathbb{R}^n$ and respective binary class label $y_k \in \{-1, +1\}$, the SVM classification initiates from the subsequent assumption:

$$\begin{cases} w^T\varphi(x_k) + b \geq +1, & \text{if } y_k = +1, \\ w^T\varphi(x_k) + b \leq -1, & \text{if } y_k = -1. \end{cases} \quad (2)$$

That is equal to

$$y_k[w^T\varphi(x_k) + b] \geq 1, \quad k = 1, \ldots, N. \quad (3)$$

Now, the nonlinear function $\varphi(\cdot): \mathbb{R}^n \longrightarrow \mathbb{R}^{n_h}$ maps the input space to a high-dimensional feature space. It is noteworthy that the n_h dimension of this space is determined in an implicit manner (it is an infinite dimension). The b represent a bias as follows:

$$y(x) = \text{sign}[w^T\varphi(x) + b]. \quad (4)$$

But, at the same time, it is never evaluated in this form. One determines the optimization issue:

$$\min \mathscr{J}(w, \xi) = \frac{1}{2} w^T w + c \sum_{k=1}^{N} \xi_k, \qquad (5)$$

subjected to

$$\begin{cases} y_k \left[w^T \varphi(x_k) + b \right] \geq 1 - \xi_k, & k = 1, \ldots, N, \\ \xi_k \geq 0, & k = 1, \ldots, N. \end{cases} \qquad (6)$$

To permit misclassification in the subset of inequalities (because of overlapping distribution), the minimalization of $\|w\|_2$ corresponds to a maximalization of the margin among the two classes. c indicates a positive real constant and must be taken into account as a tuning parameter. The Lagrangian can be expressed as follows [17]:

$$L(w, b, \xi; \alpha, \nu) = \mathscr{J}(w, \xi) - \sum_{k=1}^{N} \alpha_k$$

$$\left\{ y_k \left[w^T \varphi(x_k) + b \right] - 1 + \xi_k \right\} - \sum_{k=1}^{N} \nu_k \xi_k. \qquad (7)$$

The Lagrange multiplier is $\alpha_k \geq 0, \nu_k \geq 0, (k = 1, N)$. Figure 2 depicts the SVM hyperplane. It is familiar from the optimization concept that the solutions are considered by the saddle points of the Lagrangian:

$$\max_{\alpha, \nu} \min_{w, b, \xi} \mathscr{L}(w, b, \xi; \alpha, \nu). \qquad (8)$$

One attains

$$\begin{cases} \dfrac{\partial L}{\partial w} = 0 \longrightarrow w = \displaystyle\sum_{k=1}^{N} \alpha_k y_k \varphi(x_k), \\ \\ \dfrac{\partial L}{\partial b} = 0 \longrightarrow \displaystyle\sum_{k=1}^{N} \alpha_k y_k = 0, \\ \\ \dfrac{\partial L}{\partial \xi_k} = 0 \longrightarrow 0 \leq \alpha_k \leq c, \quad k = 1, \ldots, N. \end{cases} \qquad (9)$$

By substituting w in the Lagrangian, one attains the subsequent binary problems (in the Lagrange multiplier α), i.e., the quadratic programming problems:

$$\max_{\alpha} \mathcal{Q}(\alpha) = -\frac{1}{2} \sum_{k,l=1}^{N} y_k y_l K(x_k, x_l) \alpha_k \alpha_l + \sum_{k=1}^{N} \alpha_k. \qquad (10)$$

Thus,

$$\begin{cases} \displaystyle\sum_{k=1}^{N} \alpha_k y_k = 0, \\ 0 \leq \alpha_k \leq c, \quad k = 1, \ldots, N. \end{cases} \qquad (11)$$

Now w and $\varphi(x_k)$ are not estimated. According to the Mercer condition, one takes a kernel as

$$K(x_k, x_l) = \varphi(x_k)^T \varphi(x_l). \qquad (12)$$
Figure 2: SVM hyperplane.

Lastly, in binary space, the nonlinear SVM classifiers become

$$y(x) = \text{sign} \left[\sum_{k=1}^{N} \alpha_k y_k K(x, x_k) + b \right]. \qquad (13)$$

α_k is a positive real constant, and b is a real constant. The nonzero Lagrange multiplier α_k is known as support value. The respective data point is known as a support vector and is placed near the decision boundary. This is the data point that contributes to the classification method. The bias b follows from the KKT condition that isn't considered further.

Various selections for the kernel $K(\cdot, \cdot)$ are feasible.

(i) $K(x, x_k) = x_k^T x$ (linear SVM)
(ii) $K(x, x_k) = (x_k^T x + 1)^d$ (polynomial SVM of degree d)
(iii) $K(x, x_k) = \exp\left\{ -\|x - x_k\|_2^2 / \sigma^2 \right\}$ (RBF kemel)
(iv) $K(x, x_k) = \tanh(\kappa x_k^T x + \theta)$ (MLP SVM)

The Mercer conditions hold for each σ value in the RBF case, but not for each feasible selection of κ, θ in the MLP case. In the case of an MLP or RBF kernel, the amount of hidden units corresponds to the number of support vectors.

3.4. Design of the QOCSO Algorithm for Parameter Tuning.

For optimally tuning the weight values of the NLSVM model, the QOCSO algorithm is utilized. The CSO algorithm is assumed as a metaheuristic technique that was primarily established by Yang and Deb [18]. Actually, this CSO method simulates the breeding performance of cuckoo birds that are supposed to be a type of parasitism. The cuckoo birds place their eggs from other nests and play to host the egg. The cuckoo birds attempt for raising the hatch possibility of their individual eggs by generating them the same as

```
Begin.
    Objective functions of f(x), x = (x1, x2, ..., xd)T
    Populations initialization of n host nests xi,
    While (t < Maximum_iteration) or (termination condition)
        Get a cuckoo arbitrarily via Lévy flight
        Determine the qualities/fitness as Fi
        Select nest amongst (n, j) arbitrarily
    If (Fi ≥ Fj),
        Substitute j in newly attained solution;
    End
        An fraction (pa), poor nests are discarded and new one is derived;
        Retain optimal solution, (with quality solution);
        Sort the solutions and determine current best
    End
    Postprocess and visualize results
End
```

ALGORITHM 1: Pseudocode of the CSO algorithm.

2013	17037.957	17134.99	17056.94	17098.97	17102.96	17028.95
2014	17675.816	17767.80	17563.80	17820.81	17781.81	17734.82
2015	18176.991	18110.02	18125.98	18285.98	18211.01	18294.03
2016	18860.411	18924.41	18782.41	18806.42	18750.44	18970.43
2017	19999.445	19966.48	20106.45	19960.45	19859.44	19874.43
2018	21138.478	21028.50	21282.49	21097.47	21184.48	21098.48
2019	21730.776	21822.77	21680.80	21651.76	21680.76	21627.80
2020	22231.951	22310.96	22177.95	22379.96	22330.96	22374.97

the host egg with respect to size, shape, and colour, or by throwing other native eggs (Algorithm 1).

In the CSO technique, cuckoo eggs from distinct nests signify the generation of candidate solutions to optimize problems. Actually, the search starts with particular nests with a solution per nest. This solution was progressed dependent upon the model of cuckoo's recognition (p) which was inspired by eliminating the solution of exchanging novel ones.

In the CSO method, a random walk was utilized dependent upon the Lévy flight distribution for producing novel candidate solutions (cuckoos) in the present one as follows:

$$\text{cuckoo}_i^{(t+1)} = \text{cuckoo}_i^{(t)} + a \oplus \text{Levy}(\lambda), \quad (14)$$

where $\text{cuckoo}_i^{(t+1)}$ refers the ith cuckoo value t. An a and λ stand for step sizes (generally fixed to one) and coefficients ($1 < \lambda < 3$) correspondingly. A number of novel solutions were created in the optimum present ones by Lévy walks for performing a local search with self-improvement [19]. Besides, a few novel solutions were created away from the optimum present ones. This reduces the chance of getting stuck from the local minimal and ensures the searching ability. The CS execution also makes sure elitism as the optimal nest is retained under the iteration.

The OBL method was proposed with the aim of decreasing the computation time and improving the ability of various EAs [20]. Therefore, the comparisons among an arbitrary CSO algorithm and its opposite might result in the global optimal with fast convergence rates. Further, the quasiopposite number and showed that it is nearer to the optimum solution when compared to the opposite number. Therefore, the population initialization of this method is created according to the QOBL concept. For arbitrary number $\chi \in [a, b]$, its opposite number χ_0 is represented as follows:

$$x_0 = a + b - x. \quad (15)$$

However, the opposite point for multidimensional searching space (dimension) is determined by the following equation:

$$x_0^i = a^j + b^i - x^i, \quad i = 1, 2, \ldots, d. \quad (16)$$

The quasiopposite no. x_{qo} of arbitrary no. $\chi \in [a, b]$ is represented as follows [21]:

$$x_{qo} = \text{rand}\left(\frac{a+b}{2}, x_0\right). \quad (17)$$

Likewise, the quasiopposite point for multidimensional searching space (d dimension) is determined by the following equation:
Figure 3: Actual and prediction analysis of the QOCSO-NLSVM technique.

$$x_{qo}^i = \text{rand}\left(\frac{a^i + b^i}{2}, x_0^i\right). \qquad (18)$$

For obtaining an objective function that could generalize the SVM outcome with no utilization of testing data, the cross validation approach is utilized. The cross validation process partitions the training dataset D randomly into S different parts $\{G_s, \quad s = 1, \ldots, S\}$, and utilizes $(S-1)$ parts to train the model and to test the model. This process gets iterated for S times by varying the lasting parts, and the generalization efficiency can be determined by the use of MSE (mean squared error) over every test result.

$$MSE_{CV} = \frac{1}{N} \sum_{s=1}^{S} \sum_{i \in G_s} (y_i - f(x_i|\theta_s))^2, \qquad (19)$$

where G_s indicates the s-th part for the testing process and θ_s signifies the solution vector attained at the time of training process.

4. Performance Evaluation and Discussion

The performance validation of the QOCSO-NLSVM technique using the economic data from the Niti Aayog website and the Reserve Bank of India were inspected. The data
Figure 4: MSE analysis of the QOCSO-NLSVM technique with distinct runs.

includes several features such as fiscal deficits, revenue deficits, interest payments, capital expenditure, nominal NSDP series, social sector expenditure, electricity generation, infrastructure projects, per capita NSDP at factor cost (at constant prices), per capita NSDP, number of factories, state-wise fixed capital, sectoral growth rate, and pattern of land use. Table 1 and Figure 3 investigate the actual and predicted result analysis of the QOCSO-NLSVM technique over distinct years. The results portrayed that the QOCSO-NLSVM technique predicted the economic status much closer to the actual value under all runs.

For instance, with an actual value of 16855.712, the QOCSO-NLSVM technique has attained predicted values of 16854.72, 16784.71, 16716.72, 16799.72, and 16851.73 under runs 1–5, respectively. At the same time, with the actual values of 18176.991, the QOCSO-NLSVM system has accomplished forecasted values of 18110.02, 18125.98, 18285.98, 18211.01, and 18294.03 under runs 1–5 correspondingly. Furthermore, with the actual values of 21138.478, the QOCSO-NLSVM method has achieved forecasted values of 21028.50, 21282.49, 21097.47, 21184.48, and 21098.48 under runs 1–5 correspondingly. Moreover, with the actual values of 22231.951, the QOCSO-NLSVM algorithm has reached predicted values of 22310.96, 22177.95, 22379.96, 22330.96, and 22374.97 under runs 1–5 correspondingly.

A brief MSE analysis of the QOCSO-NLSVM technique under various runs and years is provided in Figure 4 and Table 2. The experimental values are denoted by the QOCSO-NLSVM technique, which has resulted in an effective outcome with minimal MSE values. For instance, in the year 2012, the QOCSO-NLSVM technique resulted in at least MSE of 70.997, 138.996, 55.994, 3.979, and 0.995, respectively. Simultaneously, in the year 2015, the QOCSO-NLSVM system has resulted in a minimum MSE of 51.009, 108.987, 34.014, 117.037, and 66.972 correspondingly. Simultaneously, in the year 2018, the QOCSO-NLSVM model has resulted in a minimum MSE of 144.010, 41.006, 46.005, 39.996, and 109.978 correspondingly. Likewise, in the year 2020, the QOCSO-NLSVM method has resulted in a minimum MSE of 54.003, 148.011, 99.014, 143.021, and 79.009 correspondingly.

A brief RMSE analysis of the QOCSO-NLSVM method over many years and runs has been demonstrated in Table 3 and Figure 5. The experiment values showed that the QOCSO-NLSVM method has resulted in outstanding results with the smallest RMSE value. For example, in the year

Table 2: MSE analysis of the QOCSO-NLSVM technique with distinct runs.

2012, the QOCSO-NLSVM system resulted in a minimal RMSE of 8.426, 22.790, 7.483, 1.995, and 0.997 correspondingly. Concurrently, in the year 2015, the QOCSO-NLSVM approach resulted in a minimum RMSE of 7.142, 10.440, 5.832, 10.818, and 8.184 correspondingly. Simultaneously, in the year 2018, the QOCSO-NLSVM process has resulted in the smallest RMSE of 12.000, 6.404, 6.783, 6.324, and 10.487 correspondingly. Likewise, in the year 2020, the QOCSO-NLSVM method has resulted in a minimal RMSE of 7.349, 12.166, 9.951, 11.959, and 8.889 correspondingly.

Table 4 presents a full comparison study of the QOCSO-NLSVM approach.

Figure 6 offers the MSE analysis of the QOCSO-NLSVM technique with recent methods. The figure shows that the LSTM and ARIMA models have obtained poor performance with a higher MSE of 149.997 and 142.235, respectively. Similarly, the GRU and multivariate LSTM models reached a moderate MSE of 128.357 and 95.184, respectively. However, the QOCSO-NLSVM technique has accomplished effective outcomes with a minimal MSE of 70.548.

Figure 7 provides the RMSE of the QOCSO-NLSVM model with current methodologies. The abovementioned figure exhibits that the ARIMA and LSTM systems have gained poor performance with a high RMSE of 11.926 and 12.247 correspondingly. Simultaneously, the multivariate LSTM and GRU methods have attained reasonable RMSE of 9.756 and 11.329, respectively. But, the QOCSO-NLSVM process has gained remarkable results with the smallest RMSE of 8.399.

From the abovementioned figures, it is ensured that the QOCSO-NLSVM model is an effective regional economic prediction method over the other existing techniques.

5. Conclusion

In this research, a proposed QOCSO-NLSVM technique has been developed for regional economic prediction. The QOCSO-NLSVM technique encompasses several subprocesses, namely, DTW based preprocessing, DBSCAN-based clustering, NLSVM-based prediction, and QOCSO-based parameter optimization. The use of the DBSCAN model enables the computation of identical states depending upon the per capita NSDP growth trends and socioeconomic-demographic features in a state. In addition, the application of the QOCSO algorithm helps to properly select the parameter values and thereby reaches the maximum predictive outcomes. The QOCSO-NLSVM technique is used to discover identical states based on per capita NSDP growth trends and socioeconomic-demographic characteristics in a state. QOCSO-NLSVM is used to run a variety of simulations on regional economic data and is also used to assess a region's present economic position. The experimental validation of the QOCSO-NLSVM technique and the results are examined in various aspects. The comparative analysis revealed the enhanced outcomes of the QOCSO-NLSVM technique over the recent approaches. With a minimum MSE of 70.548, the QOCSO-NLSVM approach produced effective results. The QOCSO-NLSVM technique had remarkable results, achieving the lowest root mean square error (RMSE) of 8.399. In the future, advanced DL models can be used to improve the overall prediction outcomes.

With the rapid development of Internet of Things (IoT) technology, IoT terminal nodes are facing many challenges in data storage, distribution, and data management. In particular, in the IoT terminal nodes considering access cost, the corresponding data distribution and storage are professional, complex, and miscellaneous. Based on the abovementioned current situation, this article innovatively proposes a complex sensor data placement algorithm based on the cloud storage distribution of IoT terminal nodes. Under this algorithm, the accurate division of IoT data I/O methods is realized through reasonable configuration. Through the adaptive sensing algorithm, while fully considering the access cost of the algorithm, the performance of the IoT data storage system is further optimized. In the corresponding terminal node load balancing problem, this article innovatively proposes the terminal node data sorting and distribution algorithm through the node data. The sorting and distribution algorithm realizes the precise segmentation of the IoT data to be processed, thereby realizing the improvement of data reading and processing speed. Based on the proposed algorithm, this article designs a load balancing cloud storage data distribution optimization system of IoT terminal nodes considering access cost and carries out experimental verification in a real environment. The experimental results show that the data pattern division accuracy corresponding to the proposed distribution strategy is improved to 97.13% and the corresponding data access efficiency is improved to 98.3%, compared with the traditional distribution strategy. Therefore, the data distribution strategy proposed in this article has obvious performance advantages and further promotion value.

1. Introduction

The main architecture of the Internet of Things (IoT) includes the perception layer, network layer, management layer and application layer. The conventional sensing layer is mainly used to collect relevant physical information, such as temperature, humidity, air composition, and optical signals. The continuous collection and storage of data by the relevant sensor networks of the IoT cause problems of data distribution and data management [1–3]. The relevant data of the IoT are mainly classified into structured data and unstructured data. The corresponding structured data mainly depend on open-source databases and other products, while the storage of the corresponding unstructured data depends on the database software developed by the corresponding unstructured data model. At the data storage level of the IoT, cloud storage technology, as the development direction of

data storage, mainly processes and analyzes a large number of different types of data generated by the IoT through cluster application, network technology, and distributed storage technology and provides external data access and storage [4, 5]. The conventional cloud storage architecture includes the application interface layer, infrastructure layer, and storage layer. The corresponding application interface layer mainly includes network access, user authentication, permission management, public API interface, application software interface, and network service interface. Moreover, the corresponding infrastructure layer includes the cluster system, distributed file system, grid system, content distribution and data deduplication, data compression, and data encryption processing. The corresponding storage layer mainly includes storage virtualization, centralized storage management, status monitoring, maintenance, and upgrading [6]. Data placement and node load balancing are

important technologies of distributed storage in cloud storage technology. Load balancing mainly realizes the dynamic expansion of storage resources to further improve the utilization of resources, minimize the data response time, and further reduce the fault recovery and data switching time to ensure the quality of user data access in the IoT system [7, 8]. At the level of corresponding data placement and distribution, the flat distribution of the data system is of great significance. The directory organization corresponding to the traditional data distribution is unreasonable, and the node data distribution is too scattered or too centralized, which will further affect the response-ability of the data system, further reduce the system performance, and increase the data maintenance cost [9, 10]. Compared with other storage models, cloud storage has the following advantages: (1) easy to expand: the storage space is expanded in time according to the number of users and space of the server, which will also not affect the use of the front-end users; (2) reliable and safe: data synchronization effectively avoids media storage of data. Cloud storage can fully realize load balancing, which can realize the flow distribution control service of distributing access traffic to multiple back-end cloud servers according to the forwarding strategy. More-over, the external service capabilities of the application system are extended through traffic distribution, and the availability of the application system is improved by eliminating single points of failure.

The traditional cloud storage data distribution strategy of load balancing of IoT terminal nodes has some disadvantages in data placement and load balancing technology. At the data placement level, the disadvantages are as follows: differences in data storage performance and availability storage cost between different data storage service providers and differences in different data reading and writing modes in the IoT sensor network. Therefore, the traditional data placement algorithm only meets a single optimization goal and cannot meet the application storage requirements under the huge amount of data in IoT. Based on this, constructing an efficient data placement algorithm to optimize the performance of different data access is of great significance to improve the performance of cloud storage data systems for load balancing of IoT terminals [11, 12]. For the problem of load balancing, after the corresponding IoT data are initialized, as the storage system continues to serve various big data-related applications on the upper layer, the data layout corresponding to each cloud storage system will be unevenly distributed, which will lead to a serious decline in the performance of data access [13–15]. After the storage system has been running for a period of time, it will become normal that the cor-responding data load is seriously unbalanced. Once the corresponding load of a data storage service provider is very high, the system may be blocked and stagnant. When the data are stagnant, the corresponding outside world must send out sudden data access and the whole system will have a bottleneck [16, 17]. Based on this, we aim to realize the load balancing of IoT terminal nodes to make the system achieve load balancing and realize the application opti-mization access function.

Based on the disadvantages of the corresponding data distribution and storage of IoT terminals considering the access cost, this article will propose a complex perceptual data placement algorithm based on the cloud storage dis-tribution of IoT terminal nodes and realize the I/O mode of accurately dividing IoT data by reasonably configuring hybrid perceptual algorithm and adaptive perceptual algo-rithm to optimize further the performance of the IoT data storage system considering the access cost. Aiming at the problem of terminal node load balancing, this article in-novatively proposes the terminal node data sorting and distribution algorithm, which realizes the accurate seg-mentation of the IoT data to be processed through the node data sorting and distribution algorithm to further accelerate the data reading and processing speed. At the same time, a periodic load balancing algorithm is added to the terminal node data sorting and distribution algorithm so as to further solve the problem of unbalanced node data layout. Based on the proposed algorithm, this article designs a load balancing cloud storage data distribution optimization system of IoT terminal nodes considering access cost and carries out ex-perimental verification in a real environment. The experi-mental results show that the data pattern division accuracy corresponding to the distribution strategy proposed in this article is improved to 97.13% and the corresponding data access efficiency is improved to 98.3% compared with the traditional distribution strategy. The data distribution strategy proposed in this article has obvious performance advantages and further promotion value.

The main structure of this article is as follows: the second section will mainly analyze the current research status of the load balancing cloud storage data distribution system of IoT terminal nodes considering access cost. The third section will focus on the analysis of complex perceptual data placement algorithm and terminal node data sorting and distribution algorithm and design the cloud storage data distribution optimization system for load balancing of IoT terminal nodes considering access cost. The fourth section will verify the system and analyze its data. Finally, the article is summarized.

2. Related Research: Research Status of Load Balancing Cloud Storage Data Distribution System of Internet of Things Terminal Nodes considering Access Cost

A large number of researchers and scientific research in-stitutions have studied and analyzed the data placement and load balancing problems faced by the load of terminal nodes of the IoT. At the research level of data placement and distribution, relevant cloud storage manufacturers in the United States put forward simple storage services, and their corresponding storage mainly involves three indicators: basic storage unit, unique identifier, and storage object container. When there are a few corresponding IoT data, the corresponding distribution strategy is relatively simple; therefore, not too much data will be stored in the corre-sponding storage object container. However, once there is

too much or blocked data, the performance of the cloud storage system will decline, which is not conducive to the maintenance and dynamic development of the system [18, 19]. European cloud storage service providers propose a static directory layering strategy, which mainly adopts a two-tier static object distribution model, alleviating the problem of too centralized data distribution on nodes to a certain extent, but this model still has certain limitations. The even distribution of the corresponding data depends on the corresponding IoT data level [20]. At the level of corresponding load balancing algorithms, relevant Chinese researchers have proposed a scheme to realize load balancing distribution in a distributed environment. However, this scheme does not consider the corresponding data copies, which may lead to multiple data copies appearing on the same data node after the relevant migration. At the same time, this load balancing strategy does not explicitly specify how much data can be migrated during the migration process. If the corresponding migration amount is too large, the load node will exceed the threshold [21]. Relevant European researchers have proposed a load balancing algorithm based on private cloud storage, which mainly realizes the balanced storage of data by calculating the weight corresponding to the storage node. However, the algorithm does not fully consider the heterogeneity of the node itself in the operation process. It treats all nodes equally, and it does not fully consider the heavy data at this time; if the data is too heavy, data migration will lead to the risk of increasing system bandwidth [2, 22]. Based on the analysis of the above research status, the current traditional load data placement algorithm and load balancing algorithm of IoT terminal nodes have more or fewer disadvantages, which leads to the accuracy of data mode division of cloud storage system and then leads to a serious decline in the corresponding data access efficiency.

3. Research on Load Balancing Cloud Storage Data Distribution Strategy of Internet of Things Terminal Nodes considering Access Cost

This section mainly analyzes and studies the corresponding key algorithms and system design of the IoT terminal node load balancing cloud storage data distribution system considering access cost. The corresponding system principle block diagram is shown in Figure 1. As shown in Figure 1, the key algorithms proposed in this article mainly have two points: the complex aware data placement algorithm and node load balancing strategy for processing data placement. At the corresponding hardware system design level, it also includes the distribution of IoT terminal nodes, IoT network element data management layer, IoT file service layer, and IoT data node control layer. There is no data management layer in the corresponding system, including IoT user and equipment management, IoT user data node allocation, IoT monitoring data management equipment, and IoT migration data management. The corresponding IoT file service layer includes the upload and download of IoT data files, the upload and download of quantity network audio and video files, the deletion of IoT files and other related modules. The whole system includes monitoring system components.

3.1. Complex Perceptual Data Placement Algorithm. The complex perceptual data placement algorithm proposed in this article mainly solves the problem of data placement distribution in the IoT. The complex perceptual data placement algorithm is mainly divided into two processing levels. Firstly, the I/O mode of the terminal data nodes of the IoT is identified and classified based on the decision tree algorithm. Then, the placement strategy is formulated based on the processed IoT data. The principle block diagram of the corresponding complex perceptual data placement algorithm is shown in Figure 2.

The IoT data I/O mode discrimination and classification algorithm based on decision tree mainly discriminates the data I/O type based on the six key factors of IoT data. The corresponding six factors are as follows: IoT data size, data type, IoT data life cycle, IoT data creation time, the last creation time, and the last modification time of IoT data [23–25]. Based on the above six factors, the I/O mode of IoT data is determined. The modes determined in this section are as follows: read-only mode, write-only mode, read more and write less mode, read less and write more mode. The IoT data I/O mode discrimination and classification algorithm based on decision tree mainly follows the following operation steps:

Step 1: calculate the gain value of IoT terminal node data based on six factors: IoT data size, data type, IoT data life cycle, IoT data creation time, IoT data last creation time, and last modification time. The corresponding calculation formulas are shown in formulas (1), (2), and (3), the corresponding IoT data size is V, the data type is L, the life cycle of IoT data is S, the creation time of IoT data is C, the last creation time of IoT data is L, and the last modification time is D.

$$\begin{aligned} G(\text{data}, D) = & Q(\text{data}_1 + \text{data}_2 + \cdots + \text{data}_i) \\ & - Q(\text{data}_1|D_1) + \cdots Q(\text{data}_i|D_i), \end{aligned} \tag{1}$$

$$\begin{aligned} Q(D) = & -[\eta_1(a_1)\log(\eta_1(a_1))) + \cdots \\ & + \eta_i(a_i)\log(\eta_i(a_i))), \end{aligned} \tag{2}$$

$$\begin{aligned} Q(\text{data}|D) = & \eta(D_1) * Q(\text{data}_1|D_1) + \cdots \\ & + \eta(D_i) * Q(\text{data}_i|D_i). \end{aligned} \tag{3}$$

Step 2: divide the I/O mode of the IoT data according to the gain value calculated in Step 1, and repeat the operations of Step 1 and Step 2 for the IoT data until all the IoT data can be defined as unique data mode.

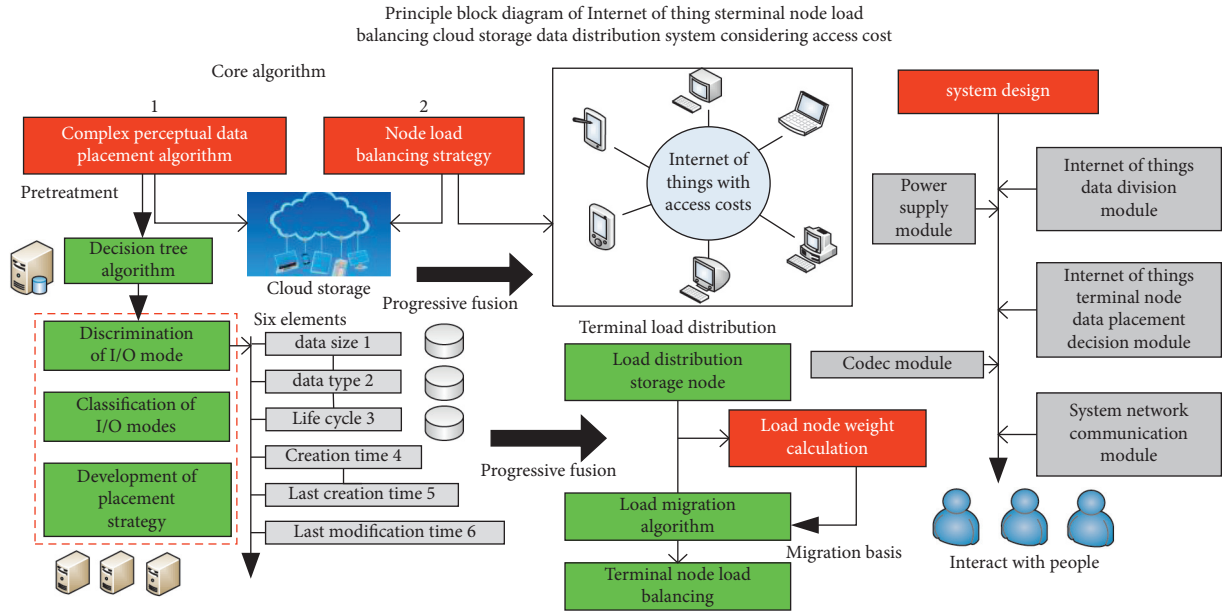
Step 3: generate a data I/O mode classification model of IoT terminal nodes based on a decision tree to determine the complete data I/O type.


Figure 1: Principle block diagram of Internet of Things terminal node load balancing cloud storage data distribution system considering access cost.
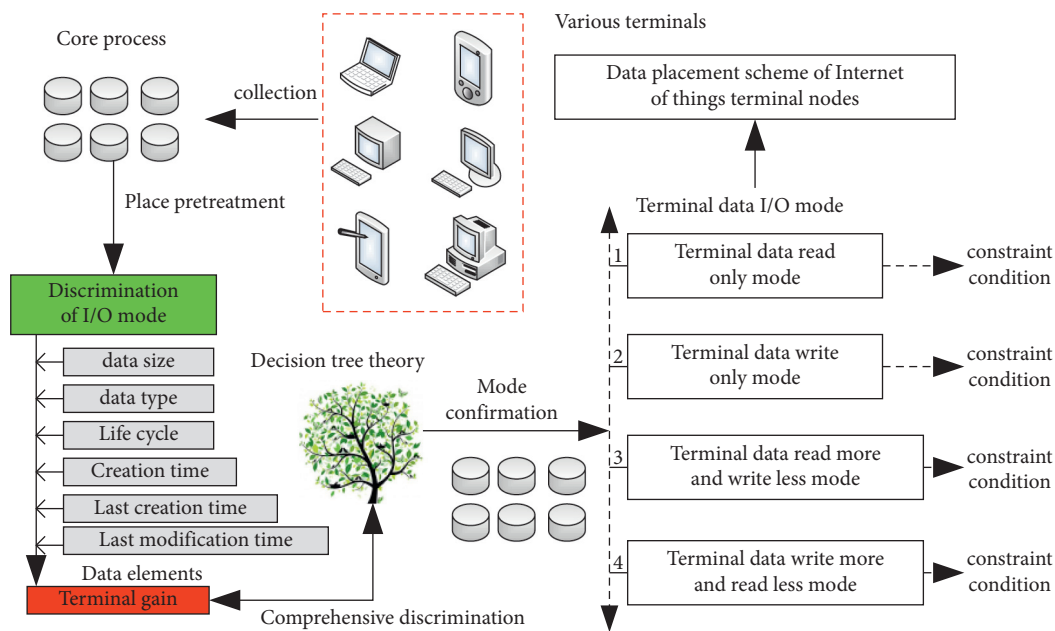

Figure 2: Principle block diagram of complex perceptual data placement algorithm.

Step 4: continuously collect the data to be placed, collect its corresponding six eigenvalues, call the corresponding decision tree IoT terminal node data I/O mode classification model, and constantly put new prediction results into the model so as to improve the accuracy of the model until all IoT terminal node data can be finalized.

After being processed by the I/O mode discrimination and classification algorithm of IoT data in the decision tree, it enters the link of the adaptive data placement algorithm. This algorithm is mainly based on the I/O mode type of IoT data to further determine its corresponding placement strategy and placement scheme. Based on this assumption, the read more write less mode is mode 1, the read less write

multimode is mode 2, the read-only mode is mode 3, and the write-only mode is mode 4. Take the read more write less mode and read less write more mode as case modes, and formulate their corresponding placement strategies.

The placement strategy objective function corresponding to the read more write less mode is shown in formula (4).

$$S = \min\left[\frac{(L * G_1(\text{mode1}))}{(A * d * w)}\right], \tag{4}$$

$$L * G_1(\text{mode1}) = \max\frac{\left(C_1^4 * \lg_1 + \cdots + C_i^4 * \lg_i\right)}{m_i, \quad 1 < i < n}, \tag{5}$$

$$A_1 = \left(\prod i \in N_i(1 - a_1) * \prod i \in N_i(a_1) + \cdots + \prod i \in N_i(1 - a_i) * \prod i \in N_i(a_i)\right), \tag{6}$$

$$A_1^s + A_1^g + A_1^T < a * A_1, \tag{7}$$

$$A_1^T = \left(a_1^4 * P_{\eta_1}^T * G_{d_1}\right) + \cdots + \left(a_1^4 * P_{\eta_i}^T * G_{d_i}\right). \tag{8}$$

The placement strategy objective function corresponding to the read less write multimode is shown in formula (9). This mode is mainly relatively sensitive to write delay. The

This mode has large downlink traffic and is sensitive to the read delay of the corresponding IoT data. The corresponding data placement constraints in this mode are shown in formulas (5)–(7) and (8). In the corresponding formula, A represents the cost proportion threshold and C represents the downstream data cost.

corresponding data placement constraints in this mode are shown in formulas (10)–(12) and (13).

$$S = \min\left[\frac{(L * G_2(\text{mode2}))}{(A * d * w)}\right], \tag{9}$$

$$L * G_2(\text{mode2}) = \max\frac{\left(C_1^2 * \lg_1 + \cdots + C_i^3 * \lg_i\right)}{m_i, \quad 1 < i < n}, \tag{10}$$

$$A_2 = \left(\prod i \in N_i(1 - a_1) * \prod i \in N_i(a_1) + \cdots + \prod i \in N_i(1 - a_i) * \prod i \in N_i(a_i)\right), \tag{11}$$

$$A_2^s + A_2^g + A_2^T < a * A_2, \tag{12}$$

$$A_2^T = \left(a_1^2 * P_{\eta_1}^T * G_{d_1}\right) + \cdots + \left(a_1^2 * P_{\eta_i}^T * G_{di}\right). \tag{13}$$

Through the confirmation of the above data placement scheme, the data sorting and distribution of IoT terminal nodes can be further confirmed so as to further optimize the data placement of the system.

In summary, based on the above algorithm, the heterogeneity of IoT terminal node data can be fully considered so as to realize the rationality of IOT terminal node data placement considering access cost and then prepare for load balancing.

3.2. Terminal Node Load Balancing Strategy. The terminal node load balancing strategy proposed in this section mainly includes load distribution, storage nodes, and load migration. The principle block diagram of the corresponding load balancing strategy is shown in Figure 3.

From Figure 3, we can see the load distribution, storage nodes, and load migration of the entire wireless sensor network.

In data node allocation, the weight of terminal node data needs to be calculated first. The corresponding calculation formula is shown in formula (14). The corresponding S represents the data state of the node, the corresponding a represents the heterogeneous weight of the data node, W_s represents the storage space used by the corresponding node data, and W_n represents the number of IoT nodes currently allocated. When the corresponding data weight is larger, the comprehensive available resources of the corresponding data node are smaller.

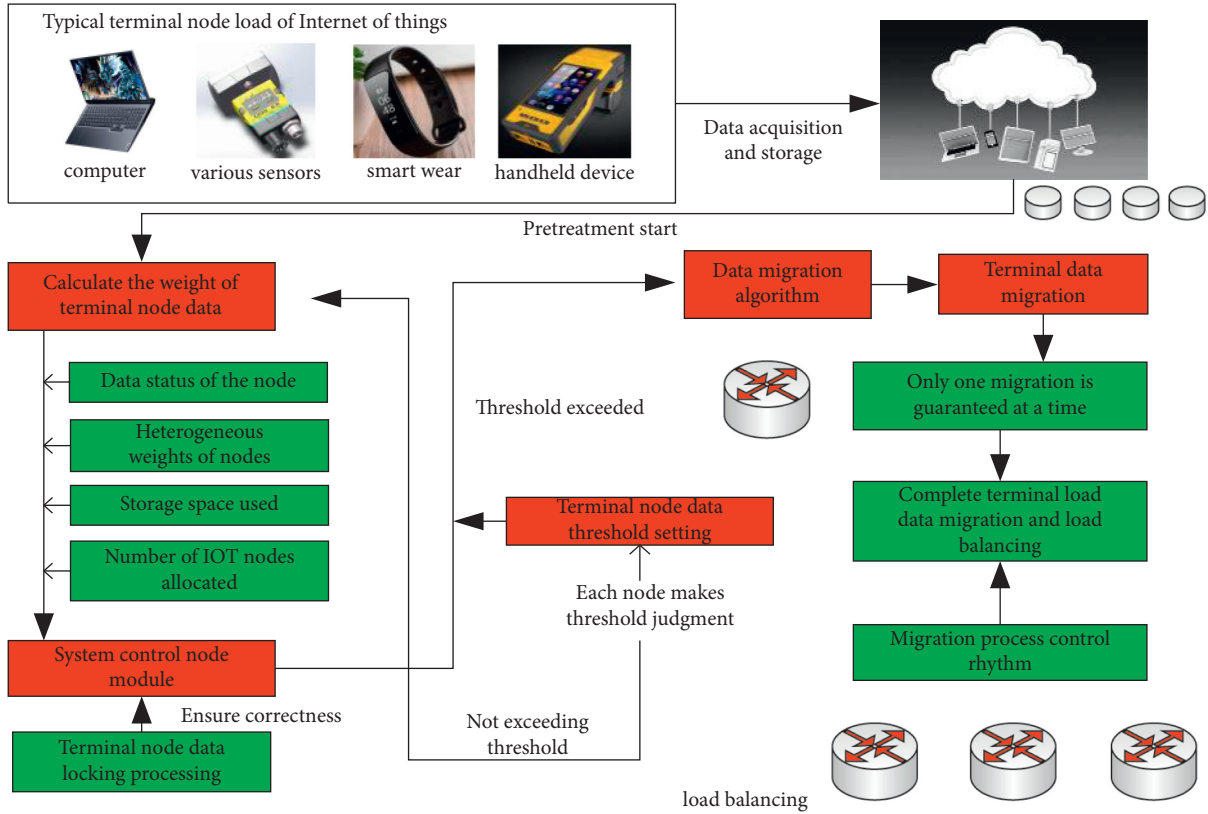
$$W = \frac{(S * W_s)}{(W_T * A) * W_n}. \tag{14}$$


FIGURE 3: Principle block diagram of terminal node load balancing algorithm.

The corresponding data node allocation process is shown in Figure 4. It can be clearly seen from Figure 4 that each storage node corresponding to the wireless sensor network needs to continuously calculate the heterogeneous weight of its corresponding data node and feed the data back to the corresponding control node of the wireless sensor network in real-time. At the same time, the data also cover key information such as the storage space used by data nodes and the number of IoT nodes allocated. In order to ensure the correct rate of the algorithm of the entire system, the system is implemented with a locking scheme when multiple IoT data nodes are concurrent.

After completing the data node allocation, carry out the data migration operation. First, set the data load threshold as Wy, judge whether the load of IoT terminal nodes is too heavy based on this threshold, and carry out relevant migration actions. When the load weight of the corresponding cloud storage system is far less than the load threshold and the weight of the corresponding single load node is greater than the load weight of the whole system, notify the system to trigger the corresponding data migration algorithm for data migration. When the corresponding system load weight is much greater than the load threshold, notify the system to add the corresponding data storage node and notify the system that the load is too heavy at this time. In the actual data migration process, in order to ensure the correctness of data migration, the system needs to ensure that only one data migration operation is allowed at the same time, and the system needs to control the migration rhythm.

3.3. Design of Cloud Storage Data Distribution System for Load Balancing of Internet of Things Terminal Nodes Considering Access Cost.
The design framework of the cloud storage data distribution system for load balancing of IoT terminal nodes considering access cost is shown in Figure 5. It can be seen from the figure that the corresponding hardware system mainly includes IoT data division module, IoT terminal node data placement decision module, system network communication module, and IoT terminal node data encoding and decoding module.

At the design level of the corresponding IoT terminal node data division module, it mainly realizes the I/O mode division of the placed data. The module includes the data I/O model determination strategy, and the corresponding implementation method realizes the data type division model based on the decision tree through scikit-learn. The corresponding data placement decision module of the IoT terminal node is mainly a module to formulate the corresponding data placement strategy, which includes the data placement strategy algorithm. The corresponding network communication module is mainly to realize the interaction between multicloud storage, provide the function of cloud storage to obtain data and services from the upper server, provide the function of independent search and modification and other related operations of the IoT terminal, and provide the function of obtaining and monitoring cloud storage operators. The IoT terminal node data encoding and decoding module mainly helps restore relevant data. This module encodes the IoT

terminal data through the encode() function and decodes the relevant IoT terminal data through the decode() function.

4. Experimental Verification and Data Analysis

In order to further verify the advantages of the actual system and the corresponding data distribution algorithm, this article is verified by the performance comparison experiment with the traditional distribution algorithm.

In the data mode division accuracy experiment, this article selects 100, 1000, 5000, and 10000 IoT terminal node files for comparative experiments. The corresponding experimental data are shown in Figure 6. It can be seen from the figure that the data distribution strategy proposed in this article is improving with the increasing number of files. When the number of files reaches 10000, the corresponding data partition accuracy is improved to 97.13%, which has obvious advantages over the traditional data distribution strategy.

Verify the response speed advantages of the distribution algorithm at the read, write, store, and delete levels when the number of files corresponds to 100, 1000, 5000, and 10000. The corresponding experimental results are shown in Figures 7(a), 7(b), and 7(c). As can be seen from the figure, at the corresponding write operation level, the write speed of the algorithm proposed in this article is about 15% higher than that of the traditional algorithm. At the corresponding read operation level, the write speed of the proposed

algorithm is about 20% higher than that of the traditional algorithm. At the corresponding storage operation level, the writing speed of the proposed algorithm is about 17% higher than that of the traditional algorithm. At the corresponding level of delete storage operation, the writing speed of the proposed algorithm is about 17% higher than that of the traditional algorithm. Based on the above data, it can be seen that the performance of the algorithm proposed in this article has been comprehensively improved compared with the traditional algorithm at the basic operational level.

In order to verify the advantages of this algorithm in the level of load balancing, the comparative verification is carried out when the number of files of IoT terminal nodes is 100, 1000, 5000, and 10000, and the corresponding load number of each storage node in the system is observed in the experiment. Under different file numbers, the corresponding load distribution is shown in Figure 8. It can be seen from the figure that the load distribution of the distribution algorithm proposed in this article is relatively uniform in each memory. At the same time, with the increase of the number of files, the number of files between the corresponding memories fluctuates little, while the corresponding load is seriously unbalanced under the corresponding traditional distribution strategy.

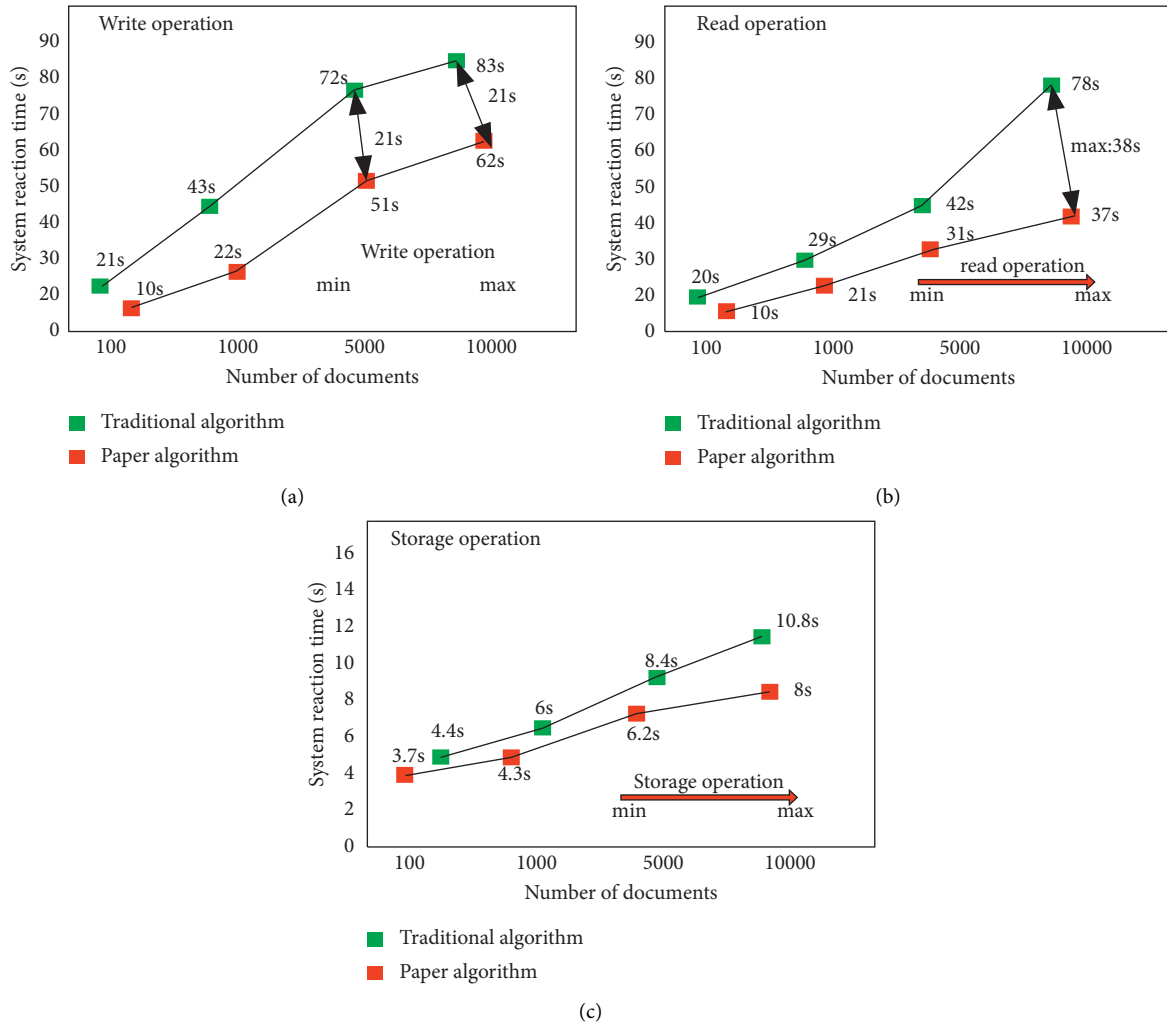
In order to verify the superiority of the algorithm proposed in this article in system data access efficiency, a comparative experiment is carried out based on the traditional distribution strategy. The experimental results are shown in Figure 9. It can be seen from the figure that the


FIGURE 7: (a) Write operation level performance comparison column chart. (b) Read operation level performance comparison column chart. (c) Storage operation level performance comparison column chart.

distribution strategy proposed in this article has the highest system data access efficiency of 98.3%, which is nearly 20% higher than the traditional distribution algorithm. Therefore, this algorithm has obvious advantages over traditional algorithms.

The above analysis and experimental results further show that the algorithm proposed in this article has obvious advantages over the traditional algorithm in the cloud storage data system of load balancing of IoT terminal nodes considering access cost, and it can realize the optimization of data placement and load balancing. This greatly improves the accuracy of the system's data mode division of IoT terminal nodes and further improves the data access efficiency of the system.

FIGURE 9: Comparison of system data access efficiency under different numbers of files.

5. Conclusion

This article mainly analyzes and studies the relevant research algorithms of cloud storage data distribution system with load balancing of IoT terminal nodes considering access cost and analyzes and compares their advantages and disadvantages. Based on the existing problems, this article proposes a complex sensing data placement algorithm based on the cloud storage distribution of IoT terminal nodes and realizes the accurate division of I/O mode of IoT data by reasonably configuring hybrid sensing algorithm and adaptive sensing algorithm so as to further optimize the performance of IoT data storage system considering access cost. Aiming at the problem of terminal node load balancing, this article innovatively proposes the terminal node data sorting and distribution algorithm. Through the node data sorting and distribution algorithm, the accurate segmentation of the IoT data to be processed is realized so as to further accelerate the data reading and processing speed. At the same time, a periodic load balancing algorithm is added to the terminal node data sorting and distribution algorithm. Thus, the problem of unbalanced node data layout is further solved. Based on the proposed algorithm, this article designs a load balancing cloud storage data distribution optimization system of IoT terminal nodes considering access cost and carries out experimental verification in a real environment. The experimental results show that the data pattern division accuracy corresponding to the distribution strategy proposed in this article is improved to 97.13% and the corresponding data access efficiency is improved to 98.3%, compared with the traditional distribution strategy. The data distribution strategy proposed in this article has obvious performance advantages and further promotion value. In the follow-up research, the article will focus on analyzing the energy consumption of wireless sensor networks. At the same time, it will further optimize the load balancing situation in the load balancing strategy. Moreover, it will further discuss the load balancing strategy problem of the traditional cloud storage network considering the cost.

This paper introduces the basic concepts and main characteristics of parallel self-organizing networks and analyzes and predicts parallel self-organizing networks through neural networks and their hybrid models. First, we train and describe the law and development trend of the parallel self-organizing network through historical data of the parallel self-organizing network and then use the discovered law to predict the performance of the new data and compare it with its true value. Second, this paper takes the prediction and application of chaotic parallel self-organizing networks as the main research line and neural networks as the main research method. Based on the summary and analysis of traditional neural networks, it jumps out of inertial thinking and first proposes phase space. Reconstruction parameters and neural network structure parameters are unified and optimized, and then, the idea of dividing the phase space into multiple subspaces is proposed. The multi-neural network method is adopted to track and predict the local trajectory of the chaotic attractor in the subspace with high precision to improve overall forecasting performance. During the experiment, short-term and longer-term prediction experiments were performed on the chaotic parallel self-organizing network. The results show that not only the accuracy of the simulation results is greatly improved but also the prediction performance of the real data observed in reality is also greatly improved. When predicting the parallel self-organizing network, the minimum error of the self-organizing difference model is 0.3691, and the minimum error of the self-organizing autoregressive neural network is 0.008, and neural network minimum error is 0.0081. In the parallel self-organizing network prediction of sports event scores, the errors of the above models are 0.0174, 0.0081, 0.0135, and 0.0381, respectively.

1. Introduction

With the mature application of neural network technology and the rapid development of Internet, the research of data prediction has emerged. Data prediction often faces some noisy, messy, and nonlinear data. Neural networks have good robustness, [1]. This article briefly introduces the main clustering algorithms in data prediction, conducts an in-depth study, and optimizes the SOM learning algorithm, which improves the network iteration to a certain extent. The speed of training layer expansion self-organizing mapping network (GHSOM) was studied, the gray relational analysis was introduced into the GHSOM network, and the GRAGHSOM algorithm was proposed. The experimental results show that the GRAGHSOM algorithm reflects the importance of each component of the sample vector in the model in the process of high-dimensional data clustering and can perform clustering more accurately [2–5].

Because the fitting of a single neural network to a nonlinear dynamic system is generally computationally intensive, slow in convergence, time-consuming, and poor in generalization ability, a modular neural network chaotic parallel self-organizing network prediction method is proposed. That is, the phase space after the reconstruction of the chaotic parallel self-organizing network is divided into multiple subspaces, and an unbalanced subnet strategy is adopted. A neural network with a different structure is used in each subspace to calculate and track the local attractor trajectory, and the prediction result is finally passed into integrated module output [6]. This method not only makes use of the characteristics of self-organization and self-learning of neural networks but also greatly improves its

computational performance compared with a single neural network. It can track the attractor trajectory more accurately in the subspace, thereby improving the overall prediction. Clustering refers to the grouping of objects in the database into meaningful subsets, so that the members in a class are as similar as possible, and the differences in members among different classes are as large as possible. Clustering has unsupervised learning capabilities and is widely used in many fields [7–10].

This article first reviews the commonly used BP neural network and self-organizing neural network in neural network models. Then referring to the article, a new self-organizing difference theoretical model was established on the basis of self-organizing, and a better neural network structure was found through comparison. A better model was found by comparing the number of different classes and the prediction error of the hidden layers. The reference article combines the self-organizing neural network with the autoregressive model, improves the weight initialization and learning rate of the neural network, and finds a model with less error by comparing the number of different categories. In the article, the BP neural network is selected as the comparison model to evaluate the effect of the new model. The single-even network and multi-even network forecast models of the forecast system are studied. Matlab 6.5 programming is used to train the breakout forecast system based on the nonlinear neural network, using the simple, practical, and easy-to-program Visual C++ software for interface design, and a visual forecasting system based on nonlinear neural networks was developed. Experiments have proved that the use of a breakout prediction system based on a nonlinear neural network for breakout prediction can improve the prediction accuracy.

2. Related Work

Therefore, in recent years, the prediction method of chaotic parallel self-organizing network based on a neural network has obtained preliminary theoretical and application research results. However, on the one hand, most of the current researches are focused on the optimization of the network structure itself and the improvement of the two independent processes of phase-space reconstruction parameter selection, without considering the two as a whole. The reconstructed phase umbrella is divided into subspaces in order to track the attractor's trajectory with higher precision locally.

Torrents et al. [11] believe that the phase space of the system can be reconstructed from the parallel self-organizing network of a variable, and all the information of the entire dynamic system is contained in the chaotic parallel self-organizing network itself. The embedding theorem of Grossberg [12] further proves the idea and provides a theoretical basis for predicting the chaotic time series. However, how to construct the prediction model according to the phase reconstruction theory, select the reconstruction phase-space parameters, and predict model parameters is a key problem in the prediction of chaotic parallel self-organizing networks. For this reason, many nonlinear prediction methods for

predicting chaotic parallel self-organizing networks have been proposed. Among them, the neural network-based prediction method has distributed processing, self-organization, and self-adaptation. The excellent characteristics of self-learning columns and fault tolerance can better deal with uncertain and nonlinear prediction problems, so more research and applications have been obtained in the prediction of chaotic parallel self-organizing networks. Mohammadi et al. [13] used the neural network global method to predict the chaotic parallel self-organizing network. The results proved that when the MLP neural network is used as a global prediction method to predict the chaotic parallel self-organizing network, the effect is better than most local prediction methods. RBF networks have a strong biological background and are often used in the prediction of chaotic parallel self-organizing networks. Researchers are committed to improving the hidden layer node function and number selection of classic RBF networks.

The initial global prediction methods for chaotic parallel self-organizing networks mostly used feed-forward neural networks. There are many types of feed-forward networks, mainly including multilayer perceptrons (MLP) neural networks and radial basis functions neural network, nonlinear neural network (WNN), and fuzzy neural network (FNN). A representative MLP network is Park [14], which uses a multilayer feedforward network to simulate Lorenz chaotic sequences, where m represents phase-space reconstruction. The embedding dimension and its conclusion illustrate the important role of neural network in the prediction of chaotic time series. Yuan and Li [15] studied the gradient changes of the parallel self-organizing network. The experimental results show that the prediction performance of the classic RBF network has been improved [16]. The researchers proposed a cross-validation subspace method to select the optimal number of hidden layer nodes. This method is used in the prediction of noise-containing chaotic parallel self-organizing networks. The simulation object is the chaotic sequence of radar sea echoes. Nonlinear neural network is a new type of feedforward neural network based on nonlinear theory. Nonlinear neural network is compatible with the superiority of nonlinear and neural networks [17–20].

3. Construction of Sports Event Score Prediction Model Based on a Parallel Self-Organizing Nonlinear Neural Network

3.1. Parallel Self-Organizing Architecture Nesting. According to the different objects to be studied, the behaviors of parallel self-organizing networks are very different. Even for the same object, there will be different performances at different times. Therefore, in order to treat different time series in different ways, parallel self-organizing networks can be classified according to the way of data selection and the form of data changes over time. Figure 1 shows the nested parallel self-organizing architecture.

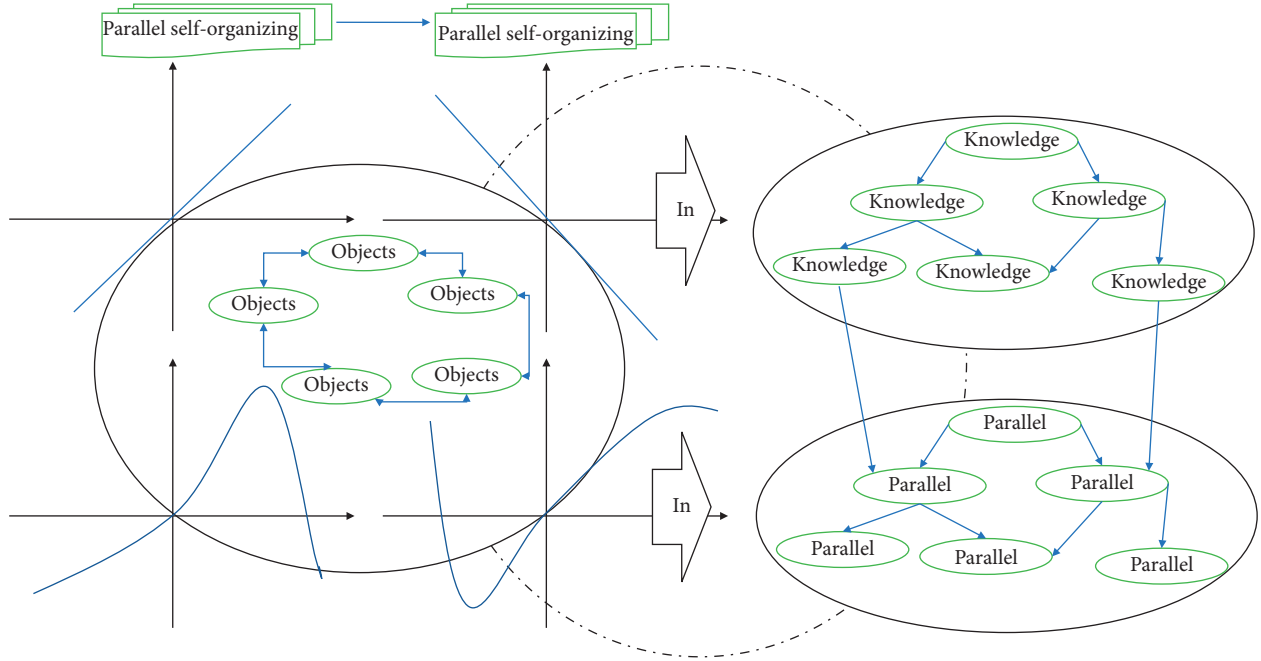
When using the combination of difference weighted average to predict the parallel self-organizing network, the


FIGURE 1: Parallel self-organizing architecture nesting.

self-organizing neural network to the historical data is first used and the input data are divided into several categories. The target value is calculated according to the formula to calculate the weighted average of the difference. When predicting the behavior of new data, first classify it according to the trained self-organizing neural network and then add the weighted average corresponding to the class of the data to the last value of the new data, which is the prediction corresponding to the new data.

$$R - \int_0^\infty \left(R_{FR} + R_{F1} - \frac{R_{FR} + R_{F1}}{R_{FR} R_{F1}} \right) dt = 0, \tag{1}$$

$$\exp\left[i \, df(w_i) \right] - \exp\frac{|D|}{\left| \{D_i: D_j \in w_j\} - 1 \right|} = 0. \tag{2}$$

First, we must establish a self-organizing neural network to classify the known data. The known data exist in the form of vectors. The elements of each vector are the parallel self-organizing network values selected from the parallel self-organizing network at a certain time interval. And all vector elements are selected in the same way. Let the dimension of the vector be l. The network weights of the initial self-organizing neural network are randomly selected. The risk value of the network is obtained by adding the risk value of the host

$$u(k, t, x(k, t)) = \begin{cases} \varepsilon(i, n) \times w(k, t), & 0 < t < k, \\ \delta(i, n) \times w(k, t), & t > k, \\ y(n) \times w(k, t), & t < 0, \end{cases} \tag{3}$$

$$\sum \nabla^2 \frac{\alpha - 1}{a^2} * \frac{\partial^2 \alpha}{\partial t^2} + \int \frac{\rho}{\varepsilon} dx dy = 0. \tag{4}$$

When all the known data are input to the self-organizing neural network, the optimal neuron is obtained, and the weight vector of the optimal neuron and its surrounding neurons are adjusted, and the self-organizing neural network completes one step of training. Then, the data are re-input into the self-organizing neural network for the next step of training, until the optimal neuron corresponding to each input vector in the two trainings before and after does not change, and the self-organizing neural network completes the training. Taking the weight vector of the neurons in the competitive layer after training as the clustering center, the data can be classified finally.

$$f(x_i, x_2, x_3) = G(F(x_1, W(x))) G(F(x_2, W(x))) G(F(x_3, W(x))). \tag{5}$$

The neurons receive the data passed by the neurons in the previous layer and adjust the data according to their own transformation functions. We perform the transformation and then pass the transformed data to the next layer of neurons. The last part receives the data of the last layer of hidden layer neurons and calculates the final result and error of this input.

3.2. Nonlinear Neural Network Node Output.

Structurally, the characteristics of nonlinear neural networks are as follows: (1) distributed storage: that is, all neurons of the neural network jointly complete the information processing function, and each neuron has an independent function to process data; (2) parallelism: that is, the ability of all neurons of the neural network to complete information processing concurrently; and (3) fault tolerance: a single neuron's error in information processing will not affect the entire system. In terms of ability, the neural network can spontaneously react to external input and output data and makes appropriate adjustments to its own network parameters according to the

input and output samples to adapt to the new input samples. Each neuron in the input layer stores an element of the input vector, and all neurons assign data values to the discriminant function of the neurons in the competition layer through the connection with the data according to the discriminant function, select the best matching neuron by comparing the value of the discriminant function of each neuron, and modify the network connection weight parameter according to the input data. The connections represent a certain distance between neurons in the competition layer. The distribution of this weight in one or two dimensions is fixed and will not change during training. Figure 2 shows the distribution of nodes in a nonlinear neural network.

In a forward network without feedback, once a signal passes through a neuron, the neuron's processing process ends. In an interconnected network, signals have to be repeatedly transmitted between neurons, and the network is in a dynamic state of constant change. Starting from a certain initial state, after several changes, it will reach a certain equilibrium state. According to the structure of the network and the characteristics of neurons, the operation of the network may also enter periodic oscillations or other equilibrium states such as chaos. This parallel self-organizing network can also be called the aggregate index parallel self-organizing network, which is a statistical sequence arranged in time, and the data content is the statistical value of the same phenomenon or characteristic value. From the absolute parallel self-organizing network, the overall level of the phenomenon to be studied in a certain period can be observed, and it can also reflect the level of the phenomenon at a certain point in time. Therefore, the absolute parallel self-organizing network can be further divided into time series and time-point series according to the time selection method. The changes in the value of the curvilinear parallel self-organizing network are also inclined, but the tendency is not fixed, the magnitude and direction of the change may change, and the change of the value is not periodic. The linear parallel self-organizing network value changes have a certain tendency; that is, within a long time range, the value of the parallel self-organizing network gradually rises or decreases, and an upward or downward trend can be observed.

3.3. Quantification of Score Prediction in Sports Events.
The normalization of artificial neural network sports score prediction requires proper processing of data to meet the special requirements of artificial neural network for data. According to different neuron transfer functions, many artificial neural network models only accept numerical data in the range of [0, 1] and [−1, 1]. Therefore, the data must be scaled down to this interval. Scalar numerical data are generally evenly distributed in a certain range and can be directly mapped to the interval [0, 1]. If the distribution of numerical data is not uniform, you can use piecewise linear equation or logarithmic equation to transform the data, and then scale down d, N to specify the interval. Discrete data are represented by encoding them with 0 and 1, or assigning a value to them in a specified continuous interval. Numerical

data represented by vectors or arrays can sometimes be processed in groups; that is, the vector as a whole is subjected to regularization processing. There are several regularization methods, the most commonly used is to calculate the square root of the sum of the squares of the elements, and then it is used to remove each element. The second method is to first find the sum of all the elements, and then it is used to divide each number. In this case, the sum of the elements after regularization is 1.0, and the value of each element represents their contribution to the group. The third method is to remove each element with the maximum value in the vector. Figure 3 shows the quantitative processing of score prediction for sports events.

Therefore, all of the above factors can be converted into time factors, and the parallel self-organizing network analysis method can be used to mathematically model the time factor, that is, the value of the score of a sports event. Through the historical value of the score of a sports event, it is possible to discover the change of the score of a sports event over time and predict the future development of sports event scores. On the other hand, the score of sports events is a relatively open data, which is relatively easy to obtain, which also provides convenience for research. The parallel self-organizing network of sports scores is a parallel self-organizing network with the value of sports scores as data elements. The scores of sports events can be taken every hour, every day, or other time as the parallel self-organizing network of sports scores. In competition, a vector is used as the input of the neural network. Each unit of the competition layer will form a discriminant function according to the weight of its own network and calculates the discriminant function with the input vector as the value of the independent variable, and the function value is the best. The neuron becomes the best matching neuron in this input. Other neurons surrounding the best matching neuron within a certain range will participate in the cooperation and become the neuron to be adjusted in the process of self-adaptation. Adaptive neurons within the topological neighborhood of the optimal neuron must modify their own network connection weights according to the value of the input vector to achieve the discriminative mode of these neurons.

3.4. Recursive Prediction Model Weight Factor.
Data preprocessing is an important step in the data prediction process. The quality of the data directly affects the quality of the mining effect. Data preprocessing includes data cleaning, data integration, data conversion, and data reduction. The task of data cleaning is to eliminate noise or inconsistent data. The inconsistency of the data will reduce the credibility of the data prediction results.

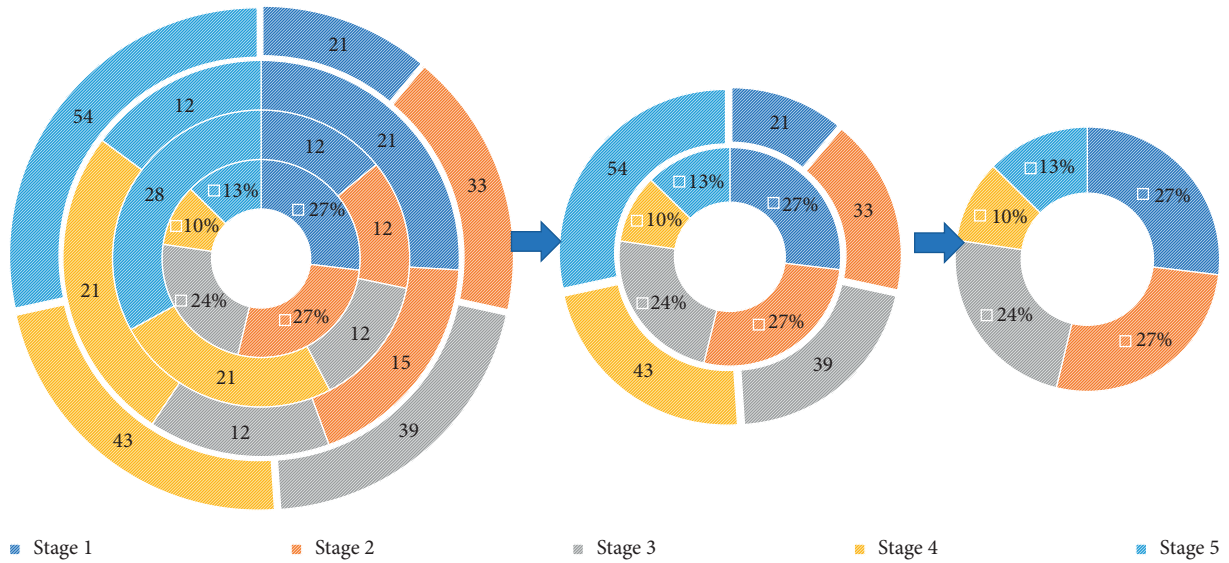
The risk value of the host is obtained by adding the risk value caused by the vulnerabilities of the related state nodes. The database construction module is responsible for processing the system configuration information and vulnerability information obtained by the scanning module, extracting their nonquantitative attributes and quantifiable attributes, forming an information database and a


Figure 2: Node distribution of the nonlinear neural network.
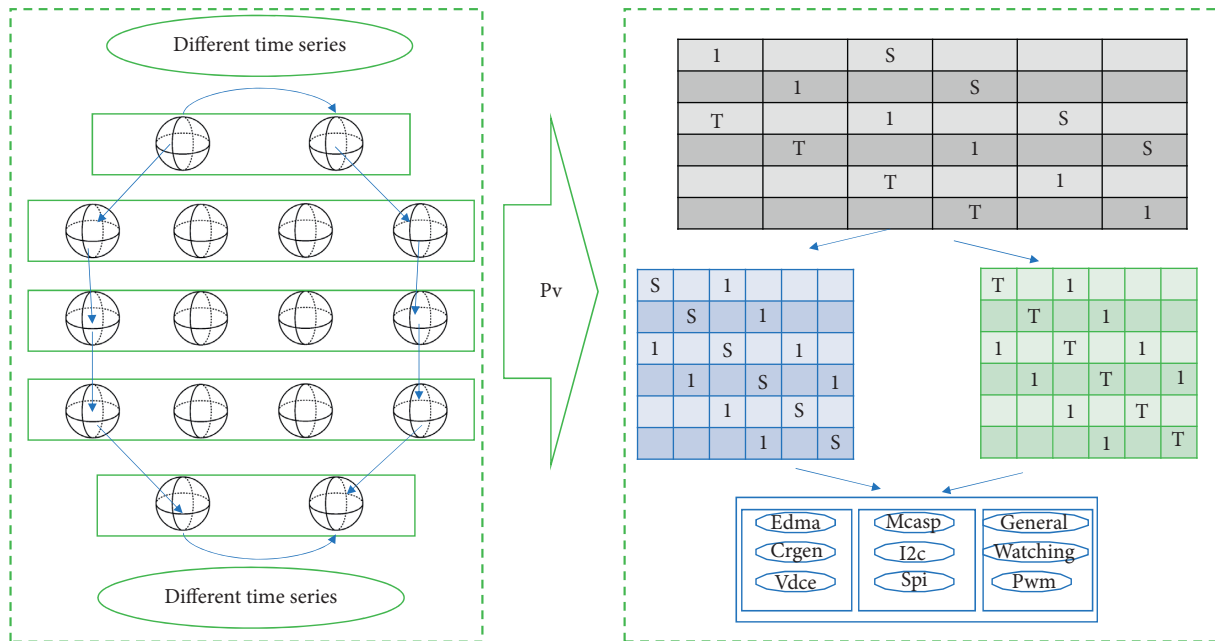

Figure 3: Quantitative processing of score prediction for sports events.

vulnerability database; it is also responsible for analyzing the relationship among vulnerabilities. Mining was performed to form a vulnerability database. The data used for data prediction may come from multiple actual systems, so there is a problem of heterogeneous data conversion. Because there may be many inconsistencies between the data of multiple data sources, data integration is not a simple copying process. Data transformation is the transformation or unification of data into a form suitable for mining, including data generalization, normalization, attribute construction, and smoothing. Data reduction includes operations such as data aggregation, attribute selection, and data compression. Figure 4 shows the clustering of the weight factors of the prediction model.

Multilayer perceptron is a popularization form of the single-layer perceptron. The information of the multilayer perceptron network is forwarded layer by layer, and each unit of the lower layer is connected to each unit of the upper layer. The input unit operates layer by layer according to the input/output relationship, and the connection weight between each layer can be adjusted by learning rules. It can be seen that the multilayer perceptron is actually a design of multiple single-layer perceptrons through appropriate combination, which can realize any shape division. In this method, each discrete class is assigned a value from 1 to N represented by a binary number. For example, if a variable has 32 possible values, it can be represented by a binary vector of length 5. As long as the discrete value is arbitrary
FIGURE 4: Weight factor clustering of the forecasting model.

and does not have any order, binary code is a better representation. However, when the discrete value is converted to a binary code, the bit value varies greatly. For example, the binary code of the seventh element in a discrete class is 000111, and the binary code of the eighth element is 001000. Hamming distance is a measure of the similarity between two binary numbers, expressed by the number of bits of different symbols in two codes. In this case, the Hamming distance between 7 and 8 is 4. If you want the neural network to think that the two input modes of 7 and 8 are similar, you must choose the thermometer code.

4. Application and Analysis of Sports Event Score Prediction Model Based on Parallel Self-Organizing Nonlinear Neural Network

4.1. Parallel Self-Organizing Nonlinear Neural Network Data Preprocessing. The nonlinear neural network selected in this paper has a hidden layer, and every 10 pieces of data are used as a set of inputs. In the training phase, a matrix composed of 500 groups of 10-dimensional input vectors is selected as the input matrix, and the matrix composed of the target value corresponding to each group of input vectors is used as the output matrix. The parameters are adjusted until the error reaches the target value of training times, stop training. In the prediction stage, the new data are used as the input vector, the corresponding predicted target value is calculated according to the adjusted BP neural network, and the actual target is compared to evaluate the performance in Figure 5.

For the measured parallel network, we calculate the ratio of pseudo-neighbors from the minimum embedding dimension. When the ratio of embedding dimension m to pseudo-neighbors is less than 5%, pseudo-neighbors no longer increase with embedding dimension. When it decreases, it can be considered that the singular attractor is fully expanded, and m at this time is the minimum embedding dimension. Generally speaking, when the distribution of phase-space points is relatively sparse, it is better to use the pseudo-neighbor point method, because this method can automatically adjust the distance scale with the sparse changes of the phase-space points so that the statistical results are more reliable. When the phase-space points are

densely distributed, it is more reasonable to use the saturated correlation dimension method.

To quantify the risk value of the state node, it is necessary to calculate the probability that the attacker can successfully attack to reach each state node. It can be seen that the average relative error of the PCA-GABP prediction model is both the smallest. The number less than 3% is 39, which is 2 more than the number where the absolute value of the relative error of the GABP model is less than 3%. After comparing and analyzing the data in the article, it can be concluded that the model whose input data have been processed by PCA has a higher prediction accuracy than the unprocessed model; at the same time, regardless of whether the input data has been processed by PCA, the BP neural network improved by GA prediction accuracy is significantly higher.

4.2. Realization of the Simulation of the Score Prediction Model for Sports Events. Also taking the sports event factor as an example, the GA nonlinear neural network has 48 inputs; that is, there are 48 neurons in the input layer of the network, and the output is also 48; that is, there are 48 neurons in the output layer of the network. Using the floating-point coding scheme, each connection weight or threshold is directly represented by a real number, and each individual contains a network ownership value and threshold. The weight of a network is composed of two parts.

Finally, the asset damage value caused by the related vulnerabilities is multiplied by the asset value of the host node to quantify the risk. This article has 48 input neurons and 48 output neurons. Assuming there are 36 hidden layers, plus the thresholds of the hidden layer and the output layer, the code length of each individual is $48 \times 36 + 36 \times 48 + 36 + 48 = 3540$. We input the training samples in the article into the prediction model, and after many debugging, it is finally determined that there are 36 nodes in the hidden layer. The simulation results of the GABP neural network model are as described in the text. Figure 6 shows the score forecasting training situation of sports events.

If the total input of the neuron is far away from the threshold, the actual output of the neuron is either the
FIGURE 5: Distribution of connection points of parallel self-organizing nonlinear neural network.
FIGURE 6: Score prediction and training situation of sports events.

maximum value or a small value due to the saturated nonlinear characteristics of the neuron. When the total input of a neuron is too far above the threshold, it is said to enter the saturation zone. When the total input falls into the saturation zone and the actual output contradicts the target output, it is incorrect saturation, that is, false saturation. At this time, there needs to be a large amount of modification to the weight, but in fact, because the derivative value is close to zero at this time. The amount of modification of the de-rivative weight is very small. The same is true for hidden layer neurons, but the error is calculated by error back propagation. Once learning enters the false saturation state, it will take a long time to get rid of this state or even unable to find the global optimum. Table 1 is the description of hidden layer neuron training.

Calculated by the pseudo-neighbor method, the mini-mum embedding dimension m is 9, the DRNN model is

TABLE 1: Description of hidden layer neuron training.

Index number	First level	Second level	Third level
		0.31	0.64
1	DRNN layer capability	0.22	0.21
		0.54	0.08
		0.24	0.13
2	DRNN layer ability	0.46	0.56
		0.11	0.34
3	Hidden layer neuron training	0.09	0.24
		0.27	0.32

constructed, the recursive delay is 1, and the same $9 \times 21 \times 1$ nonlinear neural network is constructed. The first 2000 points among the 3000 points are used as training data, and the last 1000 points are used as prediction data. Since the predicted curve is relatively close to the actual curve, it is

difficult to distinguish it from the graph, so only the absolute error $P(1)$ of the DRNN model and the nonlinear neural network prediction are given.

When network administrators find unknown vulnerabilities, they need to integrate the vulnerability information and submit it to the national information security vulnerabilities by e-mail. In the training phase, the network is used to layer the input data into several categories and calculate the weighted average difference corresponding to each category of data. In the prediction stage, the trained neural network is used to divide each group of input data into a certain classification area, and then, the prediction is made based on the calculated weighted average difference. The article lists the results of the self-organizing difference weighted average method to predict the results of the parallel self-organizing network of the sports event score, that is, when the number of historical data classifications is different.

4.3. Example Application and Analysis.

In the experiment, we set the output as $y(t+1)$ and then input as $x(t-4)$. The network has 5 nodes, and the time interval between each neuron is 1. In the experiment, 2500 data are generated on each chaotic parallel self-organizing network of the benchmark, and the whole of them is divided into three parts: training data, verification data, and test data. The ratio of the amount of data of the three parts is $14:6:5$, that is, 1,400 training data, 600 verification data, and 500 prediction data. It can be seen that the hidden layer nodes should be twice the input layer, that is, 10 nodes.

Then, the staff will analyze the vulnerabilities, and only after several working days can the information such as the category and hazard value of the vulnerabilities, be published on the official vulnerability platform. The output layer has only one neuron, that is, the predicted value of the stock closing index on the next day. The structure of the recurrent neural network is 51. The DRNN model in this paper is greatly improved relative to the nonlinear neural network model, and it can be seen that the fitting degree of the true exponential curve is also better than the fitting degree of the nonlinear neural network model. It can be seen that the error of the recursive model in this article is concentrated between $(-20, 20)$, the error value is small, the error of the nonlinear neural network model is between $(-80, 40)$, the error value is large, and some points deviate greatly from the true value, which is caused by the high degree of the feedforward network. Figure 7 shows the output effect of the sports event score prediction network.

This will not only cause a huge workload for the vulnerability management staff, but, more importantly, the network administrators will not be able to obtain information about unknown vulnerabilities in a timely manner. Because these feature variables may have high correlations, these features are redundant features. The results show that although the overall detection rate is very high, the U2R class is almost undetectable, and the R2L detection rate is relatively low. There is no doubt that this is because the number of samples is too small, which makes it difficult to build a
FIGURE 7: The output effect of the sports event score prediction network.

classifier for these attack classes. The error detection rate is high, and the two types are mostly detected as normal types, which are absolutely not allowed in IDS. To avoid this, deduplication is performed before training. In order to improve the performance of the classifier without greatly changing the number of samples in the data set, this article increases the number of U2R samples in the data set to ensure the basic classification performance. The system structure adopts the client/server structure. The server is responsible for scanning the hosts and devices in the network to obtain the configuration information and vulnerability information of all the hosts in the network; the client is responsible for collating the scanning results to form various databases. On this basis, certain mathematical methods are used to measure the overall risk assessment value of the network and determine the risk level. Therefore, in addition to filtering irrelevant features, the optimal feature subset must also filter redundant features. Figure 8 shows the convergence of the sports event score prediction network.

There are N individual individuals to form the initial population. The value of the population number N will affect the efficiency of the entire algorithm. If the value of N is too large, the calculation amount will increase, and the running speed will be too slow. If the value of N is too small, although the operating speed can be increased, the diversity of the population is reduced to a certain extent, which may cause premature convergence, that is, premature maturity. According to experience, the value of N is generally between 10 and 200.

Feature selection methods can affect machine learning performance, model complexity, and model running speed. One of the more popular feature selection methods is to select n variables that are highly correlated with categorical
Figure 8: Convergence of the sports event score prediction network.

variables. Therefore, only the first six principal components need to be extracted under the condition that the loss of the original data is not too much information, so as to achieve the purpose of principal component extraction. It can be seen that the prediction points with larger relative errors are significantly reduced, which is 0.5% less than the maximum relative error of the nonlinear neural network, After taking the absolute value of 48 relative errors, 4 points have an error of more than 5%, 4 points are between 4% and 5%, 3 points are between 3% and 4%, and 8 points are between 2% and 2%, and the improved BP neural network has achieved better prediction results.

5. Conclusion

By reviewing relevant materials and literature, we outline data prediction and neural network related research. The artificial neural network data prediction, data transformation, data representation, and data preprocessing are studied. We made a more in-depth study on the use of artificial neural network methods for clustering, based on the in-depth study of the SOM clustering algorithm, optimized the SOM learning algorithm, and then studied the layer expansion self-organizing mapping network (GHSOM), and put forward the GRAGHSOM algorithm that introduces gray relational analysis. Regional competitiveness is a typical nonlinear complex giant system, and it is difficult for traditional linear methods to obtain satisfactory prediction results. At the same time, the experiment proves that this model has great advantages in pattern recognition. The hidden layer quantum neuron of the nonlinear model uses the linear superposition of the nonlinear basis function as

the activation function. At the same time, the thesis gives the learning algorithm of a nonlinear neural network. However, in feature selection, combining variables that are highly correlated with categorical variables may not necessarily improve the performance of the classifier. The neural network method can handle systems that are difficult to describe with mathematical models. It has strong parallel processing, self-adaptation, self-organization, and arbitrary approximation to nonlinearity. The experimental results show that the GRAGHSOM algorithm reflects the importance of each component of the sample vector in the model in the process of high-dimensional data clustering and can perform clustering more accurately; for the application of local sports score prediction (LWF) in training, we studied the perceptron neural network and successfully applied the perceptron neural network to the local sports event score prediction system.

Research Article

Big Data Precision Marketing Approach under IoT Cloud Platform Information Mining

Wang Li (ID)

Business School, Xijing University, Xi'an, Shaanxi 710123, China

Correspondence should be addressed to Wang Li; 20030007@xijing.edu.cn

In this article, an in-depth study and analysis of the precision marketing approach are carried out by building an IoT cloud platform and then using the technology of big data information mining. The cloud platform uses the MySQL database combined with the MongoDB database to store the cloud platform data to ensure the correct storage of data as well as to improve the access speed of data. The storage method of IoT temporal data is optimized, and the way of storing data in time slots is used to improve the efficiency of reading large amounts of data. For the scalability of the IoT data storage system, a MongoDB database clustering scheme is designed to ensure the scalability of data storage and disaster recovery capability. The relevant theories of big data marketing are reviewed and analyzed; secondly, based on the relevant theories, combined with the author's work experience and relevant information, a comprehensive analysis and research on the current situation of big data marketing are conducted, focusing on its macro-, micro-, and industry environment. The service model combines the types of user needs, encapsulates the resources obtained by the alliance through data mining for service products, and publishes and delivers them in the form of data products. From the perspective of the development of the telecommunications industry, in terms of technology, the telecommunications industry has seen the development trend of mobile replacing fixed networks and triple play. The development of emerging technologies represented by the Internet of Things and cloud computing has also led to technological changes in the telecommunications industry. Operators are facing new development opportunities and challenges. It also divides the service mode into self-service and consulting service mode according to the different degrees of users' cognition and understanding of the service, as well as proposes standardized data mining service guarantee from two aspects: after-sales service and operation supervision. A customized data mining service is a kind of data mining service for users' personalized needs. And the intelligent data mining service guarantee is proposed from two aspects of multicase experience integration and group intelligence. In the empirical research part, the big data alliance in Big Data Industry Alliance, which provides data mining service as the main business, is selected as the research object, and the data mining service model of the big data alliance proposed in this article is applied to the actual alliance to verify the scientific and rationality of the data mining service model and improve the data mining service model management system.

1. Introduction

Industrial integration refers to the dynamic development process in which different industries or different sectors of the same industry penetrate and cross each other and merge into a whole, gradually developing into a new industry. Industrial integration is not only studied as a development trend, currently, but industrial integration has also developed into a realistic choice for the development of the communications industry [1]. From the perspective of the development of the telecommunications industry, in terms

of technology, there is a trend of mobile substitution for fixed networks and triple-play convergence in the telecommunications industry, and the development of emerging technologies represented by the Internet of Things and cloud computing has also led to technological changes in the telecommunications industry, making telecommunications operators face new development opportunities and challenges. In terms of business, full-service operations have been used as the main mode of operation in the telecom industry around the world [2]. Big data trading platforms led by data production or service enterprises have become the

main medium for data trading activities, and these enterprises have actively explored in specific fields and industries and formulated data trading rules, norms, and targets for their respective platforms, but there are generally unclear boundaries in functional positioning, forming multiple-segmented trading markets, making it difficult to achieve scale and industrial development, leading to low mobility of data resources [3]. This requires enterprises in different fields to integrate or cooperate as well. These companies have made active explorations in specific fields and industries, and formulated data transaction rules, specifications, and goals for their respective platforms. However, there are generally unclear boundaries in functional positioning, forming multiple-segmented trading markets, and it is difficult to achieve scale. The development of globalization and industrialization has led to low data resource mobility. Although enterprises with strong capital can supplement the data by acquiring small enterprises, one enterprise cannot achieve the comprehensive data required by market demand anyway, not to mention that acquisition activities are also unattainable for many SMEs. Therefore, many geographically dispersed data resource-based enterprises, technology-owned enterprises, service-application enterprises, network business enterprises, infrastructure enterprises, etc. The big data industry chain relies on advanced Internet and mobile Internet and other communication methods to provide data services as the mainline, by bridging the data resource gap of alliance members, in data transactions and big data industry operations, to complement each other with resource advantages [4]. By bridging the data resource gaps of the alliance members, the alliance aims at complementing resource advantages, innovating business service models, and enhancing their competitive advantages in data trading and big data industry operation, and finally forms a new cross-enterprise organization form of benefit sharing and risk sharing—big data alliance.

Although the IoT public cloud platform is developing fast and provides comprehensive functions, public cloud can support more user access and reduce cloud platform load, the public cloud access is mainly HTTP, HTTP is suitable for some devices with low sensitivity to real time, and the devices with high sensitivity to real-time are not suitable for accessing the public cloud, such as logistics monitoring in industrial production, which requires real-time monitoring logistics information flow, and when you need to control or send orders to a certain aspect of the logistics chain, you need very good real time to ensure that the orders are delivered accurately and on time. And in some enterprises, enterprises have high-security requirements for data in production, such as security monitoring, and some design enterprise originality and commercial secrets of data cannot be stored in the public cloud platform, such as the collection of enterprise equipment data, and enterprises need their servers to save equipment data [5]. What enterprises need is a platform that can meet the production needs of enterprises, especially for domestic small and microenterprises, enterprises focus on different directions, the product data in the enterprise are also

different, the demand for the platform is also different, so the public cloud platform is not suitable for diverse needs. For different data needs of different enterprises, scalability should be built to meet the needs of enterprise data platform, so a private platform for different enterprises with different data requirements should be built, a scalable platform should be built to meet the data requirements of enterprises, so building a private platform for enterprise IoT is more capable of promoting the combination of IoT technology and actual enterprise production [6].

The construction of the data aggregation service model of the original-level data aggregation service, the feature-level data aggregation service, and the decision-level data aggregation service of the big data alliance enables the members of the Alliance to break through their development bottlenecks and form a value-added industrial chain with the sharing of data resources as the cooperation link and promotes the virtualized cross-regional operation of the Big Data Alliance; on the other hand, with the data warehouse as the centre, relying on the Big Data Alliance data aggregation service model, it can provide convenient and real-time quality data services for the majority of users. Therefore, the data aggregation service model of building high-quality original-level data aggregation service, feature-level data aggregation service, and decision-making-level data aggregation service for big data alliance can rapidly accelerate the efficiency of using and sharing data resources of big data alliance and, finally, realize the value-added of data resources of big data alliance. Taking data services as the main line, by making up for the data resource gap of alliance members, in the operation of data transactions and big data industry, with the goal of complementing resource advantages, innovating business service models, and enhancing its own competitive advantages, it has finally formed benefit sharing and risk sharing a new cross-enterprise organization form.

2. Related Works

Nowadays, the competition between the major giants in the field of e-commerce is becoming more and more fierce, and in the way of marketing coordination, the effective self-operated coordination and precision marketing strategy has been more widely used and achieved certain results. As an emerging industry and tool, with the rise of e-commerce, precision marketing is also a new thing in the advertising industry, and the research results are not supported by specific systems [7]. But it is undeniable that precision marketing in today's new network business model is a more reduced cost, can bring accurate traffic means of communication, can be for small- and medium-sized enterprises in the industry in the case of tall buildings for more benefits, and have their foothold [8]. For large enterprises, accurate customer can greatly save publicity costs, and operating costs can make the enterprise to the customer's service more personalized. Future-oriented precision marketing is coming soon due to the role of capturing people's needs in the mainstay of the advertising industry [9]. With the rapid spread of information, the concept of precision marketing

has become familiar and is gradually developing into a new marketing concept. For this reason, based on the background of the rapid development of e-commerce, the connotation of personalized precision marketing and its characteristics will be targeted research, and its marketing strategy will be analyzed and discussed [10]. Personalized precision marketing has several characteristics and advantages, and the main strategies for e-commerce enterprises to carry out personalized precision marketing are to improve the level of personalized services, accelerate the process of enterprise informatization, and develop the precise positioning of enterprises [11].

The target market is the market demand that the enterprise must meet in the process of marketing, that is, the object of the enterprise's service [12]. No enterprise or product can meet the overall needs of all consumer markets, so it can only choose a certain range of target markets for the enterprise as well, and market positioning is a certain market position that the enterprise specifies to highlight its products according to the consumer demand level. After selecting the target market, due to market competition and a wide range of information, to gain market advantage, the enterprise must form a product with different characteristics from its competitors after understanding their characteristics to form a strong impression in the minds of consumers. The purpose of market positioning is to gain a competitive advantage and attract more potential consumers. This theory is very applicable to operator big data marketing [13]. This is because the marketing of operators' big data is not only to sell the operators' data to the target customers after "desensitization," but also to bundle the operators' big data with the customers' interest chain to achieve a solution where everyone benefits, and as a communication service provider, good service is crucial to the development of big data business [14].

Big data marketing generally includes four processes such as data collection, data mining, and analysis, predictive analysis, and data result in feedback. Compared with traditional marketing methods, big data marketing has advantages such as high timeliness, individual customization, high-cost effectiveness, and relevance promotion. The advent of the era of big data has brought great changes to social production and life. As a representative innovative technology, the mobile Internet has brought massive user behavior data, providing unprecedented space and potential for industries and enterprises to obtain deeper and more comprehensive insights, which makes big data marketing break through the boundaries of Internet companies, so that all walks of life can have the opportunity to have an in-depth understanding of their market environment, service targets, customer groups, or even competitors. The economic environment is an important factor in realizing demand. The operation and development of the economic environment will directly or indirectly affect the market decisions of enterprises, and it is mainly expressed in marketing as the level of economic development of a country or region and the purchasing power of consumers, which determines the size of the enterprise market.

3. IoT Cloud Platform Big Data Information Mining Precision Marketing Analysis

3.1. IoT Cloud Big Data Platform Construction. The overall architecture of the enterprise-oriented IoT cloud platform system needs to be designed from the perspective of data and enterprise users. For data, the flow between the data from the collection device to the storage system needs to be considered, and for enterprise users, the cloud platform only needs to provide users with the services they need, and the internal implementation of the cloud platform and the underlying data collection is transparent to the users [15]. Therefore, the architecture needs to meet the function of each subsystem, determine the responsibilities between each subsystem and the interface definition of other subsystems, and conform to the principle of high cohesion and low coupling defined by software engineering, and the overall architecture is easy to maintain and expand later. For example, security monitoring, and some design companies' original and commercial secret data cannot be stored on public cloud platforms. For example, corporate equipment collects data, and companies need their own servers to store equipment data. The system provides relevant services in the form of interfaces and only needs to explain the interface-related use issues and use methods, and the internal implementation logic is transparent to the user, and the user only needs to operate in the local client to complete the relevant tasks.

Data communication is the foundation of the enterprise private cloud platform and the starting point of the cloud platform architecture. In enterprise production, due to the wide variety of hardware, each hardware specification is different, communication format and device access are different, such as vehicle positioning equipment can directly connect to the open interface of the cloud platform to transmit data, but some small embedded devices such as GPS equipment cannot directly use the HTTP protocol to transmit data, so it needs embedded gateway as middleware to transmit data. Due to the different kinds of equipment measurement data and the different functions of each device, the data reporting period of some devices is very long; for example, the level meter in safety monitoring only needs to report one data a day, which does not require high real time, but, for example, in the MES workshop intelligent manufacturing system, it needs to monitor the state of the material transportation process in real time, so it needs to upload data every minute or even every 30 S or shorter period. This kind of equipment has high requirements for real-time data and for real-time commands issued by the cloud platform, as shown in Figure 1.

For the different data requirements of different enterprises, a scalable platform that meets the data needs of the enterprise should be built. Therefore, building a private platform for enterprise Internet of Things can further promote the combination of Internet of Things technology and actual enterprise production. The enterprise private IoT cloud platform needs to be able to be compatible with the connection of different types of devices with different real-time requirements. The whole communication system has
FIGURE 1: Structure of communication services.

three layers: the bottom device and embedded gateway, the intermediate device access interface layer, and the cloud platform data processing layer. For the device layer and the interface layer, due to the different real-time requirements of the devices, the cloud platform provides two types of device access: HTTP protocol access, and TCP protocol access. Since the cloud platform must support many devices, to improve the device access capability of the cloud platform, the combination of HTTP and TCP is used to complete device access. First, for devices with high real-time requirements, the cloud platform provides a real-time device access interface, and devices can directly connect to the cloud platform through the TCP to directly transmit data, and the cloud platform can actively send commands to the devices to ensure the real-time data upload and command delivery [16]. Netty is a highly available multiplexed network framework, and the underlying poll implementation can support highly concurrent connections and data exchange to improve the efficiency and speed of the system.

The data storage subsystem is built by combining the relational database MySQL with the nonrelational data available MongoDB cluster, which ensures that all data can be efficiently stored and queried through a unified data access layer to access different formats and types of data. The system uses the MySQL database for the storage of structured data, such as user data, application data, device data, system log data, and device configuration, which is used to realize the structured storage and fast access of correlated data. As the cloud platform accesses different types of devices, the data format and data dimensions collected by the devices are different, and it is difficult to store unstructured data with a relational database, the system selects MongoDB for unstructured IoT data with the simple data model, strong flexibility, huge data volume, and high requirements for data access. It can quickly accelerate the

use efficiency and sharing efficiency of data resources of the big data alliance and ultimately realize the value-added of the data resources of the big data alliance.

The cloud platform needs to provide enterprises with a range of data-based services to visualize and analyze data, using Echarte as an analysis tool to visualize and analyze data in various ways. Use Baidu Map API to provide location services for users with location needs. The platform open development interface, the caller can cognize the function of the interface role, convenient to call the development of personalized applications, as shown in Figure 2.

The IoT cloud platform consists of a communication server cluster, management server cluster, MongoDB cluster, and MySQL cluster; the communication server cluster is responsible for accessing the underlying devices, processing device uploads, processing user commands, pushing real-time data, and providing application development interfaces. The MongoDB database cluster is responsible for accessing the uploaded data of devices, and the MySQL database cluster is responsible for storing relational data of users and devices in the cloud platform.

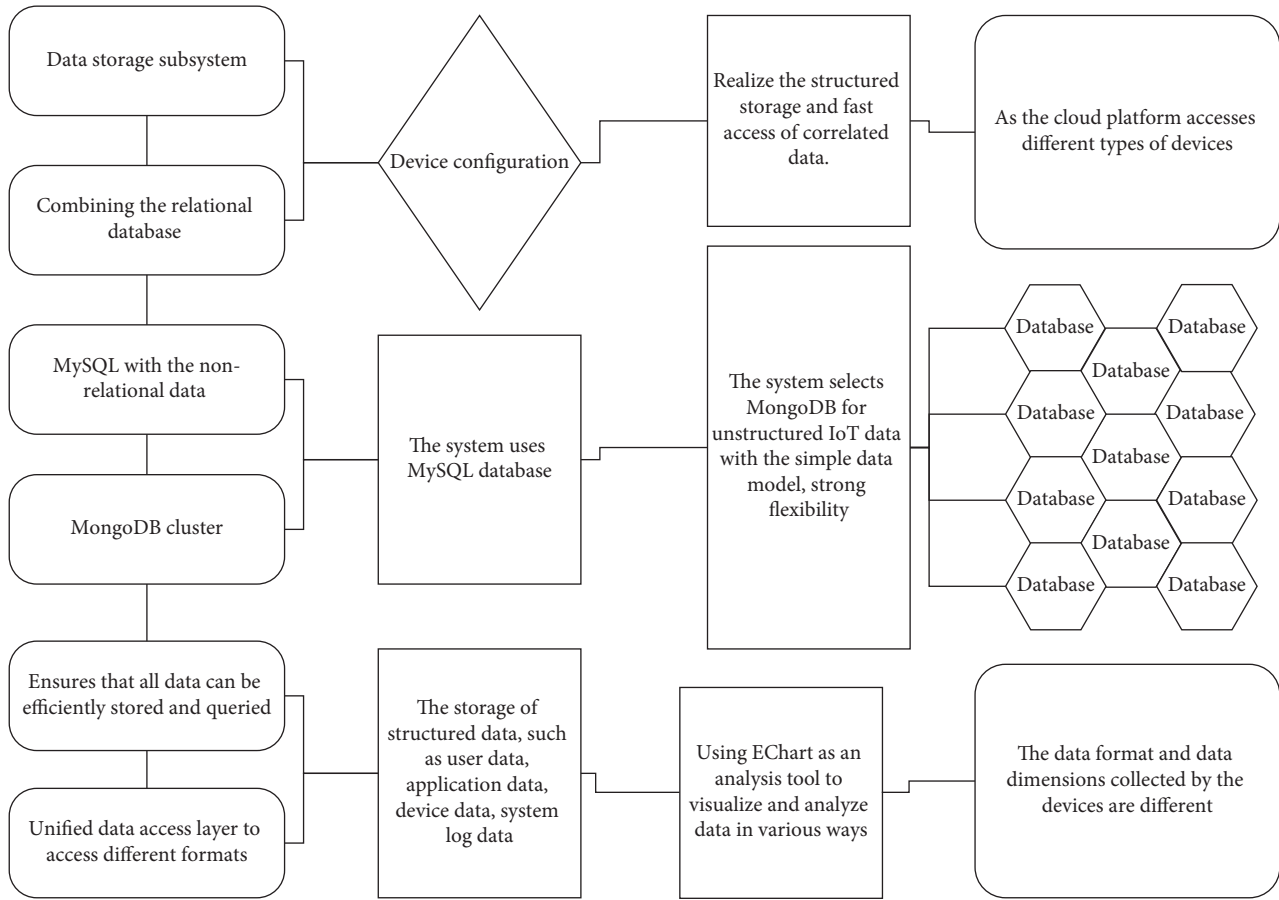
After the device establishes a connection with the gateway, the acquisition module of the device is in the dormant state, the device does not upload data and sends heartbeat information to the gateway every time, the gateway receives the heartbeat information and parses the heartbeat, and uploads it to the cloud platform after the cloud platform receives the heartbeat information, it does not query the issued command of the device in the pending issued command table, the cloud platform replies to the gateway with the heartbeat confirmation, and the gateway receives the heartbeat confirmation. After receiving the heartbeat confirmation, the gateway sends an acknowledgment frame to the device, and the device is disconnected from the


Figure 2: IoT cloud platform cluster solution diagram.

gateway. When the device acquisition module starts to collect data, the device sends the original acquisition data to the gateway, the gateway parses and re-encapsulates the acquisition data and sends it to the cloud platform, after the cloud platform receives the acquisition data and does not query the down command of the device in the pending command table, the cloud platform returns the data confirmation to the gateway, the gateway sends the data confirmation frame to the device after receiving the data confirmation, and the device is disconnected from the gateway.

When the acquisition module is collecting data, the cloud platform sends commands to the device. The device sends raw data to the gateway at regular intervals, the gateway forwards it to the cloud platform, the cloud platform receives the acquisition data and brings back the command sent by the management system to the gateway, the gateway receives the command and encapsulates the command into a command frame and sends it to the device, the device confirms the command after receiving it and sends the command confirmation frame to close the connection, the gateway sends the command confirmation message to the cloud platform, and the cloud platform transfers the command from the to-be-sent. The cloud platform transfers the commands from the command table to the already sent command table after receiving the command confirmation information.

The concept of putting the customer first has swept the world, and we are increasingly looking at what the customer thinks. Precision marketing is essentially the optimization and upgrading of segmented communication, and this model is beginning to be favoured by business owners and advertising agencies [17]. The development of precision marketing has gone through three cycles: the first stage is defined as the targeting of regional advertising messages; the second stage is the targeting of personalized customer preferences; and the third stage is the development of mobile network technology and the establishment of a personal database of Internet users, which collects and establishes a database and analyses the personalized needs of users, and then uses programmatic means to bid for advertising space in real-time, to present more precise advertising services to the public. The third stage is the development of mobile web technology and the establishment of a personalized database of web users, collecting and building the database and analyzing their personalized needs.

3.2. Information Mining Precision Marketing Design. The tag system refers to the formation of a user tag system based on basic user data through aggregation and inductive analysis, which is not directly operated externally but only used as

part of the data source for precision marketing products and other products such as the capability open platform. Data capability open platform is based on the demand of partners for data and platform resources, for partners to share Unicom data resources and infrastructure resources in a multitenant secure isolated way by opening the sample data with user identification information removed in the Unicom environment. Conduct in-depth discussions and research, and formulate corresponding marketing improvement countermeasures, which have a certain enlightening effect on the company's optimization of marketing strategies. Digital marketing is relying on massive data and big data processing capability, and under the premise of ensuring data privacy and security, optimizing the placement strategy and channels for customers in various industries through in-depth mining and analysis of big data, providing accurate marketing reach means to achieve the purpose of reducing marketing costs, and improving marketing effectiveness. Smart Footprint is to provide big data analysis services of user groups such as population density, cross-domain migration, and travel analysis for urban planning, traffic planning, and outlet location by pinpointing the number of populations within a certain granularity.

Internet data are limited by its own data genes, which are manifested in the following four aspects: first, the data of Internet companies are fragmented, e-commerce only has e-commerce sales data, no Baidu search data, and the data exists locally; second, due to company strategy and data security requirements, few Internet companies are willing to open their data to partners or competitors. Even if there is openness, more are only at the business model level and application level, and the data level is still relatively closed; third, Internet data integration is difficult, and the registered personal account is also short-term, and the account information is unstable; and fourth, the business field of Internet companies directly determines the content of data, and the scope of data is not comprehensive. Data flow requires multipart cooperation, so the architecture needs to clarify the functions between each subsystem, determine the responsibilities between each subsystem, and define the interface for other subsystems.

$$u_A = qk_0 (\beta_A - \delta_A \xi_{BA} - \delta\beta\alpha_{AB} + q_0 k_0 \zeta_{AB}),$$
$$u_A' = qk_0 (\beta_A + \delta_A \xi_{BA} - \delta\beta\alpha_{AB} - q_0 k_0 \zeta_{AB} + w). \tag{1}$$

Through the division of labour and cooperation, member companies in the big data alliance jointly develop the technologies required in the field of big data processing and provide data service solutions for users, and data resource sharing runs through the entire data service-application development process of the alliance [18]. Combined with the previous analysis process of the equilibrium state of data resource sharing in a big data alliance, the growth process of data resource stock of each member under the influence of the data resource sharing coefficient is shown in Figure 3. The results show that the data resource sharing coefficient shows a positive feedback relationship with the equilibrium state of data resource
FIGURE 3: Market share of big data applications by industry.

sharing, which directly affects the equilibrium point values under different sharing relationship patterns. By adjusting and coordinating the coalition data resource sharing coefficients, the data resource stock growth will show different equilibrium states.

Data aggregation refers to the use of scientific aggregation methods to orderly connect the scattered and isolated data resources scattered among different members of the big data alliance in a certain way, and implement the structural system rebuilding, so that data resources from different sources, at different levels, and with different contents can be integrated comprehensively, thus forming a valuable and complete system. Data correlation refers to the value transformation process of data to information (knowledge) by extracting information or extracting some knowledge from data resources by organizing and extracting features in data resources based on correlation analysis, and achieving some interesting discoveries. Data fusion refers to the process of conversion, integration, and merging in information or knowledge by using advanced big data processing technology to further concentrate and refine to form new information and new knowledge, to construct effective information resources and knowledge resources for users' domain problems-solving and release the deep potential value of big data:

$$\text{POS}_p(Q)_{(x)} = \cup PX(x^2),$$

$$\prod_B^A A(I_1, I_2, \ldots, I_m) = \bigcap_{a_j \in B} Ajl_j^2. \tag{2}$$

From the perspective of value cocreation, data aggregation is the data aggregation at the original level of the big data alliance, the data value breeding stage. In the very early days, data were considered valuable, but data that could breed great business value were not data in the traditional sense but should be referred to as data elements or data resources. This is because while data contain a great value, it needs to be further developed and utilized before the value of the data can be gradually released and amplified, which is essentially like elements and resources. In the operation of a big data alliance, whether the data resources scattered in different channels correctly and effectively brought together in the alliance is the key to the aggregation of data at the original level, which will directly affect the efficiency of the alliance operation and the final service results. It is necessary to consider the overall performance loss caused by the mutual calls between subsystems and the flow of data between the various subsystems, as well as the complexity of the cloud platform in the development process:

$$M_B = \{D_k^2 | D_B^2\},$$

$$y(x) = \text{sgn} \sum_{k=1}^N a_k \varphi(x, x_k^2). \tag{3}$$

In general, core enterprises in big data alliances tend to be more willing to proactively share data resources to maintain their core position in the network, and noncore enterprises mainly play the role of supporting support. Data sharing will be more likely to occur when a mutually beneficial symbiotic relationship is formed among the member enterprises of the alliance. In particular, the more the values of different types of member enterprises in the alliance converge, the easier it will be to understand and trust each other in cooperation, which is conducive to forming a consensus and sense of identity for data sharing:

$$F = \arg \min(M_{K \times H} g_H^2). \tag{4}$$

A service tagging system is a tag library built around multiple entity objects and connections between entities using the method of tagging description, which is an important foundation for building portraits, graphs, and networks [19]. The big data alliance establishes a rich tag library through a combination of manual and machine tagging methods while monitoring the use and effects of various types of tags, counting popular and selected tags in real time, replacing unreasonable tags in the library, and continuously adding new tags according to the needs of the business to further promote the improvement of the big data alliance data tagging system and form a dynamic collection of data interpenetration-related service tags. At the same time, if users have many instances of data resources, they can support the classification management of instance resources on the platform by binding tags to the instance resources, so

that users can customize the new tags, as shown in Figure 4. It includes the underlying device and embedded gateway, the access interface layer of the middle device, and the data processing layer of the cloud platform.

In the process of feature-level data aggregation services, the complex data structure at the bottom of the alliance is separated by the tag model view layer to achieve the flexible configuration of data resources, which can greatly enhance the operational experience of member enterprises in specific situations. Specifically, we try to flexibly build the required business modules on top of the tags, use the tags as tools to realize unified business computing operations on data, and support on-demand tag selection according to the needs of business scenarios. In the actual operation process, under the premise that the big data alliance needs to integrate the data resources of multiple members, this dynamic tag extraction approach has very good scalability [20]. In the whole service panorama modelling process, due to the limitations and inadequacies of a single method, the cross-fertilization of a rich system of multidisciplinary fusion methods is needed to support the flexible extraction of features from these massive data resources and to realize the reasonable allocation and scheduling of service resources in the service panorama modelling process to quickly respond to the personalized needs of users. big data alliance provides the function of sharing the same label attempt between multiple modules so that the results of data interpenetration correlation analysis can be further combined with algorithm module, tool module, and method module, and the objects screened by the analysis can be combined with other application systems, such as combining multiple application scenarios such as operation and maintenance management of intelligent transportation system, customer relationship management in the marketing field, and equipment supervision of enterprise production and operation. Help users to solve the core problems in specific field contexts, and improve their data service satisfaction.

4. Results and Analysis

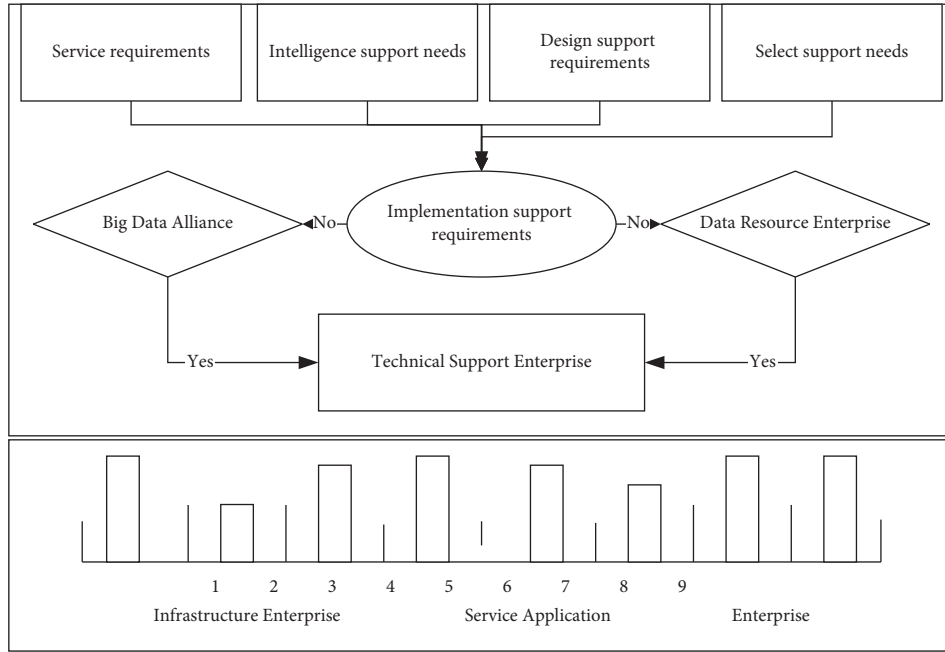
4.1. IoT Cloud Big Data Platform Performance. The shard mode is a way to slice the data horizontally, it includes a routing server mango, a configuration server mongo, and a slice server shard the data are stored by the slice server, the routing server is the entrance of the whole database cluster, and all read and write requests have to go through the routing server to distribute the requests to the corresponding. All read and write requests are distributed to the corresponding shard server. By directly transmitting data, the cloud platform can actively send commands to the device, ensuring the real-time data upload and command issuance. The TCP access method is built using the Netty framework. Netty is a highly available multiplexed network framework. The bottom layer is implemented using epoll, which can support high concurrent connections and data exchanges, and improve the efficiency and speed of the system. The configuration server stores the routing slice information of the database, and the routing server itself does not store information but reads the cluster


Figure 4: Schematic diagram of the formation of a decision-level data aggregation service offering.

configuration from the configuration server into memory at start-up. The slice server is responsible for processing the requests forwarded by the routing server to avoid excessive CPU, memory, and I/O pressure on one server. To ensure data storage security, efficient read and write, and storage system scalability, the system uses a combination of slicing and replica sets, which can ensure the data disaster recovery capability, but also enable the separation of reading and write, while the slicing mode has high scalability, can be extended to cloud computing and other data processing methods, as shown in Figure 5.

As can be seen, by the real-time analysis chart of the cloud platform system, the system can analyze the real-time fluctuation of the data to the size of the data. The data interface also analyses the data in terms of location, and the test device uploads the device coordinates, which need to be converted into the standard coordinates used by the map to improve the accuracy of the display when using Baidu Maps to display the location. The performance of the IoT cloud platform is related to the quality of the services provided by the cloud platform, which needs to be able to run stably under the pressure of high concurrency. The performance of the cloud platform is tested using the JMeter tool, which is an efficient stress testing tool based on Java technology and can simulate huge concurrency to stress test the server. In this article, we first conducted stress tests on the HTTP-based device access interface. In the basic configuration, the connection protocol is HTTP, the system test device access interface listens to port 80, the interface IP address is 192.168.3.232, the interface path is data, the device access interface sends data using POST request to send data, the data are in JSON format, the stress test data include the id of the simulated device, and the simulated data the data include temperature, humidity, latitude, and longitude.
Figure 5: Real-time analyses of data from the cloud platform.

From the test results of the cloud platform, we can see that the maximum response time of the system is 266 ms, the minimum response time is 21 ms, and the average response time is 50 ms. For actual use, due to the equipment conditions and network conditions, the equipment upload cycle is greater than the maximum response time. During the stress test, the system processing error rate is 0.00%, and the request throughput of the system reaches 76.2 times per second, which means that under the operating environment of processing 76.2 requests per second, the average data processing per second reaches 219 KB, and the system is fully

capable of correctly processing the data uploaded by the device, as shown in Table 1.

It can be seen that within 100 seconds, the host accepts 4800 TCP requests and the connection is not open; it can be seen that the average processing time of the cloud platform TCP device access server for requests is 54 ms, the minimum processing time is 19 ms, and the longest processing time is 260 ms; for the high real-time requirements of the device, it can fully meet the requirements of the device for real time, and at the same time, the server throughput can reach 47.8 times per second, which means that the server simultaneously processes 47.8 requests per second and 219 bytes of data per second, the error rate of the server is 0.00%, and the system can support normal communication of the usual system in the enterprise.

The platform application module functions, device module main functions, device configuration, issuing commands, and data display module were tested to meet the functional requirements of the cloud platform analysis, and it can fulfill the requirements of equipment access, data processing, data storage, data analysis, and so on. In the performance test, the cloud platform used the JMeter stress test tool to test the data processing capability of the cloud platform in the face of large-scale device access, and the system first used JMeter to test the performance of the HTTP protocol-based device access interface; the average processing time is 50 ms, and the maximum throughput can reach 76.2/sec. Then, the real-time device access interface was tested for performance. The test results show that the processing speed and results of the cloud platform can meet the actual production needs when facing large-scale device access.

4.2. Information Mining Precision Marketing Results. In the big data industry chain, the core competencies vary due to the different positions of the alliance members and have the following characteristics: members located in the downstream of the industry chain usually have strong capabilities in data collection, processing, and handling; members located in the midstream of the industry chain usually have strong capabilities in analysis, technology, and model building; and members located in the upstream of the industry chain usually have strong comprehensive capabilities and decision analysis, and knowledge expression capabilities. Therefore, the big data alliance establishes a capacity collaborative scheduling mechanism to give full play to the capacity advantages of each member and promote the alliance can customize data mining services for users with the optimal capacity combination. The cooperative scheduling guarantee among members is an organizational form of scheduling guarantee based on resource collaborative scheduling and capability collaborative scheduling. Through collaborative scheduling among members, it facilitates experience sharing, knowledge exchange, and member interaction to stimulate group wisdom. Therefore, the big data alliance establishes the members' collaborative guarantee mechanism to realize the integration of multiple subjects' wisdom and thus create high value in the process of realizing customized data mining services.

TABLE 1: Platform performance.

Label	Sample	Average	Max
HTTP	4.41	3.18	4.75
Request	2.46	6.12	8.82
Total	5.71	8.62	8.47
Mean	3.24	8.94	8.41

When a user makes a data mining service request, their service request needs to be analyzed and service searched. Retrieve whether there are similar historical service cases in the service case library of the big data alliance data mining service platform. If similar historical service cases exist, then service acquisition needs to be performed in the selected intelligent data mining service model, while if there are no service cases like the target case in the big data alliance historical service case library, then service acquisition needs to be performed using customized data mining services, as shown in Figure 6.

Big data alliance customized data mining services are provided by data resource-based enterprises, data technology-based enterprises, and data application-based enterprises to provide users with more targeted and personalized customized data mining services when the standardized data mining service content cannot meet user needs. The gateway receives the command and encapsulates the command into a command frame and sends it to the device. The device confirms after receiving the command and sends a command confirmation frame to close the connection. The gateway sends the command confirmation message to the cloud platform. The sending order list is transferred to the already issued order list.

Firstly, the guiding role of user-user needs should be clarified, and the construction of a feedback system for data aggregation services at the decision-making level should be emphasized as the key to the orderly development of the big data alliance. Secondly, the layout of service facilities should be scientifically formulated and reasonably planned, the allocation of service resources should be optimized, efforts should be made to cover a full range of user needs, and multilevel service feedback channels and channels should be developed. Finally, for the same user's service feedback information should pay attention to the collection from multiple channels, to form a closed-loop complete circuit of data aggregation services at the decision-making level, as shown in Figure 7.

As an emerging decision support system, the decision-level data aggregation service model extends the scope of its users to governments, enterprises, organizations, individuals, etc. Especially for enterprises, it not only supports strategic decisions of middle and senior management but also serves front-line business personnel, even including suppliers and partners. The decision-level data aggregation service model assigns service tasks to specific member enterprises through the data aggregation service platform, which requires continuous cooperation and a high degree of collaboration between different types of member enterprises so that the relevant service business content is agreed upon and the consensus is reached among the service subjects without easy ambiguity, and the joint provision of
FIGURE 6: Capability vector distance.
FIGURE 7: Results of the business model selection problem attributes.

intelligence support products, design support products, selection support products, and implementation support products service solutions.

5. Conclusion

For the heterogeneous characteristics of data, the combination of the MongoDB database and MySQL database is used to store data in data storage, which achieves efficient storage and fast access of massive IoT data, and optimizes the

data storage method for the temporal nature of IoT data, and stores the data in aggregation to improve the data reading speed. For the storage of massive IoT data and data security, the cloud platform designs a MongoDB database cluster for IoT data storage, which uses a combination of sharing and replica sets to improve the scalability of data storage and the processing capability of a large amount of data storage access. Through the analysis of the big data marketing environment, its advantages in big data marketing are greater than its disadvantages, and with the guidance of government policies and enterprises for their own development needs, big data marketing in Gansu also has a better external environment, to seize market opportunities through differentiated marketing strategies. Based on the problems and shortcomings of the big data marketing strategy, the target market of big data marketing is repositioned, and it is concluded that the government-industry, tourism industry, financial industry, and SME customer market are the key target markets of big data, and for these target markets, the marketing strategy that is more suitable for the long-term development of big data marketing is designed, that is, the strategies of product creation differentiation and operational process differentiation. In this way, we can enhance the comprehensive competitiveness of big data.

In this paper, we propose a cooperative strategy-based self-organization mechanism to reconstruct the network. The mechanism includes a comprehensive evaluation algorithm and structure adjustment mechanism. The self-organization mechanism can be carried out simultaneously with the parameter optimization process. By calculating the similarity and independent contribution of normative neurons, the effectiveness of fuzzy rules can be jointly evaluated, and effective structural changes can be realized. Moreover, this mechanism should not set the threshold in advance in practical application. In order to optimize the parameters of SC-IR2FNN, we developed a parameter optimization mechanism based on an interaction strategy. The parameter optimization mechanism based on a joint strategy, namely multilayer optimization engine, can split SC-IR2FNN parameters into nonlinear and linear parameters for joint optimization. The nonlinear parameters are optimized by an advanced two-level algorithm, and the linear parameters are updated with the minimum biological multiplication. Two parameter optimization algorithms optimize nonlinear and linear parameters, reduce the computational complexity of SC-IR2FNN, and improve the learning rate. Using the principal component factor analysis method, seven representative common factors are selected to replace the original variables, which include the profitability factor of the financing enterprise, the solvency factor of the financing enterprise, the profitability factor of the core enterprise, the operation guarantee factor, and the growth ability of the financing enterprise. Factors, supply chain online degree factors, financing enterprise quality, and cooperation factors, can well measure the credit risk of online supply chains. The logistic model shows that the profitability factor of the financing company, the debt repayment factor of the financing company, and the profitability of the core company are three factors that have a significant impact on the credit risk of online supply chain finance. Based on the improved credit calculation model, we developed an online clue risk calculation. This method is based on site conditions and can evaluate credit risk. From the test results, the improved credit scoring system is the result of facing speculative and circular credit fraud and implies that the traders of risk commentators are in a leading position in each electronic device. The results show that risk analysis is effective in any case.

1. Introduction

At present, artificial intelligence is developing rapidly, and artificial neural network algorithm is the core of research [1]. The combination of artificial neural networks and traditional industries is an effective way to solve traditional agricultural problems. The research purpose of this subject is to combine the fuzzy logic system and the artificial neural network into the fuzzy neural network through research and use it in

e-commerce credit risk assessment [2]. Fuzzy control is to imitate people's judgment and plot reasoning to deal with problems that are difficult to solve by general methods, especially nonlinear problems, problems that cannot be modeled but require precision. The membership function and rule design in fuzzy logic control are all artificially set, and in software design, the more the rules there are, the worse the real-time performance of the control operation will be. The artificial neural network has good self-adaptive

learning ability. It mainly works by simulating the biological neural network, but the disadvantage is that its ability to express rules is poor. Therefore, the fuzzy logic system and neural network are combined to make full use of the advantages of both, make up for the shortcomings of both, and form a fuzzy neural network algorithm [3, 4].

With the development of the e-commerce industry, its risk issues have become increasingly prominent [5]. Credit risk has become an important reason hindering the development of the industry. Various disputes and complaints caused by credit risk issues reduce consumer trust and repeat purchase rates, increase customer acquisition costs and user transaction costs of e-commerce platforms, and hinder the further development of e-commerce [6]. According to the investigation of the Internet fraud observation website, in areas with mature e-commerce markets such as the United States, the amount of money lost by traders due to seller credit risk is also increasing year by year; while China's market system is imperfect, legal and credit systems are imperfect. The traders are more likely to suffer losses because of this. Relevant scholars believe that the issue of credit risk has become an industry and social problem that needs to be resolved urgently [7]. The influencing factors of e-commerce credit risk issues include technical reasons not only caused by the separation of time and space on the Internet but also related to whether the management of the virtual market is perfect and the soundness of the legal system, and the most important thing is the credit choice of the transaction subject [8]. The information asymmetry caused by the virtual nature of the network has aggravated the inequality of information between the parties to the transaction. From the perspective of the transaction characteristics of e-commerce, the e-commerce platform has large user traffic and low stickiness, which leads to short-term interests driven by sellers and triggers their actions [9, 10].

The interval class II fuzzy neural network structure asks the problems of solution difficulty and computational complexity to design the interval class II structure. The interval second kind of fuzzy Shinto network is constructed in an organized structure, and the computational complexity is low. B2C electronics led event supply finance credit risk crunch creates a comment price model and defines a comment price index by analyzing the models attributed to factor analysis and logistic back. When calculating the risk of a transaction, according to historical transaction records, the risk calculation is divided into three categories. When calculating the risk, the commodity price, seller credit value, seller credit rating, historical average price, and transaction failure threshold are considered. The calculation of the risk of cycle deception also takes into account the important factor of the deception cycle. At the same time, this article also gives the algorithm idea of seeking the deception cycle. Through experiments on periodic fraud and credit speculation transactions, we can see the impact of commodity prices, credit values, credit ratings, and transaction failure rates on the value of risk. The graphic image drawn by MATLAB illustrates the historical transaction process. The credit scoring method proposed in this article closely links to credit and risk and divides commodity prices into ranges.

The scoring of "good reviews" and "bad reviews" changes dynamically with the progress of transactions. This method effectively suppresses periodic fraud by increasing the opportunity cost of users with high credit values. Using the range occupancy rate of commodity prices to score effectively suppresses credit speculation and protects the interests of sellers who only sell low-priced commodities. The experimental results show that the scoring method is effective and feasible.

2. Related Work

Relevant scholars improved the genetic algorithm and then used the improved algorithm to optimize the weights of the feedforward network so that the training accuracy of the algorithm was significantly improved [11]. Researchers combined the traditional BP algorithm and the differential evolution algorithm to propose a new weight training method and used it in breast cancer prediction experiments and achieved good results [12]. Related scholars combined the differential evolution algorithm with EANN to construct the MPANN network model, which improved the function approximation ability [13].

Relevant scholars introduced mutation operators on the basis of the PSO algorithm and then intelligently fused with wavelet neural network, diagnosed transformer faults, and obtained good experimental results [14]. Relevant scholars optimized the convolutional neural network and proposed a convolutional neural network acceleration algorithm based on parameter and feature redundancy compression, which was used for image processing and proved the optimization performance of the algorithm [15]. Neural network technology has gradually developed and been used in fault detection, prediction, and classification.

It realizes the processing and expression of the ambiguity in data through membership functions and fuzzy neurons. Relevant scholars combine evolutionary computing with neural networks to propose multiple groups of classification algorithms to effectively adopt the membership functions of the fuzzer and defuzzer to the data set and use actual economic data to successfully test [16]. Related scholars have proposed a new online sequential learning evolution RL neuro-fuzzy model design and developed a dynamic evolutionary fuzzy neural network (DENFIS) function approaching the RL system method [17]. Relevant scholars apply a fuzzy neural network to environmental safety assessment, using fuzzy neural networks to deal with the characteristics of fuzzy phenomena, and have achieved good results [18, 19].

Relevant scholars use weighted Euclidean distance to improve traditional clustering, use rough sets to reduce attributes, build a neural network based on the clustering results, and establish a new prediction model and have achieved good results in wind speed prediction [20]. The researchers gave a theoretical overview of the fuzzy nervous system, discussed related knowledge, introduced two network models, and proved the performance of the model through simulation experiments [21]. Relevant scholars proposed that the data can be input in batches during the reasoning process, and the data generated by the overall rules

can be divided, thereby reducing the number of rules and completing the algorithm optimization of the fuzzy neural network, which makes it more advantageous in processing high-dimensional data [22]. Relevant scholars analyzed biological principles and proposed the method of using gene overlap to optimize the fuzzy neural network, generating T-S fuzzy rules through genetic code shifting, combining genetic algorithm with fuzzy control, realizing genetic mutation, and improving the performance of the algorithm [23].

Relevant scholars have incorporated average purchase prices, transaction density, and historical transaction records into the evaluation index system to comprehensively reflect the credit status of sellers in the transaction process [24]. Researchers and others introduce commodity prices and the credit of the evaluation subject into the credit evaluation model to identify whether there are false evaluations in the transaction process between buyers and sellers, thereby reducing the uncertainty of credit evaluation results [25]. Relevant scholars have proposed that an effective way to distinguish honest sellers and prevent dishonest sellers from trading is to establish an effective credit evaluation mechanism [26].

On the basis of previous studies, relevant scholars have investigated the historical transaction volume of sellers and the credit level of evaluation subjects and objects into the credit evaluation model [27]. Relevant scholars pointed out that the current credit evaluation model indicators cannot provide sufficient differentiation [28]. Therefore, indicators such as the historical credit of buyers and sellers and the number and amount of transactions should be increased to more accurately reflect the user's credit.

Researchers propose an online credit evaluation method that measures the similarity between new transactions and past transactions in the dimensions of product type, number of sold products, and transaction amount, thereby establishing a multidimensional credit evaluation index system [29]. From the perspective of evaluation semantics, relevant scholars have proposed an online credit evaluation system based on context, which aims to assist consumers in measuring the credibility of sellers and to screen whether consumers' evaluation opinions are of reference [30].

The topology of the neural network has a greater impact on its performance and calculation speed. Compared with the general neural network, the IT2FNN structure is more complex and contains more parameters and faces a greater computational burden in practical applications. In general, more neurons can ensure that the neural network has better performance, but too many neurons will make the calculation of the neural network too complicated, which is not conducive to practical applications. In addition, fewer neurons will reduce the performance of the neural network. Therefore, how to determine the appropriate IT2FNN structure has always been the focus of research.

3. Method

3.1. Interval Type 2 Fuzzy Neural Network. IT2FNN not only has excellent uncertainty processing capabilities but also has adaptive learning capabilities, so it can well realize the identification and control of complex nonlinear systems with uncertainties and time-varying properties. Different from a type 1 fuzzy neural network, IT2FNN adopts an interval type 2 membership function to convert the exact value into an interval fuzzy set so that it can better deal with the uncertainty in the system. In addition, IT2FNN avoids the use of primary and secondary membership functions in the type 2 fuzzy neural network to cause an overly complicated calculation process so that IT2FNN can be better applied in practical engineering.

The structure of IT2FNN is shown in Figure 1. Its structure specifically includes five layers of neurons, which are the input layer, subordinate layer, rule layer, subsequent layer, and output layer.

The output of IT2FNN is as follows:

$$
y(t) = y'(t)q(t+1) - y''(t)[1 - q(t+1)],
$$

$$
y'(t) = \frac{\prod_{j=0}^{M-1} f'_j(t)h_j(t+1)}{\prod_{j=0}^{M-1} f'_j(t)},
$$

$$
y''(t) = \frac{\prod_{j=0}^{M-1} f'_j(t)h_j(t+1)}{\prod_{j=0}^{M-1} f''_j(t+1)},
$$

$$
h_j(t) = \prod_{i=0}^{n-1} \left[w_{ij}(t+1)x_{i+1}(t) \right] + b_j(t).
$$

where $y'(t)$ and $y''(t)$ are the lower and upper output bounds of the consequent layer at time t, $q(t)$ is the scale factor, $h_j(t)$ is the consequence of the j-th fuzzy rule, $w_{ij}(t)$ is the consequent weight of the i-th input corresponding to the j-th regular neuron, and $b_j(t)$ is the j-th deviation. In addition, n represents the number of input neurons in the input layer; M represents the number of regular neurons in the regular layer; and $f_j(t)$ and $f''_j(t)$ are the lower and upper bounds of the activation intensity of regular neurons, respectively. It can be expressed as follows:

$$
f'_j(t) = \sum_{i=0}^{n-1} u'_{ij}(t),
$$

$$
f''_j(t) = \sum_{i=0}^{n-1} u''_{ij}(t+1).
$$

3.2. Design of Self-Organization Mechanism of Self-Constructed Interval Type 2 Fuzzy Neural Network. In order to improve the performance of IT2FNN, the article proposes a self-constructed interval type 2 fuzzy neural network based on collaborative strategy, including a self-organization mechanism based on collaborative strategy and a parameter optimization mechanism based on collaborative strategy. The self-organization mechanism uses a comprehensive evaluation algorithm and a structure adjustment mechanism to make the structure adjustment of the self-constructed interval type 2 fuzzy neural network
FIGURE 1: Interval type 2 fuzzy neural network structure.

coordinate with the parameter optimization process. The comprehensive evaluation algorithm uses the interneuron and interlayer information to comprehensively evaluate the structure of SC-IT2FNN and then uses the structure adjustment mechanism to add and delete fuzzy rules to realize the structural self-organization of SC-IT2FNN. In addition, SC-IT2FNN does not need to preset any threshold when making self-organizing judgments in the learning process. This feature is conducive to practical applications.

In IT2FNN, the activation intensity of regular neurons reflects the ability of fuzzy rules. Effective or redundant fuzzy rules can be found so that SC-IT2FNN has a suitable network structure. In the comprehensive evaluation algorithm, the similarity is as follows:

$$
\begin{aligned}
S_{ij}(t) &= \frac{\prod_{z=0}^{Z-1}\left[F_j(z-t-1)+F'(z+t+1)\right]\left[F_i(z+2t-1)-F''(z-t+2)\right]}{\left[F_j(z-t-1)-F'(z+t+1)^2\right]^{1/2} \cdot \left[F_i(z+2t-1)^2+F''(z-t+2)\right]^{1/2}}, \\[2mm]
F_j(t+z-1) &= 0.5\left[f_j'(t-2z-1)-f_j''(2t+z-1)\right], \\[2mm]
F''(t-2z-1) &= \prod_{j=0}^{M-1} F_j\left(\frac{t+2z}{M-1}\right), \\[2mm]
C_j(t) &= \frac{S_{ij}(t)}{d_j(t)}, \\[2mm]
d_j(t) &= \left\{\left[F_j(t+1)-Y(t-1)\right]V(t)^{-1}\left[F_j(t+1)-Y(t-1)\right]^{T}\right\}^{1/2}, \\[2mm]
F_j(t) &= \left[\,F_j(t-1)\ \ F_j(t)\ \ \dots\ \ F_j(t-1+Z)\,\right]^{-1}, \\[2mm]
Y_c(t) &= \left[\,y(t-1)\ \ y(t)\ \ \dots\ \ y(t-1+Z)\,\right]^{-1}.
\end{aligned}
\tag{3}
$$

The comprehensive evaluation algorithm uses the similarity and independent contribution of rule neurons to evaluate the effectiveness of fuzzy rules. Similarity can indicate the necessity of each fuzzy rule, and independent contribution degree can indicate the effectiveness of each fuzzy rule. Through these two evaluation indicators, it can be

judged whether each fuzzy rule in SC-IT2FNN is redundant and effective. At the same time, when calculating the similarity and independent contribution of fuzzy rules, the state value of the rule neuron is used to ensure the accuracy of the similarity and independent contribution.

In the design of this coordination mechanism, the connection of fuzzy weights and the independent transmission of degrees are three structural transformation states, which correspond to three stages of adjustment. Structure diagram of adjustment mechanism is shown in Figure 2.

3.3. Design of Parameter Optimization Mechanism for Self-Constructed Interval Type 2 Fuzzy Neural Network.

Traditional optimization algorithms such as backpropagation algorithm, gradient descent algorithm, Newton method, and Levenberg–Marquardt algorithm are widely used in the parameter optimization of neural networks, but these algorithms have the problems of slow convergence speed and difficulty in obtaining optimal solutions, such as backpropagation algorithm and gradient descent algorithm. The calculation process of Newton's method and Levenberg–Marquardt algorithm is complicated and time-consuming. There are many restrictions in the use process. Due to the numerous parameters of the interval type 2 fuzzy neural network, more calculation time is required in the process of optimizing the parameters.

In order to optimize the parameters of SC-IT2FNN, the article proposes a parameter optimization mechanism based on a collaborative strategy, that is, a hierarchical optimization mechanism. In this hierarchical optimization mechanism, the parameters are divided into nonlinear and linear parameters for collaborative optimization. Nonlinear parameters are updated using an improved second-order algorithm, and linear parameters are updated using a least-squares algorithm. This layered optimization mechanism can quickly update the SC-IT2FNN parameters, effectively improve learning accuracy, and reduce computational complexity. The hierarchical optimization mechanism includes two parts: parameter analysis and parameter optimization. In the parameter analysis, the SC-IT2FNN parameters including uncertain mean, standard deviation, scale factor, subsequent weights, and deviations will be divided into two types: nonlinear parameters and linear parameters. The following parameters are nonlinear parameters:

$$\Phi_N(t) = \begin{bmatrix} \sigma_{ij}(t-1) & q(t) & m_{ij}(t+1) \end{bmatrix}. \quad (4)$$

where $\Phi_N(t)$ is a nonlinear parameter set containing three nonlinear parameters. Therefore, SC-IT2FNN can be expressed as follows:

$$Y(t) = \Phi_L(t+1)E(t) + \Psi[x(t), \Phi_N(t)],$$
$$\Phi_L(t) = \begin{bmatrix} w_{ij}(t-1) & b_j(t) \end{bmatrix}. \quad (5)$$

There are two parts: updating nonlinear parameters using a modified second algorithm and optimizing linear parameters using at least two algorithms. But the usual parameter normalizer is the best. In addition, SC-IR2FNN

process is optimal for construction and general parameter modification, as well as nonlinear and general linear parameters. The improved quadratic algorithm and least square algorithm are used in the structure transformation process. The SC-IR2FNN network structure is used to adjust and total parameters. We downloaded it based on sales connect policy SC-IR2FNN and learned about the real stacking steps of processing. By designing a self-adjusting learning rate, the difficulty of choosing a learning rate is solved. For SC-IT2FNN, the layered optimization mechanism can effectively improve accuracy and reduce computational complexity. Using multiple sets of sample data to calculate the similarity and independent contribution of the ruled neurons not only avoids frequent adjustments to the network structure that may cause the network to fail to converge but also ensures the accuracy of the network structure evaluation and reduces the computational burden. Therefore, SC-IT2FNN has the characteristics of good generalization performance and fast calculation speed. The specific implementation process of the learning process of SC-IT2FNN is based on collaborative strategy as shown in Figure 3.

4. Result Analysis

4.1. Logistic Model and Data Selection.

In terms of supply chain financial risk management, foreign countries have developed a variety of methods to measure supply financial risk. Traditional methods include expert scoring method, fuzzy comprehensive evaluation method, credit rating method, BP neural network, and logistic model. The logistic model has the following advantages:

First, the logistic model has relatively simple requirements for data collection and processing and has strong operability; second, the model predicts the probability that the result is between 0 and 1, which can intuitively see the credit risk of the financing enterprise; Third, the model's preconditions are relatively loose and can be applied to continuous or categorical independent variables. Therefore, this paper finally chooses the logistic model to evaluate the credit risk of B2C e-commerce online supply chain finance.

Suppose the conditional probability of credit risk in financing enterprises is p. When the value of p is closer to 1, it indicates that the credit status of the enterprise is better; otherwise, the credit is not good. The logistic model does not theoretically have a critical value, and 0.5 is used as the critical value during model analysis. Therefore, this paper also uses 0.5 as the critical value when studying corporate credit risk. If the calculated value is greater than or equal to 0.5, the company's credit is considered good; otherwise, the company's credit is bad.

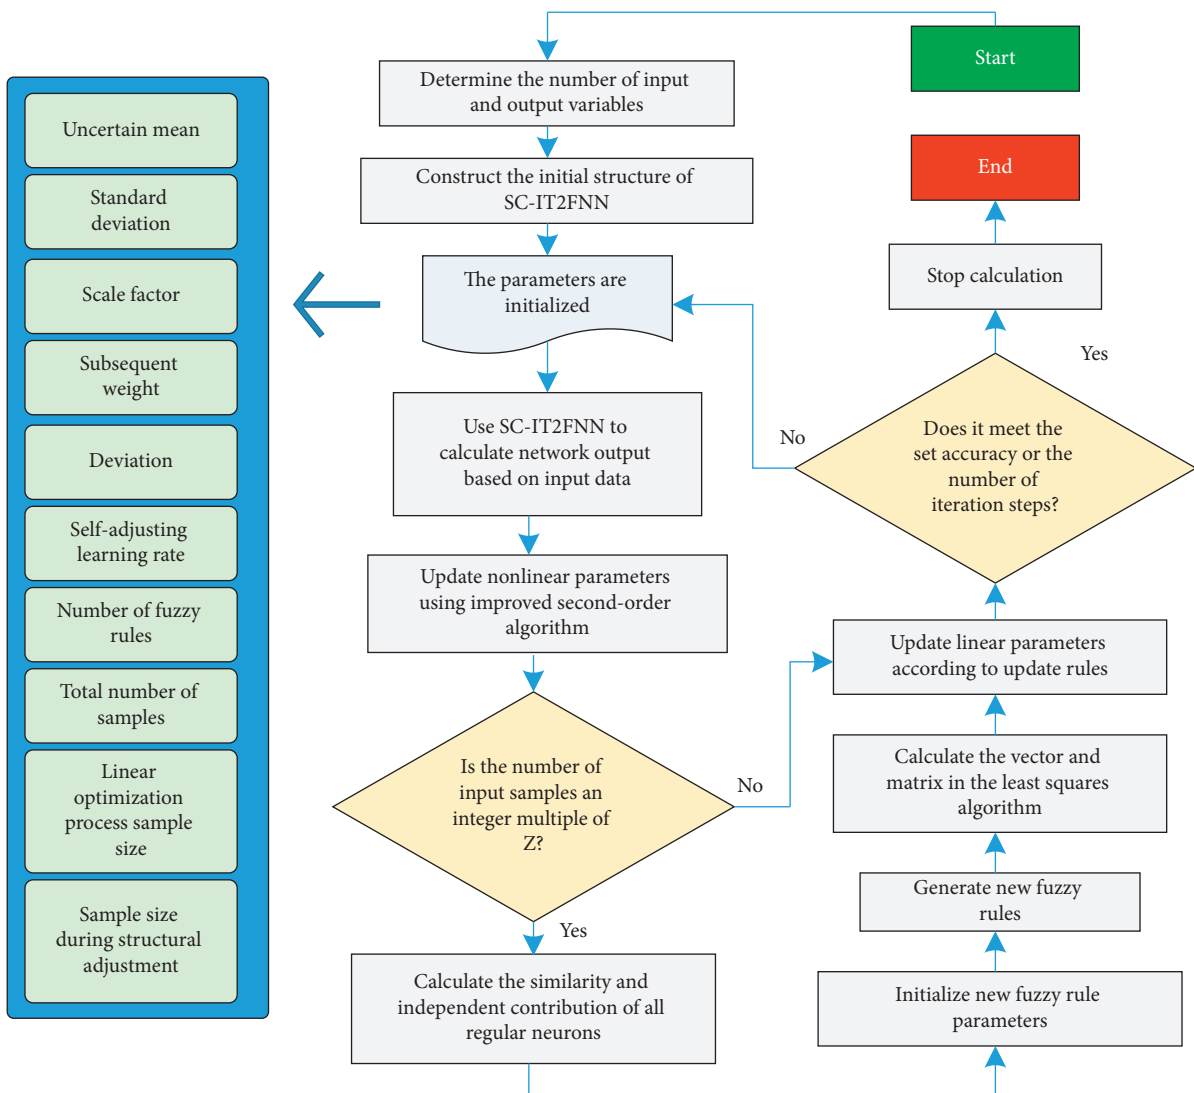
This article takes an e-commerce company's participation in online supply chain finance as an example, applies the evaluation index system established above, comprehensively evaluates the company's credit status based on the online supply chain financing model, and compares and analyzes the results. The example quantitatively analyzes the effectiveness of the logistic model on the financial credit risk control of the B2C e-commerce online supply chain.
FIGURE 2: Structural adjustment mechanism.


FIGURE 3: The specific implementation process of the learning process of SC-IT2FNN based on collaborative strategy.

E-commerce is one of the previous generation B2C online shopping platforms. There are many kinds of household appliances, such as traditional household appliances, 3C household appliances, and daily necessities. Online finance and e-commerce is one of the main directions. The supply of financial consumption platoon, investment asset management, tips, ointment, prepaid cards, preleasing, private equity financing, and other businesses have been launched. Its attempts in the internet field have further expanded the influence of an e-commerce company and realized collaboration and cooperation with upstream and downstream enterprises for a win-win situation.

The supply chain finance business of an e-commerce company is developed on the basis of its one-stop supply chain service platform. Customers can realize the transaction and financing process on the platform. However, as the business layout expands, an e-commerce company has also encountered applications. In order to help an e-commerce company better cope with the credit risk of small- and medium-sized enterprises in online supply chain finance, this article selected 40 e-commerce companies on an e-commerce platform and upstream and downstream companies in the supply chain from the Wonder database as samples. We take the lower value of the interest-bearing debt ratio of each industry in 2020 as the limit. Among the existing 40 sample companies, 6 companies have breached the contract, and 34 companies have not breached the contract.

4.2. Factor Analysis.

When using the logistic model to model the data, it is required that there should be no collinearity between the independent variables. Therefore, we first use factor analysis to standardize the variables and select representative independent variables to replace the original indicator variables. The newly acquired common factors are linear combinations of the original variables.

First, we need to check tapinle's data with Bartlett to see if the indicators selected by individuals are factor analysis. If KMO is 0.9 or greater, factor analysis is considered to be used. If it is 0.8–0.9, it is open. 0.6–0.8 spacing is normal. At one level, we then do factor analysis. The results of the Bartlett and KMO tests are shown in Figure 4.

The KMO test coefficient in this article is greater than 0.5, and the partial correlation between variables is strong. The Sig. of the Bartlett sphere test is less than 1%, indicating that we can do factor analysis.

4.3. Logistic Regression Model Analysis.

We have to substitute the logistic regression model for the seven principal components. The sample companies are used as dependent variables, and the seven principal component factors are used as independent variables. The factors F1~F7 are substituted into the logistic model for regression analysis using the entry method, that is, all variables are substituted into the equation at one time. The results of using SPSS software are shown in Figure 5.

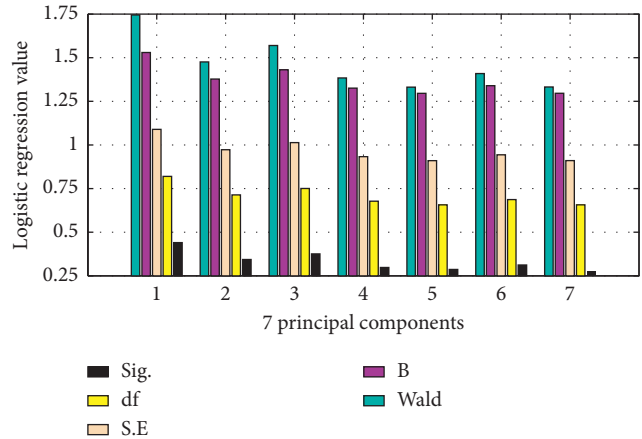
It can be seen from the regression results that the final explanatory variables of the seven models are all retained,
FIGURE 4: Bartlett and KMO tests.


FIGURE 5: Logistic regression results.

and their Sig. values are all less than 0.5, indicating that these seven variables are very convincing for predicting the credit risk of financing enterprises.

4.4. Results and Verification of Model Analysis.

The seven principal component factors calculated by using SPSS software are used as independent variables of the model, and two types of enterprises (the value of enterprises with credit risk is 1, and the value of enterprises without credit risk is 2) are selected as dependent variables. The sample results are shown in Table 1.

As shown in Table 1, we can see that in these 40 samples, among the 29 risk-free companies that have been observed, 29 risk-free companies have been predicted using the model, with an accuracy rate of 100%. Among the 6 observed high-risk companies, 5 were predicted by the model to be risky companies, with an accuracy rate of 87%. Therefore, the final comprehensive accuracy rate of this model reached 89%. This shows that the prediction accuracy of the model is high. Table 2 shows the results of the significance test using SPSS.

As shown in Table 2, the Sig. value of the model test is 0.021, which is significantly lower than 0.05, indicating that the logistic regression equation obtained is significant at the 95% level. This illustrates that the seven factors, namely, the profitability factor of the financing enterprise, the solvency factor of the financing enterprise, the profitability factor of the core enterprise, the operation guarantee factor, the growth ability factor of the financing enterprise, the online degree factor of the supply chain, and the quality of the

financing enterprise and cooperation factors, have a significant relationship with the credit risk of the enterprise and further illustrates the practical application value of the model.

4.5. Anticycle Deception Analysis.

Here, we select a set of experimental data with this feature to compare and analyze the difference between the credit scoring method proposed in this article and Taobao's credit scoring method. The experimental results are shown in Figure 6. It can be seen from Figure 6 that the scoring method using RBF neural network credit accumulation is completely powerless against periodic deception. The credit scoring method of a fuzzy neural network describes the process of cyclical deception in a very specific way and inhibits the growth of credit value, which is conducive to the risk judgment of buyers and can also play a supervisory role for sellers. Within the transaction failure threshold, the credit value will not be degraded, and when the threshold is exceeded, the credit value will be degraded. Therefore, the setting of the threshold of transaction failure rate is critical. If the number of negative reviews specified by the transaction failure rate threshold is not reached, the credit value begins to degrade, indicating that the threshold is set too large and the actual transaction failure rate is small. Conversely, if the number of times specified by the threshold is reached and the credit value has not been degraded, it means that the threshold setting is too small, and the actual failure rate is relatively large.

4.6. Analysis of Anticredit Hype.

We select realistic data that meet this situation for analysis, and the experimental results are shown in Figure 7.

Under Taobao's credit scoring method, although the seller did not cheat after the credit speculation, the credit at this time has been greatly reduced, and the buyer is easily confused by the credit value. It can be seen from Figure 7
FIGURE 6: Comparison of the credit value growth process of cyclic deception.

(a)

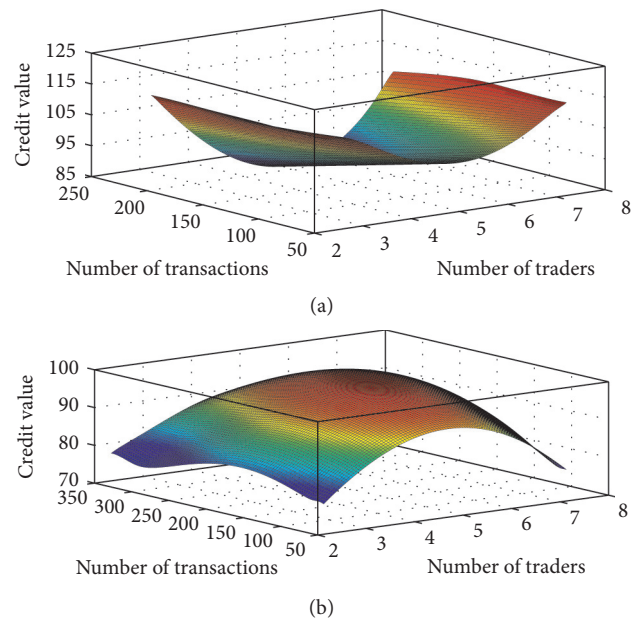
(b)


FIGURE 7: The credit value of the cycle deception after the credit hype: (a) results of RBF neural network method and (b) the results of the fuzzy neural network method.

that the credit scoring method of the RBF neural network cannot curb fraudulent behavior after credit speculation. And through the fuzzy neural network, it can be clearly seen that the deceptive credit value after the credit hype has been reduced.

5. Conclusion

From the empirical results, it can be seen that indicators such as net sales interest rate, return on net assets, and net profit rate of total assets are positively correlated with the profitability factor of financing enterprises. At the same time, the profitability factor of financing enterprises is positively correlated with the compliance probability of online supply chain finance SMEs. Therefore, the higher the net profit margin of the financing company's sales and the net profit margin of the financing company's total assets, the lower the credit risk of SMEs participating in online supply chain financing. The solvency of financing companies is negatively related to the probability of online credit risk. That is, the stronger the solvency of SMEs, the smaller the credit risk in their online supply chain financing business. From the empirical results, we can see that the current ratio, quick ratio, and interest coverage are positively correlated with solvency, and the debt-to-asset ratio is negatively correlated with solvency. Therefore, the higher the current ratio, quick ratio, and interest protection multiple, the stronger the solvency of SMEs, and the lower the credit risk of their participation in online supply chain financing; the higher the debt-to-asset ratio, the lower their solvency. The online degree factor is negatively related to the probability of the occurrence of financial credit risk in the online supply chain. That is to say, the stronger the online degree of this business, the smaller the credit risk of this online supply chain financing business. It can be seen from the component score coefficient matrix that the indicators reflecting the online degree of the supply chain, such as the electronic order processing capacity and the degree of information sharing, are positively correlated with the online degree factor of supply chain finance, and the online degree factor is related to the compliance of small- and medium-sized enterprises. The probability is positively correlated. Therefore, the higher the electronic order processing capability and the degree of information sharing, the lower the credit risk of SMEs participating in online financing business. When dealing with the problem of using low-priced commodities for credit speculation, the improved credit scoring method considers prices in different segments, and the increase in credit value is related to the ratio of price segments in all price segments. The closer the price range of the goods sold, the faster the credit growth of sellers. Once the price range of the goods sold by the seller fluctuates sharply, the growth of the credit value slows down. In this way, credit hype can be curbed while protecting the interests of sellers who only sell low-priced goods. Comparative experiments show that the self-constructed interval type 2 fuzzy neural network is effective in suppressing credit speculation. When dealing with the problem of periodic fraud, the improved credit scoring method sets different credit levels according to the level of credit value. In different credit levels, different deduction coefficients are set. A high credit rating sets a high deduction factor to increase the opportunity cost of periodic deception. Through this kind of punishment, the cycle of deception is effectively curbed. The comparative experiment shows that the self-constructed interval type 2 fuzzy neural network is effective in punishing the periodic deception.

Under IEEE-754 standard, for the current situation of excessive time and power consumption of multiplication operations in single-precision floating-point operations, the expanded boothwallace algorithm is used, and the partial product caused by booth coding is rounded and predicted with the symbolic expansion idea, and the partial product caused by single-precision floating-point multiplication and the accumulation of partial products are optimized, and the flowing water is used to improve the throughput. Based on this, a series of verification and synthesis simulations are performed using the SMIC-7 nm standard cell process. It is verified that the new single-precision floating-point multiplier can achieve a smaller power share compared to the conventional single-precision floating-point multiplier.

1. Introduction

According to a study by Stanford University, the demand for arithmetic power in artificial intelligence has doubled every three to four months since 2012, a rate that has surpassed Moore's law (doubling the number of transistors in a chip every 18 months) [1]. That is, the current rate of Moore's law has lagged far behind the speed of the growth in demand for computing power, relying solely on the progress of process technology that has been entirely unable to meet the demand for computing power growth. According to Intel's latest study, for computationally intensive applications, floating-point operations account for 75% of processor core power consumption and 45% of total processor power consumption [2], as shown in Figure 1, while its operator power consumption accounts for 39.57% in Think-II, an artificial intelligence inference chip developed by the first team of the Institute of Microelectronics at Tsinghua University [3]. From this, it can be seen that floating-point operation is a module with a very large power consumption ratio in big data computing, so it is significant to reduce the power consumption of floating-point operation.

As an important indicator of scientific computing capability, floating-point arithmetic is an important computing method for processing various information in today's electronic information tools. Floating-point numbers have a large dynamic range compared to fixed-point numbers; however, the structure is more complex and power consumption is higher, so it is a meaningful breakthrough to achieve multiplicative power optimization of floating-point numbers. In the past, 60% of the performance improvement of microprocessors depended on process advancement [4]; now, we need a breakthrough in design to achieve the demand of arithmetic power growth.

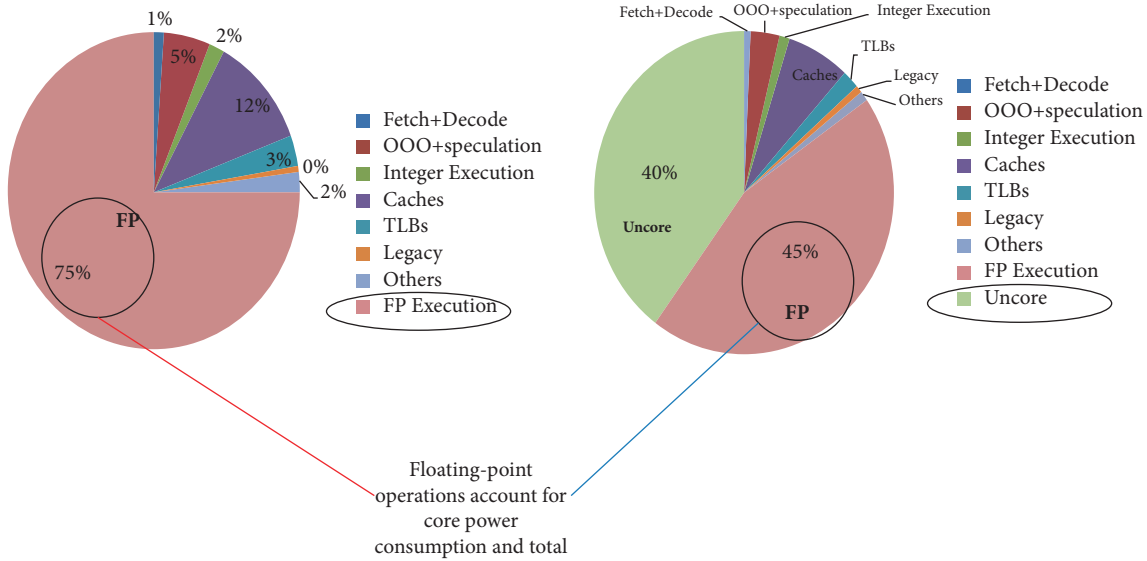
This paper focuses on the power optimization of single-precision floating-point multiplication operations in floating-point operations. The single-precision floating-point multiplication calculation can be divided into three parts, namely, the judgment of symbolic bits, the summation of exponential bits, and the multiplication of trailing bits. The first two conventional designs are similar in this paper, but the core of the design optimization is in the multiplication of trailing bits.


Figure 1: Intel's microprocessor core-level.

The conventional design for the trailing part of the multiplier is mainly a Wallace tree structure with a combined CSA and 4-2 compressor, mainly in the form of a booth code. Finally, the final product is obtained with an overrunning adder [5]. Figure 2 shows the conventional tail partial multiplier design.

In this paper, we hope to improve the coherent design to reduce the power consumption of single-precision floating-point multipliers.

2. Materials and Methods

2.1. Ideas and Advantages of the Design Algorithm Based on Boothwallace Tree. For the current design of single-precision floating-point multiplication, this paper divides the design into three parts as the direction of optimization: how to appropriately increase the throughput of data processing when emitting signals; how to process the partial products caused by the multiplication of trailing bits and reduce the number of operations and storage at the same time; and how to effectively reduce the workload of summing and reduce the hyperactive operations in the process of partial product summing.

This design is considered for processing a huge amount of multiplication data operations at 2 GHZ frequency. If we just follow the timing sequence to process one data and then continue to process the next data, such a way is actually very inefficient. Therefore, this paper adopts the form of flowing water to improve the throughput of data processing and increase the frequency of the clock. Although the primary delay $(n * (T1 + T2))$ is added in the first stage of processing, the pipelined operation can substantially improve the overall data processing efficiency because the register delay must be smaller than the combinational logic delay. The difference time between the register delay and the combinational logic delay can be saved almost every time the pipelined data processing is done under the huge data processing. The

disadvantage of pipelining is that it increases power consumption, area, and hardware complexity. Therefore, while using pipelining to improve data processing efficiency, it is important to weigh the loss of power consumption, area, and software complexity.

The encoding operation of the partial product caused by the trailing bits in the multiplication stage can significantly affect the final power consumption and area. If the partial product is used directly or a simple booth-2 coding operation is done, the power consumption loss and the area occupied are too large. Adopting the booth-4 encoding form can reduce half of the partial product caused by booth-2, compared to the direct use of the partial product form that reduces the part beyond 1/2, which can significantly reduce the time consumption caused by the subsequent operation of partial product, but also can significantly reduce power consumption. Although in the case of booth-4 coding operation, there will be some assignment and logic operations, which will lead to this coding operation will consume a certain amount of time and power consumption, as well as occupy part of the area, still, for a large number of data operations, the increased consumption of this part is much smaller than the consumption saved by the subsequent partial product operation of the data, so this paper uses the booth-4. The symbolic bit expansion method is used in this paper [6]. The symbolic bit expansion can predict the partial product sum form, which can appropriately compress some redundant operations of the partial product sum, and use a certain logical relationship between the two summed partial products to establish the variable relationship, which can compress the area and reduce the power consumption to a certain extent to achieve a comprehensive multiplication of multiple bits, and a large number of partial sums can save a lot of areas and power consumption effect and for subsequent operations can reduce more add operations [7].

In the partial product summation stage, using the direct array summation form or the rounding reservation form will
Figure 2: Conventional multiplier design.

result in a large blanking hypervalue, which will not only occupy a large area but also increase the nonessential addition operations leading to increased power consumption and time. Using the Wallace tree in the form of overlay summation in the form of tree depth reduction will greatly reduce the number of nonessential addition operations and reduce the amount of white space, resulting in a significant improvement in time. Although multiple uses of the full adder can cause a slight loss of power consumption, but for a large amount of data processing, it brings better rate gain and is therefore chosen [8].

2.2. Implementation Platform and Implementation Algorithm

2.2.1. Implementation Platform and Process. Figure 3 shows the experimental platform and the validation process [9].

The first step is to build a golden model database in the MATLAB platform about single-precision floating-point multipliers and multiplied numbers and generating control group products. Since the range of single-precision floating-point designs is too wide to be verified by the exhaustive method based on hardware limitations, it is the idea of the design to create a database of golden models as the basis for verification calls. The simple steps are to use the rand function and the num2hex function to generate random data and convert single-precision floating-point data. A database of 100 million multipliers and multiplied numbers are created, saved as num and hex types, respectively, and multiplied together in MATLAB to form a product database as a control group for later testing processes as an accuracy standard. After generating the data, the hist function is used to demonstrate the uniformity of the generated database to ensure that the generated database is the golden model database and reduce the uncontrollable experimental error. The following are the functions for generating random data and converting type functions:

$$a(i) = f + 2 * e * \text{rand}(1, 1, \text{single}),$$
$$a\_\text{temp} = \text{num2hex}(a(i)). \tag{1}$$

Under the foundation of the golden model database with good calls, a suitable testbench environment needs to be established as a way to verify the authenticity of the source code logic and debug the source code logic optimization. The platform for design implementation is the NC-Verilog platform. Here, in addition to calling the golden model database and generating the verification

product library, the direct window output under the waveform file is also done. The display function is called with embedded precision verification judgments to simplify verification access.

In order to subsequently implement the power consumption parameter analysis and obtain the simulation data for each of the source codes, a synthesizable implementation of the source code is required. The design is implemented in the Design Compiler platform. The original description of the source code is modified, and the source code is reshaped in the specified hardware description language. After invoking the synthesis environment, the synthesis simulation of the source code is realized, and the simulation data of each source code can be obtained, and the required slack data and area data can be extracted as the final control index. In the process of synthesis, the required netlist file is generated as a sample for subsequent calls. It should be noted that the DC environment CLK needs to be annotated when calling Design Ware samples, and the source code constraint in this paper is 2 GHz. Here, this paper relies on the final code to generate the circuit netlist to observe the structure of the circuit diagram.

After generating the required circuit netlist file samples, call the samples to verify them in the testbench environment, noting that it may be necessary to create a process library for import. After verification, the VCD waveform file sample is exported, and the circuit netlist sample and VCD waveform file sample are imported into the PTPX platform to create the required PTPX environment to generate the corresponding power analysis report sample. Based on the samples and the required theory, the source code is designed and optimized, and the optimized samples are saved. And save the Design Ware samples as a control group to achieve the desired results.

2.2.2. Logic Design and Optimization. The basic single-precision floating-point multiplier is built on the basis of the binary floating-point representation formula, which extracts the sign bits, the tail f, and the step code e from the 32-bit binary data, respectively. Figure 4 represents the arithmetic structure of this 32-bit single-precision floating-point number. The core part is the fixed-point multiplication of the trailing part af:{1′b1, a[22:0]}, bf:{1′b1, b[22:0]}. In the based code, this multiplication structure is the simplest shift judgment flow structure. In the optimization structure, the main thing is also the fixed-point multiplication in the tail
FIGURE 3: Design verification and simulation flow.

part and the optimization of the accuracy in the combination of the final product c parts [10].

The booth-4 encoding has been introduced above to effectively reduce the number of partial products caused by the fixed-point multiplier. In this paper, the single-precision floating-point multiplier is actually optimized by the booth-4 encoding for the trailing part (i.e., the 24-bit fixed-point multiplier). In addition, this paper also deals with the symbolic bit expansion of the booth-4 encoding. Since this 24-bit fixed-point multiplier is treated as a symbolic number by default, a simple processing should be done. af is processed as aff:{1′b0, af}. In this paper, bf is treated as the transcoded original code of booth-4 in the code as bf_b: {2′b00, bf, 1′b0} form, and then the transcoding process is performed corresponding to Table 1, hosting the symbols of each part (neg) and generating the transcoding code (zero, one, two). According to the transcode, the aff is operated accordingly, with zero being taken, one being unchanged, and two being shifted left by one. Then, determine whether the operation of taking the inverse plus one is needed according to the neg symbol. There is an important logic here such that the neg symbol is 0 by default under the premise of determining zero. This is an important logic point in the subsequent symbolic bit expansion [11].

In the case that the basic encoding has been completed, it is necessary to do another simplification of booth-4, which is used as a prediction of the booth algorithm with a rounding, again compressing its partial product [12]. Then, according

to the partial product logical association of each line to do symbolic bit expansion simplification, here note that if there are zero cases, the front added symbolic bit neg default is 0, ~neg is 1. So far, we get 13 partial product prod, the end of the first flow level, into the second level of flow. Figure 5 shows the comparison of the partial product after the expansion with symbolic bits after the booth processing.

In the second level of flow, what this paper has to do is based on the first level of the partial product of 13 prods' multiple coverage compression to the last only one layer of product situation. According to the 3-2 compressor theory (2-2 compression is 3-2 compression in one additive to zero states), make add compression module; in the second level of flow in six levels cover the compression of 13 layers of prod so as to get the final result product. Therefore, a compression module needs to be added at each level to avoid bias. In the last level of the six-level overlay compression, the last two levels are added directly to obtain the final fixed-point 24-bit multiplication product using the system's built-in overfeed adder [13]. Figure 6 shows the compression coverage of the six-level level.

In the Wallace tree above, we have obtained the product of fixed-point multiplication results for the trailing part so that the symbolic bits, the order part, and the trailing part of the resultant floating-point number have been obtained. Nowadays, rounding and direct rounding are popular in
Figure 5: Schematic diagram of symbol bit expansion.
Figure 6: (a) The first-level compression diagram. (b) The second-level compression diagram. (c) The third-level compression diagram. (d) The fourth-level compression diagram. (e) The fifth-level compression diagram. (f) The sixth-level direct overfeed summation.

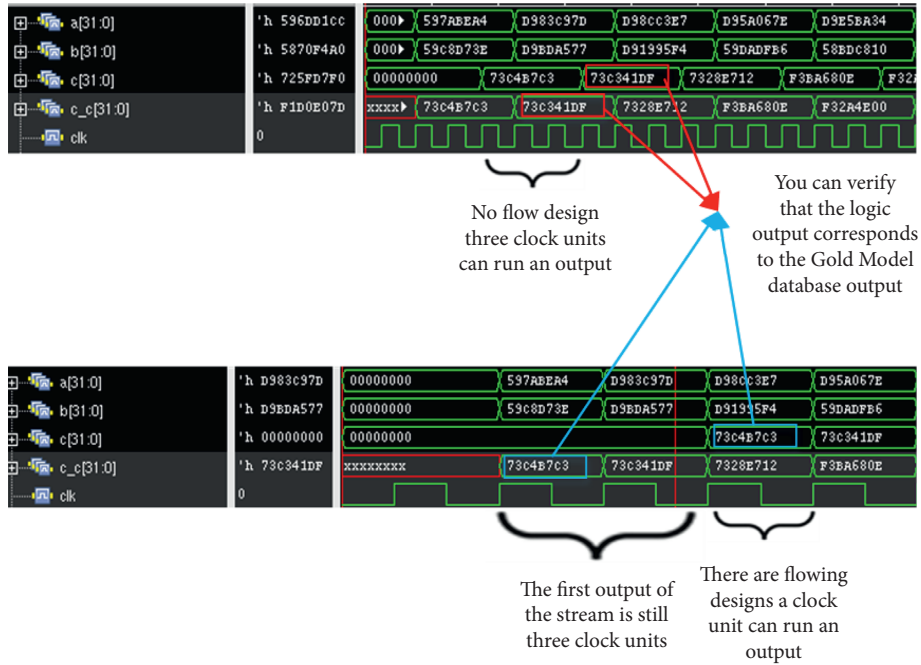
precision, and the former scheme is adopted in this design. In the end, the first result of the final fixed-point product is judged to be 1 to determine the overflow of the ordinal code. If the first place of fixed-point product is 0, the order code exceeds 382 as the maximum overflow and is below 127 as the minimum overflow, and the fixed-point product result cf2<=[45:23] is extracted in the nonoverflow case. If the first place of the fixed-point product is 1, the order code beyond


Figure 7: Logic output diagram of flowing and nonflowing water.
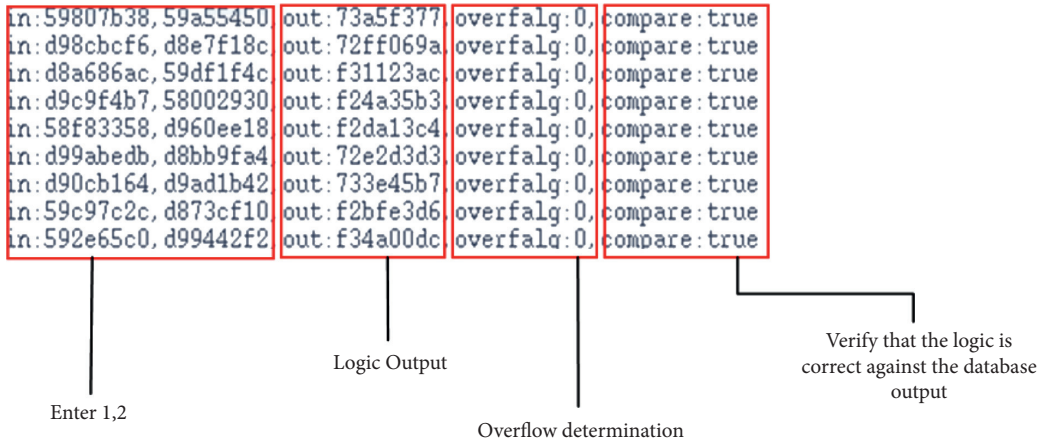

Figure 8: Logic function verification diagram.

381 is the maximum overflow, below 126 is the minimum overflow, and the result of extracting the fixed-point product in the nonoverflow case is cf5<=[46:24]. Then, do the precision constraint part, judge the latter bit of the extracted result part, and judge whether it is required as a feed. Here, it should be noted that the condition needs to be attached whether the extracted part is all one, or the order code is the maximum number 255, that is, whether the overflow result may be caused in the rounding state, if not, then the extracted part cf5 + 1. So, this paper gets a single-precision floating-point multiplier with the accuracy to meet the usage requirements. Complete the design requirements.

3. Results and Discussion

3.1. Code Logic Functional Verification

3.1.1. Testbench Environment Creation. Here, in this paper, we first write the most basic single-precision floating-point multiplier, whose core 24-bit fixed-point multiplier uses the simplest shift-hosted binary multiplication, and here we can get a series of codes for single-precision floating-point multiplier. After writing the codes, we make the corresponding comparisons on the flowing water, citing the nonflowing water format and the flowing water format. And

FIGURE 10: Final code logic verification diagram.

the source code is verified by the relevant logic, and the corresponding verification code is written in testbench, and the comparison output true for the code output is consistent with the MATLAB gold model production product result. See waveform in Figure 7 and logic verification in Figure 8.

As you can see, after the source code is written, the logic function is verified to be error free, and the accuracy is fully up to the requirements. The comparison between the waveform graphs of nonflowing and flowing formats also shows that the throughput in the flowing format is much larger than that in the nonflowing format so that the basic code is established, and the following is the code modification of the source code, adding the booth and Wallace tree modules, after which the combination and generation of partial product modules are optimized accordingly to achieve the desired goal.

3.1.2. Logic Validation after Adding the Boothwallace Tree Module.
In this paper, we add the optimized boothwallace module here to generate the final code, and then add and reduce the state of the running module, and use the original testbed environment to functionally verify the final code, and again compare the raw product of the code with the raw product in the MATLAB gold model database for numerical comparison. Figures 9 and 10 show the waveforms obtained from the verification.

Here, the verification related to the logic function of the code has been concluded in this paper, and the algorithm is

extracted and analyzed for each parameter to verify whether it achieves the expected effect of this paper when the use of the function can be confirmed without errors.

3.2. Comparison of Power Consumption of Fixed-Point Multipliers.
Here, in this paper, we first analyze the power consumption of the fixed-point multiplier in this paper and take out the 24-bit fixed-point multiplier of the most basic fmpy shift-hosting direct sum, the multiplier of the simple added booth module and Wallace module, and finally, the 24-bit fixed-point multiplier of boothwallace after optimization in this paper. Because these are all combined logic parts, this paper sets its max_delay to 0.5 ps, that is, according to the frequency of 2 GHz work, combines logic area, and measures its power consumption data. The data are recorded and compared at 25c, 85c, and 125c for three temperature process angles to get a relatively detailed report. They are displayed as Tables 2, 3, and 4, respectively.

The obtained statements are organized to obtain area (Figure 11) and power consumption comparison (Figure 12) for the three fixed-point module algorithms corresponding to different temperature process angles.

Here, we get the corresponding power consumption data of each fixed-point multiplier module. This paper can analyze that, with the maximum delay parameter set, the area of the combinational logic part of the original fmpy_24 fixed-point multiplier is the smallest under the process angle model of each temperature, resulting in its power

fmpy_24	0.5	298.752	$2.894E-05$
normal_24	0.5	529.4208	$2.947E-04$
boothwallace_24	0.5	324.2592	$2.116E-04$

TABLE 4: Power consumption of each fixed-point multiplier of 125c.

2 GHz (WC-125C)	max_delay	Area (combination)	Power
fmpy_24	0.5	298.752	$2.345E-05$
normal_24	0.5	529.4208	$3.397E-04$
boothwallace_24	0.5	324.2592	$2.309E-04$
FIGURE 11: Comparison of the combined area of fixed-point modules.

FIGURE 12: Comparison of total power consumption of fixed-point modules at three temperature process angles.

consumption in all aspects being lower than the normal value. The area of the fmpy_24 fixed-point multiplier is the smallest, resulting in a lower than normal power consumption in all aspects. The area of the fmpy_24 fixed-point multiplier is increased by simply adding the booth code and the Wallace tree module, and the power consumption is increased accordingly. Since the fixed-point multiplication part is the core operation module of single-precision floating-point multiplication, the optimized power consumption and area of the fixed-point multiplication module are of great significance for the power consumption and area of the entire single-precision floating-point part. The following is a comparison of the power consumption of the single-precision floating-point section.

3.3. Single-Precision Floating-Point Multiplier Power Consumption Comparison. After the analysis of each bit of data of the internal module 24-bit fixed-point multiplier module

was carried out above, here the analysis of power consumption data is done for the source code fmpy, the algorithm of adding booth and Wallace normally, and the final algorithm of the optimized boothwallace module to get the final power consumption statement. The different temperature process angles from 25c, 85c to 125c are shown in Tables 5–7. In addition to the data on the above aspects, this paper adds a record on the peak power, which helps to clarify the choice of chip power. In the integrated netlist section of this paper, the timing.sdc file is designed with an excitation of 0.5 ps, reaching the final measurement frequency of 2 GHz.

The combined and noncombined area comparison of the floating-point multiplier for the three algorithms is obtained in Figure 13, the total power consumption comparison in Figure 14, and the peak power comparison in Figure 15.

From the above tables, we can see that after the modification of the algorithm in the noncombination of the area is greatly reduced, although the combination of logic part compared to the most just fmpy algorithm way to increase, but adding combinatorial logic modules to the fixed-point

Figure 14: Comparison of total power consumption of floating-point multipliers at three temperature process angles.

modules will definitely create excess losses. The area of the floating-point algorithm is still much smaller than that of the fmpy algorithm of the shift-hosting method and the normal algorithm of simply adding the booth and Wallace modules. The total power of the modular algorithm of simply adding booth and Wallace is much lower than the original shift-hosting fmpy algorithm in the power analysis, with a reduction of 45.95%, while the optimized boothwallace algorithm module total power algorithm compared to the shift-hosting fmpy algorithm reduction of 58.69%, proving that optimizing Wallace will get very significant power savings, and on top of that adding a symbolic bit expansion module there is a not insignificant secondary improvement. In the peak power measurement, in various temperature process angles, the peak power reduction of the normal algorithm with the simple addition of the booth and Wallace modules and the optimized boothwallace algorithm compared to the
FIGURE 16: Integrated results' netlist diagram.

original shifted hosting fmpy algorithm are 3.79% and 7.97%, respectively, showing that the optimized algorithm also has a very significant improvement in peak power, which can make it a more generous choice in terms of power supply. At this point, the design fully meets the usage requirements.

The final result comes down to the resulting integrated netlist picture and cell diagram in Figure 16.

4. Conclusion

At this point in the paper, the single-precision floating-point multiplication algorithm has been logically designed and ultimately power-optimized through a series of rigorous verification and simulation processes. From source code writing, modification, verification on various platforms, synthesis, simulation, to the final experimental data, a comparative analysis of the experimental and control groups on multiple databases is performed. By using the symbolic bit expansion method to predict the partial product caused by the booth-4 code by rounding, the area of the resulting partial product tree is reduced. Then, the corresponding add operation and storage area are reduced in the covering structure of the Wallace tree, achieving the requirement of reducing the area and reducing power consumption. At this point, the algorithm design meets the expected requirements.

In recent years, due to the simple design idea and good recognition effect, deep learning method has attracted more and more researchers' attention in computer vision tasks. Aiming at the problem of athlete behavior recognition in mass sports teaching video, this paper takes depth video as the research object and cuts the frame sequence as the input of depth neural network model, inspired by the successful application of depth neural network based on two-dimensional convolution in image detection and recognition. A depth neural network based on three-dimensional convolution is constructed to automatically learn the temporal and spatial characteristics of athletes' behavior. The training results on UTKinect-Action3D and MSR-Action3D public datasets show that the algorithm can correctly detect athletes' behaviors and actions and show stronger recognition ability to the algorithm compared with the images without clipping frames, which effectively improves the recognition effect of physical education teaching videos.

1. Introduction

With the development of society, more and more sports teaching videos have entered people's daily life. The analysis of PE teaching video can more effectively improve the teaching effect. Object detection and human pose estimation for sports video are the basis of sports video analysis and understanding. The existing target detection and human pose estimation technologies have achieved good performance in the general scene detection task based on pictures [1], but there are few algorithms and data for target detection in sports video scenes. For a new data field, accurate athlete detection and pose estimation are important links in sports video analysis. The existing human target detection and pose estimation algorithms have achieved good performance in the general human body detection task, but they will detect athletes and spectators at the same time in the physical education teaching video, so they cannot further distinguish athletes' targets, which will interfere with the subsequent video analysis. At the same time, the sports video data with human body annotation is scarce [2], and the cost of obtaining a model suitable for the field of sports video is

high. Athletes are a special case of general human body detection task. If the general human body detection model can be used to detect and estimate athletes in sports video, it can undoubtedly save a lot of cost. In order to reduce the labelling cost and training cost, the detection and pose estimation of athletes in sports teaching video are realized.

Among the traditional methods, the two-dimensional behavior recognition technology based on RGB video has been widely studied [3]. The early method is to extract local spatiotemporal descriptors from the input video and encode these descriptors into word bags with visual vocabulary for classification. At the same time, the local feature method has become an effective way in motion recognition, because these local features do not need algorithms to detect the human body and are not sensitive to factors such as background, illumination, and noise. The calculation of these local features can usually be divided into two parts. The calculation of these local features can usually be divided into two parts: detector and descriptor. Detector is to find the significant and informative region of action understanding and descriptor, and descriptor is to describe the visual model of the extracted region. Laptev proposed spatiotemporal

points of interest by extending Harris angle to spatiotemporal dimension [4], and Kviatkovsky et al. proposed a covariance descriptor to realize online action recognition [5]. Local descriptors for video representation include histogram of oriented gradient (HOG) features and histograms of optical flow (HOF) features [6]. The two-dimensional convolution neural network used for RGB static pictures cannot meet the requirements of extracting time features. Another method is to apply the three-dimensional convolution neural network, but the three-dimensional neural network has a great disadvantage that there are too many parameters to be optimized, so it needs a large-scale dataset for training [7].

Inspired by the successful application of depth neural network based on two-dimensional convolution in image detection and recognition, this paper takes physical education video as the research object and constructs a depth neural network based on three-dimensional convolution to automatically learn the temporal and spatial characteristics of human behavior, which is used for human behavior recognition. Combining convolution neural networks and recurrent neural networks, convolution neural networks are used to extract spatial features, and then cyclic neural networks are used for time series modeling. This method can avoid the demand for optical flow and better meet the real-time requirements. Taking the deep learning method as the key technology, VGG16 convolutional neural network is used to extract the highly abstract features of video frames, and an athlete behavior recognition algorithm in sports teaching video is designed and implemented.

2. Related Work

At the beginning of this century, some foreign universities began to pay more attention to the research of human behavior recognition. Today, a lot of research has been carried out in the field of human behavior recognition [8], and more and more valuable research results have emerged. The recognition methods have made rapid progress and changed with each passing day. With the rise of deep learning, the research on human behavior recognition using deep neural network has begun to be more and more in depth. Compared with foreign countries, China started late in this area, and there is still a certain gap to catch up. In recent years, it has begun to strengthen research. Davis and Taylor [9] first used contour to describe the global feature of human body, which is a two-dimensional feature. Motion energy image (MEI) is used to indicate the position where motion has occurred, motion history image (MHI) is used to indicate the spatial position and time sequence of motion, and then recognized by Mahalanobis distance classifier, these two kinds of feature images are obtained by background frame difference method. The optical flow method based on pixel level can capture and locate the moving object. When the background frame difference method cannot extract the foreground object well, the optical flow method can be used for recognition and location. It is easy for the optical flow method to introduce the motion noise of noninterested objects. Literature [10] only calculates the

optical flow at specific positions (such as the approximate center point of the object), which reduces the influence of noise to a certain extent.

Blank et al. [11] first obtained 3D spatiotemporal volume (STV) from silhouette information in video or picture sequence, then derived local spatiotemporal interest points and their directional features through Poisson equation, and obtained a 3D global feature by weighting these local points. In contrast to the global feature, the local feature adopts the bottom-up research thinking, and only relatively independent image blocks in the object region are extracted. Since the region of interest (ROI) [12] does not have to be a complete object with practical significance in the real world, accurate object region positioning and tracking are not required. The usual approach is to calculate some spatiotemporal interest points in the video or picture sequence, then expand and fuse them into image blocks one by one, and finally combine all image blocks to generate total features. Because it does not depend on the accurate positioning and tracking of the bottom layer, the sensitivity of local features to noise, angle change, and occlusion is not high. However, due to the need for a large number of stable interest points related to action categories, various complex preprocessing processes cannot be avoided. At the same time, the motion of the camera will also affect the calculation and detection of interest points. In the traditional human behavior recognition algorithm, it is necessary to artificially control the complex process of feature extraction and data reconstruction. By using the deep neural network, the picture can be directly used as the input of the network, and the recognition effect can be better than that of the traditional method [13]. Deep neural network does not completely break away from the traditional methods and start a new stove but integrates the complex steps of the traditional methods into the network and simplifies the whole process. All connections and parameters in the network reflect some ideas of the traditional methods. Compared with the traditional shallow neural network, deep neural network, as its name implies, has more network layers in structure and a large number of parameters, and its internal connection mode will change greatly with the different types of networks. The multilayer structure of the network enables it to learn higher-level and more abstract expressions [14], so that the features extracted from the input data will have higher discrimination.

Human posture estimation is also called human joint point regression, which detects the position of each joint point of the human body and then connects it to the human skeleton. Human posture estimation is not only the basis of behavior analysis and motion recognition but also an important part of video analysis [15]. If the human joint points are returned to 3D for expansion, RGB images are input, and 3D human key points are output, it is 3D human pose estimation. This is a very valuable research direction. The traditional human posture estimation algorithm divides the human body into multiple parts according to joints, hand, head, leg, and body and then performs feature matching based on the manually extracted features of each part to detect the limbs in the figure. Taking the body as the trunk,

the detected limb parts are spliced according to the Gaussian model of human posture distribution to obtain a complete human posture [16]. This method needs to manually design human features, and the feature engineering steps are complex. When the scene is complex, it is difficult to cover all the situations, which has great limitations and cannot be effectively popularized. With the development of deep learning, human pose estimation algorithm based on deep learning has become the mainstream. The human posture estimation algorithm based on deep learning regards human posture detection as a key point regression problem, trains through a large number of data with joint point category and position annotation, and finally obtains a model that can predict the position and category of human joint points [17].

The existing deep learning models mainly include convolutional neural networks (CNNs), recurrent neural networks (RNNs), restricted Boltzmann machine (RBM), and deep belief network (DBN) [18]. These methods give full play to the self-learning ability of neural network and let the network adapt to the characteristics of data. The method of manually selecting features is avoided. A large number of studies show that these models can achieve better results than the original methods in handwritten numeral recognition, target detection and recognition, speech recognition, and other scenes.

2.1. Athlete Behavior Recognition Model Based on Deep Neural Networks

2.1.1. Athlete Behavior Tracking. There are strong rules in shooting and editing techniques in sports video. The characteristics of different shots and the differences between different shots are obvious. In the far shot, the competition field accounts for the largest proportion, and the athletes are also concentrated on the competition field. Therefore, the competition field area is detected first. After the athletes are detected, the more accurate athletes can be obtained by removing the field color by using the consistent color characteristics of the sports field. In the middle lens, the field color still accounts for a certain proportion in the image, so if the far lens scene has been processed, the main field color is stored to remove the nonathlete area of the image belonging to the competition field.

Athlete detection is a classifier that combines the characteristics of athletes and background in various types of shots in sports video and uses middle-level feature blocks to train and distinguish athletes. The middle-level characteristics of neural network often contain rich information, which plays a connecting role in the whole neural network. In this paper, CamShift algorithm is used to track athletes, and its core algorithm is mean shift algorithm. Mean shift algorithm is a nonparametric probability density estimation method. Its algorithm block diagram is shown in Figure 1. It finds the peak points in the probability distribution through the iterative process and makes each point "drift" to the local maximum of the density function. CamShift algorithm is an extension of mean shift algorithm. It realizes the tracking of moving objects in continuous video frames by adaptively adjusting the size and position of search window. It has the characteristics of good robustness, fast speed, and less computation. Using kernel function estimation method, when the sampling is sufficient, it can gradually converge to any density function; that is, it can estimate the density of data subject to any distribution. In this way, the convergence of mean shift algorithm can be guaranteed, and the mean shift vector can be used for iteration. It can better track the irregular motion of nonrigid objects and has good antinoise ability.

An important step in CamShift algorithm is to convert the original video image into a probability distribution map by using the backprojection of the color histogram of the target object. Each pixel value in the map represents the probability that the pixel belongs to the target object. Because HSV color space separates color (H) from saturation (S) and brightness (V), using the H channel of HSV color space to establish histogram can reduce the sensitivity to illumination changes. The traditional method of calculating histogram is as follows:

$$q_u = \sum_{x \in R} \sum_{y \in R} c\delta(x, y) - u^2, \quad (1)$$

where $\{q_u\} u = 1, 2, \ldots, m$ is the histogram; R is the target area where histogram needs to be calculated; the function C: $R_2 \longrightarrow \{1, 2, \ldots, m\}$ is used to convert the pixel value with coordinates of (x, y) into the histogram level value; and δ is the Kronecker symbol:

$$\delta[i - j] = \begin{cases} 0, \text{other} \\ 1, i = j \end{cases} \quad (2)$$

In order to make the obtained probability distribution map within the range of [0255], the histogram needs to be scaled:

$$p_u = 255 \cdot \min\left(q_u q_{\max}^{-1}, 1\right), \quad (3)$$

where $u = 1, 2, \ldots, m$; $q_{\max} = \{\max(q_u)\} u = 1, 2, \ldots, m$. Let the value of the pixel at (x, y) in the video image be $I(x, y)$ and p be the probability distribution map corresponding to the image, then, $P(x, y) = P_{f[I(x,y)]}$, where $\{P_u\}, u = 1, 2, \ldots, m$ is the histogram; function $f[I(x, y)]$ finds the corresponding level value in the histogram according to the value of $l(x, y)$.

CamShift is a semiautomatic tracking algorithm, which needs to explicitly specify the initial size and position of the search window. In order to realize automatic tracking, this paper takes the detected athlete area as the initial search window. In the iterative process, the i centroid (x_c, y_c) of window w is

$$x_c == \sum_{x \in w} \sum_{y \in w} x P(x, y) \left[\sum_{x \in w} \sum_{y \in w} P(x, y)\right]^{-1},$$

$$y_c = \sum_{x \in w} \sum_{y \in w} y P(x, y) \left[\sum_{x \in w} \sum_{y \in w} P(x, y)\right]^{-1}. \quad (4)$$

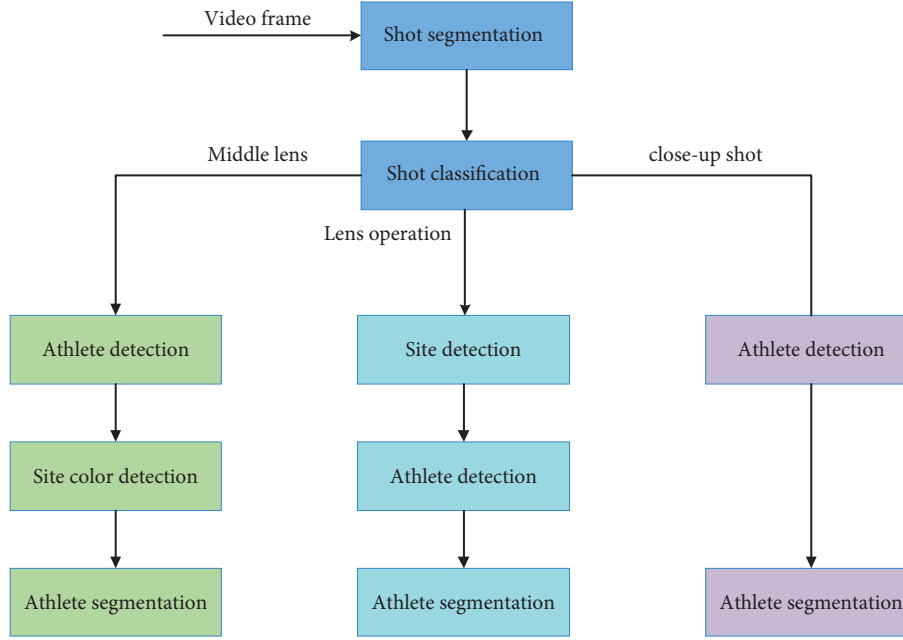
Each iteration resizes the window to $2^{-3} \left[\sum_{x \in w} \sum_{y \in w} P(x, y)\right]^{1/2}$.


Figure 1: Monitoring and segmentation of athletes in sports teaching video.

Because the traditional histogram only uses the information of H channel, it is easy to fail to track when the hue distribution of the target object is similar to that of the background.

In order to make CamShift's tracking algorithm more robust, this paper uses the weighted histogram method to improve the algorithm. In the athlete's area, the pixel farther away from the center of the area has lower reliability, and the pixel is more likely to be covered by other objects or belong to the background. Therefore, it is reasonable to assign a relatively low weight to the pixel far away from the center of the area when calculating the histogram. The weighted histogram is calculated as follows:

$$q_u = \sum_{x \in w} \sum_{y \in w} k(r) \left[c\delta(x, y) - u^2 \right], \qquad (5)$$

where $K(r)$ is a monotonically decreasing function, (x_c, y_c) is the regional center, and $r = \sqrt{(x - x_c)^2 + (y - y_c)^2}$. In order to ensure the real-time tracking, this paper sets the number of iterations of each mean shift as 15 times, and the convergence standard is to drift one pixel.

2.1.2. Behavior Feature Extraction Based on VGG16 Model.
The feature extraction layer of VGG16 convolution neural network model is used to process the frame picture. The input of the model is the cropped frame picture, which needs to be normalized to 224×224; this paper takes the output of the feature extraction part, which is a 4096-dimensional vector. Each picture in the frame sequence needs feature extraction and finally forms a feature sequence.

VGG networks are divided into several classes according to the number of layers. The structures of all classes are very consistent, and almost all convolution layers use 3×3 size convolution kernel (only one class uses 1× the convolution

kernel with the size of 1 being regarded as a linear mapping of space), and the pooling layer also adopts 2×2 size aggregation. Using a smaller convolution kernel can reduce a considerable part of the parameters under the action of weight sharing. In shallow convolution neural network, less parameters often lead to insufficient generalization ability of the model, resulting in underfitting. At this time, the network parameters can be effectively increased and the expression ability of the model can be improved by superimposing convolution layer. In addition, it also creates conditions for more nonlinear mapping and enhances the fitting ability of the network. Common VGG networks usually have 16–19 convolution layers. There are obvious groups between these convolution layers. At the end of each group, there is a pool layer, and the output of this group is downsampled. VGG16 network model is adopted in this paper, with a total of 16 convolution layers. Its structure is shown in Figure 2.

In Figure 2, there are 5 groups of convolution layers, and the size of convolution kernel is 3×3. The first group has two convolution layers, each layer has 64 convolution cores to extract features from multiple angles and dimensions, the second group has two layers, 128 convolution cores per layer, the third group has three layers, 256 convolution cores per layer, and the fourth and fifth groups also have three layers, 512 convolution cores per layer. Each group of convolutional layers is followed by a 2×2 pooling layer. At the end of the network is a 3-layer fully connected layer. The entire network has a total of 138 million parameters to be trained.

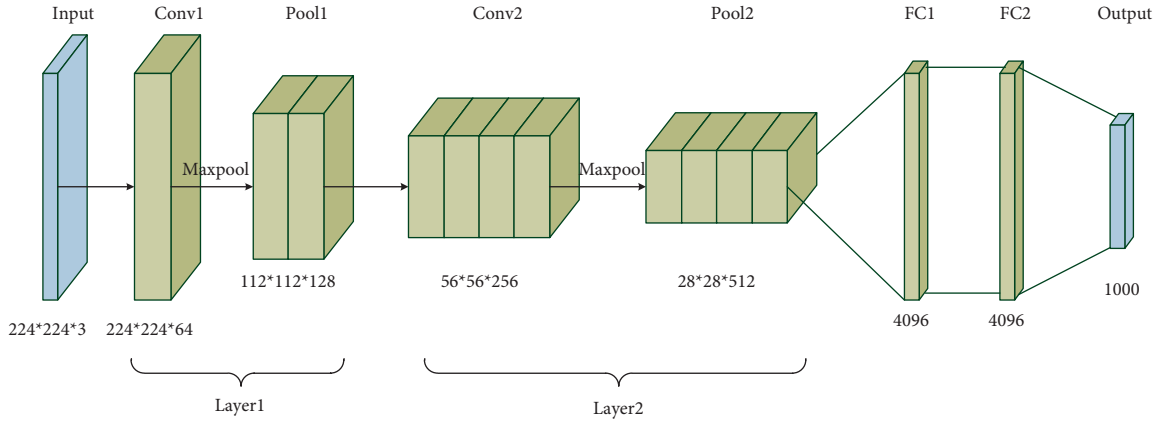
In terms of training, VGG16 will first perform necessary preinitialization of some layers, including include_top: whether to include the top fully connected layer; weights: None stands for random initialization of "ImageNet," which stands for pretrained weights loaded on ImageNet;


FIGURE 2: VGG16 network model structure diagram.

input_tensor: Optional, Keras tensor is used as the input of the model (that is, the tensor output by layers.Input()); input_shape: Optional, input size tuple, valid value when only include_top = False; pooling: Optional. When include_top is False, this parameter specifies the pooling method for feature extraction. In addition, the depth of the network and the small size of the convolution kernel have the effect of implicit regularization, so it only needs a few iterations to start convergence. This paper uses the VGG16 model fully trained on ImageNet, because its input scale is fixed at 224×224, so the pictures in the frame sequence need to be reduced to the corresponding size before they can be sent to the network. The length width ratio of the cropped frame picture is about 219×214, so there will not be too much distortion after zooming. In addition, the network itself has certain scale invariance, so it can be put into the network for feature extraction.

In terms of calculation, as mentioned above, the convolution layer mainly convolutes or performs correlation operations on the pictures, the pooling layer mainly subsamples each feature image obtained from the previous layer to reduce its size and retain useful information while reducing the amount of data, and the full connection layer integrates local features to achieve higher abstraction or data classification or prediction (the last layer is the full connection layer). Like most deep neural networks, the activation units of all convolution layers in the network adopt the modified linear unit (ReLU) activation function. The activation function of artificial neuron generally adopts nonlinear monotone function which is continuous and differentiable everywhere, and the value range of the function is a fixed interval. The requirement of nonlinearity is that the linear function can only play the role of linear amplification of the input, and the linearity will greatly reduce the performance of the network, and it is easy to degrade the multilevel network function into a single-level network function, which is a fatal defect. The training algorithm can calculate the gradient and adjust the parameters by using the gradient. Monotonic performance can effectively improve the efficiency of network training. The bounded value range that can be given by the actual demand can make the gradient decline more stable and prevent the

network from entering the saturation state: if the input is generally small, the value range can be adjusted to have a larger gain. If the input is generally too large, adjust the value range to get a smaller gain.

The activation effect of ReLU function is similar to that of biological neurons, and its mathematical expression is shown as follows:

$$f(x) = \begin{cases} 0 & x < 0, \\ x & x \geq 0. \end{cases} \tag{6}$$

As shown in Figure 3, the blue line and red line, respectively, represent the convergence effect of ReLU activation function and sigmoid activation function. It can be seen from the figure that the convergence speed of training model with ReLU activation function is significantly faster than that with sigmoid activation function, which greatly shortens the learning cycle.

Deep learning is actually a feature driven method. As a typical method of deep learning, the network model composed of convolutional neural network is no exception. Usually, the output of the feature extraction layer of the network can be taken out separately as a feature description of the data, and these feature descriptions can be used to classify or predict the data in other ways. In VGG16, after layer by layer calculation, the input image gradually transitions from local feature extraction to global feature construction. The output of each layer can be taken out separately as a feature description. The last three layers of the network are fully connected to the network layer, except the last layer (used to directly process the features extracted by the previous layer to classify or predict the data) that can well describe the global features of the image. Take the output of the first fully connected layer, whose output form is 4096-dimensional vector, and the extracted feature description will be used as the input of the next layer network.

2.1.3. Training Method of Athlete Classifier in Sports Teaching Video. In sports video, the characteristic of athletes and background is that all pictures contain background and athletes, and there are basically no frame images without athletes. In addition, in addition to close-up shots, athletes
FIGURE 3: Comparison of convergence effect.

account for a small proportion of the frame images in other shots, and most of the frame images are background blocks. Moreover, the background in the sports scene is the competition venue, and the competition venue structure of the same type of sports competition is very similar. In this case, it is not feasible to mine middle-level feature blocks by unsupervised iterative clustering detection. In the initial clustering, due to the large number of background blocks and unified structure, most of the classes with less than or equal to three image blocks in the discarded class are foreground blocks. The cohesive clustering algorithm makes decisions according to the local pattern without considering the global structure of the data. Therefore, cohesive clustering is very suitable for identifying smaller classes. When using unsupervised iterative clustering detection method, the first thing to do is to separate the background from the athlete block. Because the sample collection stage can only be separated manually, the workload is too large.

From another point of view, these characteristics of athletes in sports video can simplify the definition of middle-level feature blocks. In the close-up shot, the athlete only has a bust, and there are not many types of athletes. There are not many kinds of blocks that contain different parts of athletes. In the middle shot and far shot, the proportion of athletes in the image is small; especially in the far shot of football, tennis, and badminton, most athletes can use a small block for complete segmentation. The number of blocks with large difference between athletes in the image segmentation of middle lens and far lens is not very much. Based on this feature, the middle-level feature block that can distinguish athletes and nonathletes is defined as the block with the most athlete contour. All qualified blocks are used as the positive samples of the training athlete classifier, and other blocks are used as the negative samples of the training athlete classifier. The following will explain how to collect positive samples and negative samples to train the athlete classifier in the sports video.

The steps of collecting positive and negative samples of the classifier for training athletes are shown in Figure 4. It should be noted that, in order to calculate the most similar

blocks and the K-means clustering results in the classification results more accurately, the pictures of each segmented block are from the same video. The image is segmented with a fixed window and step size to obtain the image block set. The image blocks with the largest athlete contour and different parts are selected as seed blocks, and the k most similar blocks and k least similar blocks of each seed block are calculated, respectively. Taking all the blocks most similar to the seed block as the positive sample set and the least similar block as the negative sample set, the hog features of all positive and negative sample blocks are extracted, and the SVM classifier is used to train the athlete's classifier, which is the initial athlete classifier. In the later iteration, the classifier is used to classify and detect all blocks, and then K-means is used to cluster the pictures with positive and negative results. Manually check whether the classification corresponding to each clustering result is wrong. If it is wrong, add the wrong class to the correct sample, so as to expand the positive and negative sample set. At the beginning of the next iteration, reextract the features of the sample set and train a new classifier, which optimizes the classifier. Iteratively detect, cluster, and update the optimized classifier until the classifier correctly classifies a certain number of new video picture sets.

2.1.4. Athlete Behavior Recognition Model and Overall Recognition Process Based on Deep Neural Network. Combining the feature extraction of spatial dimension and the information integration of time dimension, we combine to form a VGG16-BiLSTM athlete behavior recognition model, as shown in Figure 5.

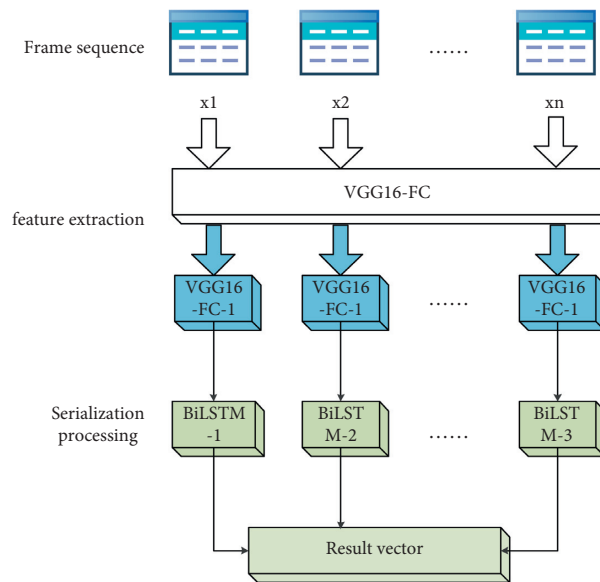
The model takes the cropped frame sequence as the input and the output vector of the last time of the cyclic neural network as the result. The first part of the model is the feature extraction layer of VGG16 deep convolution neural network, which adopts the weight parameters fully trained on ImageNet and takes the output of its first full connection layer as the extracted image features. The second part is the bidirectional long-term and short-term memory model with
FIGURE 4: Process of training athlete classifier.


FIGURE 5: Model diagram of deadlock detection method for hierarchical scheduling system based on time constraints.

more advantages in integrating time dimension information. Its weight parameters are trained with the feature sequence extracted from the real shooting data of physical education teaching video used by the subject as the training data. It takes the feature sequence obtained in the first part as the input and outputs the recognition results of the whole model. Integrating all the above research contents, Figure 6 shows the overall identification process in the final athlete behavior detection system.

3. Experiment and Analysis

3.1. Experimental Setup and Pretreatment. Two public datasets, UTKinect-Action3D and MSR-Action3D, are used to evaluate the proposed method. They are the behavior video data of physical education teaching video captured by Kinect. There are 10 behaviors in UTKinect-Action3D, namely, walk, sit down, stand up, pick up, carry, throw, push, pull, wave hands, and clap hands. There are 10 PE teaching videos, each behavior in each teaching video twice, and a total of 199 effective videos. For the convenience of calculation, all 200 videos are used. There are 20 behaviors in MSR-Action3D dataset, which are shot by 10 subjects, in which each athlete completes each behavior 2-3 times.

According to the experimental settings in the basic project research of the PE teaching video dataset, 20 behaviors are divided into three behavior subsets, AS1, AS2, and AS3 (as shown in Table 1). Each behavior subset contains 8 different behaviors.

In order to reduce the impact on different experimental results, each video is simply preprocessed before the experiment:

(1) Background removal: in depth video, the depth information of the background is consistent, while the depth information of the foreground is changed. The background information can be removed according to this feature. Gaussian model is a common method of background removal in video image detection. This method is suitable for dynamic video image feature detection, because the foreground and background are separated in the model. The benchmark for separating foreground and background is to judge the change rate of pixels. The learning with slow change will be regarded as the background, and the learning with fast change will be regarded as the foreground.

(2) Determination of bounding box: for each video, the bounding box that can and can only frame the athlete's behavior is obtained according to each frame, and the maximum bounding box of all frames is taken as the bounding box of this video (see Figure 2).

(3) Normalization: use interpolation technology to normalize all videos processed in the previous step to a unified size, where the number of normalized video frames is equal to the middle value of all video frames. At the same time, the min max method is used to normalize the depth information values of all

videos to the range of [0, 1]. Finally, all samples are turned horizontally to form new samples, so as to multiply the training samples in the dataset. After preprocessing, the behavior video sizes of UTKinect-Action3D and MSR-Action3D are $28 * 32 * 32$ and $38 * 32 * 32$, respectively, including the number of frames, frame width, and frame height in the video from front to back. The experiment depth neural network model part is compiled by torch platform, and the data preprocessing part is completed by Matlab platform.

3.2. Performance of Athlete Behavior Recognition Algorithm Based on Deep Neural Network. Firstly, the effectiveness of the research method is verified on the MSR-Action3D dataset. According to the experimental setting of [19], the research method is compared with the benchmark project research of the dataset [19] and several main methods based on artificial feature extraction in recent years. Figure 7 shows the method and the accuracy of behavior recognition on three different behavior subsets. From the recognition results, it can be seen that the athlete behavior recognition method based on 3D convolution depth neural network can effectively recognize human behavior, and the recognition accuracy and average accuracy of each behavior subset are better than the benchmark research of the dataset.

This is mainly because the 3D word bag model is used to extract the features in the behavior video. This feature can extract the representative 3D word bag information in the physical education teaching video but ignores the spatial and temporal information in the video. When doing video evaluation experiments, we need to select representative video sequences according to certain conditions. Temporal information (Ti, temporal perceptual information, also known as temporal complexity) and spatial information (Si, spatial perceptual information, also known as spatial complexity) can be used to measure the characteristics of video. Where Si is high, there are more spatial details of video frames (high spatial complexity). Where Ti is high, the video frame content moves violently (with high time complexity). The athlete behavior recognition method based on 3D convolution depth neural network adopts 3D convolution operation for the video, which effectively maintains the spatial and temporal features. Therefore, better performance is obtained. Table 2 shows the comparison between the research method and the current method with the best recognition efficiency [20]. The experiment adopts the setting of the method in [20]. The results show that the proposed method can maintain consistent recognition performance with the methods in [20], which fully shows the effectiveness of this method (Figure 8).

In the UTKinect-Action3D dataset, the research method is compared with the benchmark research project on the dataset. Literature [21] used leave-one-out cross validation method (LOO-CV). For the convenience of the experiment, the study uses leave one subject out cross validation (LOSO-CV); that is, only one subject's all behavior videos are used as the test set at a time, while the data of other subjects are used
FIGURE 6: Flowchart of the identification process in the final athlete behavior detection system.

TABLE 1: The action subsets AS1, AS2, and AS3 in MSR-Action3D dataset.

AS1	AS2	AS3
Horizontal arm wave	High arm wave	High throw
Hammer	Hand catch	Forward kick
Forward punch	Draw x	Side kick
High throw	Draw tick	Jogging
Hand clap	Draw circle	Tennis swing
Bend	Two-hand wave	Tennis serve
Tennis serve	Forward kick	Golf swing
Pickup & throw	Side boxing	Pickup & throw

extraction links. It only needs simple processing of the original video, and the deep neural network model can automatically extract features and complete the recognition and classification process. The method is simple and involves fewer links.

3.2.1. Behavior Recognition Parameter Experiment. If the extracted frame image sequence is directly sent to the network model for training, recognition, and classification, the recognition effect will not be ideal because of too many interference factors. Direct training can not model complex video, and the video modeling effect with long time is not good. Although the recognition subject in the video is an athlete, other moving objects appear in the picture due to the angle and complex actual scene during video shooting, and their dynamic changes will interfere with behavior recognition. Therefore, in the process of preprocessing the data, the support vector machine is used to detect the gradient direction histogram characteristics of each region in the frame picture to locate the athlete's region and then cut off the picture information outside the region of interest. After the model is trained, the multiscale detection method is used to detect the target in a picture. The multiscale method uses the image pyramid and sliding window, which involves two important parameters: the downsampling scaling factor scale: the divisor of the width and height of the image divided by each downsampling.

Sliding step means that how many pixel units the sliding window slides each time it slides horizontally or vertically. The variation range of detection scale directly affects the detection effect and consumption time. Setting these two parameters reasonably is a key to optimize the recognition effect and recognition time. In the sequence data, the "sliding window" is used to intercept sequence fragments, thereby reshaping the original data into samples of a specified length for model modeling. On the premise of achieving the best detection effect, we should reduce the scale range as much as possible to reduce the detection time.

100 frame pictures from different videos are selected as the test data. Taking the ability to correctly detect the athlete's area and further obtain the athlete's area as the standard for successful recognition, two variables are controlled for detection, respectively. The detection results are shown in Figure 9, in which the ordinate represents the scale factor, and the abscissa represents the sliding step of the sliding window in the form of (horizontal sliding step, vertical sliding step).

It can be seen from the table that the average detection time is inversely correlated with the scaling factor and sliding step size. Considering the data in Figures 9 and 10, it is finally decided to select the scaling factor of 1.2 and the sliding step size of (16, 16).

as the training set, so as to train a deep neural network model for each subject. Obviously, the experimental conditions are more stringent than those in [20].

It can be seen from Table 2 that the average accuracy rate of behavior recognition of each subject is 80.125%, which can basically correctly identify the behavior of most subjects. However, the recognition accuracy rate on physical education teaching videos 5, 6, 7, and 10 is relatively low, which may be due to the large deviation of perspective of athletes in these sports teaching videos when shooting action behavior because UTKinect-Action3D is a multiperspective dataset. However, there is still a certain gap between the research method and the 90.92% recognition rate in [21], with a difference of nearly 8 percentage points. It may be because it makes full use of the skeleton information in the depth video and uses hidden Markov model (HMM) to establish the temporal model of skeleton information. Its disadvantage is that the behavior recognition framework is too complex, and the system performance is affected by skeleton information extraction and HOL3D feature extraction, feature LDA projection, behavior word clustering, HMM model training, and other links, and literature [21] can see that skeleton extraction is a complex process, and the accuracy of the extracted skeleton information depends on the shooting of depth video. At the same time, the experimental conditions of the research method are more stringent than those in [20], the experimental data are relatively small, and the training of the model is insufficient, which are also the reasons for the poor recognition effect. Nevertheless, compared with the methods of feature extraction such as [21], the method based on deep learning has better generalization performance, and the research method does not need complex artificial feature

FIGURE 9: Accuracy rate of multiscale detection (%).

FIGURE 10: Average time of multiscale detection (ms).

The experimental data are 250 training videos and 60 test videos. All videos take 30 frames at equal intervals and then use VGG16 network model to extract features and train and test through two-way long-term and short-term memory network model. Under the control of other variables, the frame sequences before and after clipping are used,

respectively, for experiments; the contrast effect before and after clipping is shown in Figure 11. After cutting, the overall recognition effect has been significantly improved, the recognition rate has increased from 42% to 27%, the single category false alarm rate has decreased, and the average false alarm rate has decreased by nearly half, as low as 9%.
FIGURE 11: Comparison of recognition effect before and after cutting.

4. Conclusion

This research is based on a deep neural network and uses the CamShift algorithm to track athletes. It collects positive and negative samples of the training athlete's classifier and extracts the HOG features of all positive and negative sample blocks. CamShift can effectively solve the problem of target deformation and occlusion. Resource requirements are not high, time complexity is low, and good tracking results can be achieved in a simple background. However, when the background is more complicated, or there are many pixels that are similar to the target color, it will cause the tracking to fail. Therefore, the SVM classifier is used to train the athlete's classifier and uses the algorithm of cutting frame pictures and VGG16 model to recognize athletes' behavior. After some interference information in the picture is cut out in the data preprocessing of the system, in order to further strengthen the attention of the network model to the actions of athletes' key parts, the mechanism of adding attention in the cyclic neural network can be used to further improve the recognition effect. Although some progress has been made in improving model reusability and reducing labelling and training costs, there are still many aspects that can be improved, such as improving the speed of sports video target detection and human posture estimation. The adjacent frames in the video have very high similarity. This paper uses this to fuse the multiframe results, which improves the detection accuracy, but also brings a lot of redundant detection. In the later stage, we can consider accelerating the detection according to the redundant information between frames.

In this paper, the authenticity of news information on the 5G Internet of Things (IoT) is studied, and a network false news information screening platform is designed and optimized by IoT combined with passive RFID. The electronic license chain based on data sovereignty is established, in which, combined with the identity identification and strong correlation ability based on the electronic license chain, a cross-industry, cross-business, and cross-field behavior record base database is formed; then, a digital library is constructed based on this base library; finally, through data sharing and management, a false news information feature extraction and screening platform is formed for the orderly management and reasonable dispatch of government resources and reducing various risks. The main functional modules implemented by the platform are the acquisition of news data and comment data, the retrieval and analysis of news data, the false detection of online news, and the visualization of false news data. However, there is still much public who are not aware or do not understand that news truth is this dynamic form. Therefore, this paper aims to inform the public that news truth in news context is a dynamic process by 5G Internet of Things combined with passive RFID. The public understands the circumstances where news truth may be dynamic truth to avoid being misled by false news.

1. Introduction

News truth is the lifeline of news; the news, true or not, will affect the public's trust in news; therefore, the press always takes truth as the life of news and insists on news truth as one of the most basic business norms and the most important working principles [1]. Scholars in different periods will continue to change the research and results of news truth with the requirements of technology and society, constantly exploring and deepening that the connotation of news truth is the source of making news alive and everlasting. In recent years, news inaccuracies have frequently appeared, mostly in new media platforms, and the status and authority of news media have been greatly impacted, and the truthfulness of news has been questioned, so in this context, it is of practical significance to rethink the truthfulness of news reports in the context of news [2]. By reexamining the dynamic process of news authenticity, journalists, especially the audience, can understand that news authenticity is more prominent in the

new media context as a dynamic expression and realize that "news authenticity is a dynamic process" to reach a consensus and reshape the authority of news media, which is important to reduce false news and maintain social stability. And it is of great significance to reduce false news and maintain social stability [3].

In the network news release link, the media plays an important role, and creating a healthy network environment requires the media to supervise each checkpoint. Traditional media is strengthening integration and development, continuing to play the role of authoritative media in the Internet environment, using the Internet to present news content in traditional media to users in more diverse forms, but for now, traditional media has formed in the Internet of Things [4]. The influence of Internet media is growing. Therefore, the governance of Internet false news incidents still needs to rely on Internet media, by improving the media literacy of online media and exploring the characteristics of its gate-keeping mechanism, effectively preventing the spread of

online false news incidents [5]. News production in news contexts affects the production logic of news truth; news verification before reporting is converted to verification after reporting, and news truth is transformed from conclusion truth to process truth, all of which are closely linked to the characteristics of news contexts. The algorithmic mechanism is a new thing in the Internet era, and the research in this field in the academic industry is not yet mature. As the core mechanism of Internet information flow, machine algorithms have a certain impact on citizens and society through the collection and processing of information distribution [6]. The balance between technical rationality and value rationality can make technology better serve human beings, and the opposite is easy, to put the cart before the horse. How to balance the two requires contemporary researchers to propose more advanced and contemporary theories as to the basis. Most scholars have selected a definite ethical issue to study the phenomenon of this new phenomenon, but few scholars have looked at the essence of the phenomenon to analyze its intrinsic problems.

Network fake news is defined as false information posted by users on social media, that is, news information or rumors that are not consistent with the facts and cause a certain amount of public opinion released by individuals without official confirmation. Chapter 1: Introduction: this chapter first summarizes the research background and significance, research content, development trend, and application fields of Internet false news information feature extraction and screening based on 5G Internet of Things combined with passive RFID and finally gives a detailed description of the main research content of this article and the organization structure of the article. Chapter 2: Research on the Internet of Things News Screening Platform: the current research status is introduced. At the same time, an algorithm for feature extraction and screening of Internet false news information based on 5G Internet of Things combined with passive RFID is proposed, and an optimization platform for Internet false news information is established. Chapter 3: Result Analysis: with the optimization algorithm proposed in this paper as the core, the experimental process and experimental results are described and analyzed, and the effectiveness of the method proposed in this paper is verified through comparative experiments. Chapter 4: Conclusion: this chapter summarizes the full text, summarizes the main points of the full text, and looks forward to future work.

2. Research on 5G IoT News Feature Extraction Platform

2.1. Related Work. A study by Miloslavskaya pointed out that secure, well-attributed data sources are critical to data accountability, forensics, and privacy [7]. A decentralized trusted cloud data source architecture using IoT is proposed. IoT-based data sources provide tamper-proof records, increase the transparency of data accountability in the cloud, and contribute to the privacy and availability of source data [8]. In the paper, ProvChain is designed and implemented to collect and verify the architecture of cloud data sources by embedding source data into IoT transactions utilizing cloud

storage scenarios and selecting cloud files as data units to detect user actions to collect source data [9]. The results of the performance evaluation of this approach show that the source user privacy and reliability of cloud storage applications are minimal, so the source data collection, source data storage, and source data verification are needed [10]. The study by Hoang points out that data-based encryption, especially attribute-based encryption based on ciphertext policy, plays an important role in data sharing [11]. The study of an efficient and privacy-preserving traceable attribute-based encryption scheme for IoT is proposed. The scheme uses a preencryption technique to quickly generate ciphertexts and hides the attributes of anonymous access control structures by using attribute bloom filters. The source of misused keys can be audited in case of misuse.

Uslu et al. collected official rumor information on news platforms as an experimental data set. Through research, they found that the geographic location and terminal equipment used by users when posting Weibo have an important impact on rumor recognition. The feature is added to the feature set of the rumor, and the rumor detection based on the Weibo platform is realized by constructing an SVM classifier [12]. Kumar combined 5G IoT electronic data to become common evidence, from the perspective of judges reviewing the authenticity of electronic data, explored the possibility of electronic data being tampered within various aspects of collection, extraction, preservation, and transmission due to its intangibility and vulnerability to destruction, as well as the difficulty of discerning the authenticity and integrity of electronic data, which affects the admissibility and probative value of electronic data, and concluded IoT-based technology for multiparty deposition, to ensure the authenticity, security, and validity of electronic data conclusion [13]. Research on the compatibility of UHF RFID and cellular networks is based on reflection modulation and proposes a design scheme for passive cellular IoT systems, including cellular IoT base stations, passive terminal software and hardware architectures, and mainstream benefits compatibility. Although it is still a theoretical study, it can be seen that the research of cellular networks supporting passive IoT has also been put on the agenda, and the research direction of 5G supporting passive IoT access also has a certain foundation. In the past development process of the Internet of Things, the passive Internet of Things seems to have no intersection with the cellular network. Today, the vision of allowing 5G to carry hundreds of billions of Internet of Things access is indispensable for passive IoT support. Driven by this goal, cellular mobile communication networks are closely integrated with passive IoT for the first time and become the future largest group in 5G connections.

Fake news refers to news reports that do not reflect the objective truth and contain false elements and can be divided into two categories: one is news reports in which the communicator intentionally fabricates facts out of thin air for some purpose and disseminates them; the other is news reports that are generally true, but some details of the description appear to be false or intentionally or unintentionally misinterpreted or falsified. Reverse news is "news

that is initially reported in the opposite direction, and as the news report goes deeper and deeper, the truth is presented to the readers more objectively and comprehensively, and the readers' position is sharply reversed and they show the opposite attitude from before." Reversal news is distinct from fake news. This article combines news text similarity features, news and comment data emotional tendency features with some statistical-based user features to construct feature vectors, and uses IoT classifiers to train the data to obtain the final fake news detection model through the model "detect news data and display the classification results in the system."

2.2. Information Feature Extraction Algorithm. In intelligent algorithmic backend applications, the algorithm decides what content can enter the distribution channels, what information each user likes to read, and what news reports can occupy the main part of the distribution content and seem to evolve into the decision of the audience, which will lead to algorithmic news catering to the entertainment needs of the audience, ignoring the impact of the news itself on the public, industry, and society. Usually, post-truth news is the result of a significantly different public opinion sentiment that accompanies modern public opinion and is an important sign of the reversal of public opinion [14]. Fake news will not necessarily be clarified. The "reversal" of reversal news is the process by which the truth is continuously discovered. Reversal news will generally cause strong repercussions and create a strong public opinion situation.

Robots for data collection have become an important source of information for new media; a few days ago, the algorithm recommended news mainly relying on three production push mechanisms: one is the user portrait algorithm, in full accordance with the user hobby mapping recommended information, using the similarity of two or more user attributes to find the same cluster of users. These three content distribution models have in common the pushing model of giving different weights to algorithms to seek attention to the news, which makes it difficult for the public to scientifically select the social and cultural values embedded in the news, which requires gatekeepers to adhere to the confirmation and review of information, to guide the public to rational behavior, and to ensure that objective and accurate news will not be lost in the ocean of information. Therefore, in the stage of intelligent media, the existence of gatekeepers is reasonable, and the breakthrough can be made by personalized news, with algorithms and professional editors acting as gatekeepers, avoiding algorithms occupying the main position of gatekeepers, ensuring that news content meets the ethical and moral requirements of journalism, and reshaping the authority of gatekeepers, as shown in Figure 1.

The news media has the function of guiding social opinion and simultaneously setting important events in society as fixed issues. Although robots have changed the news production and content distribution mode, robots cannot replace the monitoring function [15]. The mass media in the traditional sense represents the public opinion

and is a collection of public opinions and issues. Public opinion supervision is completely different from rigid forms of supervision such as administrative supervision; it is a special form of soft supervision without strict regulations and requirements, and thus not compulsory, but it can play a role in educating and spreading mainstream values to the public. The media assumes the role of a public issue person in public opinion supervision, and as robotic writing becomes an important development trend in the media industry, it does not completely change the status of machine algorithms replacing human beings as the main body of supervision, which seems to be a cause for celebration. By continuously adding or deleting features, the accuracy of the model is tested on the verification set to find the optimal feature subset. The wrapped method usually has higher accuracy because of the direct participation of the model, but because each feature changes, the model must be retrained, so the calculation cost is high. Another disadvantage is that it is easy to overfat.

$$F(D_i) \leq H_i - \|T_i\| \|\nabla T X\|_i \|d_i N_i^2\|. \tag{1}$$

In the digital world, everyone has a physical presence, and all communication and collaboration will be based on the digital world as the norm and core, while the customary physical world becomes an aid and supplement to the digital world. This process is not only the realization of technology. The IoT security gateway reports news information recognizes news information in the unified management platform, and displays news distribution and true and false status in real time. Combined with the internal network isolation and baseline detection of the Internet of Things gateway, it blocks terminal intrusion detection and propagation.

$$X = \lim_{N \longrightarrow \infty} \sum_{i=1}^{N} \beta_i^n (d_i - 1). \tag{2}$$

We can achieve objective, fair, and scientific supervision and full supervision of credit evaluation through the comprehensive application of IoT and other technologies and, at the same time, strengthen the supervision of credit evaluation agencies to ensure that their evaluation is fair and untamable [16]. One is to use data sovereignty IoT technology to guarantee the operation right and basic bookkeeping right of IoT, and the core institution of data sovereignty to carry out the support and application of operation, to effectively guarantee the safety of people and national information property; the second is to use IoT technology to supervise the operation process of power operation, livelihood application, public service, and other affairs in the whole process.

To observe *X*, the signal *X* is projected using a matrix of *M* to obtain the observation vector *Y*.

$$Y = A_i^{CS} (\beta - 1) \beta_i^n. \tag{3}$$

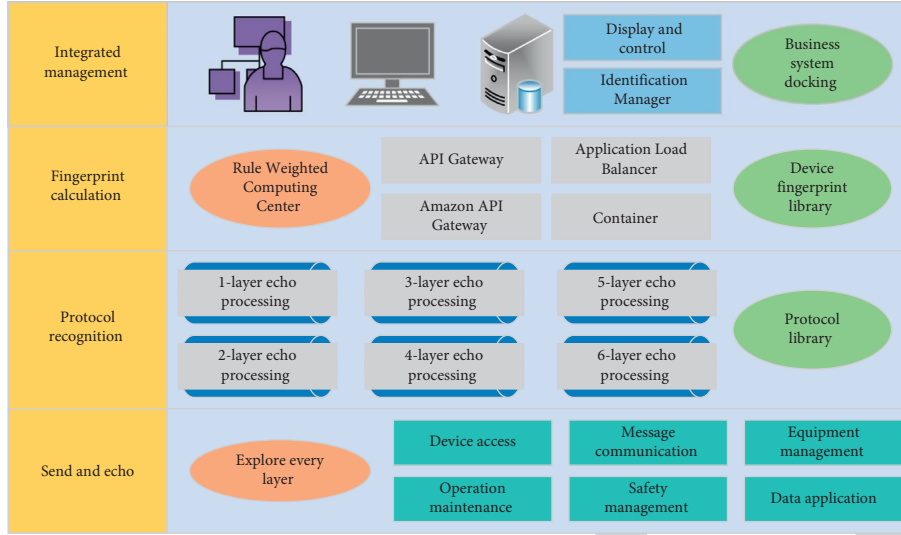
IoT technologies are devoted to developing key technologies at the protocol and infrastructure layers that can take credit scoring-related data collaboration to a higher level. Meanwhile, a high-performance and secure credit data exchange network


Figure 1: IoT information screening model architecture.

based on IoT technology can improve data quality, reduce data collection costs, expand data coverage, and ultimately create better credit scoring models through artificial intelligence used to update and calculate the network parameters that affect the model training and model output to approximate or reach the optimal value, thereby minimizing (or maximizing) the loss function. Therefore, IoT technology can not only play the advantages of high security and benefit-sharing, but also achieve the performance requirements needed for industry scenarios. Formula (4) is a performance statistical function, where β represents the statistical type, and n represents the statistical period.

$$\beta = \arg\max \left\| \beta_i^n \right\|^2. \tag{4}$$

Because laws and regulations can only be remedied after the fact through state intervention, while technical rules can be prevented beforehand through code. The function and role of law and code under the Internet society can be considered high and low. However, the translation of legal rules into technical rules is not an easy task. A legal code is a general rule that is essentially ambiguous and written in language; a technical code, in contrast to a legal code, can only be expressed through the code and necessarily relies on algorithmic forms and digital models. While code increasingly mimics or even replaces some of the traditional functions of law in the digital world, in the last few years, especially since the emergence of IoT technologies and smart contracts, the law has also come to display some of the characteristics of code. The feature extraction and screening of false news information are shown in formula (5), where U represents the feature set, t represents the collection time, s represents the screening method, and c represents the extraction method.

$$U_t = \frac{y_i^2(t,s)\left(1 + e^{x_m c_m \nabla A}\right)}{e^{x_m c_m \nabla A}}. \tag{5}$$

This information recommendation method helps users find the information they are interested in and read daily in a sea of information, reducing the time spent on information search, and people seem to have used to this way of receiving the news [17, 18]. The algorithm replaces the user's way to find information and invariably replaces the individual user's information selection, creating private customization of the information content platform, allowing irrelevant news to be lost in the sea of information, and making the user refuse to receive social issues from other public areas, which will generally reduce the public's social cognitive ability in the long run.

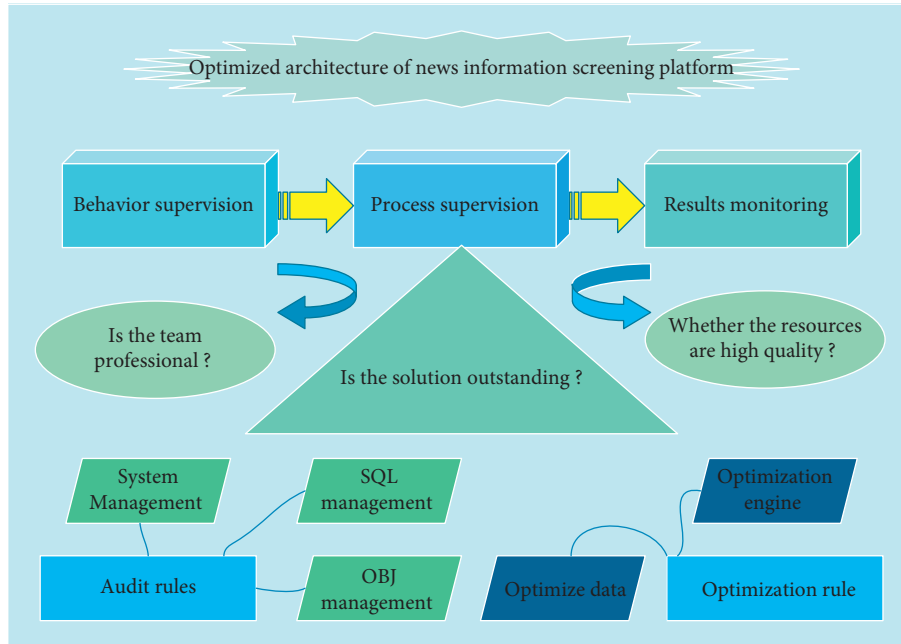
2.3. Fake News Optimization Combined with Passive RFID. It is reflected in the internal verification process of journalists, which is the most reflective link of the main position of journalists and belongs to the prereporting verification. For a long time, journalism at home and abroad has always held "news truth" as the lifeline of news and requires journalists in the process of news reporting must ensure that news events are reported in a completely true and objective way; therefore, journalists in the acquisition of newsworthy information about recent events must go through a verification [19]. In the process of verification, journalists must collect as many accounts as possible from different parties or eyewitnesses to restore and reproduce the actual event from multiple angles and in a comprehensive manner. Verification of news content is a necessary process to ensure that news reports are authentic and credible, and so is news production. Figure 2 represents the optimized architecture of the news information screening platform combined with passive RFID. The main purpose of the online fake news detection system is to detect online fake news. The system contains four main functional modules, namely, the acquisition module of Internet of Things network news data and comment data, the analysis and retrieval module of network news data, and the network false news detection module, and the data analysis result visualization module, among which the IoT false news detection module is the most important functional module in the system.


Figure 2: Optimized architecture of news information screening combined with passive RFID.

The process of authenticity identification service design is as follows: firstly, the client node in the IoT platform calculates the digital digest of the local file, calls the authenticity identification API, and initiates a request to the server node; then the server node authenticates the network certificate held by the node, and if the verification passes, the node is authenticated, and the file access authority is verified; if the verification fails, an error message is returned, and the call is terminated [20]. If the verification passes, and the nodes on the chain reach consensus, the relevant data in the process will be written to the block and packaged, and the corresponding message will be returned to the client node; otherwise, an error message will be returned, and the call will be terminated, thus ending the authenticity identification service.

News reporting is the reporting of newly occurring or newly discovered facts, and the object of its reporting is the matter that is available in the objective world. Epistemology believes that the objective material world is always in the process of movement and change; therefore, from the perspective of the object to explore the dynamic process of news reality, it is necessary to clarify a point of view; that is, the fact itself is in a state of motion of constant change and development, and then the news reality corresponding to the event will also necessarily be in a dynamic process [21]. Many news reports of the event with special characteristics and complexity, in those instant reports of the news process, due to the reporting of the event at the time of some matters or details have not been fully revealed; instant reporting can only present the facts that have been revealed partly, and then with the development of the event for follow-up reports, in such a continuous and dynamic reporting, the overall reality of the news event also shows a dynamic presentation. In such continuous and dynamic reporting, the overall truth of the news event is dynamically presented. Second, the fragmented news text in the news context can hardly present the complicated and objective world completely. Therefore, the news truth from the object perspective is also in a dynamic development process with the development of news events.

Traditional mainstream media are limited by technology to a longer time limit for news reports and limited channel resources, and news reports are more inclined to one-time final reports, with many news being reported only after the development of the matter is over, and after in-depth digging and verification by reporters. Therefore, the content of these reports is completed, and the news reality shown to the audience is also more complete. Only a small number of news events with a relatively large impact, such as sudden disaster events, are released for the first time to inform the public, and then follow-up reports of the events are released continuously. In contrast, news reporting in the news communication context has shown recent changes and forms due to the real-time nature of news releases and the brevity of news content, as well as the competitive pressure of information release channels. To grab headlines, professional news media often release concise news stories to let audiences know that something has happened before it is finished and then follow up on the news to grab headlines. The complex communication ecology of the news communication context drives news reports to keep pace with the development of news events and makes the dynamic characteristics of news truth more prominent. In the news communication context, news truth also presents a gradual and dynamic process because of the development process of news events.

IoT technology has the characteristic of "data sharing," which refers to the sharing of data storage and exchange level

[22–25]. The IoT network makes multiple copies of the data on the chain and stores them on multiple storage nodes at the same time, so from the data point of view, the data is shared to multiple nodes and can be downloaded from any node. However, from the perspective of data content, the platform can encrypt the data content through encryption technology. Even if we get the encrypted data, we cannot access the actual information contained in the data without the decryption key. Therefore, the platform identifies the legitimate users based on the account mechanism, assigns the users the contents they have a right to view and the decryption key through the permission mechanism, and ensures data security by encrypting the data on the chain through the encryption technology. The platform supports the information security mechanism based on permission and encryption functions. In simple terms, the integrity file platform needs to be completed with a system that supports identity-based permission control and password mechanism and only responds to user requests through the IoT gateway, specifically including filtering out requests from illegal users and cross-authority requests from legitimate users.

All data compiled in this study included all online news headlines from seven major websites with names in the title and time from 2010 to 2019. A total of 8825000 news headlines were collected, and the results are shown in Table 1.

The network false news detection module detects false news based on the constructed test model. In the system design of this article, the test model generated in advance based on the training data is stored in a txt file, and the news collected in this system can be detected and identified. When you click on fake news analysis, you can use a visual mode to show the trend changes in the number of comments related to the news and the analysis results of the text and comments.

3. Analysis of Results

3.1. News Information Feature Extraction Results. Social platforms such as microblogs, which are based on Internet technology, have the functions of both information dissemination and social interaction, allowing users to express their opinions or respond to others' opinions through comments, retweets, and private messages. The dissemination of information on the microblogging platform is not restricted by time and space, and users can spontaneously and actively participate in discussions, actively verify the information, and provide other information after news reports are released, which invariably constitutes a unique "self-clarification" mechanism in the online environment, as shown in Figure 3. Among them, the information of the day accounted for the highest proportion, reaching 32.5%, and the proportion of information over two weeks was the lowest, accounting for only 11.2%.

Among them, the information of the day accounted for the highest proportion, reaching 32.5%, and the proportion of information over two weeks was the lowest, accounting for only 11.2%. Those that are longer than two weeks are the event itself that is still in the development process, so it takes

2019	958426
FIGURE 3: Length of news true clarification.

a relatively long time. Overall, the real clarification time of news in the context of Weibo is relatively short, and clarification can be obtained relatively quickly.

Filter out the useless comment data, and extract the features of Weibo content and comment-related content, based on the original feature, the combination of the original feature and the newly extracted text feature, and the original feature and the newly extracted text feature. The combination of text and comment features was experimented separately. Through the data in the test, the reliability and performance stability of the IoT platform are reported. However, in the process of false analysis of news and sentiment analysis, due to the processing of more data, there will occasionally be longer response times. The detection efficiency of the IoT platform still needs to be improved.

Through the analysis of 60 cases and overall, it is found that 73.33% of the news reports present dynamic reality because of the lack of verification or being reported and reprinted without verification, 11.67% of the news reports are fictitious news to win the audience's attention, and other factors include poor professionalism of journalists, unfinished events, and lack of authoritative information, as shown in Figure 4.

Figure 4 reveals that the main reason for the prominence of the dynamic process of news in the current microblogging context lies in the lack of prerelease verification of news reports. The cause for the widespread of many fake news stories is that professional news media simply copy and paste them without verifying the news content, all at the cost of losing the credibility and authority of the news. The phenomenon of backstage news foregrounding has emerged along with the weakening of the verification process in the professional news media. Goffman introduced theatrical elements and staging techniques into interpersonal interactions and put forward "drama theory," which compares interpersonal interactions to personal performances and proposes the concepts of front stage and backstage. The front stage performance is more formal, while the backstage performance is relatively relaxed and unruly. Some studies have introduced Goffman's drama theory into the news reporting industry and explored the relationship between news media and audiences, arguing that news also has a front and backstage, in which the production work before the release of news reports is the backstage, TV, newspapers, and official microblogs belong to the front stage, and each news report is treated as a front stage performance, and the news reports that audiences are exposed to are front stage acts, and the previous news front and backstage boundaries and behavioral segmentation. The previous news front and backstage boundaries and behaviors are relatively clear. However, in the microblogging context, the front and backstage boundaries of news reports are blurred, because the verification process of news media is weakened, which reduces the authenticity of news reports, and many news are reported after netizens raise questions, or some knowledgeable people point out that the news reports are not in line with the actual situation, which leads to the verification behavior of the backstage being moved to the front stage and the front stage turning into the backstage. This is one of the reasons why news reality in the microblogging context presents a dynamic process.

Figure 5 shows the changing pattern of network size at each dissemination stage, and the numbers of nodes and edges of the network are the indicators of network size. Among the four stages of online opinion dissemination, the numbers of nodes and edges are the largest in the outbreak period with 3864 and 1610, respectively, indicating that the network scale is the largest at this time, and most microblog users are involved in opinion dissemination. In the latent stage, the network size is the smallest, and the numbers of nodes and edges are small, but the difference is not very large, while, in the growth and decay stages, the number of nodes of the network is greater than 1000, and the number of edges is about 330, indicating that although many users participate in the discussion in these two stages, only a small number of users have retweeting relationships with each other.

From the trend of the maximum node degree of network nodes in Figure 5, it can also be seen that although the maximum node degree of network nodes differs significantly from the network nodes and edges in terms of number, the trend of change does approximate the same. The maximum

node degree of network nodes also reaches its maximum value during the outbreak of public opinion. News from different information sources is brought together, and news truth becomes more complex and difficult to discern. Often, the public must increase their capacity to select and screen information and consciously develop their thinking about news counterfeiting. Do not jump to conclusions blindly, but keep a skeptical attitude. If necessary, you should combine life experience and common sense to make judgments, just like in daily life, and not believe in things that fall from the sky; similarly, in the microblogging platform, you should not believe in information that is inconsistent in wording and things that do not make sense and also be easily convinced and spread it, but you should reserve your opinion about some uncertain information. It is better to wait patiently for the professional media to provide authoritative information, to minimize the negative impact brought by the process of real news dynamics.

3.2. Platform Optimization Results. As shown in Figure 6, the latent period of public opinion has both large network density and average network degree, but the average shortest distance length of the network in this period is particularly large, which makes the connection between users in the latent period very close but hinders the dissemination of public opinion information more difficult due to the longer dissemination path. While the values of network density in both the outbreak and decay periods of public opinion are relatively small, and information transmission is not very easy, the average shortest distance length of the network is much smaller than the rest of H periods, and the average degree of the network is also relatively large, so that, in the outbreak period, public opinion information is transmitted quickly among users, and communication among users is more frequent; on the contrary, in the decay period, the average shortest distance of the network is very large, and the average degree of the network is relatively small, so that, in the decay period, public opinion information is spread slowly, and users are less connected to each other and interact less.

Figure 7 shows the statistics of the number of news retweets. These users have a common characteristic; that is, they have a certain status of speech in the society, and the blog posts and opinions they publish will be responded to by a group of a not small number of people and exert a large influence, which is what we call opinion leaders. These users have a huge circle of fans and a large influence, so they do not have to deliberately publish numerous blog posts or follow others on purpose. When public opinion occurs, the information released by each person only represents the opinion, and the quality of information from certified users is relatively much higher, which also plays a role in the supervision of online information. These users will post or forward blog posts that can represent their emotional tendencies, thus influencing the remarks and emotions of other information recipients and playing a role in the spread of public opinion.

operation data of all aspects of the constructed integrity file platform meet the technical requirements, realize the electronic license chain based on data sovereignty IoT technology, and can realize the efficient application of electronic license in anticounterfeiting, impersonation verification, privacy protection, safe sharing, visualization, and authority. This set of integrity file systems built based on integrity data sources with communal sharing in

the whole field has laid a solid foundation for the subsequent in-depth research of data sovereignty IoT technology.

In the process of modern news dissemination, the report form of any piece of news has to go through many processing processes. In these processing processes, news facts are recognized, formed into images, latent processing, written expressions, value judgments, and
Figure 6: Trends in network characteristics at each dissemination stage.
Figure 7: Distribution of the number of forwarding.

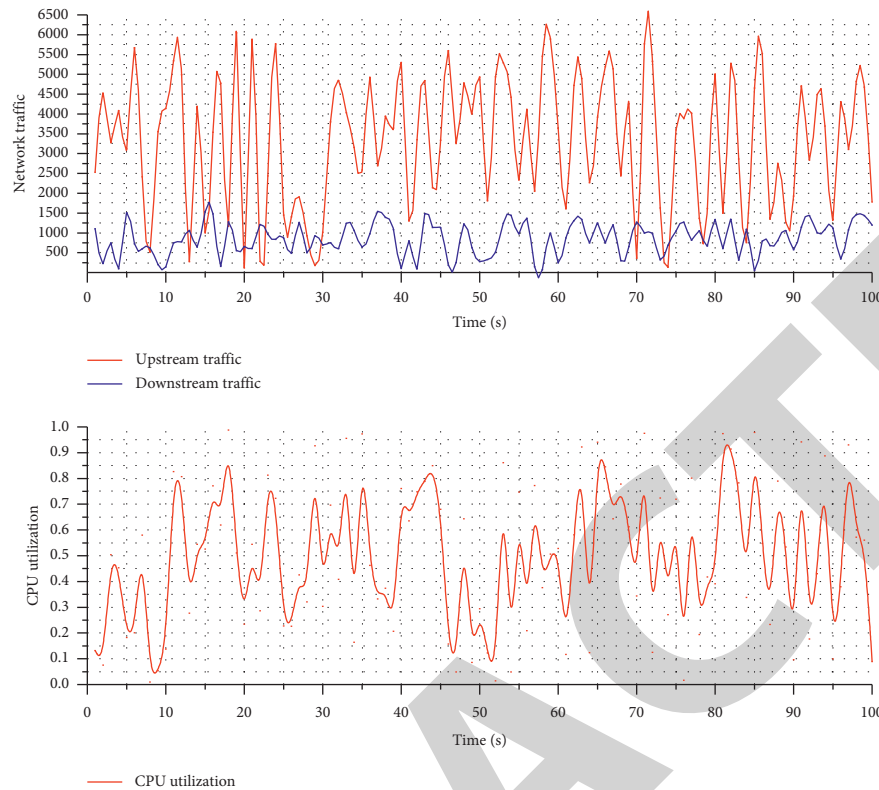
disclosures. There are many links such as publication, and each link is operated by humans. This not only helps ensure the authenticity of the news, but also greatly helps the news writing process and enrichment of the content. It is also the basis for writing good articles. As journalists in an era of unprecedented fierce competition, we should remember that any report we make must be personally and meticulously investigated and researched before it can be published responsibly to a broad audience. As long as this is achieved, the authenticity of the news will be fundamentally guaranteed, and the lifeline of the news media will be fundamentally ensured.


FIGURE 8: Node data.

4. Conclusion

The paper elaborates the theoretical system, principle, and development process of the key technology of the news information feature extraction platform based on data sovereign 5G Internet of Things and demonstrates and tests the prototype system of the news information screening platform combined with passive RFID. The truth of news reports is as a small part reflecting the overall social reality, and the facts of news reports from different angles and positions that finally present the real picture of the whole society through the stage and dynamic reports. Also, because the production process was more rigorous and thorough during the traditional media era, the truthfulness of the news was better assured. The limited human knowledge of technology and self-knowledge, coupled with the public's blind pursuit of the excitement and novelty of new technologies and the lack of corresponding rational thinking, has exacerbated the degree of ethical misconduct in journalism on some levels. Data sources can be expanded in future research. How to obtain these data from the media and how to analyze fake news purely from a textual perspective are a long-term and meaningful thing, so the screening of fake news still needs to be further investigated. The experiment and analysis of data mining technology are used to identify fake news and thus develop a more accurate fake news screening system.

Since industrialization, manufacturing has been an important pillar of a country's economic development. Under the dual pressure of the new trend of global manufacturing development and the loss of competitive advantage of manufacturing industry, it is especially important to accelerate the enhancement of national high technology innovation capacity and the optimization of high technology policy innovation management mechanism driven by advanced evolutionary Internet of Things (IoT) arithmetic. The main of this paper thus introduces the effective method of optimization of high technology policy innovation management mechanism driven by advanced evolutionary IoT arithmetic. To study the optimization of high technology policy innovation management mechanism, a conceptual analysis of currently popular information technologies, such as big data technologies, artificial intelligence technologies, and Internet of Things technologies, and an overview of the application of these technologies in microgrids are given. In the paper, all factors are studied using the STP innovation management mechanism-based approach, and finally, all factors are classified into two categories of cause and effect factors by this approach, and the importance of all factors is ranked. Secondly, a wind power prediction algorithm based on data mining technology and an improved algorithm and a PV power prediction algorithm based on a deep neural network were established with the technical support of high-tech information technology such as big data and artificial intelligence. Finally, the majorization of high technology policy innovation management mechanism driven by advanced evolutionary IoT arithmetic is proposed.

1. Introduction

High technology innovation is the fundamental driving force of a country's development, and the high technology policy and innovation management mechanism of every country in the world today cannot hold a laissez-faire attitude towards high technology innovation in the process of economic development, especially in developed countries paying more attention to the development of high technology innovation [1], and their high technology policy and innovation management mechanism have been formulating a large number of high technology innovation policies to guarantee and promote the high technology innovation activities. Especially in the twenty-first century, mankind has entered the era of economic globalization, informatization, and networking, and the traditional economic development model has undergone significant changes. From the international perspective [2], an innovative economy will gradually become the mainstream form of economic development, innovation has become the focus of the development strategies of developed countries and regions, and innovative countries have become an important symbol of scientific and technological power. To gain long-term development advantages in the competition of economic globalization, scientific and technological innovation is imminent [3].

High technology is the source of a country's sustainable development, and high technology innovation is gaining

ground in economic and social development, becoming a core element affecting national competitiveness. Improving the level of national high technology innovation has become the focus of attention of scholars and innovation management mechanisms of high technology policies in various countries [4]. For a long time, the leading countries in high technology have taken enterprises as the main body of high technology innovation, but the management mechanism of high technology policy innovation plays an important role in the process of promoting high technology progress. Because of the high risk and uncertainty of both market and technology in the process of development, and the monopoly of enterprises on scientific and technological achievements, all these situations will lead to market failure in the process of allocation of scientific and technological resources. Therefore, the role of the innovation management mechanism of high technology policy driven by advanced evolutionary IoT calculus is revealed. Innovation supports development and high technology lead the future [5].

Through the analysis of high technology policy innovation management mechanism high technology innovation policy orientation research, it can be seen that, in the rapid development of high technology today, to improve productivity and promote social progress at the same time, the need for continuous innovation, how to properly guide the innovation of high technology, and by whom to guide has become the current concern. The purpose of this paper is very clear for this topic, aiming to study the role played by high technology policy innovation management mechanism in the process of high technology innovation and how high technology policy innovation management mechanism promotes the formulation of high technology innovation policy. Optimize the index system of high technology innovation policy assessment. Clarifying the content of high technology innovation policy, exploring the main factors affecting the effect of high technology innovation policy, and constructing a reasonable and effective assessment index system are the prerequisites for correctly assessing the effect of high technology innovation policy. Based on the connotation and composition of high technology innovation policy, this paper selects indicators from three aspects, such as high technology innovation foundation and input, output and result, and regional economic benefit, and adopts factor analysis to screen the indicators, and finally determines the regional high technology innovation policy assessment indicator system, which is a useful supplement to the construction of high technology innovation policy effect assessment indicator system and provides a reference for the future high technology innovation policy effect assessment indicator system. It is a useful supplement to the construction of the STI policy effect assessment index system and provides a reference for the optimization of the future STI policy effect assessment index system.

2. Relevant Studies

After the introduction of "innovation" into economic theory for the first time in the literature, Western economists have explored the issue of innovation in greater depth, mainly

from two perspectives: one is to introduce technological innovation as an exogenous variable into the production function to explain the role of technological innovation on economic growth; the other is to endogenize technological innovation [6]. It is believed that sustained economic growth does not rely on exogenous push, but endogenous technological progress. After the 1980s, a considerable number of studies on high technology innovation have been conducted, and their research is mainly based on the deepening and expansion of the endogenous economic growth theory, which contains organizational innovation, institutional innovation, and management innovation in addition to technological innovation. The literature studies innovation based on the management perspective and argues that energy creation is not enough to rely only on technological improvements, but also on other potential behaviors to improve the wealth creation of resources [7], such as management innovation. The literature includes institutional innovation as an endogenous variable in the innovation process and the empirical analysis of maritime transport productivity over the period 1600–1850 concludes that institutional improvements are more likely to cause productivity growth than technological changes [8]. Thus the literature argues that institutional innovation determines technological innovation rather than technological innovation determining institutional innovation. The literature investigates the role of income disparity in influencing the evolutionary path of innovative products and the returns to innovation, pointing out that the smaller the income disparity, the more conducive it is to stimulate innovative behavior, thereby promoting economic growth; conversely, it discourages innovative behavior and inhibits economic growth. The literature proposes the "quality of innovation," which further elevates the previous criteria for judging innovation, such as novelty [9], unconventionality, and creativity, to the level of quality, i.e. standardization, systematization, and low variance. The literature argues that a firm's innovation capabilities include R&D, production, learning, marketing, resource development, organization, and strategic management. The literature explores the relationship between the price of innovative products and innovation behavior, stating that the price of innovative products is not an exogenous variable and that increasing the price of innovative products can increase the profitability of innovation when the income gap widens; on the other hand, a price increase can lead to a decrease in the rate of market demand, which in turn can reduce the return to innovation. The literature argues that innovation is a management process and that the scientific application of methods, rules, and institutions can be the efficient rate of completing innovative work [10].

The literature defines technological innovation based on the continuum of innovative behavior, design, manufacturing, and commercial activities involved in the process of producing new products, using new processes or new production equipment, and this activity process is in the order of process innovation, product innovation, and innovation diffusion [11]. The literature analyzes innovation from the perspective of the main position of enterprises and

combines technological innovation with enterprises. It believes that innovation is a series of activities in which enterprises reallocate and combine production factors and conditions to obtain potential profit opportunities, rapidly capture market information, and establish highly efficient, effective, and low-cost production systems. In addition, the literature points out that technological innovation in a broad sense refers to the entire process from the conception of a new product or process to its development [12], technology diffusion, and realization of its market value. The literature suggests that technological innovation can be broadly defined as all actions from the conception of a new idea to the production of a new product, including not only the outcome of the innovation itself but also the introduction, diffusion, and application of the technology. The literature constructs an index system for evaluating scientific and technological capability from three perspectives: scientific and technological research and development capability, scientific and technological achievement transfer capability, and scientific and technological support capability, and conducts a longitudinal and cross-sectional comparative analysis of the scientific and technological innovation capability of City A [13].

Based on the endogenous economic growth theory, the literature introduces the endogenous knowledge stock into economic growth and measures the output of high technology activities by using high technology funding input, knowledge stock input, capital input and labor input, and human capital input as input indicators and explores the relationship and development trend between high technology input and high technology output performance in China. Based on the Cobb-Douglas production letter model with GDP as the dependent variable and labor input, capital input, and rate of scientific and technological progress as independent variables, the literature uses an econometric model to study the impact of scientific and technological progress on economic growth in country A during 1980–2004 and applies Solow's surplus to calculate the degree of contribution of scientific and technological progress to study the development of scientific and technological progress [14]. The literature argues that high technology innovation and economic development are complementary to each other, one is that high technology innovation drives rapid economic development, and the other is that economic development, in turn, provides strong support for high technology innovation. The literature adopts T-shaped correlation analysis to empirically study the contribution of economic investment in high technology and investment in scientific and technological talents in economic growth in country A during 2000–2007, and the results show that R&D investment has a very significant role in economic growth, while the role of scientific and technological talents in economic growth is not obvious. Economic growth is more dependent on the introduction of new technologies. In exploring the interaction between regional marine high technology innovation and blue economic growth, the literature points out to regional marine [15].

There is a high correlation of the growth of the regional blue-blue economy of ocean high technology innovation,

and the relationship between them is not simply linear; it is necessary to establish a synergistic and efficient interactive operation mechanism to guarantee and support the positive interaction between the two and promote the coordinated development of regional marine high technology innovation and blue economy [16]. The literature discusses the mechanism of the role between high technology investment, high technology innovation, and regional economic development and proposes that there is a causal relationship between the three; i.e. high technology investment supports high technology innovation, and high technology innovation and regional economic development support each other, and high technology investment and regional economic growth are mutually reinforcing [17].

3. Optimization of STP Innovation Management Mechanisms Driven by Advanced Evolutionary IoT Arithmetic

3.1. Advanced Evolutionary IoT Arithmetic Example. The concept of the Internet of Things (IoT) was first proposed in 1991, and since then IoT has gradually entered people's vision. The Internet of Things uses Radio Frequency Identification (RFID), wireless communication, and other technologies to construct a physical Internet covering everything in the world based on the computer Internet. In the future, the continuous breakthrough of modern information technology will greatly promote the development of the Internet of Things, with the "Internet + Internet of Things," "artificial intelligence + Internet of Things," and other concepts of the perfect combination [18].

The Internet of Things (IoT) is a kind of convergence application and enhancement after the development of modern information technology to a certain stage, based on RFID identification technology, to realize people and things, things and things can "communicate" with each other, forming an intelligent network that can sense the real world. In simple terms, it is mainly composed of two parts: the radio frequency tag and the decoder. The tag is attached to the surface of the item to be identified, and after entering the magnetic field, it receives the signal from the decoder and sends out the product information stored in the chip (passive tag or passive tag) by relying on the energy obtained from the induction current, or the tag actively sends out a signal of a certain frequency (active tag or active tag), and the decoder reads the information and decodes it and sends it to the central information system and finally performs relevant data processing and analysis. According to the three main aspects of IoT data processing, its logical functions are recognized as three levels, i.e., perception layer, network layer, and application layer. The perception layer mainly collects, identifies, and intelligently controls physical information in the real world; the network layer serves as a link between the perception layer and the application layer to guarantee the transmission, routing, and control between IoT information data; the application layer is the topmost layer in the three-layer structure, and its core functions include two aspects, one is to complete into the processing

and management of various data, and secondly is the integration of these data with various industrial applications to achieve real-time control of the physical world. The general framework of the IoT is shown in Figure 1.

The current IoT technology mainly includes key technologies in the fields of perception and identification, intelligent control [19], embedded system, power supply, and energy storage, new material technology, wireless communication, chip design, and manufacturing, etc. The breadth of the involved fields and the complexity of the involved arts make it an extremely huge technical project. According to the presidential framework of IoT, the IoT technology system can be divided into three levels, such as perception layer technology, network layer technology, and application layer technology. Its formula principle lies in

$$\int \sqrt{d^2 + x^2} = \frac{d\sqrt{b^2 - 4ac}}{2}. \tag{1}$$

The first formula of the article summarizes the algorithm carried out in the article and summarizes the essence of the article. It is the basis of the algorithm mentioned in the article, and the following formulas are also mentioned. Among them, the sensing layer technology is the basis of the whole technical framework, the network layer technology is the technical guarantee of the whole information transmission, and the application layer technology is the terminal of the input and output control. The IoT technology system is shown in Figure 2.

The core technology of IoT is quite complex and fine, while the current overall R&D capability of China's IoT technology is weak, and when facing complex application requirements, it will be found that there is still a gap between the chip technology, hub components, and other high-precision technologies and the international leading level. Therefore, the development of IoT technology needs to be combined with China's specific national conditions and the current situation of industrial development to give priority to the development of IoT technology and provide a scientific basis for the country's macrodecision. At the same time, it is necessary to accelerate the development of the standardization of IoT technology [20] and steadily promote the promotion and application of IoT, to improve the overall level of IoT technology in China. With the rapid development of information technology, the scale of the IoT market will gradually expand, not only bringing huge economic benefits to society but also effectively safeguarding national security. IoT technology can be widely used in basic strategic areas such as security, electricity, food, oil, etc. It can also prevent the destruction of strategic resources such as strategic bases, public facilities, and forest land by hostile forces, terrorism, and natural disasters. The extensive use of IoT technology at the national strategic level provides a strong technical guarantee for securing homeland security. Its formula lies in

$$\int \sqrt{d^2 + x^2} = \frac{1}{2} \frac{n!}{r!(n-r)!} + \sqrt{b^2 - 4ac}. \tag{2}$$

The Internet of Things (IoT) applies a variety of modern information technologies to various industries, which itself is a complement and enhancement of the integration of two, which is also a component and application area of IoT technology. The concept of IoT is the integration of IT technology into automation control systems to form an intelligent network system that is efficient, safe, and energy-efficient. Using various advanced technologies such as perception, modern communication, artificial intelligence, and automation, the IoT reorganizes production factors and supply chains extensively and becomes a realistic carrier of informatization-driven industrialization. Therefore, the development of the Advanced Internet of Things Safety is a natural combination of industrialization and informatization, a powerful tool and substantial driving force to promote the integration of the two, and a realistic need to accelerate the integration of the two, whose realization model is shown in Figure 3.

3.2. Optimization of High Technology Policy Innovation Management Mechanism.

High technology policy is the policy adopted by the government to promote the development of high technology and to use high technology to achieve national goals. Its policy texts are generally expressed in the form of circulars, plans, opinions, regulations, and laws and regulations. The theoretical basis of high technology policy includes three aspects, such as market failure theory, system failure theory, and scientific social contract theory. The objective of high technology policy is to promote economic and social development, the development of political civilization and national defense as well as the development of high technology, and the improvement of the country's comprehensive national power and international competitiveness. The high technology policy also contains the high technology talent policy in terms of the development of high technology talent. For the meaning of high technology policy, most scholars believe that high technology talent policy is a series of strategies, laws, regulations, decrees, ordinances, measures, and methods for managing and regulating the behavior of high technology talents. The high technology management system is the overall institutional arrangement of a country's high technology management, including the setting and management of high technology-related institutions, the process of high technology policy formulation and implementation, and many other elements, which plays an irreplaceable role in releasing national innovation vitality, improving the efficiency of the national research system, and maintaining the long-term stability of innovation.

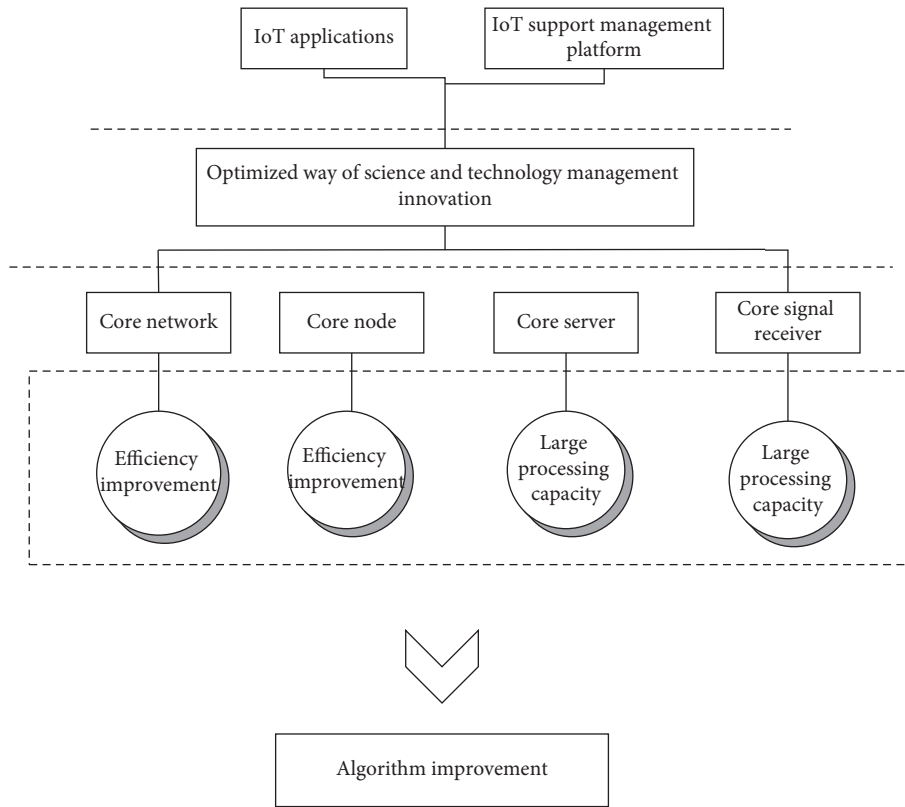
There are several types of national S&T management systems: centralized, dualistic, and decentralized. Centralized systems usually involve the establishment of national ministries of high technology management at the national level to unify the country's high technology activities, and such unification usually facilitates the full protection and nurturing of research institutions and the conduct of long-term, high-risk research. However, scientific and technological development can easily run counter to actual needs or be distant from the mission of other government agencies, affecting the utilization of scientific and technological


FIGURE 1: General framework of IoT.
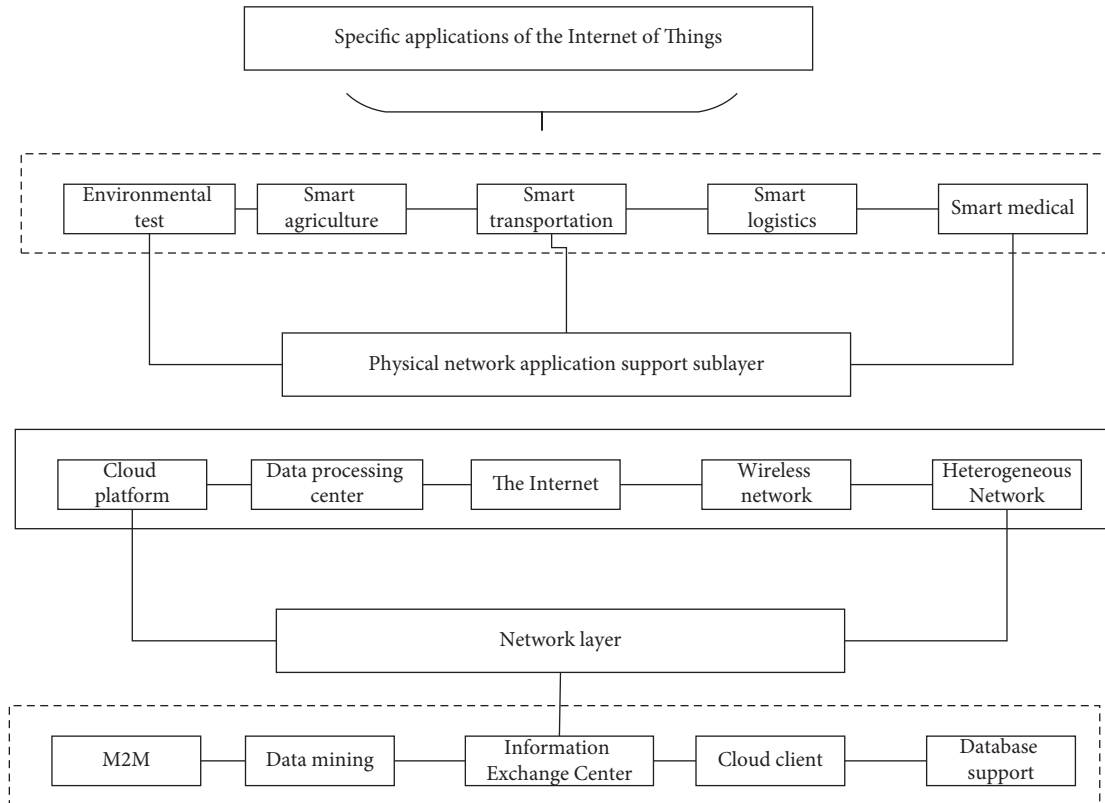

FIGURE 2: IoT technology architecture.
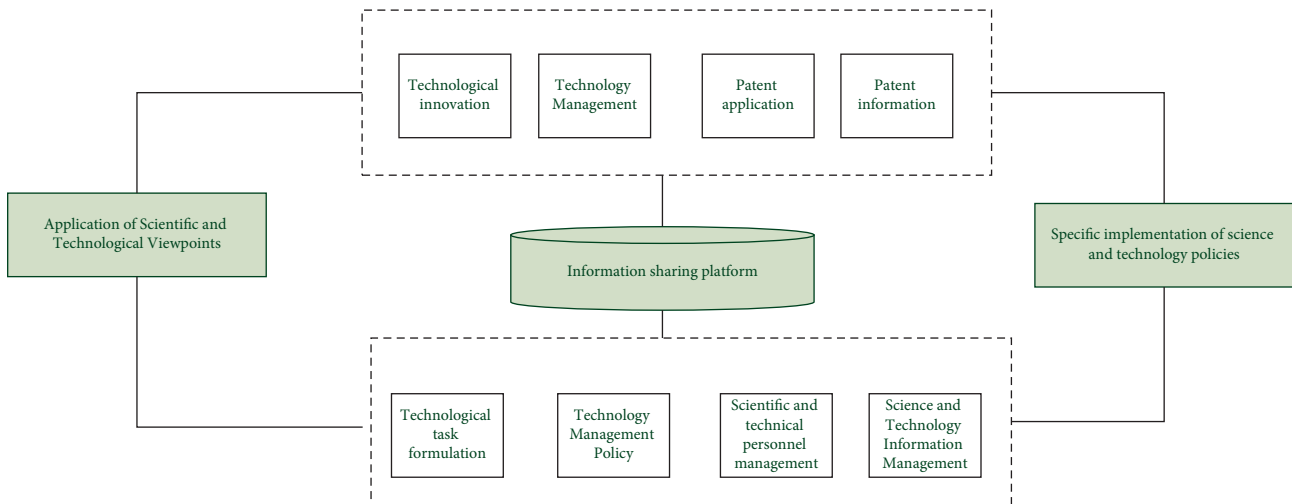

FIGURE 3: Diagram of industrial integration model.

results. The decentralized system, in contrast to the centralized system, usually does not have a macro-high technology management ministry at the national level. This decentralized high technology management can ensure that each government ministry determines the meat of its n work according to its functional areas and management purposes and can respond to various problems promptly, and high technology development can be more W oriented to external needs and maintain high efficiency in the application of high technology results. The dual system is an intermediate type between centralized and decentralized, the national high technology system is generally managed through the national and regional administrative ministries of high technology education, high technology policy is mainly formed through a combination of a top-down and bottom-up approach, and the formation process is accompanied by the participation of many interest subjects, usually the product of the coordination of interests between the systems. With the development of high technology, international competition in high technology has become increasingly fierce, and the demand for innovation in countries has prompted countries to constantly adjust their internal decision-making institutions and organizational frameworks to meet their own internal innovation development needs and adapt to various new requirements. There are also many differences in S&T management systems among countries due to differences in political and economic systems. As one of the many functions of government, high technology management is as important as political, economic, cultural, and social management as a public management function of government. However, due to the special nature of high technology, there are many differences in the ways, systems, and procedures of management compared to other management functions of government.

In summary, the optimal program of high technology management includes the following specific aspects: (1) The planning function. Planning is the prediction of future actions in light of the present situation. High technology planning refers to the actual situation of high technology development as the basis for the future implementation of high technology activities to develop a program. The planning function of government high technology management mainly refers to making plans for future high technology development work by clarifying the objectives of high technology development, reasonably allocating high technology resources, and indicating the direction for the development of high technology, to obtain the maximum promotion of high technology for social and economic development. The planning function of local government high technology management is that the local government, based on implementing and executing the national guidelines, policies, laws, and regulations on high technology development, makes plans, strategies, and policies for high technology development and high technology for economic and social development in a certain period in the future and formulates corresponding laws and regulations according to the actual situation of local high technology development. High technology plans are the fundamental guides to scientific and technological activities carried out by the main body of scientific and technological activities; to more effectively promote the development of local high technology, local governments at all levels have developed a plan for the development of high technology in line with the actual local situation and planning as the basis for scientific and technological activities to improve the level of local scientific and technological development, to better promote the development of the local wild economy. (2) Organizational functions. The organizational function of government high technology management is the premise and basis of its specific high technology management work, but also to achieve the goals of high technology management guarantee. The organization functions of local government high technology management means that the local government through the setting of the appropriate organizational structure, equipped with high technology management personnel, the provisions of high technology management departmental authority, and a clear relationship between the relevant ministries and personnel, achieve specific high

technology management goals. Organizational functions are the preconditions for the realization of other high technology management functions, but also the basis for the orderly conduct of high technology management activities; local governments at all levels to better play the role of high technology management are actively improving its high technology management organizational functions, with the establishment of orderly high technology management operating mechanism to ensure the orderly implementation of government high technology management activities. (3) Coordination functions. The coordination function is an important part of the government's high technology management functions and is the guarantee of the smooth development of high technology activities. The coordination function of local government high technology management includes internal coordination and external coordination; internal coordination is the coordination between government high technology management related ministries, because the government's high technology management functions are scattered in a number of government ministries, in addition to the ministry in charge of high technology management; certain government ministries also have the function of high technology management; in order to ensure the orderly conduct of high technology management, it is necessary to coordinate the relationship between various ministries and agencies. External coordination is to coordinate the relationship between the government and other subjects of high technology activities; there are many subjects of high technology activities; in addition to the government ministries that undertake high technology management functions, universities, research institutions, enterprises, and intermediary organizations that provide services for government high technology management are all subjects of high technology activities. To ensure the smooth development of scientific and technological activities, we must coordinate the relationship between the subjects of scientific and technological activities and clarify the status of each subject in the management of high technology. The government is in a special position in many subjects of high technology activities and has the function of high technology management; therefore, the government must coordinate the relationship between the subjects of high technology activities to provide an orderly social environment for the development of local high technology. After undergoing optimization, its STI efficiency diagram is shown in Figure 4.

4. Experimental Results and Analysis

4.1. Experimental Results. The increase in the number of policy texts involving the departure and on-the-job entrepreneurship of scientific and technological personnel during the period of scientific and technological innovation indicates that the mechanism for the mobility and allocation of scientific and technological personnel in country A is gradually improving, but the proportion of policies on the management of scientific and technological personnel only accounts for 15% compared to other policy categories, indicating that the management of scientific and technological personnel is still weak in the system of scientific and
FIGURE 4: Optimized innovation efficiency display chart.

technological personnel in the context of dual innovation, and the mechanism for the selection and use of scientific and technological personnel needs to be improved more. The problems that arise in the management mechanism of scientific and technological personnel are mainly the identity barriers of scientific and technological personnel leaving and starting a business on the job and the ambiguity of the policy of scientific and technological personnel innovation and entrepreneurship. Only by breaking the identity and geographical restrictions of scientific and technological personnel can China's human resources flow and be effectively allocated. Its efficiency diagram after the majorization of high technology management policies is shown in Figure 5.

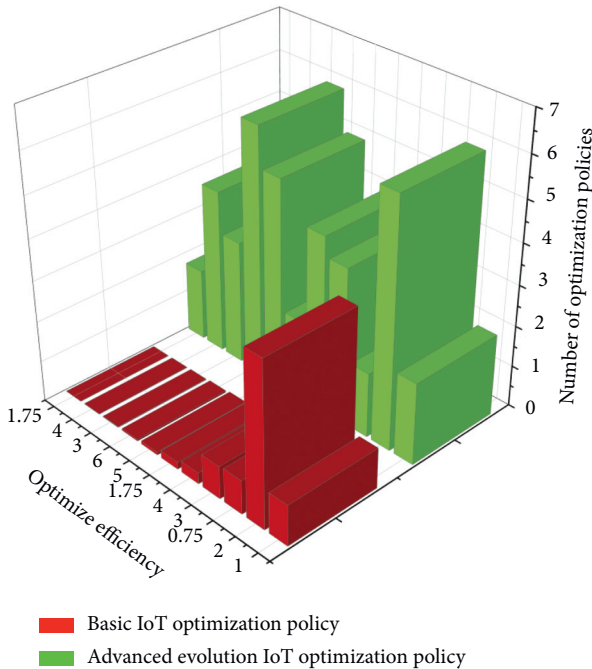
Subject to the traditional administrative management model, the government's high technology management work has the problem of overcontrolled thinking; the government's high technology management department in the management of high technology will see itself as the leading high technology management, trying to carry out a full range of high technology work, no omission of control. However, the government's high technology management function should be macroscopic guidance, the government's intervention is only to make up for the shortcomings of the market, in high technology activities to give full play to the role of the market to truly promote the development of high technology; the excessive intervention will only make the development of high technology deviate from the normal track, inhibiting the progress of high technology. Therefore, the local government in the management of high technology must establish the concept of service, do a good job in the management of high technology macrocontrol as the main task, and provide a good social atmosphere for the management of high technology, to provide services as the goal and pursuit. After its optimization, there is a significant improvement for high technology innovation, and its quantity changes as shown in Figure 6.
Figure 5: Comparison graph of experimental results.


Figure 6: Trends in volume changes.

Figure 7: Trends in the efficiency of the mechanism system.

4.2. Experimental Analysis. To ensure the smooth implementation of high technology management, it is necessary to establish a sharing platform for high technology information, with the ministry in charge of high technology or a specialized agency responsible for summarizing and releasing high technology information on the information platform for sharing by high technology activity subjects. The first step in building a high technology information-sharing platform is to clarify the functional positioning of the high technology information-sharing platform, which should be a comprehensive, vertical, and horizontal exchange information system, and all information and resources related to high technology should be shared on the sending platform.

The government's high technology management department can understand the progress of local high technology work through the information-sharing platform, and other subjects of high technology activities can also understand the government's high technology trends through the information platform, to avoid the blindness of high technology activities and achieve the maximum benefit. Secondly, it is necessary to clarify the main body of the information-sharing platform. The information-sharing platform of high technology is not a way for government ministries to disclose information but should be an information platform jointly constructed by government ministries of high technology management, other relevant ministries, large high technology-based enterprises, universities, and institutes, and relevant enterprises and institutions. The high technology information released by the information platform should be all-rounded, with professional people ± responsible for classifying the high technology information to be released, forming a systematic information network, breaking the regionalization and compartmentalization of information, improving the efficiency of supervision, making up for the information asymmetry problems of ministries and related high technology industries, and eventually forming an information-sharing platform with the local high technology management ministry as the lead and other related high technology activity subjects as the cooperation. The trend in the efficiency of the system of mechanisms formed is shown in Figure 7.

Establishing a pluralistic decision-making advisory system, China's administrative decision-making has long relied mainly on official advisory bodies, and high

first thing is to improve the legal status of high technology assessment by way of legal regulation. One of the reasons why high technology assessment in developed countries can play a good role is that the legal status of high technology assessment is established in the form of laws, and the legal system of high technology assessment is promoted through the formulation of clear legal norms of assessment. Only then can the majorization of the management mechanism of high technology policy innovation driven by the advanced evolutionary IoT calculus reflect its advantages. The algorithm used in the article should pay attention to the efficiency of its operation in the subsequent development process, and the code used by the algorithm should use a more efficient algorithm language to improve the speed and efficiency of the algorithm.

technology decision-making advice is generally controlled by the Government's Ministry of High Technology Management, and the administrative tendency of decision-making advice is relatively serious. The purpose of establishing an expert consultation system for high technology decision-making is to improve the scientific nature of high technology decision-making, and only by ensuring the independence of the advisory body and establishing a diversified advisory system can the role of expert consultation be truly brought into play. The efficiency trends following the adoption of this method are shown in Figure 8.

5. Conclusion

High technology assessment is professional consultation and evaluation activity carried out by a specialized assessment agency by specific assessment requirements of the client, following certain assessment standards, procedures, and principles, and using scientific assessment methods to assess high technology policies, high technology plans, high technology projects, high technology results, and other relevant high technology activities that need to be assessed. Effective high technology assessment can improve the level of scientific research activities, ensure the quality of scientific and technological achievements, improve the efficiency of the use of scientific and technological resources, and provide a basis for the formulation of relevant high technology policies. A standardized and institutionalized assessment mechanism can greatly improve the quality of high technology assessment, and most developed countries have already built a relatively complete high technology assessment system and made the high technology assessment mechanism an essential part of high technology management and decision-making work.

High technology assessment can effectively guarantee the scientific nature of high technology management, and to give full play to the role of the assessment mechanism, the

This article takes the development and superiority of the human resource system under the IoT technology as the background and adopts the popular IoT architecture and the current latest technical theories to develop and improve the human resource management system. First, we introduce the establishment of the J2EE development environment and then introduce the realization of the three layers of the overall IoT architecture of the system, namely, the realization of the presentation layer, the realization of the layer, and the realization of the data and then the realization of the main modules of the system; finally, we explain the function test of some modules of the system. After that, we mainly analyze the requirements of the system, first the overall requirements analysis and then the function and nonfunctional requirements analysis of the system. On the basis of perfecting the service-oriented modeling of manufacturing resources, the integration and optimization of resources are carried out according to the requirements of manufacturing tasks, and the discovery mechanism and matching methods of manufacturing resource services are studied to reduce the solution space of resource allocation. Aiming at the problem of optimal utilization of manufacturing resources, this paper establishes a scientific and reasonable evaluation index system to reduce resource service costs and improve resource utilization. At the same time, after analyzing the problem of real-time distribution of resources in the manufacturing Internet of Things environment, the real-time information of resource distribution is designed. The interactive mechanism and a two-tier optimization method based on real-time information-driven resource distribution tasks are proposed. The simulation experiment results show that the optimization method proposed in this paper, compared with the traditional resource distribution method, not only reduces the carrying distance of human resource distribution but also reduces the empty load rate, thereby reducing the waste of human resources.

1. Introduction

With the help of this technology, traditional human resource management is also facing unprecedented opportunities and challenges [1]. In enterprises, human resource management has become an indispensable part of enterprise management. Manual human resource management is time-consuming and laborious, prone to errors, cumbersome, and inefficient, and the existing personnel system is highly coupled with the enterprise [2]. Therefore, the previous management model has changed and been replaced by the information network management model. With the penetration of the concept of the Internet of Things in the manufacturing field, the development process of manufacturing companies has evolved from the traditional "black box" model to a "three-dimensional space plus time multidimensional, transparent ubiquitous perception" model, which is driven by information perception technology [3–5]. This article uses advanced computer technology to develop enterprise human resource management system, networked and informatized human resource management. Such a system can reduce the work burden of enterprise employees, move employees' positions in real time and efficiently according to local conditions, maximize employees' potential, and improve the economic benefits of the enterprise [6–8].

Li et al. [9] proposed a shift in the focus of corporate personnel information management, which marked the emergence of research on the theory and practical application of human resource management. The human resource management system developed by Oracle mainly reduces the cost of enterprise management through system analysis, management mode, and establishment of employee incentive mechanisms. The human resource management system developed by IBM mainly provides solutions and management services. The recruitment of teachers in space is open, and the teacher data and other employment information of the schools are very transparent, which has achieved a reasonable flow of talents [10–13]. Chen et al. [14] proposed a new service-oriented model of physical entities and proposed a method of secondary combination reasoning to speed up the combination process. In the same year, they further proposed a new context-aware resource-led service model. Awoyemi et al. [15] studied the extended OWL-S model to describe the contextual characteristics of service providers in CPS and also studied technology for generating task demand planning. Fang et al. [16] conducted research on dynamic material distribution in the workshop under the IoT environment. Aiming at the problems of low transparency in the production process, difficulty in collecting material information, low material distribution efficiency, and poor information interaction, they proposed a real-time sensing information-driven. Fischer et al. [17] studied the application of the Internet of Things technology in the disaster relief material distribution management system, using the real-time monitoring data collected by the Internet of Things to analyze and judge the results and play a comprehensive auxiliary decision-making process for the entire material distribution and transportation process. Some scholars studied the material distribution and monitoring system of mixed-flow assembly workshops and put forward the overall framework of material distribution and tracking in response to the requirements of material distribution and monitoring on the production site and assembly error prevention [18]. Since the status information of each distribution carrier, pallet, and so forth (such as location, material category, and quantity) can be sensed in real time, the description of dynamic resources based on real-time process perception can be further optimized. In addition, by constructing a real-time information interaction mechanism and perfecting the optimization of real-time information-driven resource distribution tasks, it is also a problem to be finished in resource distribution in the manufacturing Internet of Things environment [19–21].

In order to cope with the future expansion of the functions of the Internet of Things enterprises, this system adopts J2EE technology, B/S platform mode, and SSH framework to develop the human resource deployment system. Logging in to office is in the concept of cloud office. At the same time, the ULHA evaluation model is introduced into the enterprise human resource management system to better help the enterprise evaluate the company's employees reasonably, conduct comprehensive and humanized management, and help companies make better decisions in the recruitment process. Due to the complexity of the regression model, it cannot be done by relying solely on the spatial analysis function of GIS. The regression analysis must be done with the help of professional statistical analysis software SPSS. Firstly, the background and significance of the system research and the main existing problems are explained, and the related technologies and theories of the system are introduced; secondly, the functional requirements and nonfunctional requirements of the system are analyzed; and finally, the main modules of the system are implemented and tested, and the test results basically meet the design requirements of the system. The developed system is easy to operate, simple to use, and easy to expand, which improves the operation efficiency and market competitiveness of the enterprise and at the same time improves the enthusiasm and work efficiency of employees.

2. Optimization Analysis Model of Human Resource Allocation in Colleges and Universities Based on Internet of Things Technology

2.1. Hierarchical Structure of IoT Technology. At the technology level of the Internet of Things, the B/S model is a relatively popular software architecture. It is also a major trend in developing the Internet of Things architecture for large-scale systems in the future. In the B/S mode, users only need to install a browser to directly access the server and exchange data [22–25]. The three-tier system structure of B/S includes a presentation layer, a logical business layer, and a data layer. Figure 1 is the hierarchical topology of the IoT technology.

In the B/S IoT architecture, this article mainly adopts an open-source Internet of Things architecture that is relatively mainstream, relatively advanced in technology, and relatively mature and stable developed products. In other words, the SSH Internet of Things architecture is used to design and develop. According to the different needs of the system, this paper encapsulates the different subsystems, respectively. The advantage of this is that it is conducive to the integration of the various subsystems after the system development is completed:

$$f_{11} = \left(\frac{1}{n} \times \sum_{i=1}^{n} x_i^2, \frac{1}{n} \times \sum_{i=1}^{n} y_i^2 \right),$$

$$c = \Pr(c \mid o) \times \Pr(o) \times \text{IoU} = \Pr(c) \times \text{Iou}. \tag{1}$$

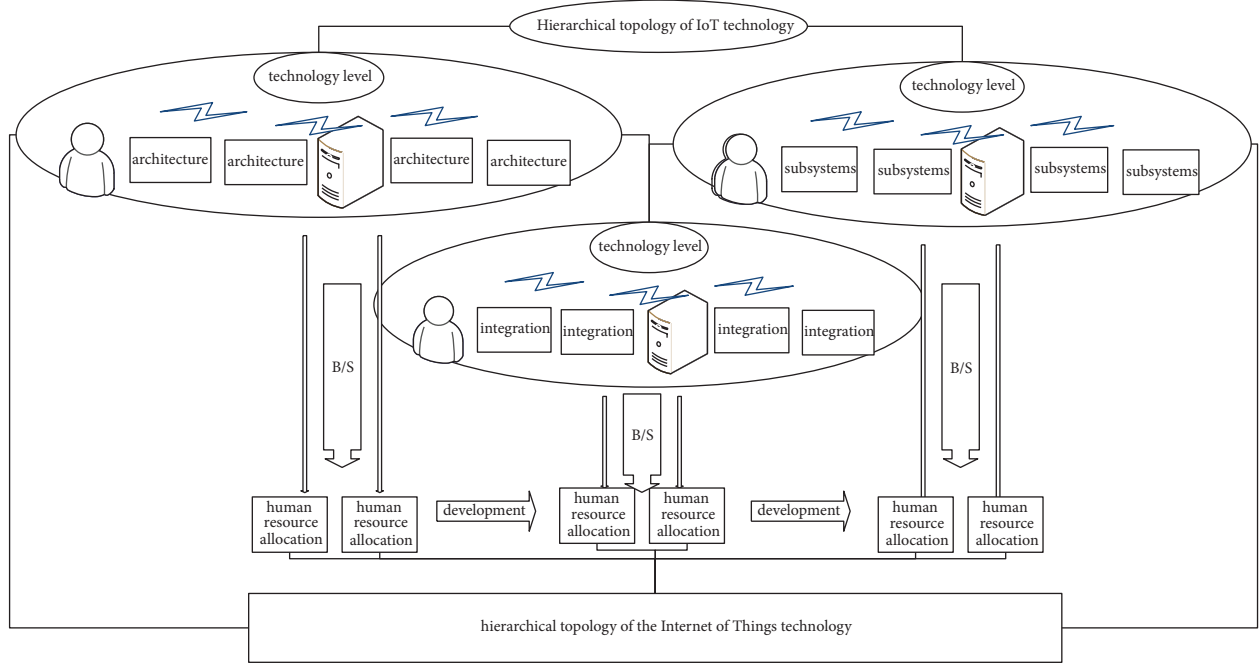
The technology Internet of Things architecture adopted by J2EE mainly adopts the idea of low-coupling hierarchical design and the distributed system Internet of Things architecture, encapsulating different logical structures into different application services for processing, and fully embodies the hierarchical design idea of the system. The presentation layer adopts the framework for design, the business layer mainly adopts the framework, and the data persistence layer adopts the Hibernate framework, which guarantees the system's stability as a whole. In the system development, the Spring structure, Struts structure, and


Figure 1: Hierarchical topology of IoT technology.

Hibernate framework have become the main flow frameworks for developing a lightweight framework system:

$$l = \alpha \times \sum_{i=0}^{S^2} \sum_{j=0}^{B} \left[(x_i - \overline{x})^2 + (y_i - \overline{y})^2 + (x_j - \overline{x})^2 + (y_j - \overline{y})^2 \right],$$

$$\psi(x) = \frac{f(x,d) - f(x,m)}{f(x,d) + f(m,d)}.$$

$$(2)$$

It can serve the functions of heterogeneous resources, provide services to the outside world with a unified and universal interface, and connect to the manufacturing platform in a loosely coupled manner to realize the full interconnection of the manufacturing services of physical manufacturing resources. However, the current manufacturing resource model mainly models the processing capability of the resource and less considers the real-time status and location of the resource, making it difficult to dynamically optimize based on the real-time status of the manufacturing resource:

$$\chi(x) = \begin{cases} e^{-\lambda L \times (1 + \lambda x^2)}, & \chi \geq \chi(x), \\ 0, & \chi < \chi(x), \end{cases}$$

$$G(x) = \begin{cases} g(x) \times [0, x, 1], & x \subset X, \\ g(x) \times [x, 1, 0], & x \subset Y, \\ g(x) \times [1, 0, x], & x \subset Z. \end{cases}$$

$$(3)$$

The real-time manufacturing information acquisition method is the premise and foundation for realizing the service-oriented modeling of dynamic manufacturing resources. According to its information structure, it is hierarchical, structurally related, and gradually superimposed and merged. It can form the basic information of the production process that has practical meaning for manufacturing resources. Then, the information is sorted and combined to form closely related production tasks and production processes. Real-time multisource manufacturing data provide data support for the production information system.

2.2. Human Resource Allocation Algorithm.

Such an Internet of Things architecture has relatively unified specifications and standards on system components, technical levels, and various service Internet of Things architectures. The advantage of this is that, for different platforms that also follow the J2EE Internet of Things architecture, that is, between heterogeneous platforms, the system performs well in terms of compatibility, allowing the enterprise to communicate well internally and externally. After SPSS software completes logistic regression analysis, the output digital matrix can also be converted into raster graphics in GIS software, thus solving the problem of mutual import of data in GIS and professional statistical analysis software. In the framework of J2EE technology, programmers only need to develop large-scale enterprise-level application systems according to the corresponding specifications, without considering the underlying hardware issues. Considering the compatibility issues between different J2EE platforms and products, different J2EE providers will also support the corresponding standards drawn up in different J2EE versions. In order to facilitate the definition and the expression of operators, this

article gives a zero-centered, odd-numbered language term set Hs = {$h3$ = excellent, $h2$ = very good, $h1$ = good, $h0$ = fair, $h-1$ = bad, $h-2$ = very bad, $h-3$ = very bad}. In order to avoid the loss of decision information in language term calculations, language terms are generally expanded. For the language term set of this article, this article adopts the following expansion scale, where q is a sufficiently large natural number.

Table 1 is the description of human resource allocation. This layer communicates directly with the database storing the data and can complete the functions of inserting, deleting, modifying, and querying data. When the business logic layer issues a request to the database, the layer responds accordingly. The function of this layer is mainly composed of two functions of OR mapping and database operation layer. It adopts the Hibernate Internet of Things architecture and is based on the OR Mapping framework to carry out persistent package management on the data operation of the system and realize the data and business data of the database. The use of such a framework does not need to consider which database is used, which can effectively ensure the independence of the system. The most resource-consuming system is access to the database operation. Therefore, to improve the content and response performance of the data, the operation of the data access layer on the database must be optimized. The application and realization of the ontology concept in the Web require a standard, common, and standardized language that can be used by computers to describe services. It uses ontology concepts to express the semantic information of Web services and accurately describes the meaning of concepts in a way that can be understood by computers to realize service discovery.

2.3. Model Optimization Analysis.

Separating the data model of the Internet of Things from the code of the user interface is the main purpose of applying the MVC pattern. According to the MVC Internet of Things architecture model, the application is separated from input, application processing, and output through high-level interfaces between objects to ensure the decoupling between the various parts of the application system and, at the same time, make each layer of the system relatively independent of processing its own business. Its main components include BeanTags, HTMLTags, Logic Tags, NestedTags, and Template Tags. The model is mainly responsible for identifying the state of the system. In this case, the method of using a stepwise linear statistical model will cause large errors in the results and even unreasonable results. As far as the structure of the entire system is concerned, ActionFormBean is used to represent a nonpersistent state. For some persistent states, the Utitle package is used, which is included in Struts itself. The advantage of this is that it becomes more convenient when operating with the database. In the Struts framework, ActionServlet plays the role of the controller, but it is not completely involved in business logic and requires interaction between Action, ActionMapping, and ActionForward. The roles and tasks of the three components are different. The main responsibility for the realization of

Table 1: Description of human resource allocation.

Index	Dataflow rate (%)	Expansion scale	Factor weight
1	17	1.21	0.38
2	14	2.01	0.09
3	25	1.89	0.12
4	31	1.77	0.41

business logic is action. The difference of business logic is represented by ActionMapping, which is to distinguish. The direction of the process is represented by ActionForward.

Figure 2 is the logical framework of model optimization analysis. In the manufacturing process, when the sensor node perceives the corresponding event (data), the designed event-driven message transmission mechanism firstly describes the event information collected by the sensor node on the resource side as having {ID, Event, Data, Time} a collection of data structures. Then, the mapping relationship F between different types of sensors and different types of manufacturing information is established in the background. Each sensor event is monitored through multithreading technology, combined with the event-driven IoT architecture (EDA) and mapping table to encapsulate and transmit the data captured by the event on the sensor. The static attributes of the manufacturing resource service give a unique identifier to the service, which summarizes the service capabilities. When a manufacturing task requires a query service, if the query content is a keyword, you can directly query through the UDDI registration center to obtain the universally unique identifier (UUID) of the manufacturing resource service that meets the requirements and return it to the information system. The matching engine finds similar concepts in the ontology database according to the semantic description, calculates the matching degree, obtains the manufacturing resource service that meets the requirements, and finds the UUID of the service in the UDDI registry and returns it to the information system.

2.4. Data Weighting Factor Recursion.

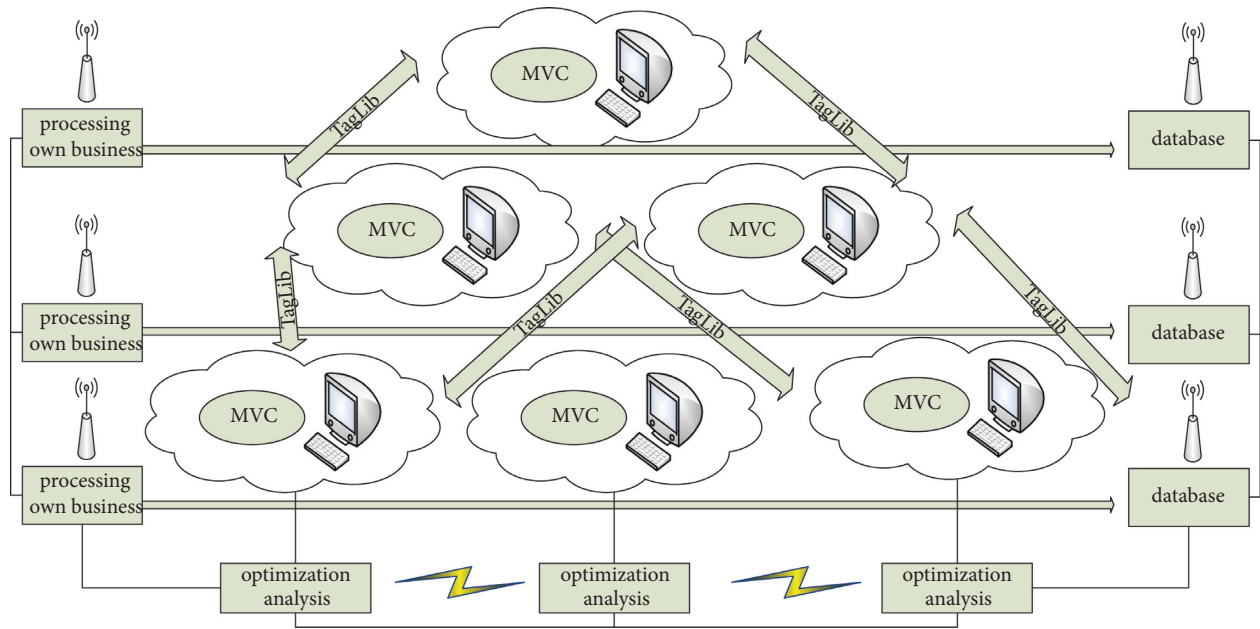
The human resource deployment data Web is an extension of traditional Web services. The resource information in the Semantic Web is no longer a simple information location, but a real way to understand the meaning of information, improve the search, and get high efficiency and intelligence of computers. For the meaning of information on Web computers, the relevant domain knowledge and relationships represented by the information need to be clearly defined. Not only can ontology provide clear definitions of related domain knowledge and mutual relations, but also the logical reasoning capabilities it supports are more conducive to computer understanding and processing. Therefore, the ontology concept model has become the foundation and core of the development of Semantic Web technology. The performance appraisal data comes from the performance appraisal scoring table and relevant system standard benchmarking and original work records. The level of work completion is determined according to the completion of the performance


FIGURE 2: Logic framework of model optimization analysis.

appraisal indicators and is divided into four levels. The actual completion of the work becomes the actual completion of the responsibility objectives and work tasks during the assessment period. The actual assessment scores are scored by the assessment unit (assessor) based on the employee's responsibility target and the completion value of the work task. Figure 3 shows the classification of data weighting factors.

Through the information collected by the Internet of Things, this article should take an employee by affecting task assignment. When these elements are available, it is not necessary to assign tasks only based on distance. Reasonably, in addition, the Internet of Things will collect data for the frequency distribution, and processing time distribution of emergency resource allocation events in each area can be obtained. We form an effective and comprehensive database, analyze and summarize the data in the database, and slowly find the human resources law from the data, which can provide a scientific basis for future human resources work.

3. Results and Analysis

3.1. Analysis of IoT Data Characteristics. In order to reflect the status quo of H company's human resource value chain, this paper uses Schuster's human resource index method to conduct a questionnaire survey on H company. The scale used in this method is designed with 64 questions and 15 dimensions. The dimensions, respectively, reflect the main and status quo of the four links of the human resource value chain management model, the relationship between the 15 dimensions of the human resource index, and the 4 dimensions of the human resource value chain, so that the human resource index survey can reflect the management status of the company's human resource value chain. The results show that the proportion of disasters in the 1 and 2 divisions
FIGURE 3: Classification of data weighting factors.

representing low levels of risk has decreased significantly, while the proportion of disasters in the 4 and 5 divisions representing high levels of risk has decreased. The questionnaire adopts the Schechter 5-point scale model, which enables the respondent to answer quickly and conveniently. A total of 112 questionnaires were issued to H company, 105 valid questionnaires were received, and the effective recovery rate was 93.3%. There are 64

questions in the questionnaire, divided into 15 dimensions, and scored using a 5-point scale. The reliability coefficient (Alpha) of this scale is between 0.757 and 0.929.

Figure 4 is the statistical distribution of the reliability coefficient of the Internet of Things optimization. It can be seen that the scores of each latitude of the H company's human resource index are generally low. Among them, the highest score is the organizational environment 3.45, indicating that the organizational environment of the employees of H company is relatively harmonious. The second highest score is organizational goal 3.25 and group collaboration, indicating that the employees of H company have done a relatively good job in improving information communication, group collaboration, and so on. The lowest score is the remuneration system, with a score of 2.58, indicating that H company's human resources compensation management is lacking, which leads to low employee satisfaction; the second-lowest score is the management quality and the overall management quality of H company is not high. In terms of recruiting and training new recruits, H company lacks reasonable measures and talent mining and value creation. The company does not conduct an in-depth analysis of the company's positions and lacks direction in the company's strategic planning. At the same time, it also reflects that the value evaluation link in the H company's human resource value chain management is not well done, and a new understanding and improvement of the overall management of the organization is needed.

3.2. Simulation of Human Resource Allocation.

The company expanded related business and elected the new executive director from the four main persons in charge. This article assumes that these four persons are A, B, C, and D. The current work mainly evaluates these four persons. The leaders, colleagues, and subordinates of these four people are evaluated in language terms, and the leaders, colleagues, and subordinates are used as representative groups to participate in the evaluation. The evaluation value of each group selects the group's evaluation range for the person in charge. Based on these theories, the four main persons in charge from the three levels finally obtained the following evaluation information based on the uncertainty language evaluation scale. The city is divided into several large districts, and each district is divided into several blocks. Each block is assigned information collectors and personnel. Therefore, the simulation system is simulated according to the district, and the simulation system is mainly divided into three modules. The first part is the data initialization module. Before the simulation experiment, you need to input the corresponding parameters. The second part is the simulation experiment algorithm part, which is divided into a scheduling module and a configuration module, used to solve the scheduling and configuration problems in the current process and ensure that the simulation experiment normally runs according to the designed logic. The third part is the data interaction module, which interacts with the database, writes necessary data, and reads the required information for queries. Table 2 is the data interaction module of human resource deployment.
Figure 4: The statistical distribution of the reliability coefficient of the Internet of Things optimization.

Using the ULHA operator in the evaluation of human resources, compared with not using the ULHA operator, the evaluation is more accurate and scientific. It has been used in many human resource management systems and has achieved very good results. The calculation accuracy is more than 10% higher than the traditional method, and this mode is simple to operate, suitable for general scenarios. First of all, the overall index M and the change trend of the employee load rate are the same as the previous part. We use the performance appraisal system of the cloud platform to improve the performance management efficiency of the enterprise; the value evaluation process is to check the implementation results of the above two links in the value chain. Salary management is particularly important. Salary management under the cloud platform makes employees more challenging and fair. The final value distribution process has an incentive effect on the entire value chain and is the basis for retaining valuable employees, as shown in Figure 5.

Through the establishment of H company's exclusive HR-cloud system, the cloud system is deployed on the Internet and positioned as a full-staff service, giving full play to the real value of the human resources value chain system and realizing the line of core modules such as personnel, salary, attendance, and performance. At the same time, it can realize employee self-service business processing, full participation in performance management, self-service reporting of training needs, and so on so that the human resources business can truly provide services for senior executives, line managers, and employees. We integrate the human resources of H company and optimize the allocation of company's H human capital as a whole. Through the HR-cloud human resources value chain management platform, employees can timely understand the human resources policies and regulations formulated by the upper leaders of H company; it can supervise the daily human resource management business of various departments to ensure the management system, which greatly improves the satisfaction of employees.

TABLE 2: Data interaction module for human resource deployment.

Number	Description	Value
1	Type, resource, quality, volume	20
2	Model, load capacity, module volume, transportation distance	40
3	Distribution demand, distribution frequency, distribution point	20
4	Module resource distance, number of modules used, delivery time limit	40
5	Meet time resource requirements, meet customer distribution needs	50
6	Distribution center to customer path, customer to customer path	70
7	Gathering goods, completion of module distribution tasks	60
FIGURE 5: Average processing time of human resource allocation.

3.3. Analysis of Experimental Results. The human resources performance appraisal indicators are uniformly set as follows: the numbers of performance appraisal indicators for the three types of management personnel of middle management, supervisor, and management assistant are set to 10, respectively; the number of performance appraisal indicators for technical personnel is set to 12; and the numbers of performance appraisal indicators for senior level, standard level, and junior/other three types of production and operation service personnel are set to 10, respectively. The performance evaluation indicators of various types of personnel are divided into three categories: work performance, work behavior, and workability. Each indicator clarifies the specific evaluation content and items. Randomly select the local area model unit, and use the CF value of each factor data type as the independent variable of the logistic regression model and the risk as the dependent variable. Import the data into the SPSS statistical analysis software, and use binary logistic regression analysis. The evaluation weights and standard scores are determined according to the job analysis and job evaluation results, and the evaluation is specified. In the future, according to the company's overall development requirements, performance management needs, and employee development needs, the employee performance appraisal indicator system will be adjusted in a timely manner. The hierarchical overall analysis is used to calculate the weight of the bottom element to the target layer element, that is, the weight of the delivery distance, the priority of the delivery task, and the utilization of the delivery resource for the optimal task plan. The largest eigenvalue of the judgment matrix G1 is an important parameter for consistency testing. The largest eigenvalue corresponding to the eigenvector (orthogonal normalization vector) is called the weight vector. Each component corresponds to the delivery time, the priority of the delivery task, and the resource. Figure 6 is a histogram of human resource performance appraisal indicators.

Based on the data accumulated by the development of network services, through data processing and analysis, real-time dynamic monitoring of operating conditions collect the dynamic change data of the online public human resources market, implement analysis, display the operation of the online public human resources market, and provide dynamic supervision functions. Due to the lack of opportunities for employees of H company to participate in management, the organizational structure of the Internet industry tends to be flat, with low management personnel, and employees rarely participate in management. However, to realize the potential of employees, it is possible to appropriately increase the opportunities for employees to participate in the management and explore technical skills. In this regard, H company urgently needs improvement in this regard.

Figure 7 shows the distribution of real-time dynamic supervision and operation of the Internet of Things. In order to verify the research on the optimization of dynamic resource distribution tasks in the manufacturing Internet of Things environment, this section designs the following manufacturing workshop material distribution scenarios. The proportion of excellent and competent employees reaches 53%. These personnel have good job competence and promotion potential and can be used as future talent reserves. Incompetent personnel belong to the department of the R&D center. The out-buffer is used to store materials
Figure 6: Histogram of human resource performance appraisal indicators.
Figure 7: Distribution of real-time dynamic supervision and operation of the Internet of Things.

that have been processed by the workstation and used in other manufacturing links; the second is the storage area, which contains a series of three-dimensional shelves to store and maintain the normal workshop; and the third is a forklift, which has real-time perception service capabilities by configuring sensors and RFID and other equipment. At the same time, relevant hardware devices are also attached to key locations and resource storage areas to collect real-time distribution information, such as attaching RFID tags at key intersections, material buffers, and shelves in the workshop to collect location information.

4. Conclusion

This system mainly uses the B/S Internet of Things architecture for design and development. First, it can effectively

protect the security of sensitive data, especially when adding and modifying records to the database. It can make general functions easier to use and ensure that complex functions interact. At the same time, it focuses on the problem of service modeling based on real-time information, service combination optimization, and resource distribution optimization of dynamic manufacturing resources in the manufacturing Internet of Things environment. Under the guidance of the resource-as-a-service ideology, a manufacturing resource modeling system with real-time perception service capabilities is organized, and the manufacturing resource contextual information modeling method, manufacturing resource servicing modeling method, and manufacturing resource service combination tasks are detailed respectively. This module uses a histogram to analyze the comparison between the existing emergency source capacity of the district and the optimized configuration. The modeling method establishes the research foundation for the dynamic manufacturing resource service combination optimization and resource distribution optimization later. In the manufacturing Internet of Things workshop, human resources, material resources, and equipment resources are the main research objects, a context-aware manufacturing resource service discovery mechanism is designed, a service composition model based on workflow diagrams is established, and gray correlation is adopted. The proposed human resource allocation plan simulation system uses the historical data collected in the smart city to deal with emergency human resources problems in various regions for simulation experiments, which can help city managers find the plan for each region based on their own needs to deal with emergency human resources issues.

Correspondence should be addressed to Suling Ma; masuling@sqgxy.edu.cn

This paper analyzes and collates the research on traditional homeschooling attention mechanism and homeschooling attention mechanism based on two-way short- and long-term memory network intelligent computing IoT model and finds the superiority of two-way short- and long-term memory network intelligent computing IoT model. The two-way short- and long-term memory network intelligent computing IoT model is improved and an improved deep neural network intelligent computing IoT is proposed, and the improved method is verified based on discrete signal homeschooling classification experiments, followed by focusing on the application research of the two-way short- and long-term memory network intelligent computing IoT model-assisted homeschooling attention mechanism. Learning based on neural network, human behavior recognition method combining spatiotemporal networks, a homeschooling method integrating bidirectional short- and long-term memory networks and attention mechanisms is designed. The visual attention mechanism is used to add weight information to the deep visual features extracted by the convolutional neural network, and a new feature sequence incorporating salient attention weights is output. This feature sequence is then decoded using an IndRNN independent recurrent neural network to finally classify and decide on the homeschooling category. Experiments on the UCF101 dataset demonstrate that the incorporation of the attention mechanism can improve the ability of the network to classify. The attention mechanism can help the intelligent computing IoT model discover key features, and the self-attention mechanism can effectively capture the internal features of homeschooling and optimize the feature vector. We propose the strategy of combining the self-attention mechanism with a bidirectional short- and long-term memory network to solve the family education classification problem and experimentally verify that the intelligent computing IoT model combined with the self-attention mechanism can more easily capture the interdependent features in family education, which can effectively solve the family education problem and further improve the family education classification accuracy.

1. Introduction

With the continuous improvement of the material level, the state's investment in family education has gradually increased, and people's demand for scientific family education concepts has become more and more urgent. The establishment of the National Family Education Association has provided favorable theoretical support for the development of family business in our country. Research articles and monographs on family education have emerged as the times require. Its research involves multiple perspectives and can be divided into three categories: one is popular science: reading materials; the second category is popular reading materials with a story complex; the third category is theoretical research works [1]. Family education is emotional, and an important feature of family education is that it is contagious. Family education is the communication between parents and children and the positive or negative influence of parents' words, actions, and behavior on girls [2]. Parents are their children's role models and life mentors in the process of growth. In the current situation, deep learning has achieved an overwhelming victory in the fields of speech recognition, natural language processing, and homeschooling recognition, which has greatly contributed to the

changes in other fields [3]. Applying deep learning to home education data processing can replace the traditional method of manually labeling data to achieve real-time processing of each piece of data received, which greatly saves the time of manual labeling and can effectively improve the efficiency of home education analysis [4].

Internet of Things technology, as a new generation of information technology, is an important third type of information technology after computer technology and Internet technology, and it is also a new wave ushered in by the information industry. The emergence of the Internet of Things regulates the communication and interactive control of information between people and things and things and things, which are integrated with the Internet through various wireless or wired networks. The attention model is applied to the analysis of the attention mechanism of family education, and the attention mechanism is added to the family education framework to weigh the input features to measure the importance of each feature to the current recognition, focusing on the important features and ignoring the unimportant features. The attention model is applied to family education attention mechanism analysis to extract feature information [5]. The self-attention mechanism, as a special kind of attention mechanism, is introduced into the homeschooling classification task to be able to learn the word dependencies within sentences and capture the internal structure of homeschooling. Therefore, this paper explores the current technical points in the field of family education analysis from the practical needs of family education analysis and seeks to find an efficient and accurate family education analysis method based on deep learning technology and self-attention mechanism. With the rapid development of deep learning technology, neural network models represented by convolutional neural networks and recurrent neural networks have obtained remarkable research results in the field of natural language processing, and people use these models for family education data analysis to obtain certain practical value [6].

While neural networks have so many advantages, they also inevitably have some drawbacks. The structure of neural networks and the corresponding training methods need to be specified in advance, which requires extensive design experience. The reasonable design of the network structure is very important to the accuracy of the modeling, the network structure is not reasonable to a large extent affecting the subsequent application of the network, and only the model structure is selected properly to make it play the proper value [7]. The selection of the initial value of the network also has an impact on the modeling, which is directly related to the convergence process of the weight training. If the initial value is not selected appropriately, it will prolong the training time, reduce the network accuracy, and weaken the generalization ability. Section 1 is the introduction. This section introduces the research background and significance of the paper and also outlines the organization of the paper. Section 2 is the related work. The direction and value of this paper's research are analyzed in light of the current research status at home and abroad. Section 3 is a study on the mechanism of home education attention based on two-way

short- and long-term memory network intelligent computing IoT model assistance. This section uses a combination of a two-way long- and short-term memory network and intelligent computing IoT model to classify the supervised education dataset, and the algorithm can greatly improve the classification accuracy of home education compared with the traditional method. Section 4 is the result analysis. This section analyzes the data for the classified family education dataset using a bidirectional short- and long-term memory network intelligent computing IoT model and attention mechanism techniques to achieve good family education classification results. Section 5 is the conclusion. This section systematically summarizes the research content of the thesis, analyzes the shortcomings, and provides an outlook on the next improvement direction.

2. Current Status of Research

The basis of computational intelligence can also be understood as the continuous evolution of structures. Since the birth of intelligent computing, its powerful intelligence, robustness, and self-adaptability have attracted the attention of many researchers, and great breakthroughs have been made in both theoretical research and practical applications of algorithms [8]. Kolomvatsos and Anagnostopoulos proposed a simple two-way short- and long-term memory network intelligent computing IoT algorithm for recommendation classification or nonrecommendation, which predicts the outcome by the average semantic of specific phrases in home education, with an average accuracy of 74% in the final experiment [9]. George and Santra proposed a combination of natural language processing and fuzzy logic techniques for analyzing homeschool content in homeschooling, and the experiments showed a very good correspondence between sentiment sets and human judgments of homeschool content [10]. Mollah et al. obtained rich emotional features by fusing machine learning methods and multiple rules and integrated them into the basic feature model, which improved the classification effect in the microblog sentiment classification experiment. Semantic rules are integrated into the support vector machine model to complete sentiment analysis tasks [11]. Experiments have verified that the support vector machine model combined with semantic rules is more effective in sentiment classification tasks [12]. The neural network can process the sequence information of text data and calculate and sort the influence of the input object on the final classification result. According to the sorting result, the words with strong emotional tendencies are assigned higher weights to reduce the loss of emotional information.

While neural networks have so many advantages, they inevitably have some shortcomings. The structure of the neural network and the corresponding training method need to be specified in advance, which requires us to have rich design experience [13]. Zhang et al. obtained C&W models by deep neural network training and applied them to processing tasks such as home education labeling and home education classification and achieved good results [14]. Ge et al. used convolutional neural networks for homeschooling

analysis tasks and conducted comparative experiments on seven datasets by combining convolutional kernels of different sizes with maximum pooling to demonstrate the effectiveness of single-layer CNNs in homeschooling classification tasks [15]. Wang and Ashwini proposed several recurrent neural networks such as RNN, MRNN, and RNTN, among which the RNTN model used syntactic analysis trees to obtain [16]. To imitate the sentence structure, McCormack et al. used a tree LSTM model to model family education and obtained excellent results in the family education classification task, which was input to the LSTM according to the temporal relationship to construct a CNN-LSTM model and apply it to the family education analysis task [17]. The content of family education should be rich and diversified, not limited to the traditional family education content, but diversified mainly in that the content of family education should involve all aspects of moral, intellectual, physical, aesthetic, and social development [18].

At present, how to apply the two-way short- and long-term memory network intelligent computing IoT model and attention mechanism to home education polarity analysis is still in the research stage, and the research goal of this thesis is to construct an efficient and accurate home education classification method. Based on this, the main research contents and innovations of this research work include the following three aspects. The loss function in deep neural networks has a significant influence on model training overfitting. To make the home education binary classification model more effective in overfitting the samples with prediction errors [19], local linearization in time limits the applicability of the proposed method in the discrete-time domain and impairs its prediction accuracy under strong nonlinear conditions. In the testing process, the idea of online learning was used for reference, and artificial judgment and relearning mechanisms were added to further improve the accuracy of network labeling. Experiments show that the automatic labeling algorithm can effectively improve the efficiency and accuracy of thermal measurement data analysis. According to the ranking results, higher weights are assigned to the categories with stronger family education tendencies to reduce the loss of family education information. Accordingly, this paper designs a bidirectional short- and long-term memory network intelligent computing IoT model and verifies the effectiveness of the model through quantitative and qualitative experiments on different homeschooling datasets [20].

3. Research on the Mechanism of Home Education Attention Based on Two-Way Short- and Long-Term Memory Network Intelligent Computing IoT Model Assistance

3.1. Feature Extraction of Family Education Attention Mechanism Based on Two-Way Long- and Short-Term Memory Network. In this paper, we combine BN-Inception with IndRNN to propose a deep learning human behavior recognition model with fused spatiotemporal networks. The spatial flow network deals with homeschooling attention

mechanism features, which are mainly used to capture features with strong differentiation for action understanding; the temporal flow network deals with continuous optical flow features, which are used to learn effective action features. This makes full use of the temporal and spatial dimensional information of the data, increases the depth of the network while reducing the complexity of the network, and finally achieves the purpose of improving the accuracy of behavior recognition. The feature model of the homeschooling attention mechanism based on the bidirectional short- and long-term memory network proposed in this paper is shown in Figure 1.

Since the obtained family education data also records the starting position of the effective value in the whole curve, firstly, the whole heat flow curve is divided into three sections according to the starting position, including the invalid data section before the effective data section, the valid heat flow segment, and the invalid data segment after the valid data segment. After that, divide the two large invalid data segments into several segments. The specific method is to use the length of the valid segment as the length of the data segment, and then from the beginning of the invalid data segment, follow the sliding window in steps of 0.9 times the length. The method moves backward in turn, thus dividing the invalid data segment into multiple segments. This article adopts the variation equation (1) of the family education problem. The first term is the regularization term to obtain a smooth displacement field.

$$
\text{variation} = \min\Bigl(\int \Bigl| \forall (x_1)^2 + \forall (x_2)^2 \Bigr| \mathrm{d}\varpi \\
\cdot \int \Bigl| H_1 (x + u(x)) - H_0 (x)^2 \Bigr| \varpi \Bigr).
\tag{1}
$$

The mean intensity difference between pixels is therefore used as the homeschooling similarity score. Thus, the target parallax map is the minimum of equation (2). The optical flow algorithm uses the H_1 parametrization to solve for minimization of the error function and minimization of the regular term of the target homeschool. Given two homeschooling frames H_0 and H_1, the objective is to find the parallax map such that the error function and the canonical term of homeschooling are minimized simultaneously, where the first term is the fidelity of the homeschooling data and the second term is the a priori canonical term. β denotes the correlation coefficient between the fidelity and the canonical term.

$$
G(x) = \int \Bigl[\alpha \beta (H_0 (x) - H_1 (x + u(x))) + \varpi (x_1, x_2) \Bigr] \mathrm{d}x.
\tag{2}
$$

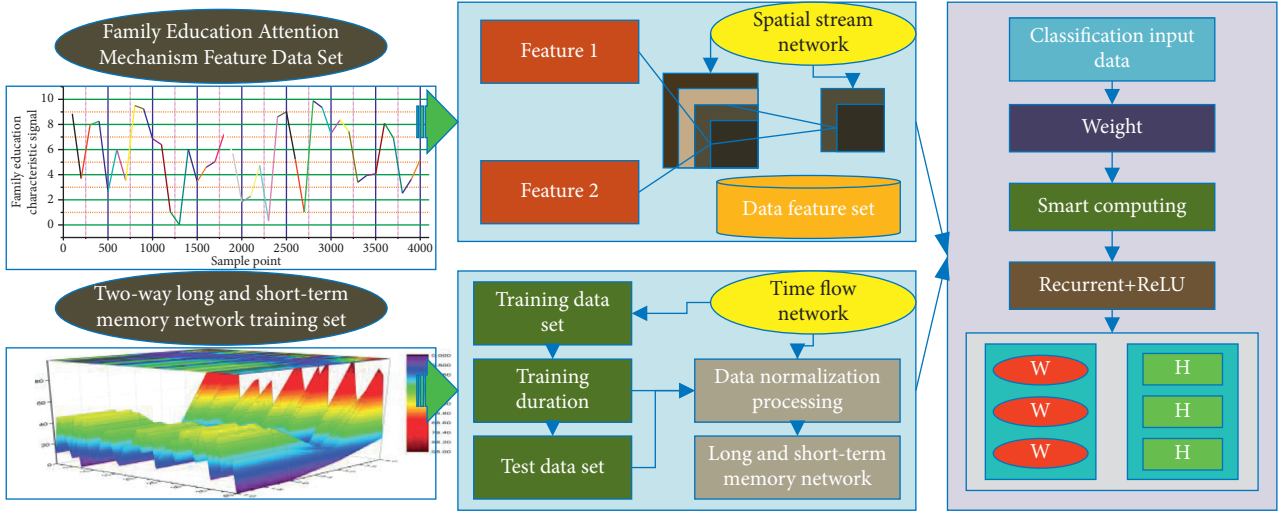
The effect of education depends on the consistency of the influence of the school and the family. If there is no such consistency, then the school's teaching and education process collapse like a paper house. School teachers communicate with parents in time through home visits and parent meetings. The weight coefficient of each subsection is learned through the visual attention mechanism, and the probability distribution of each subsection is finally fused,


Figure 1: The characteristic model of family education attention mechanism.

and the IndRNN cyclic neural network is input for sequence learning. Finally, the results of IndRNN are used in the behavior prediction of the family education level.

The bidirectional short- and long-term memory network considers the temporal dimensional association of the convolutional neural network feature sequences, and the pooling operation only produces feature vectors that keep the temporal order constant. We assume that the feature sequences extracted by the spatial and temporal flow networks are $X = (x_1, x_2, \ldots, x_T)$, so the independent recurrent neural network (IndRNN) computes a sequence of hidden vectors with N neurons at each moment t $H = (h_1, h_2, \ldots, h_T)$ and the output vector sequence $f(t) = (y_1, y_2, \ldots, y_T)$, satisfying equation (3), where A denotes the weight coefficient from the previously hidden layer to the current hidden layer, and $A(h_0)$ denotes the weight coefficient from the hidden layer to the output layer, β denotes the deviation coefficient, and $h(t)$ denotes the hidden vector of the nth neural unit at moment t.

$$\begin{cases} n = [1, 2, 3, \ldots, N], \\ f(t) = A(h_0) * h_1 + \beta(t), \\ h(t) = H\left(A(h_i)\infty * y(t) + A(h_h) * y(t-1) + \beta(t)\right). \end{cases} \tag{3}$$

The computation of the bidirectional LSTM model in the hidden layer is the same as that of the hidden layer of the LSTM and is passed between the same layers and the parameters are shared. Therefore, let the parameters of forwarding propagation be V and the parameters of backward propagation be U. Then the forward propagation formula of the bidirectional LSTM is as follows:

$$\begin{cases} \text{Lstm}(h_t) = B(t) * \sin(h(\zeta(t))), \\ \text{Lstm}(h_t^*) = B^*(t) * \sin(h(\zeta(t)^*)). \end{cases} \tag{4}$$

After the forward propagation of the network is finished, the output is done as a Softmax operation to obtain the predicted value $\hat{y}$ with the true label value y to calculate the

loss function. The experiment uses cross-entropy as the loss function, so the derivation of the backpropagation process of the bidirectional LSTM is the same as the derivation of the backpropagation process of the LSTM, as in the following equation:

$$\frac{\mathrm{d}(f(t))}{\mathrm{d}W} = \beta * (1 - \beta) * (\beta(t) + +\zeta(t) \\ + B^* * f(t) + W * M(t-1)^*). \tag{5}$$

3.2. Intelligent Computing IoT Model Construction. The practical activities in the virtual-real integration environment are different from the traditional practical activities, which put forward higher requirements on teaching, environment, model, and process. Based on the characteristics of the comprehensive practical activities course and the current situation research, this study, combined with the Internet, the characteristics of the IoT, and other information technology, made adaptable modifications based on Cooper's experiential cycle learning circle and summarized the comprehensive practical activities teaching based on experiential learning theory. The five elements of the model are precursor learning, practical inquiry, extension and expansion, observation and reflection, and communication and evaluation. The calculation process of the self-attentive mechanism is divided into three steps. Step one is to calculate the similarity between an element and a keyword, the second step is to normalize the original score, and finally, the weighted sum of the weighted values according to the obtained weighting coefficients is used to find the value of self-attentive for the element. The keyword is denoted by K, the function is denoted by F, the query is denoted by Q, the data source is denoted by S, the similarity is denoted by Sam, the attention value is denoted by A, and the value of the weight coefficient is denoted by V. Here $Q = K = V$; when home education is entered, self-attention is calculated once.

Different functions and computer mechanisms are introduced according to the query and keywords, and then the similarity between the two is calculated, and the intelligent calculation of the IoT calculation formula is shown in the following equation:

$$\text{Sam}(Q, K) = \sum_{i=1}^{N} MLP(Q, K_i). \tag{6}$$

A calculation method similar to Softmax is introduced to convert the score obtained in the previous step to obtain the weight coefficient ai. The calculation formula is formula (7). Determine a confidence threshold above the threshold is a valid data segment, and below the threshold is an invalid data segment. Input the multiple pictures finally obtained in the third step into the trained convolutional neural network again to obtain the confidence level of each picture. These confidences are compared with the previous confidence thresholds, and two demarcation segments are obtained, which are lower than the threshold and higher than the threshold.

$$f(x)\mathbb{F}ax(\text{Sam}(x)) = \frac{x^{\text{Sam}(i)}}{\sum_{i=1}^{N} x^{\text{Sam}(i)}}. \tag{7}$$

When the input sequence n is smaller than the representation dimension d, the time complexity self-attention mechanism of each layer is the smallest. When n is relatively large, one solution is a restricted self-attention mechanism; that is, each word is not calculated with all words, but only with restricted r words. The force mechanism and the convolutional neural network can be well paralleled and do not rely on the previous calculation, which is better than the cyclic neural network; in terms of long-distance dependence, the self-attention mechanism can combine any two sentences in a sentence through a calculation result. Words are connected, so the long-distance dependence feature is greatly shortened, and its maximum path length is 1, which can capture long-distance dependence. The text data within a certain sliding window is converted into a fixed-length vector B'' by the Softmax function, and then the feature data is fed into a linear SVM classifier for training and outputting the sentiment classification results, which is calculated by equation (8), where C denotes the training error of the SVM classifier, W and H denote the final obtained weight matrix and bias value, respectively, and L denotes the loss function.

$$\begin{cases} B'' = \text{Soft max}(w * Bi + \beta), \\ \\ C(W, M) = \frac{\sum_{i=1}^{M} \sum_{j=1}^{N} H_{ij}(B'')}{M * N} + \alpha * Y(W). \end{cases} \tag{8}$$

When the neural network model is trained, the selection and setting of parameters is a very important aspect, and the training results will be very different when different parameters are selected, and the parameter settings of the model in this section are shown in Table 1.

Table 1: Model parameter configuration.

Serial number	Name	Meaning
1	Batch size	Number of batch training samples
2	Learning rate	E-learning efficiency
3	VALIDATION_SPLIT	The proportion of test set in training data set
4	Return sequences	Network return type
5	Early stopping	Model stop training parameters
6	NB epoch	Model iteration times

The cross-entropy loss function, also called the logarithmic loss function, is designed for the performance comparison of classification models and can be divided into dichotomous cross-entropy and multiclassification cross-entropy according to the difference of whether the classification model is dichotomous or multiclassification. It has the mathematical expression of the following equation:

$$G(x) = \sum_{i=1}^{N} \sum_{j=1}^{N} g(x_i) + \log Y(x_i), \quad x_i = y(i) + j. \tag{9}$$

Traversing the entire dataset to compute the loss function once and update the gradient of each parameter, this method is called batch gradient descent, and the parameters are updated using equation (10). $G(x)$ is the value of the kth parameter at x iterations, $H(x)$ is the first-order partial differential of the error function corresponding to that parameter, and ρ is the step size (learning rate), which indicates the size of the step, which determines the length of each step along the negative direction of the gradient, and a current optimal value is generally obtained by the linear search, which increases the computational effort and affects the performance of the model and does not support online learning.

$$G(x + 1) = G(x) - \rho * \forall G(x) * H(x). \tag{10}$$

3.3. Classification Evaluation of Family Education Attention Mechanism.

When a predictive classifier is used to process binary sample data, we usually classify the sample data into two categories: Positive (Positive) and Negative (Negative). When the family education sample is classified as positive, it means the classification is correct, so we call it True Positive (PT) or true positive; when the positive family education sample is classified into the negative family education sample, it means the classification is wrong. Call it False Negative (NF) or false negative. Similarly, when dealing with negative sample data, if the classifier classifies the negative sample data into a negative class, the negative sample data is correctly classified, and we call it True Negative (NT) or true negative; if the negative sample data is classified into positive class, it means the classification is wrong, and we call it False Positive (FP) or false positive. The prediction effect is evaluated according to the value of the metric in the following equation:

$$
\begin{cases}
\text{NS} = \dfrac{\text{PT}}{\text{NF} + \text{PT}} * 100\%, \\[2ex]
\text{PS} = \dfrac{\text{NT}}{\text{NT} + \text{PF}} * 100\%, \\[2ex]
\text{ACC} = \dfrac{\text{NT} + \text{PT}}{\text{TOTAL}} * 100\%, \\[2ex]
\text{TOTAL} = \text{PF} + \text{PT} + \text{NF} + \text{NT}, \\[2ex]
\text{MCC} = \dfrac{(\text{PT} * \text{NT}) - (\text{PF} * \text{NF})}{\sum \sqrt{(\text{PT} + \text{PF}) * (\text{PT} + \text{NF}) * (\text{NT} + \text{PF}) * (\text{NT} + \text{FNF})}} * 100\%,
\end{cases}
\tag{11}
$$

where NS is the sensitivity metric for classification, and the magnitude of the NS value can be observed to understand how well positive samples are classified as positive samples. PS is the classifier specificity metric, which calculates the percentage of negative sample data that are classified as negative classes. Acc is the accuracy rate, and the metric reflects the percentage of positive and negative samples that are both correctly classified at the time of classification. MCC value, also known as the MCC correlation coefficient metric, reflects the Sn and PS metrics between the equilibrium degree of NS and PS is shown by the above equation; when the difference between these two indicators is smaller, MCC is larger.

In the evaluation process of the attention mechanism of family education, there are soft evaluation aspects such as the humanization of model construction and design and the innovation of model construction. Therefore, the evaluation method of this article adopts very good, good, average, poor, and very poor. Describe the related problems, realize the primary level evaluation, and then use fuzzy mathematics to make the fuzzy information numerical, to carry out quantitative analysis and evaluation.

When multiple features are included in the training model, the dimensionality of the mixed feature vector may become very large, and due to the presence of more random information and noise in the uneven initial features, it will hurt the training model, and usually to solve such problems a feature selection tool such as F-score [25] can be used to select the most effective features. Therefore, we also call F-score a metric to identify features between different categories based on the F-score value, and the larger the F-score value, the stronger the differentiation of such features between different categories. The expressions for calculating F-score are shown in the following equation:

$$
F\,(\text{score}) = \frac{\sum_{i=1}^{M}\left(x_i^+ - x_i^-\right)}{m^+ - 1} + \frac{\sum_{i=1}^{M}\left(x_i^+ - x_i^-\right)}{m^- - 1}.
\tag{12}
$$

In some of the discrete classifiers or two-classified classifiers we use, their classification decisions (Y or N) at each output can be represented by a single point in the ROC space, and all the points in the threshold interval converge into a curve, the ROC curve, so we can use this ROC curve to represent this threshold interval. Further, we express the performance depicted by the ROC curve, the AUC value, with the formula as in equation (13), while the specific diagnostic descriptions are shown in Table 2.

$$
\text{Value}\,(\text{AUC}) = \int_{-\infty}^{+\infty} (NS(x) * \text{FPR}(x))\mathrm{d}x.
\tag{13}
$$

In equation (13), x denotes the cutoff value of classification prediction probability and FPR denotes the percentage of negative samples being predicted as positive samples for the following equation:

$$
\text{FPR} = \frac{\text{PF}}{\text{NT} + \text{PF}}.
\tag{14}
$$

4. Analysis of Results

4.1. Analysis of Bidirectional Short- and Long-Term Memory Networks. The introduction of an attention mechanism can control the influence of elements in the input sequence on the elements of the output sequence and retain more important information; based on the CNN-BO and LSTM-BO models, the M value is selected from 0.1 to 1.0, increasing by 0.1, respectively. The experimental results are shown in Figure 2. The accuracy of the two models increases and then decreases with the value of N. The accuracy of the LSTM-BO model is 82.25% and that of the CNN-BO model is 88.74% at $M = 0.5$, which are both the maximum values. The loss rate of the two models shows a general trend of decreasing and then increasing with the increase of M value, and at $M = 0.5$, the loss rate of the LSTM-BO model is 0.237 and the loss rate of the CNN-BO model is 0.167, which are both the minimum values. The above experimental results are analyzed, and the threshold M of the two models in this paper is taken as 0.6.

Dropout is an optimization method proposed to solve the overfitting and gradient disappearance problems of deep neural networks. To investigate the effect of dropout on the training results, this experiment takes the value of dropout from 0.1 to 1.0 and increases it by 0.1 in order, and the experimental results are shown in Figure 3. The highest accuracy of the LSTM-BO model is 79.86%, the lowest loss

TABLE 2: Algorithm performance diagnosis description.

Serial number	AUC value range	Forecast description
1	AUC < 0.5	Not in line with the real situation
2	0.5 ≤ AUC < 0.8	Low accuracy
3	0.8 ≤ AUC < 0.8	Precise
4	AUC ≥ 0.8	With high accuracy

(a)

(b)
FIGURE 2: Accuracy and loss rate variation.

rate is 0.237, and the lowest time consumption is when the dropout is set to 0.2. The highest accuracy of the CNN-BO model is 87.75%.

4.2. Intelligent Computing IoT Model Analysis. The accuracy and F-value of the intelligent computing IoT model in the training process are shown in Figure 4, where Acc, measure, and loss in Figure 4 denote the accuracy and F-value of the training set in the training process, and val_acc and val_fmeasure denote the accuracy and F-value of the validation set in the training process, respectively. From Figure 4, it can be seen that, after 50 layers of iterations, the change curves of the four indicators have leveled off, indicating that the model in this chapter has reached the best training effect; from Figure 4, it can be seen that, after 50 layers of iterations, the loss in training has been reduced to

the lowest level, indicating that the training goal of the intelligent computing IoT model has been achieved.

The final experimental results of the four groups of models are shown in Figure 5. From the data in Figure 4, it can be seen that the algorithm model proposed in this chapter works best, and compared with the traditional CNN model, the accuracy of this algorithm increases from 87.63% to 92.51%, and the F-value increases from 87.92% to 93.22%, while its algorithmic performance far exceeds that of the SVM algorithm, which performs relatively well among the traditional machine learning algorithms.

4.3. Evaluation Analysis of Family Education Attention Mechanism. We converted the performance depicted by the ROC curve into a single scalar value by calculating the area under the ROC curve. Of course, the AUC serves as a more

(a)

(b)

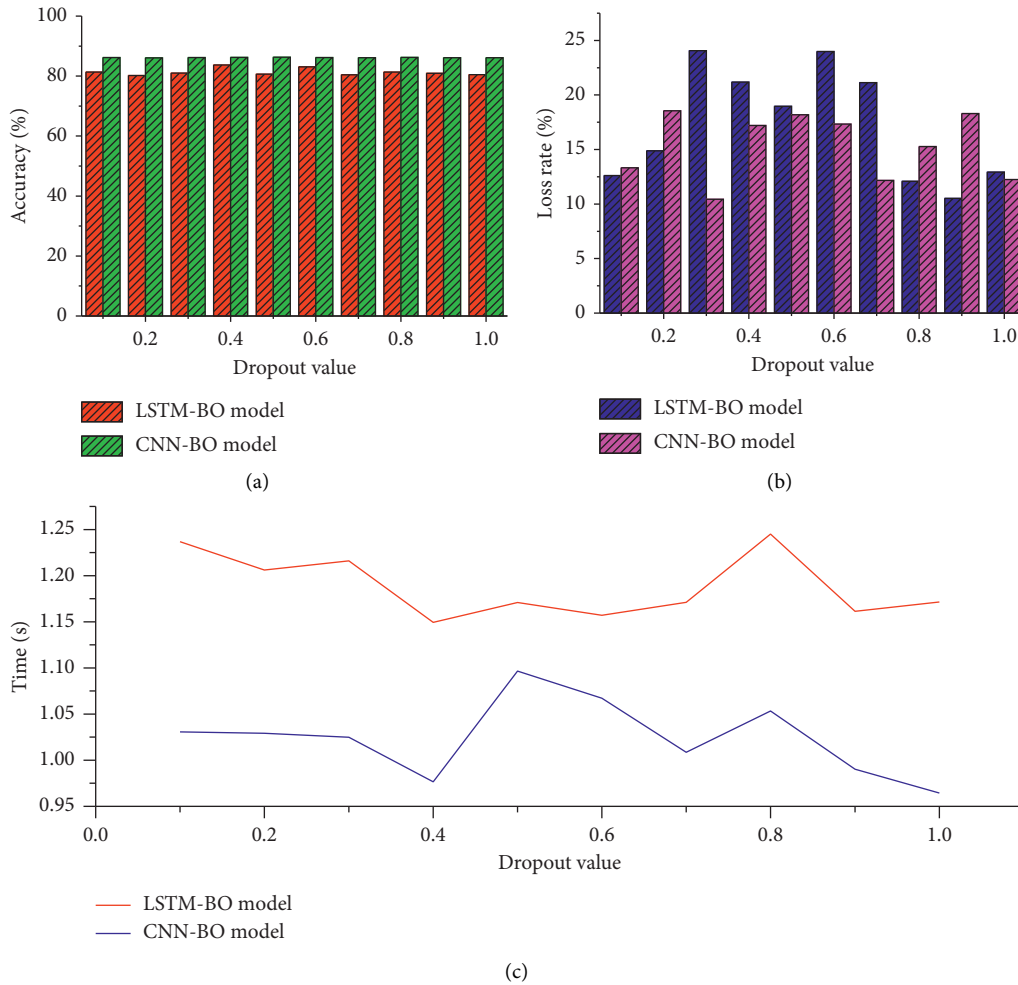
(c)


Figure 3: Dropout selection experimental results.
Figure 4: Accuracy and F-value in training.

popular binary classifier evaluation metric, where a larger AUC value indicates better performance in the prediction of family education attention mechanisms. In Figure 6, the blue

curve is generated from the first layer of the family education attention mechanism prediction, while the red curve is generated from the second layer of the family education attention mechanism prediction. The corresponding AUC values can also be seen in Figure 6. The AUC values for the predicted enhancer and enhancer strength categories are 0.934 and 0.842, respectively, and it is clear that, for identifying enhancers and nonenhancers, this AUC value is higher than the AUC value for the predicted enhancer strength category. However, both values reached a high level, which shows that the prediction of the family education attention mechanism we constructed has some accuracy and stability. When developing a classifier for predicting the attention mechanism of family education, the most important thing is to achieve the highest possible sensitivity while maintaining a low false alarm rate. The advantage of the ROC curve is that you can visualize all these performance indicators from a single image. Comparing the curve with the competitive model is a quick and easy way to choose the appropriate classification or diagnostic tool.

The dataset we used was of the same standard as the datasets of several other studies, and after we completed our prediction study to some extent, we compared the

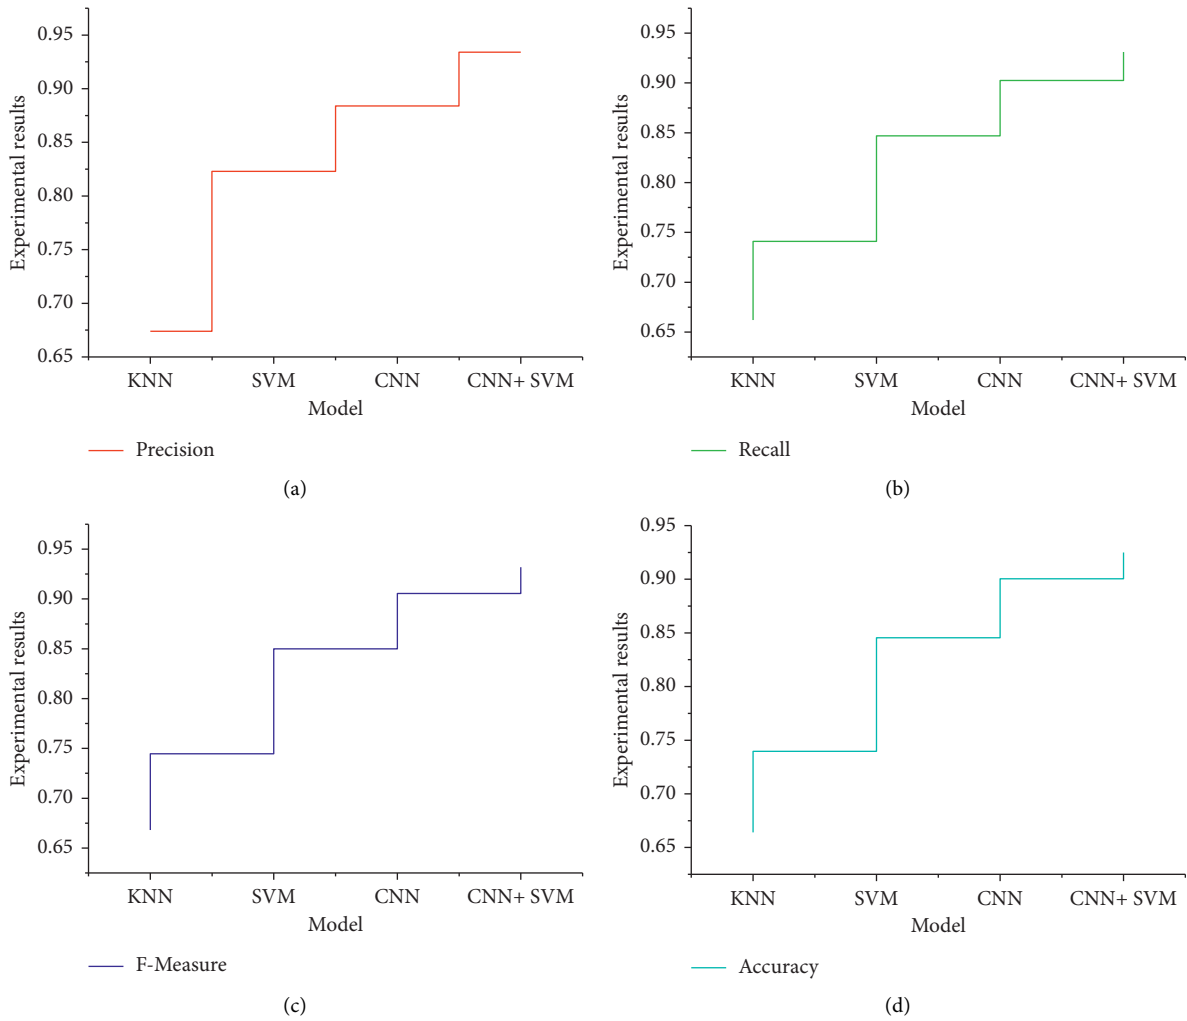
(d)


Figure 5: Experimental results.
Figure 6: The ROC plot of the predicted attention mechanism of family education.

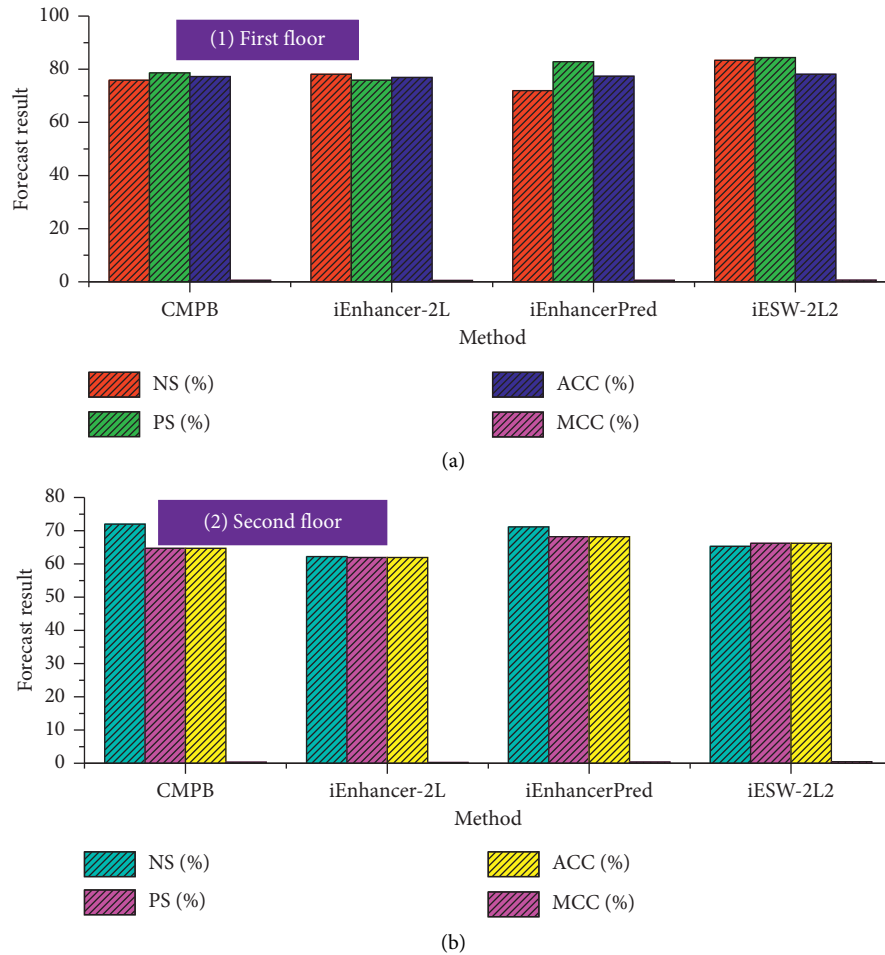
classification prediction results of various research methods to be able to analyze the effects of the study more objectively, and the results are shown in Figure 7. Comparing the Acc values of various family education attention mechanism predictions in the table, we can see that our constructed family education attention mechanism prediction iESW-2L2 is better than several existing family education attention mechanism predictions in identifying enhancers and non-enhancers, and the MCC value of the first layer of this family education attention mechanism prediction is the highest, indicating that this family education attention mechanism prediction has relatively good stability, and this paper's homeschooling attention mechanism prediction has generally improved in the first tier structure of the study. In addition, we can see from Figure 7 that the Acc value in the second layer of the family education attention mechanism prediction reaches 66.22%, which is second only to iEnhancerPred's 68.21% but has the best stability, indicating that the study has some effectiveness.


FIGURE 7: Comparison of prediction results on the benchmark dataset.

5. Conclusion

Firstly, the current mainstream model deep neural network methods inside the field of artificial intelligence and big data research, forward propagation, and backward feedback methods in deep neural networks, classification of neural networks, and the structure and application of short- and long-term memory neural networks in recurrent neural networks are studied and analyzed. On this basis, the hidden layer activation function of the two-way recurrent neural network for short- and long-term memory is improved, and the improved neural network model is proposed in combination with the Morlet wavelet function. Based on simple discrete single-symbol text classification experiments, the effectiveness and performance of the model proposed in this paper are verified, by briefly elucidating the principles of the original recurrent neural network and the short- and long-term memory neural network and proposing the combination of the traditional wavelet function with the short- and long-term memory neural network, as well as changing the model levels and activation functions to improve the experimental results. The core goal of the attention mechanism is to quickly filter out high-value information from a large amount of data.

The introduction of the attention mechanism in the homeschooling classification task can learn the dependencies within the court education and capture the internal structure of homeschooling. A two-way long- and short-term memory network intelligent computing IoT model to assist the attention mechanism of homeschooling is studied, a two-way long- and short-term memory network intelligent computing IoT model based on the two-way long- and short-term memory network is constructed, and its parameter modification rules of BP algorithm based on gradient descent are derived, respectively. To improve the recognition accuracy, a two-layer learning strategy is introduced, and the BP algorithm is used as the inner learning algorithm, while the outer learning adopts an improved particle swarm optimization algorithm, and the main innovation is to introduce the early convergence degree evaluation index to divide the population into three parts and adjust them adaptively to jump out of the local optimum, respectively. In this paper, we mainly study the sequence order information features by using various techniques to extract the sequence order information features. For feature extraction such as sequence structure, clustering algorithms, artificial intelligence analysis, and other methods can be used for in-depth research.

Research Article

Model Construction and Research on Decision Support System for Education Management Based on Data Mining

Weidan Wang (ID)

School of Political and Public Management, Zhengzhou University, Zhengzhou, Henan 450000, China

Correspondence should be addressed to Weidan Wang; wendywang@gs.zzu.edu.cn

Based on data mining technology, this paper applies a combination of theoretical and practical approaches to systematically describe the background and basic concepts related to the generation of data mining-related technologies. The classical data mining process is analyzed in depth and in detail, and the method of building a decision support system for education management based on the B/S model is studied. Not only are the data mining techniques applied to this system, but also the decision tree model with the improved ID3 algorithm is implemented in this thesis, which is further applied to the educational management decision support system of this topic. The load of the client computer is reduced, and the client computer only needs to run a small part of the program. This paper focuses on the following aspects: the overall planning of the educational management decision support system based on data mining technology. From the actual educational management work, we analyze the requirements and design each functional module of this system in detail, applying the system functional structure diagram and functional use case diagram to represent the functional structure of the system and using flow charts to illustrate the workflow of the system as a whole and in parts. The logical structure design, entity-relationship design, and physical model design of the database have been carried out. To improve the efficiency of the system, the ID3 algorithm was improved on this basis to reduce the time complexity of its operation, improve the efficiency of the system operation, and achieve the goal of assessing and predicting the teaching quality of teachers. The development and design of this system provide an efficient, convenient, scientific, and reliable system tool to reduce the workload of education administrators and, more importantly, to make reasonable and effective use of the large amount of data generated in the management, and data mining techniques are used to extract valuable and potential information from these data, which can be more scientific and efficient for the teaching of teachers and students. It can provide reliable, referenceable, and valuable information for managers to make assessments and decisions.

1. Introduction

In the current context of rapid economic growth and rising urbanization, education resources, as one of the important social public resources, are lagging in terms of technical means of management, which poses a negative impact on the deepening of education reform and the optimal allocation of education resources, thus making the development of these tasks face serious challenges [1]. With the continuous progress of information technology, information technology has been widely used in the field of education management at home and abroad to improve their management level [2]. Although the educational information management systems currently in use are also based on database construction,

such systems can only achieve simple analysis and management of data, and the decision-making function is relatively weak. The system can collect education-related data and conduct simple analysis and statistics on the collected data, but its functions are relatively weak or even absent when it comes to the comprehensive analysis of education management. Many developed countries in the world have established a complete, high-tech, and scientific education management decision support system, which has a huge guiding role in the economic development of their national systems. Many colleges and universities have also established educational management decision support systems that are suitable for their own development in local area networks and wide area networks [3]. At the same time, the use of data

mining technology in education management decision-making has also received more and more attention from universities, and better application of data mining to provide services for education management and decision-making has become a new issue facing education [4].

For quite a long time in the past, educational decision-making was based on leadership intuition as well as relevant experience or even relied on social trends, which is obviously not in line with scientific decision theory, and therefore became an important criticism content for educational research staff. Scientific decision-making is inseparable from the necessary data support, but, for a long time in the field of education, a lot of data helpful for decision-making is often scattered on the desks and beds of faculty members [5]. Therefore, strengthening the construction of information technology systems, centralizing and unifying the management of large amounts of data, and then using the corresponding algorithms to analyze them will enable decision-making managers to quickly obtain a large amount of data support, helping them to more accurately understand the strengths and weaknesses of the current educational reality to obtain scientifically correct decisions. Data mining technology can analyze large and complex datasets efficiently and quickly and can find out the information hidden behind the data and the correlations, trends, and directions among the data [6]. If data mining technology is adopted in the education management system, it has important practical significance for the long-term development of education management. We are still continuing to study improved decision tree algorithms, and corresponding improvements have been made to the C4.5 algorithm from different perspectives. Among them are the time-consuming improvements for the C4.5 algorithm to process continuous attributes, using mathematical methods. The price is infinitesimal to improve the calculation efficiency of the information gain rate and so on [7].

The study conducted requirements analysis and detailed design of each functional module for this system and applied system functional structure diagram and functional use case diagram to describe the functional structure of the system and flow chart to illustrate the workflow of the system as a whole and in parts. The logical structure design, entity-relationship design, and physical model design were carried out for the database. Then the traditional ID3 algorithm was applied to the teaching quality assessment subsystem for analysis. To improve the efficiency of the system, the ID3 algorithm was optimized and improved on this basis to reduce the time complexity of its operation and improve the system operation efficiency. The goal of assessing and predicting teachers' teaching quality is achieved. This paper is divided into 5 sections, and the structure is arranged as follows: Section 2 discusses related work, the current state of research, and the application of classical algorithms, which lays the foundation for the research use in the subsequent chapters. Section 3 is devoted to research on data mining-based decision support system for educational management. Section 4 is devoted to results analysis. Section 5 gives the conclusion. Data mining techniques are applied to educational management decision support system, relevant

teacher information data, student information data, and social background information data are collected, and then the data are preprocessed; data mining algorithms are used to build models, test models, and apply models to help educators understand students' learning characteristics as much as possible, and the factors affecting teaching quality are analyzed. The value of the data related to students' learning information is maximized, and the role of educational data mining is truly brought into play.

2. Related Work

With the acceleration of campus digitalization in recent years, many universities have developed information management systems on their own or jointly with other universities to realize paperless offices and improve the scientific and high efficiency of daily work. The use of this system has accumulated a large amount of data, but colleges and universities have only made some inquiries, statistics, and reserves on these data and have not made full use of them. To make better use of these data and discover hidden valuable information, some universities have started to use data mining techniques to study, analyze, and solve problems. Therefore data mining technology will get more attention and application in the field of education [8]. Rodrigues et al. studied the application of data mining in the analysis of college entrance examination admission data through association rules and decision tree classification in the design of the college entrance examination information analysis system. Useful knowledge is mined for educational institutions, candidates, and colleges and universities [9]. Ghorbani and Ghousi conducted an in-depth study on educational management and data mining techniques in colleges and universities, using data mining related algorithms, and integrated a simple voting strategy through the study of simple improvement method of Apriori algorithm and ID3 algorithm, which has improved the educational management of students in colleges and universities and provided valuable guidance for students' training [10]. Farouk and Zhen used the educational technology of OLAM to analyze the education and admission of colleges and universities and identified the reasons and potentially useful information affecting students' enrolment through data mining techniques based on the educational data of previous years [11].

To pursue the rationality of educational decision-making and promote educational decision-making from experience to science, scholars at home and abroad have done a lot of research and discussion on educational decision support from different perspectives. Du et al. started the theoretical research in this area by proposing a data mining-based decision support system for educational management [12]. Shen et al. used the B/S model and analyzed the process dynamics of learners in the Moodle learning platform using network analysis techniques. They saved the learner dynamic record data in the management system to form real-time analytical models or statistical reports [13]. Operations such as classification patterns, clustering patterns, association rules, and other analytical methods as well as visual

representations were formerly used, and the latter were used to represent common model generation from behavioural dynamic data. Lee et al. used data mining techniques to estimate the potential of the subjects [14]. Based on the organic integration of information about learners' meta-cognition, motivational goals, knowledge acquisition, and learning attitudes, they established models with learners as the objects and predicted the future development tendencies of learners, analyzed and improved educational method models, explored the effectiveness of various applications to learning systems, and established data-based computing models to improve and enhance effective learning of learners [15].

We use literature, academic paper statistics, and content analysis methods to systematically sort out and summarize the various literature related to educational data mining that has been published in China and abroad and then conduct an overall study and analysis to objectively analyze and compare the current research status of data mining technology in the field of education at home and abroad [16, 17]. The research trend of educational data mining in the future is discussed. Through the above literature, we can see that data mining is more oriented to the improvement of algorithms of data mining technology and the mining of existing education management data to analyze the intrinsic relationship between their different attribute values, but there is relatively little research on the valuable information that affects the relationship between new students' arrival rate and education management decisions. The purpose of this paper is to analyze and study educational management data from this perspective using mining techniques [11, 18]. The development of an educational management information management system plays an important role in promoting the development of higher education informatization. Use data mining algorithms to establish models, test models, and application models to help educators understand the characteristics of education management as much as possible, analyze the factors that affect teaching quality, and maximize the value of data related to education management information as much as possible [19]. Give full play to the due role of educational data mining [20].

3. Research on the Decision Support System for Education Management Based on Data Mining

3.1. Data Mining Education Model Construction.
Reasonable goals in the decision-making process are a prerequisite for rational decision-making. The formation of the decision goal, the size of the goal, and the decision maker's understanding of the goal will affect the smooth implementation of the decision [21, 22]. In the process of establishing the goal, the nature, structure, and crux of the problem to be solved must be analyzed clearly before a reasonable decision target can be determined in a targeted manner. The decision goal must be very clear if the goal is too abstract or ambiguous, and ambiguous decision will be

difficult to carry out, and the degree of achievement of the decision goal is also difficult to measure. The conceptual representation of the educational management decision support process is shown in Figure 1. The education management decision-making process mainly includes four basic stages: target determination, design plan, implementation plan, and evaluation plan. Each stage of the educational management decision-making process has a close relationship with the decision-making environment.

After the decision objectives are determined, a variety of possible options are further designed for decision-makers based on feasibility studies. The proposed feasible options require a combination of overall exhaustiveness and mutual exclusivity to avoid bias in the option selection process. Overall exhaustiveness means that the various options developed should include all possible options found. Mutual exclusivity means that only one option can be chosen among different options [23]. These mutually exclusive options should all be easy for decision makers to compare and choose. The analysis, evaluation, and comparison of options mean that the indicators of all options are compared including the technical, economic, and social environmental conditions, factors, and potential problems, and dynamic financial indicators related to the decision objective are compared and evaluated. The possible constraints and potential problems of each option, as well as preventive and emergency measures, are also compared and evaluated. The proper execution of the user in the data mining process can accelerate the execution of the data mining process. Providing an interactive interface provides users with easy operation, and the interactive interface conveys the generated results to the user in a timely and convenient manner, and the generated results can be diverse.

The task of data integration is to merge data from multiple data sources into a unified data store for data mining. Data sources may include multiple databases, data cubes, and data files. The main considerations of data integration are attribute matching, data redundancy, and the detection and handling of value conflicts [24]. For attribute matching, attribute merging is performed by examining the field meaning of each attribute, data type, and so forth. Redundant data is considered at two levels. For attribute-to-attribute redundancy, the meaning of attribute entities is mainly examined, and attributes are streamlined by retaining fine-grained metrics of attribute values and ignoring coarse-grained metrics. This is because coarse-grained attribute data can come from the transformation of fine-grained data. Some redundant relationships between attributes are difficult to detect and can be detected by detecting how much an attribute can contain an attribute, such as by calculating the Pearson coefficient, also called the correlation coefficient of two attributes; for example, the correlation coefficient $R(X, Y)$ given two attributes X and Y is shown in equation (1), where N is the number of tuples, x_k and y_k are the values of X and Y in tuple k, respectively, $\bar{X}$ and $\bar{Y}$ are the means of X and Y, and $\beta(X)$ and $\beta(Y)$ are the standard deviations of X and Y. The ID3 algorithm is used to establish a decision tree model based on the attributes of the database samples. The algorithm requires more logarithmic
Figure 1: Educational management decision support process.

operations, which results in time complexity and low operating efficiency. The same formula needs to be calculated repeatedly, so the algorithm still has room for improvement. The algorithm needs to be optimized.

$$R(X,Y) = \frac{\sum_{k=1}^{N}\left(x_k - \overrightarrow{X}\right) * \left(y_k - \overrightarrow{Y}\right)}{N * \beta(X) * \beta(Y)}. \tag{1}$$

Facts are numerical measures, and multidimensional data models are organized around a fact, represented by a fact table that includes the name of the fact and the measure of the fact, as well as the code of each relevant dimension table [25]. A dimension is a pivot view or entity about which you want to keep records, and each dimension has a dimension table corresponding to it for data mining and decision analysis, which are Faculty Fact Table, Research Awards Fact Table, Research Results Fact Table, Research Funding Fact Table, Research Projects Fact Table, Talent Development Fact Table, Hardware Conditions Fact Table, and Subject Books Fact Table. Each fact table is associated with multiple dimension tables, such as discipline level, time, and unit level. The specific dimension tables are determined by the fact tables as shown in Table 1.

After obtaining the discrete dataset, we first train to obtain a complete decision tree using the ID3 algorithm, which works as follows: let data D be partitioned into a training set of class-labeled tuples, assuming that the class-labeled attributes have N different values, and N different classes H_i are defined ($i = 1, \ldots, N$). Let H_{iX} be the set of tuples of class H_i in X, and let $|X|$ and $|H_{iX}|$ be the numbers of tuples in X and H_{iX}, as in equation (2), where $F(X)$ is the average expected amount of information needed to classify the tuples in X; $|X_i| * F(X_i)$ represents the weights of the i-th division; H_i is the probability that any tuple in X belongs to class H_i and is estimated by $|X_i|/|X|$.

$$\begin{cases} F(X) = \sum_{i=1}^{N} H_{ix} * \ln(X_i), \\ \\ \overrightarrow{F(X)} = \sum_{i=1}^{N} \frac{|X_i| * F((X_i))}{|X|}. \end{cases} \tag{2}$$

The Bayesian posterior theory is used to test each branch of the decision tree, and the branches that are not considered to have sufficient generalization ability or are unreliable are removed from the tree, resulting in a more compact tree [26, 27]. The testing process is targeted at the knowledge of each rule translated from the decision tree, where each classification rule is obtained by searching from the root node of the decision tree top-down to a leaf node, and each classification rule consists of a conditional attribute tuple X and a conclusion classification label H_x. For the test of each classification rule, we define two kinds of validation.

TABLE 1: Fact and dimension tables for data mining data warehouse.

Serial number	Theme	Fact table	Dimension table 1	Dimension table 2	Dimension table 3
1	Scientific research awards	Scientific research award fact sheet	Unit dimension	Subject dimension	Time dimension
2	Scientific research results	Fact sheet of scientific research achievements	Subject dimension	Award type dimension	Unit dimension
3	Research funding	Research funding fact sheet	Award type dimension	Time dimension	Subject dimension
4	Research project	Research project fact sheet	Time dimension	Unit dimension	Subject dimension
5	Talent development	Talent training fact sheet	Unit dimension	Subject dimension	Award type dimension
6	Hardware condition	Hardware condition fact table	Subject dimension	Award type dimension	Time dimension

Adequacy verification:

$$G(Hi) = \sum_{i=1}^{N} \frac{|H_{ix}|}{|X|}. \tag{3}$$

Necessity validation:

$$\begin{cases} G(H_x|Y) = \frac{|H_{x,X}|}{|X|}, \\[2mm] G(H_x) = \frac{[H_x]}{|X|}, \end{cases} \tag{4}$$

We need knowledge with clear interpretability yet do not want the classification and prediction process to be too demanding, so to facilitate the simplification of the processing problem, we draw on fuzzy theory and perform some fuzzy optimization of the decision rules in classification and prediction. The affiliation function for a certain attribute value x belonging to a certain interval $(G_1, G_2]$ is established as

$$f(x) = \begin{cases} 1 - \dfrac{G_1 - x}{G_2 - G_1}, & x < G_1, \\[3mm] 1, x = G_1, x = G_2, & f(x) \subseteq [0,1], \\[3mm] 1 - \dfrac{x - G_2}{G_2 - G_1}, & x > G_2. \end{cases} \tag{5}$$

A minimum acceptable value of affiliation u is specified, which can also be determined from a large number of experiments. In this paper, the value is set to $u = 0.9$ to simplify the determination process.

$$f(x) = \max_{i \subseteq [1,N]} (G_1 - (1-u)(G_2 - G_1), G_2 + (1-u)(G_2 - G_1)). \tag{6}$$

The complexity of the educational system makes educational decision-making more difficult; an effective and rational educational decision support system will greatly contribute to the efficiency and rationality of educational decision-making. In this paper, we combine the characteristics of the educational decision-making process, the characteristics of the educational system itself, and the structural characteristics of the new generation decision support system to propose a decision support system model of educational management for the actual situation in the field of education and teaching.

3.2. Education Management Decision Support System Design Implementation. The data mining visualization system for education management information proposed in this study aims to provide decision support for education management information management in colleges and universities. The design goal of the system is to perform data mining on a large amount of education management data accumulated in the education management database over the years, and education management staff need to perform basic data analysis and data management on candidate data information through the online national college education management system. Finally, determine whether to admit or not and announce the admission results to the admitted candidates through the education management consulting system. The admitted candidates can also inquire about the situation of colleges and universities, previous years' education management admission score line, professional education management plan, application guidance, admission result, and issuance of admission notice through the education management information service system, while the relevant education management information managers of colleges and universities can also inquire about the historical information of education management and also use the data mining system to inquire about the application and admission and reporting situation through the system. Online analysis and visualization can be used to grasp education management information and make timely education management decisions.

The education management administration subsystem completes the function of maintaining information for education management records. All operations of the system require general records to be kept, and the general records are partially handled by the logs that participate in the shared section. The system starts when the user has successfully logged in and obtained the code that can control the scope of the system and expects to perform education management

arrangement management operations. Education management arrangement includes 6 common functions of form presentation, adding, changing, deleting, finding, and detailing of education management teaching maintenance data. The administrator selects the hyperlink of education management and clicks on the specific list of each education management arrangement, and, with the help of clicking the function button given in the upper right corner, the system is commanded to complete the addition, deletion, and change of the list of activity plans.

A large part of the data application uses the report query mode for data service, and so does the education management analysis module. The flow of the report query is briefly explained below, and its flow chart is shown in Figure 2. The first step of the report query is to log in to the system, at which time the system permissions are verified and only the functions and pages that the users are entitled to access are displayed; then the users enter the specific functional report interface according to their needs; the report interface functions are built based on various data analysis methods such as trend analysis, comparative analysis, cross-analysis, and retention analysis to establish the data model for query, and then the page is built based on the data model at the front end and the data organization at the back end. In the previous section, the detailed design and implementation of data storage and processing also mentioned that the data will be extracted from the dimension fields and indicator fields in the ADS layer, and now the query module can display the user-selectable dimensions based on the dimension field table. The user selects the dimension, the dimension value, and the data to send a query request, and the server calls the corresponding controller interface based on the requested URL and parameters to complete the query of the model data and return it to the Web client for display to the user.

The education management system designed and implemented in this paper uses a decision tree classification algorithm to generate a classification rule. One of the important tasks of the university's education management is to provide career guidance for students, so the education management system can use the information about students' schools to dig out their career direction. Therefore, the classification rules provided by the education management system for career guidance are as follows: Firstly, the students' school transcripts and comprehensive assessment are used as the input of the classification rules, and the courses taken by the students are classified as theoretical and practical courses; the spare time activities are classified as athletic and linguistic, and the students' roles in the activities are classified as leadership and nonleadership; based on this input information, the industry in which the students are employed is predicted. Finally, the employment information of previous students is used as an evaluation criterion. For example, grade analysis in university education management can obtain information about the knowledge points of students' grades in terms of question types and subject knowledge points of students' grades. It is very interesting to extract the important knowledge from the data warehouse of students' performance in higher education because there is a lot of information that can help to improve teaching management. The first step is to analyze the question types and the degree of correlation between question types, scores, knowledge points, and scores to summarize the strategies to train students.

4. Results and Analysis

4.1. Data Mining Education Model Analysis. To test the effect of the improved algorithm, the objective function can be scaled up and processed, and the number of misclassified entries can be calculated directly when calculating the error rate. The improved algorithm has an obvious effect on datasets with large data volume and complex data types, so the comparison of the convergence effect on the Vote dataset is listed, as shown in Figure 3, for the convergence curves of the algorithm before and after the improved algorithm is carried out for 40 experiments and taken as the mean value. Through the experimental comparison, for the dataset with large data volume and complex data type, multiple experiments are conducted, and, within 500 iterations, the improved algorithm converges significantly faster than the unimproved one, is less likely to fall into the local optimal solution, and can converge to the global optimal value early.

Figure 4 shows the error rate of classification. When the proposed algorithm is used for classification, the error rates of all the datasets used are generally lower than those of NBC and NBC-W. If there is a dataset with a high classification error rate on the test data, it may be that the parameters set are not suitable, the training samples are not set reasonably well, or the data satisfy the assumption of conditional class independence. In general, NBC-IBA can classify accurately and reach the desired accuracy when dealing with most of the datasets. In terms of the running time of the algorithm, since the NBC-IBA algorithm needs to iteratively search for weights, the training time of the classifier is a little slower than that of NBC and NBC-W. After the training, not only is the speed comparable to that of NBC but also the accuracy rate is substantially improved in the subsequent classification process. In this chapter, the normalization criterion is applied when converting positions to weights, and the globally optimal positions are not simply used as weights.

Figure 5 shows the comparison of the time run using the 3000 datasets collected in the object, and after the above analysis is applied to the actual one, from the perspective of the overall operation process, the advantages of optimization are very obvious, which not only reduces the number of calculation, but also calculates the order of all nodes, reducing the time complexity of operation. The optimized decision algorithm converts the original logarithmic operation into a simple four-rule operation during the calculation of the information gain, say application formula, which greatly reduces the average and overall computational effort. Therefore, the improved decision algorithm reduces the efficiency without changing the overall effect of the original algorithm and can completely replace the old algorithm for application to the system.
FIGURE 2: Flow chart of report query.
FIGURE 3: Convergence curves of the number of misclassified rows in the Vote dataset.

4.2. Analysis of Educational Management Decision Support System. Figure 6 shows the comprehensive analysis, which shows the basic information of 2017–2020, the students' reports of different majors, different places of origin, and different subjects, and the final educational decision can be made by combining the educational data of four years as follows. The system analysis module shows that, except for economic management and foreign languages, which have reached the education standard in the last three years, all other key majors have not been able to reach the basic number of education standards, so it is necessary to adjust the education number of majors in this area. The specialties of computer science, environmental engineering, and other science and technology majors can be adjusted appropriately according to the actual situation to make the specialties more rational and to get more students enrolled and admitted in this way. From the above conclusions, we can see that many factors are affecting the enrolment rate, and then we can use

this as a guiding basis in our future educational work to help the college decision-makers to plan the opening of courses and the adjustment of the setting of majors, as well as to give some scientific guidance to the work of discipline management departments as well.

Figure 7 further verifies that there is a significant difference in overall assessment scores between the preceding teacher-training category and the conductive category and between male and female students, while it can be known that teacher-training category is higher than the conductive categpry, and female students are higher than male students. In terms of comprehensive assessment, The students' comprehensive assessment in the academic year is linearly related to their intelligence, and ability has a significant impact on comprehensive assessment. There is a significant difference between male and female students, with an average score of 69.96 for female students, which is higher than the average score of 60.10 for male students; there is a
Figure 4: Comparison of classification error rates of three algorithms for six datasets.
Figure 5: Running time.

significant difference between teacher training and knowledge, with an average score of 76.33 for teacher-training students, which is significantly higher than the average score of 55.28 for knowledge students. There is a significant

relationship between students' employment and their overall assessment and also with gender.

The statistical analysis results of the whole school are used as an example of the display, as shown in Figure 8,
Figure 6: Comprehensive analysis.
Figure 7: Correlation chart of comprehensive assessment scores.
FIGURE 8: Statistical chart of educational management results by faculty.

which shows the statistical interface of the bar graph of education management results. The following statistical charts can be saved online. Figure 8 takes the statistical graph of education management of each college of the whole university as an example and shows the specific distribution of 3 types of education management levels of each college according to the college as a division unit, from which it can be seen which college is worthy of attention, which college is worthy of praise, and so on; the majors of a certain college, classes of a certain major, students of a certain class, and so forth are applicable to assist decision-makers in making decisions.

From the results of the above analysis, it is clear that there is a gap between male and female majors in educational technology in numerous aspects. To avoid this current gap phenomenon, the director of the program and the dean of instruction need to actively study and take favorable measures to guide male students to be competitive in academic life and other aspects to catch up with female students and narrow the gap. When setting the weighting coefficients for the comprehensive assessment of the student's academic year, the developers should focus on the coefficients for intellectual achievement and the criteria for ability bonus points. This is because these two parameters play a crucial role in the fairness and reasonableness of the comprehensive assessment of the student academic year. There is a need to continue to maintain the high weighting ratio of intellectual achievement in the

comprehensive assessment. This will promote the all-around development of students' moral and intellectual and physical abilities while adhering to the principle that "students' primary responsibility is to learn" and giving full play to the effective means of reflecting students' learning in their intellectual performance. Professional teachers and administrators should gradually guide students to make efforts to study and stabilize their English grades from the time they enter the university, to achieve a relatively smooth passage of the fourth and sixth grades, avoiding the clinical learning style and the need to explore effective teaching methods to improve the English grades of male students. Although the results of comprehensive evaluation have an important impact on students' employment, students' single ability or special skills have a great advantage in employment. At the same time, in the employment process, the employment opportunities for men are higher than those for women, this through interviews and analysis of the employment situation in recent years, and the reason is mainly generated by the employment units in the treatment of gender differences between men and women and the point of conformity. Various activities are vigorously carried out to increase the opportunities for students to demonstrate their abilities and encourage them to take various certificate examinations to expand employment opportunities. Because of the current employment situation, female students should choose suitable majors according to gender characteristics when they are employed.

5. Conclusion

With the transformation of knowledge-based economy, the education industry is developing rapidly in this context, and modernization of education management is an important basis for promoting the sustainable development of the education industry, and an important symbol of modernization of education management is the construction of information system, which is an inevitable choice for the development of education modernization. In recent years, urbanization construction has been making breakthroughs, the population in need of education is relatively mobile, and the school layout has to be adjusted continuously as a result, which undoubtedly brings about serious problems to the education authorities, so it is extremely crucial to build an education management decision support system based on data mining. In this paper, the significance and background of the educational decision support management system are explained, and the user requirements, design scheme, and functional implementation are systematically described. The overall architecture and functions of the system are also analyzed, as well as the related system development environment and the required database design. The key technologies and difficulties involved in the development of the system are also discussed in detail. Finally, through testing the system, we found that the system can meet the user's requirements and can complete the basic education management work and has certain decision support functions. Of course, due to my limited ability, some functions of the system are not perfect, and the development of the system is still in the initial stage, so problems and shortcomings are inevitable, which are also the areas that need to be improved in the future. It is necessary to carry out research on the construction and application of various prediction models and monitoring models for the system prediction and dynamic monitoring mentioned in the discussion of the role of educational decision support system for evidence integration and benefit integration. These research skills will be a further extension and deepening of this research.

In order to successfully apply the Internet of Things and cloud computing to the administrative management of spatial structures and realize the systematization, digitization, and intelligence of administrative management, this article draws on research experience in related fields and considers the data characteristics and computing tasks of administrative management. The whole cycle of transmission, storage, postprocessing, and visualization is the main line of research, and a cloud computing-based spatial structure administrative management IoT system is constructed. First, by summarizing the application status of the Internet of Things, the general Internet of Things system is summarized into three levels, and combined with the specific work in the spatial structure administrative management, the overall framework of the spatial structure administrative management of the Internet of Things system is proposed, and the functional sublayers are carried out. Secondly, in response to the above problems, through the traditional image recognition system research and practical application investigation, in order to meet the user's requirements for the computing efficiency and recognition accuracy of the image recognition system, an image recognition system in the cloud computing environment is proposed. It proposes a fuzzy evaluation algorithm of health grade hierarchy analysis optimized for the index system and scoring system and a calculation method that uses time series to identify regular outliers. The optical image pixel-level fusion method and the infrared and visible image fusion method based on complementary information are proposed, and the image fusion software is developed. Finally, in order to enable the application layer to use cluster resources to efficiently and intelligently process massive monitoring data containing redundancy, heterogeneity, anomalies, and many other defects, according to the calculation process of each specific task of data preprocessing and postprocessing in the application layer, demonstrations are made one by one. After analysis, it is concluded that vertical storage of data blocks according to different sensor channels is the optimal strategy.

1. Introduction

With the increasing popularity of smart sensing and wireless networking technology in the field of structural administration management, large-span spatial structure administration projects involving major public safety have grown rapidly in recent years [1]. Facing the continuous accumulation of massive amounts of heterogeneous monitoring information, with cloud computing as technical support, the establishment of a spatial structure administrative management Internet of Things system to achieve

comprehensive perception, intelligent processing, and visual design of monitoring data has become an inevitable requirement for administrative management construction [2]. They study the organic combination of the Internet of Things, cloud computing, and spatial structure administrative management, establish a spatial structure administrative data management cloud platform, give full play to the advantages of cloud computing and the Internet of Things system, and provide technical support for the storage and postprocessing of monitoring data. It is conducive to the accumulation of research forces, reduces the analysis cost of

monitoring data, and improves the scale and comprehensive benefits of the administrative management system [3–5].

With the injection of powerful and flexible storage and computing resources of cloud computing, the collaboration of smart hardware and software will become closer. The Internet of Things system will gradually be different from the traditional collection and display system and become a highly information-based organic whole. With the continuous improvement of wireless sensor technology and intelligent control technology, the intelligent, automated, integrated, platform-based, and visualized administrative management of spatial structure has become an inevitable trend in the development of the industry [6]. The Hadoop platform is a parallel programming model and computing framework for processing massive data and is used for parallel computing on large-scale data sets. Grid computing is a technology that has gradually emerged and developed in recent years. It is currently widely used in many research fields such as distributed supercomputing, distributed instrument systems, data-intensive computing, and remote immersion. Using the supercomputing power of grid computing to solve the problem of image recognition is also one of the current research directions. By improving the image recognition algorithm to the nonparallel algorithm, the program is transplanted to the grid computing platform to run, and the distributed image recognition technology is realized [7]. It has a simple structure, can effectively support data-intensive applications, and is very suitable for the development of parallel digital image processing technology. The Internet of Things is an important part of the new generation of information technology and has become the third wave of the information industry after computers, the Internet, and mobile networks [8–10].

Cloud computing platforms and cloud computing network operators are at the core of the entire dynamic administrative management construction process. When an order comes, the corresponding historical data is processed through the cloud computing center, and the optimal node for the corresponding order is quickly selected for the formation of the Internet of Things. Dynamic administrative management responds to demand, so as to achieve the purpose of improving the overall efficiency of dynamic administrative management. The clustering algorithm is introduced at the transport layer to ensure high-efficiency transmission and effectively reduce data loss; at the application layer, data security levels are classified, and data of different security levels are protected to different degrees. In this strategy, the distribution of permissions must go through strict identity verification, which can avoid the security problems caused by illegal users obtaining illegal permissions in the traditional system. In addition, supporting secondary development is an inevitable requirement for the development of the Internet of Things. It is possible to classify the things in the Internet of Things to facilitate the design of users to meet their own needs. Choosing public cloud services as the development support, we establish a spatial structure administrative management cloud computing network and complete the development of the application layer of the Internet of Things system. The platform responds to various needs of users through internally encapsulated application services and realizes real-time reception, dynamic display, and comprehensive management of monitoring information, thereby establishing a complete spatial structure administrative management IoT system.

2. Related Work

In recent years, with the rapid development of communication networks and sensor components, automated and intelligent collection of monitoring data has been realized in structural administrative management technology, which also provides feasibility for real-time online analysis. In order to achieve real-time or even premastering of the state changes of structural performance, in addition to the need to improve the monitoring and collection subsystem to ensure accurate collection and transmission of information, it is also necessary to consider the interaction with users and develop a set of data mining, data display, and data storage. The monitoring data management system is integrated with other functions, so as to analyze and process the monitoring information online in real time and present the processing results to the monitoring users to assist the corresponding decision-making.

Kumari et al. [11] proposed a deep belief network model that can use an algorithm called greedy layer-by-layer training strategy for effective training, which quickly aroused people's enthusiasm for cloud computing network research. Subsequently, Sharif et al. [12] proposed that this training method is also applicable to other different types of deep neural networks and can systematically improve the generalization ability of the network model on the test samples. The convolutional cloud computing network is also a large category of cloud computing. Pasquier et al. [13] first introduced the application of the supervised backpropagation algorithm to this multilevel structure of the convolutional cloud computing network. In terms of speech recognition, Anuradha et al. [14] use the DNN-HMM architecture to replace the original GMM-HMM architecture and use the filter bank features of the original Mel domain to replace MFCC. It even dropped by half. In addition, cloud computing has also achieved high-profile results in pedestrian detection and image segmentation and has surpassed human levels in traffic sign classification. For the impulse cloud computing network, starting with the discovery of impulse neurons, Elhoseny et al. [15] proposed the first bionic impulse neuron model. Although its biological nature is very strong, the computational complexity is too high, so there is subsequent evolution of FHN, ML, IZH, IF, and other neuron models, thus greatly reducing the computational complexity. The learning rules for impulse cloud computing networks have gradually evolved from the original Hebb learning rules to STDP and IP mechanisms, thereby improving the learning efficiency of impulse cloud computing networks [16–18].

The classification and recognition accuracy of the image recognition system largely determines the quality of the entire system. Therefore, in image recognition technology, classification and recognition technology should be paid

enough attention to. Through the research and improvement of classification and recognition technology, the computational efficiency and recognition accuracy of image recognition can be improved, and the foundation for wider applications can be laid [19]. At present, the main classification techniques include decision tree induction, Bayesian classification, KNN classification, and artificial cloud computing network. Among these methods, KNN classification is a simple, effective, nonparametric method and has been widely used in text classification, pattern recognition, image and spatial classification, and other fields. The KNN algorithm is a lazy learning method, where the learning program will construct a model until the last moment before classifying the given test set. In classification, the computational cost of this learning method and the need for large storage cost were needed [20, 21].

3. System-Assisted Administrative Management Event Parameter IoT Model Construction Based on Cloud Computing Image Recognition

3.1. Cloud Computing Hierarchical Architecture. Various services of the cloud computing system exist in the network, users do not need complicated procedures, they only need to access system resources through the Internet, and the cloud computing system supports various access methods, allowing users to access various clients. The information transmission between the three levels of the Internet of Things system is not simple one-way transportation, but a two-way linkage intelligently controlled through a preset real-time feedback mechanism, which involves security technology, analysis and identification technology, service quality management, and cross-level public technology including network management [22]. Figure 1 is the cloud computing hierarchical architecture topology.

Cloud computing is a resource utilization mode, which can access configurable computer resource pools (such as networks, servers, storage, applications, and services) through the network in a convenient, friendly, and on-demand access manner. In this mode, we can quickly supply and provide services with minimal management costs. The main purpose of integrating physical resources is to integrate the services that these physical resources can provide and transform them into resource pools that provide users with different services, including computing resource pools, storage resource pools, network resource pools, and data resource pools.

$$L \times 1 + \frac{1}{L+d+N} \approx 1 - \frac{1}{L+d+N}. \tag{1}$$

The perception layer is the lowest layer in the three-tier system architecture of the Internet of Things, and it contains two application sublayers: data collection and short-distance communication. Its function is to perceive the behavior of the target thing through the sensor node, obtain the information data of the physical world, and then use the self-integrated communication protocol to organize the data exchange and transfer it to the upper layer.

$$M = \begin{bmatrix} m_{11} & m_{12} & \cdots & m_{1m} \\ m_{21} & m_{22} & \cdots & m_{2m} \\ \cdots & \cdots & \cdots & \cdots \\ m_{m1} & m_{m2} & \cdots & m_{mm} \end{bmatrix}. \tag{2}$$

The SOA building layer combines the services that cloud computing can provide to users and presents them to users through interfaces, which mainly include service interfaces, service registration, service search, service access, and service workflow. Cloud computing has good interfaces and can realize good interactions with various services.

$$l = \alpha \times \sum_{i=0}^{S^2} \sum_{j=0}^{B} \left[(x_i - \overline{x})^2 + (y_i - \overline{y})^2 + (x_j - \overline{x})^2 + (y_j - \overline{y})^2 \right],$$

$$L_{(\text{emg},k)} = \sum_{f(\text{emg},k) \in A_{(\text{emg},k)}} \left(f_{(\text{emg},n)} + C_{(\text{emg},k)} \right),$$

$$\min \sum_{i=1}^{N} a_i = \frac{1}{2} \sum_{i=1}^{N} \sum_{j}^{N} a_i \times y_j \times a_j \times y_i \times k\left(x_i^2, x_j^2\right). \tag{3}$$

As the middle layer of the Internet of Things system architecture, the network layer is mainly used to provide a long-distance communication medium for the two-way information transmission between the perception layer and the application layer on the premise of ensuring the security and integrity of the data. The development of the existing Internet long-distance communication technology has been relatively mature. As long as the data connection with the private network is completed through related protocols, the Internet can safely and in real time transport massive amounts of data in both directions.

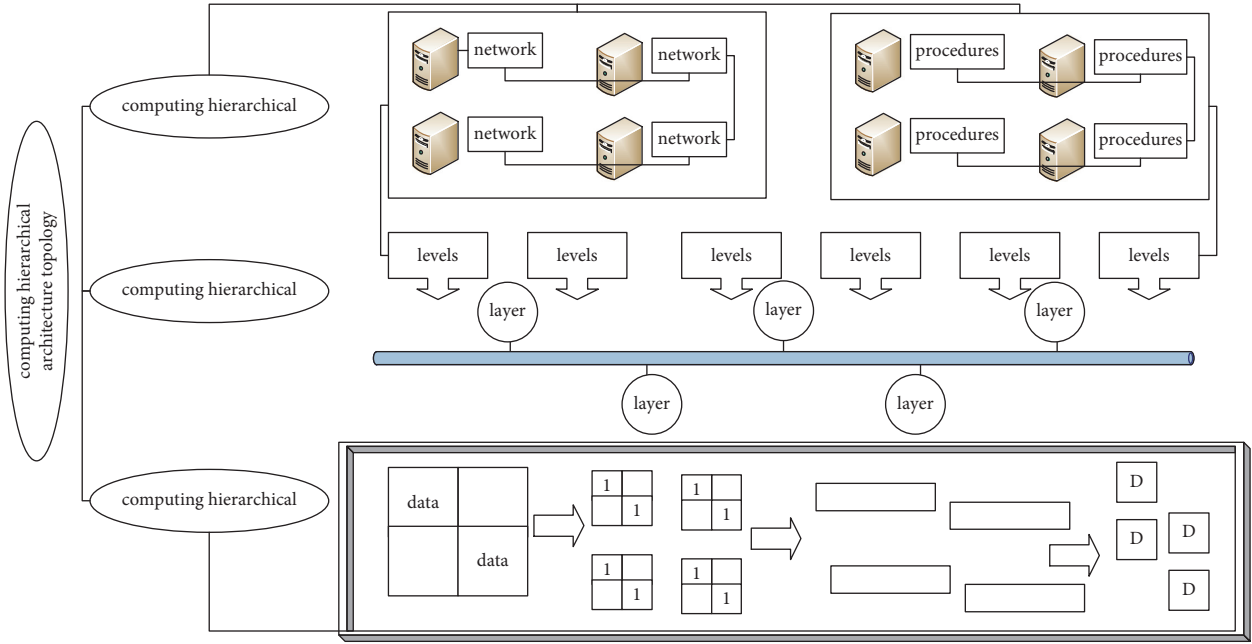
3.2. Image Recognition Auxiliary Algorithm. From the actual operating point of view, image transformation is to find a suitable orthogonal transformation kernel for the original image. In essence, image transformation has a profound physical background. For example, a Fourier transform of the image reflects the frequency distribution of the function on the system spectrum. Generally, imaging systems only have a certain range of brightness, and the ratio of the maximum value to the minimum value of the brightness becomes the contrast. Using digital image processing technology and pattern recognition theories, combined with computer technology, we analyze various formed elements in urine sediment and find out reasonable segmentation methods and classification rules in accordance with digital image processing algorithms. The system that forms the image has limited brightness, so the contrast is not enough, so the human eye has a poor visual effect when viewing the image. The visual effect is improved through grayscale transformations such as linear transformation, piecewise linear transformation, and nonlinear transformation. Geometric normalization is also called position calibration. It will help correct the size difference and angular deviation caused by the imaging distance and


FIGURE 1: Cloud computing hierarchical architecture topology.

image pose changes. Gray normalization is used to compensate the image obtained under different illumination and light source directions, so as to reduce the change of the image signal caused solely by the illumination change. This step completes the task of finding the image area in the input image. After an image is given, we check whether there is an image in the image, and if so, we give the position and range of each image. Because image detection requires detecting the existence of images and determining their position from various scenes, it is also called image positioning (positioning an image in a scene is also called segmentation). If a static image is an input, each image will be tested. If the input is video, you need to obtain the image area in every frame in the entire sequence. In addition to detecting each frame as a static image, the common strategy is to detect only the first frame of the sequence and track the following frames with the detection results of the previous frame.

Figure 2 is a pie chart of image recognition input information. External input information is transmitted to the cloud computing network through the input layer. The neurons in the input layer transmit information to the hidden layer through a certain relationship. The hidden layer is responsible for information processing. The hidden layer can be set to a single implicit according to data processing needs. After the information is processed, the hidden layer passes the information to the output layer neurons through a certain relationship, and the output layer further processes the data and outputs the information processing results to the outside. The process of inputting external information from the input layer to outputting the output layer is a process of forward transmission and learning of information. If the actual output of the cloud computing network does not meet the expected output requirements, the network will propagate the error back to the output layer,
FIGURE 2: Fan graph of image recognition input information.

hidden layer, and input layer, layer by layer, and adjust the thresholds of each layer and the adjacent two layers according to the error gradient descent method. The above process is continuously repeated until the output error is reduced to the desired level or reaches the set step. This module is based on the foundation of the subspace image recognition module, provides the function of calculating and storing data, and is the guarantee of the system's operational efficiency. The distributed structure of cloud computing improves the computational efficiency of image recognition algorithms to use HBase to store the image and its feature values for classification services.

3.3. Parameter Allocation of Administrative Management Events. Users in the administrative area can obtain the services they need from a complete computer infrastructure through the Internet. IAAS is a business model that allocates hardware resources such as data centers and infrastructure to users through the Web. The advantage of infrastructure services is that users do not need to purchase high-quality equipment but only need to build an application system that meets their needs through Internet leasing. Compared with a single agent, MAS has many unique characteristics: because multiple agents can work in parallel, they can solve the problem very quickly; the communication between the agent and the agent does not need to use raw data but adopts a high-level communication language. This greatly reduces the communication traffic; the function of a single agent is relatively simple, and the agents in the MAS system can cooperate with each other and share tasks to solve some complex large-scale tasks when a problem occurs in a certain agent in the MAS system. Compared with the traditional model, for an enterprise and organization, cloud computing can put the data center in the cloud, and professional companies can provide them with different levels and types of information services. When the responsible task fails, MAS can quickly introduce other agents or replace them with other agents to complete the corresponding tasks, which greatly improves the reliability of the system. Distributed computing technology is also the core of cloud computing technology, which is mainly developed and utilized under the premise of factors such as availability, reliability, and economy. The representative applications of distributed data storage systems in cloud computing mainly include GFS (Google file system) and HDFS (Hadoop distributed file system).

Cloud computing is a comprehensive computing method that combines parallel computing, distributed computing, and grid computing. The development of Internet of Things technology must rely on technologies such as high-efficiency storage and high computing power. Figure 3 shows the parameter assignment of administrative management events. The Internet of Things combined with cloud computing technology collects and organizes data and information through smart devices such as wireless sensors and radio frequency identification and then transmits it to the cloud computing platform at the application layer to realize data sharing and exchange and complete the control and management of the entire system. By selecting an appropriate matching strategy, the image to be recognized can be matched and compared with the known image in the database, the correlation between them can be established, and the judgment decision made can be output. There are two kinds of recognition purposes and situations that need to be distinguished: one is to verify the image, that is, to confirm whether the person in the input image has an image in the database, which belongs to supervised recognition; the other is to recognize the image, namely, to confirm the identity of the person in the input image, which belongs to unsupervised recognition. Based on the summarized

functional requirements analysis, the spatial structure administrative management IoT system should consist of the following parts: a perception network responsible for the collection and control of project site monitoring information and file integration to achieve reliable data between the project site and the remote monitoring and control room transmission network channel according to the user's instructions to call resources to perform various data analyses, and at the same time responsible for the intelligent processing cluster for data storage to provide users with rich visual design and data application display terminals and to realize the user's manual connection with the underlying data through the data interface management terminal for identification and modification.

3.4. Weight Update of IoT Model. Hadoop under the Internet of Things model is a software framework that can perform distributed processing of large amounts of data. It implements Google's MapReduce programming model and framework. It can divide applications into many small work units and put these units in any cluster. In MapReduce, an application that is ready to be submitted for execution is called a "job," and the unit of work divided from a job that runs and each computing node is called a "task." In addition, the distributed file system (HDFS) provided by Hadoop is mainly responsible for data storage on each node and achieves high throughput data read and write. In terms of distributed storage and distributed computing, Hadoop uses a master/slave architecture. We run Hadoop through different background programs, which are composed of NameNode, DataNade, JobTracker, and TaskTracker. The NameNode and JobTracker are run on the Master node, and a DataNade and TaskTracker are deployed on each node so that the data processing program running on this node can directly process the data of the machine as much as possible. Other complex issues in parallel programming, such as load balancing, fault-tolerant processing, distributed storage, job scheduling, and network communication, are all handled by the MapReduce framework. The MapReduce processing data set has the following characteristics: the data set to be processed can be decomposed into many small data sets, and each small data set can be processed completely in parallel. Figure 4 shows the weight distribution of the image recognition model.

The application layer is the top layer in the Internet of Things architecture and the core layer in most Internet of Things systems. The application layer needs to intelligently process and comprehensively manage the collected massive data and provide user-oriented human-computer interaction and data visualization design. The application layer can be divided into an application support sublayer and an application service sublayer. The tasks to be processed by the application support sublayer include postprocessing applications such as data storage, mining, analysis, query, and search. On the basis of data processing, we realize cross-industry, cross-regional, and cross-system information
Figure 3: Parameter allocation of administrative management events.
Figure 4: Weight distribution of image recognition model.

sharing, serving individuals, and organizations in different industries; the application service sublayer is a human-computer interaction interface set up for users to realize the interaction between users and applications order issuance and result feedback. Offline processing in an image recognition system refers to a series of preparations that the image recognition system needs to complete before accepting user queries to recognize images and pictures. This part of the work solves the problem of preprocessing and feature extraction of massive image data, mainly including image and picture preprocessing module, feature value and feature vector extraction module, and feature value access. The main feature of offline processing is that the real-time requirements are not high, but the image and picture index needs to be established in advance.

4. Application and Analysis of System-Assisted Administrative Management Event Parameter IoT Model Based on Cloud Computing Image Recognition

4.1. Cloud Computing Data Feature Extraction. The network structure of this experiment uses a four-layer deep belief network, the input layer is 784 neurons, the second and third layers as hidden layers each contain 500 neurons, and the last layer is the label layer and contains 10 neurons. We, respectively, represent the network weight between each layer. The Siegert neuron is used for network training, and the training method is the CD algorithm. The experiment content is divided into two parts. The first part is the

recognition mode, and the second part is the generation mode. The recognition mode is to give a gray image of handwritten digits to recognize numbers, and the generation mode is to give numbers and let the network generate handwritten digits in reverse. When the feature has a small displacement, the complex cell can ignore this effect, and the information obtained remains unchanged. This feature correspondingly achieves the pooling operation in the convolutional neural network. The grayscale image is reconstructed from handwritten digits. When testing the recognition speed of a single picture in the recognition mode, the LIF neuron is used, and the gray value of the picture needs to be normalized to a value between 0 and 1, and the pulse sequence is determined according to the proportion of each pixel value. In order to further enhance the consistency of the image mode, the statistical characteristics of the sample pictures can be normalized, considering the most basic statistics—the mean value and variance of the grayscale—and adjusting them to a given value.

Figure 5 is the feature vector curve of image recognition calculation data. When the image boundary is relatively smooth, the area density is smaller, and its density C is approximately equal to 1. When the shape of the image area deviates from the circle, the C value is smaller. When the edge of the image changes drastically, the perimeter of the image increases, but the area is relatively reduced, resulting in an increase in area density. Therefore, the area density C reflects the characteristics of the target topography to some extent. Here, we use edge detection to segment the subimages, because the canny operator has the characteristics of single edge response, accurate positioning, and no false edges. At the same time, it has the first and second derivatives of the image in the area edge extraction advantage. The specific steps are as follows: first, perform median filtering on the subimage extracted in the original image; then, perform image enhancement on the filtered subimage; secondly, use the canny edge detection operator to segment the enhanced subimage. Then, we use the morphological open operation and close operation processing and, finally, remove the small connected domains in the subimage.

4.2. Image Recognition IoT System Simulation. Handwritten image recognition is a classic experiment to verify the accuracy and efficiency of the network model. The data set used is the MNIST data set. The training data includes 60,000 handwritten digital grayscale images, and the test set includes 10,000 handwritten digital grayscale images. The image content is a number from 0 to 9, and the pixel size is $28 * 28$. Online processing refers to a series of tasks that the image recognition system needs to complete for the user to feed back the query results after the user enters the image picture or the person's identity information. This part of the work mainly includes the following: according to the image picture that the user needs to query or the person's identity information that needs to be queried, we find the corresponding person's identity information or image pictures from the HBase image database index file. The salient feature of online processing is that the real-time requirements are
Figure 5: Image recognition calculation data feature vector curve.

very high, but all the image and picture data must be compared, so the calculation efficiency is relatively high. In this system, the video capture terminal and the front-end processing terminal are configured in the front-end monitoring, and the monitoring video is collected and obtained through the video capture terminal. The obtained video information can be directly transmitted to the cloud computing system through the transmission network or realize information processing through the front-end processing terminal. Generally, in order to ensure the robustness and usability of the system, multiple video capture terminals from different angles are generally set up in the monitoring area, and the coordination between the terminals is realized through the configuration of monitoring and management software.

In order to port the image recognition application to embedded devices, this section selects the Raspberry Pi 3rd Generation B-type and USB camera as the hardware device. The Raspberry Pi hardware uses the ARM Cortex-A53 chip as the processor, and the operating frequency is 1.2 GHz. Normally, when using a computer to process data, the continuous time signal will be discretized, and the given value is the data at a specific time interval. So, a more realistic assumption is that the sensor will give a measurement result every second. Although the Raspberry Pi is very small, it also has functions such as WIFI and Bluetooth. It can also communicate with other devices through GPIO pins. Figure 6 shows the accuracy of image recognition based on the Internet of Things. After adding IP, the recognition accuracy of the entire network has improved. It can be clearly seen that 94% is a demarcation point. When the initial discharge rate is greater than 700 Hz, the accuracy fluctuates on the line, but the final value is greater than 94%. In contrast, no IP mechanism was added. When the initial discharge rate was greater than 700 Hz, the recognition accuracy showed a fluctuating downward trend. It can be seen that the time consumed to recognize a single handwritten digital grayscale image is related to the initial discharge rate. After adding IP, when the initial discharge rate is greater than 200 Hz, the average time to recognize a single handwritten digital grayscale image is about 2.5 ms. Without adding IP, when the initial discharge rate is 1000 Hz, the recognition speed is about 5.8 ms. From this analysis, it can be seen that this IP mechanism has improved the recognition accuracy of the network, and the main impact lies in the improvement of the network recognition speed. Then, we want to know why the
FIGURE 6: Image recognition accuracy based on the Internet of Things.

IP mechanism has such a big impact on the network recognition speed, and it can be seen that when the initial discharge rate is greater than 200 Hz, the broken line tends to be stable, with little fluctuation up and down.

4.3. Example Application and Analysis. In the cloud computing network, the ICP adopts a unit modular design and a universal platform that can control and connect a variety of different types of communication systems such as wired and wireless. As the core control device, ICP has dedicated interfaces for different communication methods, and each interface corresponds to a specific communication access device. The ICP interface supports an analog trunking interface, conventional intercom interface, shortwave radio interface, and GSM/CDMA mobile phone interface. Each interface independently completes the receiving and sending of audio signals, and at the same time, it can achieve complete control of the equipment for specific access devices. In order to improve the voice quality, all voice interfaces adopt a four-wire processing method to separate the sending and receiving signals to avoid mutual at the same time; in order to realize that each port can perform two-stage dialing, the external interface in the device has the independent DTMF signal detection and forwarding capabilities. Figure 7 shows the trend of image recognition transform and decomposing signals.

The process of using wavelet transform to locate the high-frequency components is as follows: decompose the image by wavelet transform, then set the low-frequency part to 0, keep the high-frequency part unchanged, and then perform inverse wavelet transform to complete the localization of the high-frequency components of the original image. In this article, the Mallat algorithm is used to decompose the image, by using Daubechies 9–7 wavelet to obtain 4 subband parts and then zeroing the low-frequency part to ensure that the high-frequency part remains unchanged; then, the reconstruction is performed, and the high-frequency part can be obtained. At the same time, we can select a suitable frequency value, which is between the defocus component, background, and component, and use this frequency value as a threshold for threshold processing.
FIGURE 7: Image recognition transformation and decomposition signal trend.

The value above the threshold is 1; otherwise, it is 0; then the place with dense brightness is urine sediment. The position of the components is finally based on the empirical threshold of the image, and the corresponding binary image is obtained by simple discrimination.

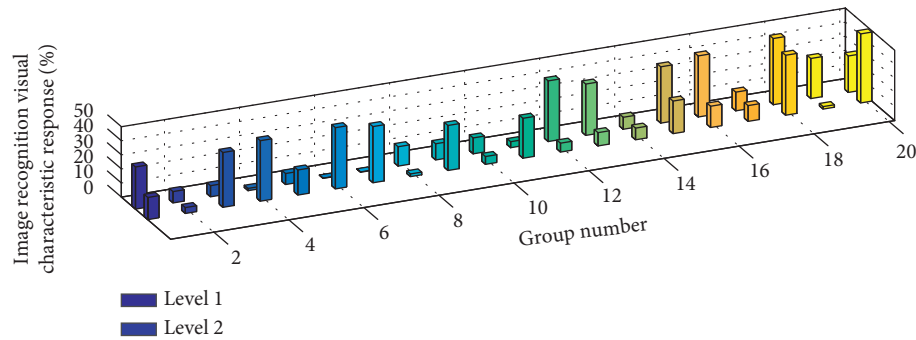
This paper uses the VGG network pretrained on ImageNet as a model for extracting image visual features. The 1 million images provided by ImageNet make VGG can train more accurate features than manual design. In order to make the feature more versatile, this study uses the 4096-dimensional vector output by the layer in VGG-16 as the visual feature of the image. Figure 8 is a histogram of the frequency response of image recognition visual features. The input layer continuously receives the stimulation of the Poisson pulse sequence over time. When the neuron membrane voltage of the input layer exceeds the threshold, the neuron fires and transmits the pulse to the next layer of neurons. When the third layer of neurons fires, the final result is displayed in the last layer, and the last layer is a $2 * 5$ matrix, which means 0, respectively. The pooling process also has the function of adjusting the output size. In practical applications, for the convolutional neural network model, when the size of the input image is different, in order to obtain a uniform size output, it needs to be realized by pooling operation at this time. The 10 numbers to 9 are numbers, among which the white dots represent the firing neuron and the corresponding identified number. It can be seen that the


FIGURE 8: Image recognition visual feature frequency response histogram.

second neuron is firing, which means that the identified number is 1. When the threshold is unchanged, we change the film time constant between 5 and 20, and the accuracy fluctuates up and down. When the threshold is between 0.2 and 1.8, the accuracy fluctuates greatly. It can be seen that the threshold is one of the main parameters that affect the accuracy of network recognition. When the threshold value is 1.5, the accuracy reaches the highest value of 93.77%.

5. Conclusion

This paper proposes a dynamic administrative management construction model based on the cloud computing network, which uses the cloud computing network as the intermediary of the connection and the decision-making body for the construction of administrative management. When choosing, the good classification performance of the evolution cloud computing network is applied, and the resource capacity of the Internet of Things can be selected. According to the matching of information and order requirements, the most suitable node Internet of Things is selected to form an optimal administrative management for the corresponding order. The system uses the traditional image recognition algorithm (PCA) and the cloud computing environment to meet the computing efficiency requirements of users for mass image recognition. Certain improvements take the use of image classification algorithms that assign weights and dynamic k values to image images to improve recognition accuracy and stability. Finally, the experiment shows that the system meets the user's requirements for the efficient calculation efficiency and recognition accuracy of the image recognition system. When modeling a dynamic supply chain with time-lag characteristics, applying the orthogonal neural network method can effectively improve the stability of the model, the speed of convergence, and the ability to approximate the optimal solution. The organizational system and structure of dynamic administrative management need to be built on a certain integrated operation platform (including knowledge/skill network, information network, logistics network, and sports network), and the basic platform for dynamic administrative management is also used to a large extent. The above stipulates the specific operation model of dynamic administrative management. Finally, using MatLab to simulate the model, the results show that the dynamic administrative management proposed in this paper has better performance than static administrative management. It can

not only reduce costs but also meet more demand orders. The two-dimensional incentive mechanism can effectively stimulate the overall efficiency of administrative management.

This paper uses an improved multiorganizational particle population optimization algorithm to conduct an in-depth analysis and study of an online English teaching model and uses the altered model for practical applications. The model building elements are extracted from it for the initial construction of a blended learning model of English-speaking teaching in junior high school. The main purpose of the first round of action research is to test the rationality of each element of the model, the main purpose of the second round of action research is to refine the model links and improve the operability of the model, and the main purpose in the third round of action research is to test the perfected model and explore the model. The main purpose of the third round of action research is to test the refined model and explore the application suggestions of the model. After the three rounds of action research, we finally obtained a more mature blended learning model for teaching English as a foreign language in junior high school. Mainly through the comparison of the pre- and posttest scores of English speaking of the experimental subjects and the comparison of the pre- and posttest data of the relevant questionnaires, the following experimental conclusions were drawn: adopting the blended learning-based speaking teaching model can effectively improve students' interest in learning English, their attitudes and their English speaking skills including pronunciation, phonetic intonation, conversational communication, and oral expression and can enhance students' group cooperation and communication ability, independent learning ability, evaluation awareness, and ability. This single-guided learning mechanism can effectively avoid the shocks that are easily caused by the dual-guided role of traditional PSO. The dimensional learning strategy constructs a learning paradigm for each particle by learning from each dimension of the individual optimal position of the particle to the corresponding dimension of the group optimal position, respectively. Dimensional learning is formally integrated into the learning paradigm only if it can improve the fitness of the paradigm so that the dimensional learning strategy can avoid the phenomenon of degradation of the learning paradigm and the phenomenon of "two steps forward, one step back." In the dimensional learning strategy, since each particle learns from best, although it has a strong exploitation capability, it may cause all particles to converge to best quickly, making the algorithm converge prematurely.

1. Introduction

With the development of information technology, traditional classroom teaching can no longer meet the diverse needs of teachers and students in terms of time and location, while online teaching breaks the time and space constraints of traditional classroom teaching and creates an environment where students can learn even outside the classroom.

For this reason, the addition of information technology has led to dramatic changes in the format of teaching, the types of teaching resources, and student learning behaviours. A new teaching model that combines the advantages of online teaching and traditional offline teaching, the hybrid teaching model, has emerged [1]. Offline teaching and online teaching have their advantages and limitations and cannot replace each other. Hybrid teaching mode is a teaching model that

combines the advantages of traditional offline teaching and emerging online teaching [2]. This model makes educational resources richer and learning activities more diverse, especially with the popularity of mobile terminals such as smartphones and iPods and the rapid development of some excellent APPs, which allows students to learn conveniently and quickly anytime and anywhere with a single click on their mobile phones, breaking the limitations of time and space for students in traditional teaching. In recent years, the smart campus is being rapidly built and promoted, education data is growing exponentially, and education is rapidly moving into the era of big data [3]. Teaching is a dynamic, interactive, and continuous process, which is bound to generate a large amount of timely and diverse data. This data serves as a basis for judging student learning, which in turn responds to teachers' teaching standards. Therefore, mining and analysing the data is necessary. Learning analytics is precisely the measurement, collection, analysis, and reporting of educational data, using different techniques to analyse learning data to discover student characteristics and understand teaching and learning. Common techniques include statistical analysis, cluster analysis, and correlation analysis. With the popularity of smart campuses, increased educators and researchers are coming to focus on students' learning behaviours. With the development of information technology in education, learners have increased ways to acquire knowledge and have higher requirements for education, with more focus on whether teachers can tailor and personalize their teaching. Personalized teaching is a new form of teaching that has emerged in recent years, and it is a way to achieve good teaching results by stimulating learners to think and develop [4]. The teaching process will be optimized for the needs of each learner and is closely related to the learner's interests. In the context of education informatization, education big data, and personalized teaching, the blended teaching model has emerged. It is of strong practical significance to analyse students' learning behaviour under the blended teaching model. Dimensional learning can only be formally integrated into the learning paradigm on the premise that it can improve the fitness of the paradigm. Therefore, the dimensional learning strategy can avoid the phenomenon of learning paradigm degradation. To gain a deeper understanding of the teaching of blended teaching mode and analyse students' learning behaviours under the blended teaching model, this study classifies students with the characteristics of learning behaviours, explores the correlation between learning behaviours and academic performance, and identifies the factors affecting learning behaviours. It is applied in practice to make up for the lack of research on learning behaviour in blended learning and teaching.

Particle swarm optimization algorithms are the primary choice for optimization problems due to less memory required, easy implementation, faster convergence, and the ability to provide better performance on different benchmark test functions and engineering problems. Particle swarm optimization algorithms are population-based iterative algorithms and the requirement of many evaluation functions for computation makes particle swarm

optimization algorithms inappropriate for optimization areas where fitness computation is time-consuming. In solving complex problems with multiple extremes, the standard particle swarm algorithm tends to fall into local extremes, resulting in premature convergence without finding the optimal value of the entire search space; when the dimensionality of the search space is high, the algorithm has poor search capability [5]. These drawbacks have limited the wider application of particle swarm optimization algorithms. Therefore, speeding up convergence and avoiding getting into local extremes have become two of the most important and attractive goals in the research of particle swarm optimization algorithms. Exploration and exploitation are the two main search mechanisms in the search for optimal solutions in particle swarm optimization algorithms. To achieve fast convergence and avoid getting into local extremes, one must balance the exploration and exploitation capabilities of the population [6]. Exploration searches the region of the search space with potentially optimal solutions; more refined searches performed in the vicinity of the population optimal solution. Overemphasis on exploration will lead to a decrease in convergence by wasting search time in nonoptimal regions. On the other hand, overemphasis on exploitation will reduce the diversity of the population in the search process, which may be the population caught in the local optimal region. Therefore, how to balance the exploration and exploitation capabilities in the search process is a question worthy of deeper investigation.

In this paper, a two-population particle swarm optimization algorithm with a dimensional learning strategy is proposed from the perspective of effectively discovering and preserving good information in each dimension of the population, and the ability of the proposed algorithm to balance exploration and exploitation intensity is discussed. The particle swarm optimization algorithm is a heuristic stochastic search algorithm, and this stochastic search mechanism lacks certainty and does not guarantee that the algorithm can necessarily find the optimal solution. Online learning platforms provide students with rich resources, such as text, images, audio, video, and animation, but these resources mostly presented directly, the organization of resources is confusing, and the content and quality need to be further optimized. This leads to the phenomenon of students' knowledge being lost in the face of numerous learning resources. Again, there is a lack of relevance and adaptability. Although student autonomy has been increased, the content and path of learning remain neat and uniform for everyone, and the test questions are fixed.

1.1. Status of Research. How to break the shackles of traditional teaching methods and achieve the personalized development of students has become a major dilemma facing education in China at present [7]. With the development of big data, cloud computing, and artificial intelligence technology, the way of learning, teaching, and cognition is undergoing radical changes. Especially the development of big data in education makes the collection

and deep analysis of educational data possible and makes the sharing of educational resources a reality [8]. How to be able to collect and integrate data and use the data to discover the hidden behind it becomes an important way to enhance the core competitiveness of education, and the whole society has entered the era of big data, helping particles escape from local extrema. TSLPSO reduces the pressure of DLPSO adaptability assessment by introducing dimensional learning subgroups. The education field has set off a boom of promoting education reform and development based on big data in education, and the research on big data has shown an unprecedented development momentum [9]. At the level of applied research, a personalized adaptive learning platform based on big data has become the focus of research. Adaptive learning platforms collect student interaction data based on big data technology and dig deeper and analyse them for learning, providing students with personalized learning services according to the individual differences of learners, which have taken root in many countries and developed into personalized adaptive learning platforms [10]. The US Adaptive Learning Platform is one of the most mature adaptive learning platforms at present. After decades of research, it integrates the research results of psychology, measurement, cognitive learning theory, and intelligent learning systems and pioneers the design and application of personalized services for big data in education. By collecting students' online learning data, it can accurately predict and analyse students' strengths, weaknesses, learning interests, cognitive levels, and participation levels and personalize learning contents. It not only meets the needs of students to a great extent but also brings great convenience to teachers, parents, and school administrators in assessment and management [11]. At this stage, China has also made many useful attempts in the theory and practice of adaptive learning, but most of the research remains at the theoretical level, and there are few applications and practices in this area, and there is no mature adaptive learning platform yet. Therefore, through the study of Newton's adaptive learning platform in the United States, it can inspire the development of adaptive learning platform and personalized teaching in China.

The neural network uses a multilayer structure where the basic processing unit is a neuron in each layer of the network and contains both linear superposition and nonlinear activation as two types of computation, so mathematically speaking, a neural network is a structure with nesting that can be used to describe highly and nonlinear mapping relationships [12]. Neural networks are not all smooth sailing, it has experienced many troughs since it was proposed, but each time it came out of the trough was when it made a breakthrough and gradually became the core algorithm of current artificial intelligence [13]. Its main feature is the backpropagation algorithm, thus significantly reducing the time required for model training. Subsequently, scholars have never stopped their research on BP neural networks. Because it did not have the problem of gradient disappearance like the neural network that used more layers of the network in the environment with a relatively small amount of data at that time, this

algorithm with the characteristics of simplicity and efficiency, fast training speed, and applicable to small sample size once overtook the deep neural network to become the mainstream of machine learning.

It has attracted many scholars and researchers to conduct in-depth research on it, thanks to its relatively simple concept, relatively easy implementation, and better global search capability when solving some more complex optimization problems, such as when the objective function is multipeaked, nonlinear, and nonderivative. Nowadays, the PSO algorithm has been applied to many engineering practices such as pattern recognition, intelligent robotics, and signal processing. The improved algorithm is used to solve the selection of parameters in the training process of machine learning, to improve the model performance and make the BP neural network in the initialization stage be in a relatively low loss for training, and to achieve the training requirements faster and better model and also can make the SVM model have better hyperparameters and the model after training have better results.

2. Improved Multiorganizational Particle Population Optimization Algorithm for Online English Teaching Model Applications

2.1. Improved Multiorganizational Particle Population Optimization Algorithm Design. The topology of a population defines the way information is shared and information has interacted between particles. Particle swarm algorithms based on neighbourhood topology control the exploration and exploitation capabilities of the algorithm according to the different information-sharing mechanisms between particles. A new information flow mechanism is proposed to update the position of each particle, namely, the full information particle swarm optimization algorithm (FIPS) [14]. The FIPS algorithm uses a weighted average of the individual optimal positions of all neighbouring particles to update the position of a given particle. The unified particle swarm optimization (UPSO) algorithm is proposed, which uses the optimal experience from both local and global neighbours to control the exploration and exploitation capabilities of the population. A dynamic neighbourhood learning particle swarm optimization (DNLPSO) algorithm is proposed, where exemplar particles are selected from the optimal positions of neighbouring particles including itself so that the velocity of a particle may be influenced by both the historical experience of its neighbours and its own historical experience; when the population perceives that the search has stalled, the population changes the flow of information. When the fitness of particle i does not improve within K generations, the particle is judged to be in stagnation, at which point the particle updates its neighbours by linking a new particle [15]. The particle uses a betting round selection strategy (based on particle fitness ranking) to select a new neighbour. In this way, underachievers who lack practice must complete as many as eight question sets or more, while students with stronger learning ability may complete adaptive follow-up after one question set.

Analysis of the PSO algorithm formulation shows that the particle flight trajectory is influenced by its own flight experience (individual optimum) as well as the global optimum information in the early stages and converges to the global optimum in the later stages [16]. This suggests that there is a better global optimum information point that will be able to guide the particle towards a better solution space. To obtain better global optimum information, the HPSO algorithm is proposed to achieve the position update by performing multiple Corsa mutations on the optimal particles. Most of the current mutation strategies for optimal particles pick all dimensions or randomly pick some dimensions for mutation; for high-dimensional complex functions, the computation of their fitness will be inefficient due to the interference between dimensions, which causes some dimensions to become better but be masked by other dimensions that become worse; compared to multiple mutations, the dimension-by-dimension mutation is more efficient. The obtained variational solutions are usually better [17]. Based on this, a variational strategy of dimension-by-dimension backward learning of the centre of gravity for the best particles is proposed, where dimension-by-dimension variation can reduce interdimensional interference and backward learning of the centre of gravity can expand the search space, increase the diversity of populations, and improve the convergence accuracy. However, the computational overhead of dimension-by-dimension backward learning is large, and it is not suitable for all particles to be mutated dimension by dimension:

$$Gbest_i = 3 \times k \times M_i + Gbest_j. \tag{1}$$

With the advent of the network era and the transformation of learning tools, methods, and resources, a more suitable connectivism for the digital information age is proposed based on behaviourism. Among them, connectionist learning theory believes that the starting point of all knowledge and learning is the individual, and the individual's knowledge can form a network, and in the process of learning and sharing knowledge, the nodes of the connection network and the nodes of other individuals, organizations, or institutions collide and interact with each other, and the connection of old and new nodes makes the continuous expansion of the individual's original network form a larger knowledge network. In the process of online collaborative learning, learners no longer exist as individual individuals but form learning groups through their will and rational choice and complete teaching tasks with learning groups as the basic unit. The learner's knowledge network collides and interacts with the knowledge networks of other members of the learning group, jointly expanding the original knowledge network, improving the learner's knowledge framework system, and enhancing the effect of online collaborative learning, as shown in Figure 1.

From the above example, we can see that when the dimensional learning strategy constructs a learning paradigm, each time the dimensional status of the temporary paradigm is updated, it is compared with the current learning paradigm, and if it is better than the current learning paradigm, the learning paradigm is updated to the current temporary paradigm; otherwise, the current learning paradigm is not changed and the learning process continues for the next dimension. The effect of face-to-face oral English teaching has been greatly improved. After class, dialogue exercises are arranged through the wing class network, and dialogue exercises are continued through the WeChat group cooperation group to achieve language review, consolidation, extension, and expansion and train students to speak and use English after class, which are good speaking habits:

$$Div = \frac{1}{n}\sum_{i=1}^{m}\sqrt{\sum_{j=1}^{m}\left(x_{i,j}+x_j\right)^2},$$

$$x_j = \frac{\sum_{j=1}^{m}\left(x_{i,j}+x_j\right)^2}{n}. \tag{2}$$

We give plots of single-peaked and multipeaked functional diversity. The dimensionality of the search space in the diversity validation experiment is 30 dimensions, the function is evaluated 300,000 times, and the population size is 20. It is seen that the integrated learning subpopulation diversity is higher than the diversity of the dimensional learning subpopulation, and the diversity of the whole population lies between the two subpopulation diversities. The results from the diversity show that the dimensional learning subpopulation maintains a smaller population diversity and therefore converges quickly. As expected, the integrated learning subpopulation maintains a higher group diversity because there is no information as a central guiding direction, so the group does not converge to a smaller extent quickly. The balance of exploration and exploitation provided by the dimensional learning subgroup in collaboration with the integrative learning subgroup resulted in an intermediate diversity ranking for the whole group, indicating that the integrative learning strategy we introduced did increase the diversity of the group. Thus, the results of the diversity comparison validate the design expectation that the dimensional learning subgroup tends to local exploitation, while the integrated learning subgroup tends to global exploration. The interaction and cooperation of the two subpopulations ensure global search and fast convergence of the population:

$$f_7(x) = \sum_{i=1}^{n}\left[x_i^2 + 10\,\sin\left(2\tau x_i\right) - 10\right],$$

$$f_{16}(x) = \sum_{i=1}^{n}\left[a_i x_i^2 - 10\,\sin\left(2a_i\tau x_i\right) + 10\right]. \tag{3}$$

It is difficult to find its optimal solution for most of the algorithms, and when the dimension of the search space is higher than 3, it can be considered as a multipeaked function (Figure 2). Therefore, most of the algorithms have unsatisfactory results on functions. Although the optimal solution for the 3 functions out of 5 single-peaked functions is found, one more than the proposed one, it performs the worst on the function. Even though only the dimensional learning strategy was used, it still achieved the optimal result on the noise function. Overall, the algorithm shows better robustness on the single-peaked functions (i.e., the first 5 benchmark functions)
FIGURE 1: Framework of improved multiorganizational particle population optimization algorithm.
FIGURE 2: Contour plot of the function.

and thus obtains a smaller sum than the champion algorithm. Multipeaked functions contain multiple locally optimal solutions, which may lead to premature convergence of the PSO algorithm. It is difficult to find the global optimal solution of the function with conventional PSO because the problem has many deep local optima far from the global optimal solution. The nodes of organizations or institutions collide and interact with each other, and the connection of new and old nodes makes the original network of individuals continue to expand and form a larger knowledge network. Once a particle of classical PSO is trapped in a deep local optimum, it is difficult to escape. The improved multiorganizational particle population optimization algorithm has better resistance to the local optimum trap and thus achieves a high accuracy of 3.82E-04. The other 5 bodies, however, cannot converge to the global optimum effectively, and the worst result is 2.38 E+03. Functions are very complex multipeaked functions with many local extrema. For this problem, algorithms that maintain better diversity tend to produce better results. The algorithm achieves

the optimal solution on both functions, 0. This is due to the dimensional learning strategy and the integrated learning strategy used in the algorithm TSLPSO, which effectively enhances the diversity of the particle search while improving the convergence accuracy.

The users have different rating values for the target object, so a weighted average of the ratings is taken as the prediction result, and the weights can be obtained from the similarity between similar users and the target user:

$$R_{ik} = \mu_{ui} - \frac{\sum_{i,j} P(U_i U_j)}{\sum_{i,j} P(U_i^2 U_j^2)^2}. \tag{4}$$

Matrix decomposition is the decomposition of a matrix into the product of two or more matrices. Matrix decomposition-based recommendation algorithms are used to build user rating prediction models by modelling known user ratings of objects, which are mainly applied to two scenarios: rating prediction and TOP-N recommendation. Currently, the widely used matrix decomposition-based recommendation algorithm is the number of hidden factor models (LFM). The basic idea of LFM is to link user interests and items through implicit features, that is, the existence of similarity. The earliest appearing hidden factor model is the singular value matrix decomposition model, referred to as SVD, which is calculated as

$$R_{M \times N} = U_{M \times N} \sum M(M \times N). \tag{5}$$

According to Wittrock, the king of generative learning theory, the essence of learning is a process of active construction and generation of meaning, in which learners construct meaning by actively establishing relationships between external stimuli and their original cognition. This construction of "special associations between external information and existing knowledge and experience" is called generation. The basic assumption of generative learning theory is that "the human brain is not a passive recipient of

information, but an active constructor" [18]. In other words, the learner is not a passive recipient, but an active participant in the learning process, actively constructing a meaningful understanding of the information in the surrounding environment. However, without attention, motivation, and existing knowledge in memory, the construction of relationships between existing knowledge and new information will not occur. The comprehensive learning subgroup maintains a high group diversity, because there is no information from the central guide, so the group will not quickly gather into a smaller area. By assimilating Plus's information processing theory, Wittrock proposes the information processing process of the generative learning model: attention, motivation, prior knowledge experience, and generation. Attention is the directional factor that guides the generative process, which points the generative process to prior knowledge and experience. Motivation refers to the desire to actively generate these two connections and to attribute the effectiveness of generating them to the degree of one's effort; prior knowledge and experience include existing concepts, reflective cognition, abstract knowledge, and concrete experience, and the learner's prior cognitive structure and level are extremely important in generating the meaning of things; generation refers to the intrinsic connections that form new knowledge and the connections between new knowledge and existing experience.

2.2. Design of Online English Teaching Model Applications.
Constructivism assumes that students' knowledge is constructed based on their prior knowledge experiences and cognitive structures and is actively acquired through meaningful construction. The meaningful construction of knowledge requires interaction with the external environment and the use of other aids from certain situations, for example, with the help of other people including teachers, classmates, and peers, using the necessary learning materials and learning resources. Constructivist learning theory emphasizes the cognitive dynamics, the contextual nature of learning, the importance of resources for the construction of meaning, and the design of the teaching environment. The learning-based instructional design theory is developed in response to the above requirements of constructivist learning. It provides new ideas and new ways of designing and transmitting teaching and learning to overcome the one-way transmission, passivity, and closure in traditional instructional design. This instructional design theory is particularly clear in the diagrammatic representation of the constructivist learning environment model proposed by David Jonathan, a contemporary advocate, and promoter of constructivist instructional design, as shown in Figure 3.

Blended learning has teacher-led student-led as its core idea, and both teacher teaching and student-led learning are extremely important. Constructivist learning theory also emphasizes the dual role of teaching and learning, which has a guiding role in the design of blended learning models. At the same time, constructivism attaches importance to the design of the teaching environment, and blended learning has rich multimedia and network technologies that can
Figure 3: Diagrammatic representation of the constructive learning environment design model.

provide material support for the learning environment required by constructivism. Through the guidance of constructivist theory, the teaching objectives of blended learning can be effectively achieved and students' abilities in all aspects can be developed [19]. Once the particles of the classic PSO fall into the deep local optimum, it is difficult to escape. It has better ability to resist local optimal traps, so it has achieved a high precision of 3.82E-04. The researcher believes that with the development of mobile Internet technology and the improvement of information delivery tools, constructivist learning theory will continue to be further developed as the concept of blended learning is proposed and practiced and provides a broader space for putting it into practical application.

When teaching English as a foreign language in a blended learning environment, the first step for teachers is to present speaking tasks. Driven by the tasks, students can use their minds to use English actively by completing specific tasks and actively participate in various tasks to truly "learn by doing" and gain and accumulate corresponding learning experiences and enjoy the fun of learning. In the practical application of oral English teaching, task-based teaching makes students immerse themselves in the situation, truly gain emotional experience and adjust learning strategies, form a positive learning attitude, and promote the improvement of their practical language skills. The flexible use of cooperative learning in blended English speaking teaching activities can create a classroom atmosphere, stimulate students' interest in learning English, overcome classroom anxiety, and motivate students to actively exert their subjective initiative or maintain a high level of participation in online learning, increase the opportunities for students to use English to communicate and complete speaking learning tasks together, and improve students' speaking learning performance and speaking communicative competence.

Multiobjective optimization problems exist with multiple optimization objectives, and these subobjectives are often independent and conflicting with each other and cannot reach the optimal solution simultaneously.

Theoretically, most optimal grouping processes are multiobjective problems, and solutions should be designed in a multiobjective framework. Based on the educational theory of collaborative learning, the basic principle of learning group formation is "intergroup homogeneity and intragroup heterogeneity," where intergroup homogeneity ensures the success of all learning groups, while intragroup heterogeneity depends on different research topics and teachers' teaching needs. According to the specific requirements and principles in the proposed model of learning group formation, the multidimensional objective functions are set correspondingly. Due to the characteristics of the problem with many constraints, adding up the constraint violation degrees of all constraints may make the feasible domain of the algorithm smaller, which directly leads to few feasible solutions found and low reliability of the algorithm. Therefore, this study adopts the scheme of treating the constraint violation degree of each constraint as an objective separately, as shown in Figure 4.

In the real world, there do not exist any single-objective problems; in other words, single-objective problems are defined mainly for simplicity. This means that most of the time a person just chooses to consider the most important objective problem and ignores the others, thus converting a multiobjective problem into a single-objective problem. In addition, sometimes just one objective is chosen, and one or more other objectives are considered as constraints [20]. In both cases, the optimization process is simplified and redefined as single-objective optimization. Theoretically, most optimal grouping processes are multiobjective problems, and solutions should be designed in a multiobjective framework. Learning group formation as a multiobjective optimization problem is an essential and complex step in effective collaborative learning, and the purpose of this study is to propose a method based on a heuristic search strategy to enhance the intergroup homogeneity and intragroup heterogeneity of learning groups in collaborative learning environments, capable of grouping any number of prequalified learners with multiple characteristics into an arbitrary number of optimal inter- and intrahomogeneous groups [21].

Therefore, learning groups with smaller total mean deviation percentages are more favourable solutions. Through the information processing theory of absorption and addition, Whitlock proposes the information processing flow of the generative learning model: attention, motivation, prior knowledge and experience, and generation. The previous statement clearly shows that heterogeneity between groups and within groups is mainly reflected by values that reflect the average ability of all groups in a solution. Minimizing the overall error value of the learning group formula does not guarantee that the error values of all groups that make up the learners are minimized simultaneously. In other words, when the optimization algorithm is arranged to evaluate each learning group by its average fitness value, it is set to be insensitive to the fitness value of the constructing learners.

3. Results and Analysis

3.1. Performance Results of Improved Multiorganizational Particle Population Optimization Algorithm. To compare the convergence speed, reliability, and successful performance of the algorithms, Figure 5 gives some key metrics, including the average number of objective function evaluations (FEs), success rate (SR), and success performance (SP) of each algorithm when it successfully achieves acceptable optimization accuracy. FEs and SRs are used to quantify the convergence speed and reliability of the algorithm. From Figure 5, TSLPSO converges fastest on 7 benchmark functions, followed by DLPSO (fastest convergence on 4 functions, i.e., functions F2, F6, F7, and F14), GL-PSO (fastest convergence on 3 functions, i.e., functions F1, F3, and F10), and L-SHADE (fastest convergence on 2 functions, i.e., functions F4 and F5). From the results of SR, TSLPSO is the most reliable with an average success rate of 100%, followed by DLPSO with a success rate of 98.62%.

From the convergence graph of single-peaked functions, the algorithm TSLPSO shows high convergence accuracy and fast convergence speed on most of the single-peaked functions except for the function F5. The convergence graphs of the multipeaked functions show that the algorithm TSLPSO not only converges with high accuracy but also converges faster than most of the algorithms. Moreover, DLPSO with only a dimensional learning strategy shows very competitive performance on these multipeaked functions. Thus, TSLPSO is generally effective for both single-peaked and multipeaked functions in terms of accuracy and convergence speed.

Most existing PSO algorithms use a linear weighting of individual optimal positions, random combination by dimension, or orthogonal combination of individual optimal positions and group optimal positions to construct learning examples, which guide the particle search instead of individual optimal solutions and group optimal solutions in the classical PSO velocity update formulation. This single-guidance learning mechanism can effectively avoid the oscillation phenomenon that is easily generated by the traditional PSO double-guidance action.

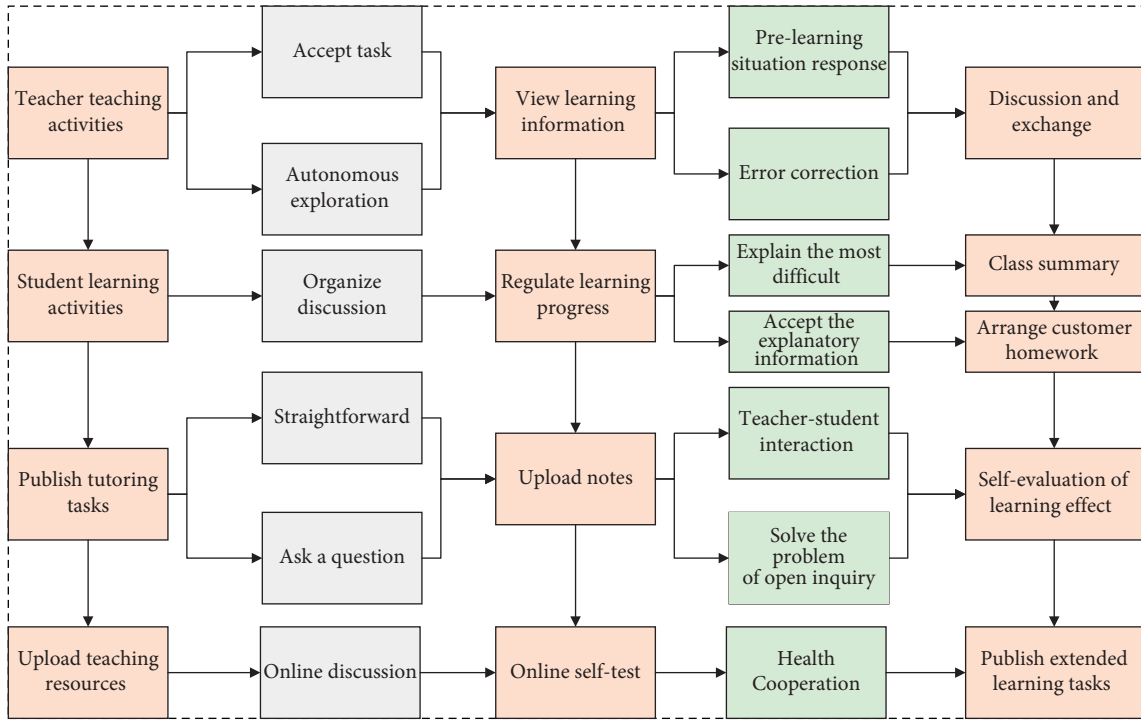
However, the learning paradigms constructed by the above methods are highly stochastic and cannot ensure that the learning paradigm will not degenerate even when the individual optimal solution and the population optimal solution evolve every generation. Particles learning from degenerate paradigms is not conducive to maintaining the efficiency of the algorithm. The dimensional learning strategy proposed in this paper allows each dimension of the individual optimal position of the particle to learn from the corresponding dimension of the population optimal position respectively when constructing the paradigm, and the dimensional learning is formally incorporated into the learning paradigm only if it can improve the fitness of the paradigm, so that the dimensional learning strategy can avoid the phenomenon of degenerating the learning paradigm and the phenomenon of "two steps forward, one step back" phenomenon, as shown in Figure 6.


Figure 4: Model application design model.
Figure 5: Comparison of the results of the tested algorithms on the benchmark function.

Although the learning paradigm constructed by dimensional learning can guide particles to search towards better regions, the fact that most of the particles are close to the population optimal position may cause premature convergence problems. To address this problem, we introduce an integrated learning strategy to enhance population diversity and help particles escape local extremes. TSLPSO alleviates the pressure of DLPSO adaptation evaluation by introducing dimensional learning subpopulations. Learners exhibit differences in learning behavior characteristics across resource presentations when learning online. In exploring document-based learning resources, this subsection focuses on three dimensions of learners' learning characteristics, namely, different learning knowledge types, course resource hotness, and course resource learning attainment, and the data visualization results are shown in Figure 6. During the study, the courseware resources that do not meet the procedural and descriptive knowledge characteristics are manually screened out, and only the courseware resources of these two major knowledge types are retained as the study objects.
FIGURE 6: Graph of problem convergence curve.

3.2. Results of Applying the English Online Teaching Model.

Adaptive follow-up assignments are personalized assignments on the Newton platform that take advantage of the instructional moment after proficiency learning to correct students' errors before they develop a basic understanding and before they move on to the next topic of study. Student work is completed to determine what students have mastered and understood and what they have not, and questions are selected from the Mastering Item Library to close individual gaps in understanding. Adaptive follow-up assignments also analyse student performance on proficiency learning tasks to select the types of assignments that are most helpful to students. Adaptive follow-up assignments are staged, with each set of questions based on the results of the previous set of questions. Promote the improvement of their language practical ability, and the flexible use of cooperative learning in mixed oral English teaching activities can create a classroom teaching atmosphere, stimulate students' interest in learning English, and overcome classroom anxiety. Students perform adaptive follow-up assignments until they complete the assigned problem set or master all concepts and material. In this way, students who lack practice and are late learners are required to complete as many as eight or more problem sets, while more advanced learners may be able to complete adaptive follow-up after one problem set. After the student completes the adaptive follow-up assignment, the student can see which questions he or she answered and how well he or she answered them. Adaptive follow-up assignments can be added to all proficiency learning tasks.

The teacher first sets the number of problem sets the student receives, each of which takes about 15 minutes, but the specifics will vary from person to person; after this, a total point value is assigned to the assignment, and finally, a deadline is set and whether the student who performs well is expected to automatically receive full credit without taking the adaptive follow-up assignment. Adaptive follow-up assignments provide students with a personalized learning experience that helps each student continue to make progress in the course at the most appropriate time and in the best way possible. Overall, Newton's assignment resources can be categorized as fully adaptive assignments and partially adaptive assignments, as shown in Figure 7.

From Figure 7, it can be seen that in the resource hotness dimension, the mean of video resources above 10 min is higher than the mean of video resources between 5 and 10 min, and the mean of video resources between 5 and 10 min is higher than the mean of video resources between 0 and 5 min. Video resources above 10 min have a higher hotness H but a lower mean of resource learning attainment G, indicating that learners did not watch the whole video. The video resources of 0–5 min have a higher mean value than the mean value of course resource learning attainment G, although the hotness is lower, indicating that learners repeatedly watch the video resources. The resource designer can adjust the length of the video according to the purpose; for example, if the purpose is only to give learners a general understanding of the knowledge, then a video length of more than 10 min or 5–10 min can be used. If the purpose is to give learners knowledge, then a video length of 0–5 min can be used. Depending on the content of the video with or without the teacher and with or without subtitles, the learning characteristics of learners were explored in three dimensions: video resource presentation, course resource hotness, and course resource learning attainment, as shown in Figure 8.

The resources used in this round of action research were mainly topic-related lesson materials as well as microlearning resources. Before face-to-face teaching, teachers posted the resources in a WeChat class group for prelesson viewing. By posting interesting and targeted resources, students' interest in oral learning can be stimulated, and students can focus on the language points before class, so that they can be fully engaged in classroom activities with "excitement" and questions, thus improving students' communicative competence more effectively. Through WeChat's video forwarding function, video resources related to the background of the topic were released for students to watch before class to understand the linguistic situation of the language, which enriched students' language materials and made them understand and think about the topic before class, greatly improving the effect of face-to-face oral
Figure 7: Analysis of video length differences.
Figure 8: Pre- and postexperimental class results.

teaching. After class, dialogue practice assigned through the wing class network and dialogue drills are continued through the WeChat group cooperation group to achieve language review, consolidation, extension, and expansion and to cultivate students' good speaking habits of speaking and using English after class.

4. Conclusion

In the three rounds of action research, the researcher designed the content and teaching process of oral language teaching for the model and continuously reflected and optimized the implementation strategy and improved the teaching process in the teaching practice. The researcher conducted several questionnaires on the practical application effects of the model in speaking teaching, and after the longitudinal and cross-sectional pre- and posttest data comparison and analysis, it was found that after the

experiment, the students in the experimental class had a greater improvement in their interest and attitude in English learning, cooperative communication ability, independent learning ability, evaluation awareness, and ability, problem-solving effect, and resource application effect in teaching compared to the students in the control class. This leads to the conclusion that using a blended learning-based speaking teaching model can effectively improve students' interest and attitude in English learning, can improve students' group cooperative communication and independent learning ability, can improve students' awareness and ability of evaluation, and can improve the effectiveness of problem-solving and the application of resources in teaching. Combining the DCOPSO algorithm with SVM, the traditional SVM hyperparameter search has the characteristics of poor globalization and low accuracy, while using the DCOPSO algorithm for search can solve these problems. The strategy enhances the diversity of the population and helps

the population to jump out of local extremes. Finally, a two-population learning particle swarm optimization algorithm with heterogeneous learning strategies is proposed based on the dimensional learning strategy and the integrated learning strategy. One subpopulation uses a learning paradigm constructed by the dimensional learning strategy to guide the local search of particles, and the other subpopulation uses a learning paradigm constructed by the integrated learning strategy to guide the global search of particles. The two subpopulations achieve mutual collaboration in the search process through different information interaction mechanisms, which effectively improves the algorithm performance.

In this paper, the IoT-based adaptive mutation PSO-BPNN algorithm is used to conduct in-depth research and analysis of the entrepreneurship evaluation model for college students and practical applications. This paper details the principle, implementation, and characteristics of each BP algorithm and PSO algorithm. When classifying college students' entrepreneurship evaluation based on BP neural network, because BP algorithm is a local optimization-seeking algorithm, it is easy to fall into local minima in the training phase of the network and the convergence speed is slow, which leads to the reduction of classifier recognition rate. To address the above problems, this paper proposes the algorithm of PSO optimized BP neural network (PSO-BPNN) and establishes a classification and recognition model based on this algorithm for college students' entrepreneurship evaluation. The predicted values obtained from the particle swarm optimization neural network model are used to calculate the gray intervals, and the modeling samples are further screened using the gray intervals and the correlation principle, while the hyperspectral particle swarm optimization neural network model of soil organic matter based on the gray intervals is established afterward; and the estimation results are compared and analyzed with those of traditional modeling methods. The results showed that the coefficient of determination of the gray interval-based particle swarm optimization neural network model was 0.8826, and the average relative error was 3.572%, while the coefficient of determination of the particle swarm optimization neural network model was 0.853, and the average relative error was 4.34%; the average relative errors of the BP neural network model, support vector machine model, and multiple linear regression model were 8.79%, 6.717%, and 9.9%, respectively. The average relative errors of the BP neural network model, support vector machine model, and multiple linear regression model are 8.79%, 6.717%, and 9.468%, respectively. In general, the entrepreneurial ability of college students is at a good level (83.42 points), among which the entrepreneurial management ability score (84.30 points) and entrepreneurial spirit (84.16 points) are basically the same, while the entrepreneurial technology ability is relatively low (82.76 points), and the evaluation results are further verified by the double case analysis method. The current problems encountered by university students in entrepreneurship are mainly the lack of practicality, which indicates that universities, industries, and national strategy implementation levels are not sufficiently focused and collaborative in entrepreneurship development to varying degrees.

1. Introduction

With the birth and growth of the Internet, all kinds of related technologies develop at a high speed, the distance between people is drawn closer and closer, and work and life are increasingly inseparable from the Internet. Internet of Things (IoT) technology, as an important branch of Internet technology, combines various information sensing devices with the Internet, completes the transmission and sharing of data through the Internet, and uses computer technology to realize the processing and application of relevant data [1]. This technology extends the information exchange once limited to human to human, to things to people, and to things to things, making the future network more intelligent and realizing the interconnection of all things. With the development of the information technology revolution and the extension of economic globalization, "innovation" has increasingly become a core element in promoting social and

economic development. To meet the trend of the times, the Party and the government have made important strategic plans for building an innovative country, and "innovation" will be the main theme for a long period. Innovation needs to be led by direction, and for this reason, the development paths of "independent innovation", "integrated innovation", and "re-innovation after introduction, digestion, and absorption" have been put forward one after another. To achieve innovation, it is necessary to cultivate and shape many innovators and entrepreneurs who meet the needs of the times [2]. Clarified the relationship between the five major elements of academic evaluation and the subjective and objective factors of creativity training, as well as the mechanism of their influence, through theoretical analysis and empirical research, pointed out that strong chemical industry evaluation's guidance for creativity training is for creativity training, and it is of great significance. How to improve the innovation and entrepreneurial competency of college students has become the focus of research in the academic field. The purpose of this paper is to construct a theoretical model of entrepreneurial competency that is consistent with the characteristics and rules of entrepreneurship development of college students by drawing on existing research results and empirical studies and to empirically evaluate and test the overall level and influencing factors of entrepreneurial competency of college students through the theoretical model, to contribute to the in-depth development of college students' entrepreneurship research and practice [3].

The scientific evaluation of the entrepreneurial competencies of science and technology students and the effective guidance of their entrepreneurial activities are theoretical issues that need to be addressed urgently. Entrepreneurship as a serious socio-economic activity has its logic and laws, and entrepreneurial behavior is in line with the consensus of economics and management, that is, entrepreneurship as a market-oriented behavior requires that entrepreneurs should have a competence structure that meets the needs of entrepreneurship, and it is absolutely difficult to guarantee the smooth development and profitability of entrepreneurs by ignoring the competence elements and to ensure that the country's strategic goal of achieving social stability and economic development through high-quality entrepreneurship of college students can be successfully achieved [4]. It is difficult to ensure that the strategic goal of social stability and economic development can be successfully achieved through the high-quality entrepreneurship of college students. Therefore, the systematic answer to the questions of what is the basic competency structure of entrepreneurship among college students, whether contemporary college students have entrepreneurial competency, the degree of proficiency in their entrepreneurial competency, and how to improve college students' entrepreneurial competency has become a major issue that cannot be avoided in the field of entrepreneurship research. How to effectively identify and construct a competency structure system is not only an inherent requirement of entrepreneurship evaluation for science and technology undergraduates but also an objective need to effectively guide their entrepreneurial activities.

The structural contradiction between university graduates and market demand is increasingly prominent. The talents cultivated by the old training model cannot match the requirements of the economic transformation on the quality and knowledge skills of talents, resulting in the embarrassing situation that enterprises cannot obtain effective talent replenishment in the labor market and college graduates can hardly meet the requirements of job positions. Thus, the participation of college students in entrepreneurship is an important means to enhance their comprehensive quality and improve their social survival ability, and it is also an effective way to drive employment through entrepreneurship and relieve social employment pressure. Entrepreneurial practice allows college students to have a deeper contact with society and understand it, to discover problems, stimulate innovation, solve problems, and create value. For college students, school is only a small classroom for learning cultural knowledge, but society is the big classroom that can bring more learning and growth space for college students. Entrepreneurial practice is like a bridge between school and society, which can greatly accelerate the process of professionalization and socialization of college students and improve their comprehensive ability to adapt to society. To sum up, the era has given innovative, practical, humanistic, and social characteristics to university students' entrepreneurship. It is these characteristics of the times that reflect the importance of guiding and enhancing students' entrepreneurial competence and stimulating and tapping their potential human capital in the context of "building an innovative country, promoting the deepening reform of higher education, and transforming the development connotation of the market economy".

2. Current Status of Research

A model of entrepreneurial process based on the view of entrepreneurship as organizational creation is proposed, which considers that the entrepreneurial process can be divided into two stages: first, the preorganizational venture formation period, in which entrepreneurial activity is mainly expressed as individual entrepreneurial behavior; second, the postorganizational venture operation period, in which entrepreneurial activity is mainly expressed as organizational behavior of the entrepreneurial enterprise [5]. Some scholars, on the other hand, divide the entrepreneurial process into five stages according to the growth process of a new enterprise: first, the proof-of-principle stage, where the main task is to verify the feasibility of the innovative technology; second, the prototype stage, where the product is produced and the prototype organizational structure is formed; third, the model sales stage, where the main task is to improve the feasibility of the product and make the necessary professional division of labor for financial, marketing, and other operational activities; fourth, the start-up stage, where the profitability of the product further increases, the organizational structure expands further, and more product and management issues arise; and fifth is the natural growth stage, where the organization enters natural expansion and the entrepreneur usually considers new

strategic adjustments or enters a new entrepreneurial cycle [6]. Avoid harming the person being evaluated. It is necessary to explore how to cultivate students' creativity in academic evaluation. This is a subject that spans two research fields. Naturally, it is inseparable from the research of creativity cultivation. The existence stage, the main goal is to make business opportunities to form enterprises, where only a small number of enterprises can earn enough cash income to enter the second stage; survival stage, where the goal is to grow the business into the next stage and cannot stagnate in the survival stage for long enough to cause cash flow to dry up; is the success stage, where the organization is taking shape and the business is earning good revenues and needs to adjust its strategy in time to prevent the business from regressing in the face of external changes; the takeover stage, where investors look for opportunities to take the business off the table and voluntary or involuntary changes in management occur; and the resource maturity stage, where the business is operating with abundant resources and effective realization of economies of scale [7].

It is proposed that the entrepreneurial process is a highly dynamic balance between the appropriate allocation of entrepreneurial opportunities, entrepreneurial team, and resources, and entrepreneurial opportunities, resources, and entrepreneurial team are the key components of the entrepreneurial process [8]. In the early stage of entrepreneurship, the key is the exploration and selection of opportunities, and the decision of the entrepreneurial team is focused on the rapid integration of resources to seize the entrepreneurial opportunities; as the new enterprise is founded and grown, resources become more abundant, and the enterprise faces a more complex competitive environment and market environment, the decision of the entrepreneurial team is focused on the rational allocation of resources to improve the efficiency of resource use, and the construction of a standardized management system to resist external competition and uncertainty [9]. A theoretical model of the entrepreneurial process based on the interaction between the entrepreneur and the new enterprise is proposed, arguing that the entrepreneur and the new enterprise are the key components of the entrepreneurial process and that the entrepreneurial process is essentially a process of close interaction between the entrepreneur and the new enterprise under the action of the external environment [10]. The only way to make entrepreneurship research more systematic based on diversification is to gradually build a framework for entrepreneurship research independent of other fields, and then provide a more comprehensive longitudinal research on entrepreneurial competency, entrepreneurial ability, and another individual level [11].

The entrepreneurial process concretely expressed as the act and activity of achieving stage equilibrium in a constant dynamic change. In the entrepreneurial process, there is never absolute stability and equilibrium, and any enterprise and organization are in dynamic change to seek temporary unity and coordination of the elements of entrepreneurship. In different stages of development, entrepreneurs need to analyze the problems and risks that may arise in the process of development from the perspective of dynamic balance and make changes and deployment of their capabilities and organizational resources according to the time and the actual situation, to achieve sustainable development of the enterprise.

3. Adaptive Mutation of the Internet of Things PSO-BPNN Algorithm-Assisted Evaluation of College Student Entrepreneurship Analysis

3.1. IoT Adaptive Mutation PSO-BPNN Algorithm Design. Random access (RA) refers to the process in which the UE or terminal sends an access request to the access control system, and the system allocates access resources such as access channels and time-frequency resource blocks after a certain algorithm and feeds this information back to the terminal, while the data transmission process generally arranged after obtaining the allocated access resources [12]. Random-access methods can be divided into two categories based on the different resource allocation methods: competition-based random-access methods and noncompetition-based random-access methods. The biggest difference between competition-based and noncompetition-based random-access methods is the different allocation of the preamble codes, competition-based random-access method by the UE side to initiate the application of the preamble codes, and the UEs do not know whether the application of the preamble codes is duplicated, so there is a problem of collision, while noncompetition-based random-access method by the access control side of the unified allocation of the preamble codes, so there is no possibility of conflict. The access process also does not require the steps of applying for the leading code and competition resolution.

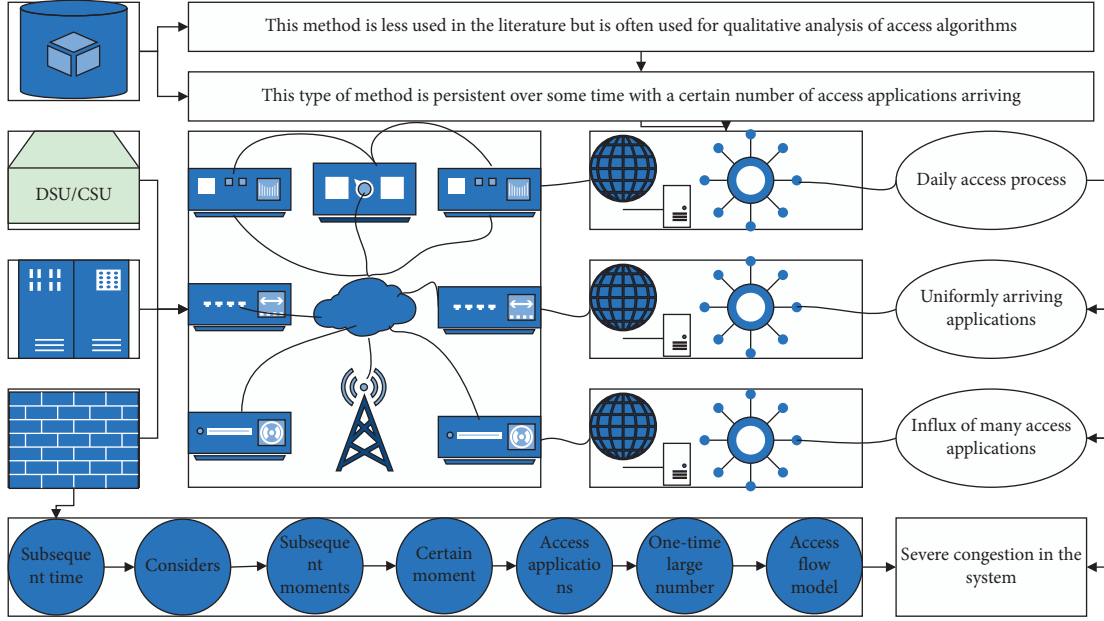
In the daily access process, uniformly arriving applications often do not cause congestion, and only the influx of many access applications in a short period will lead to severe congestion in the system. Therefore, to simplify the user access flow model, some literature only considers the impact of a one-time large number of arriving access applications on the system and only considers the one-time arrival of N MTC devices at a certain moment in the simulation, without considering whether the subsequent moments. The simulation only considers the arrival of N MTC devices at one time and does not consider whether there are further arrivals of new access requests at subsequent times [13]. This method is less used in the literature but is often used for qualitative analysis of access algorithms, such as the impact of different leading code values on the system access performance. This type of method is persistent over some time with a certain number of access applications arriving, and the specific number of arrivals per time slot can conform to different distribution rates. This type of access flow model is more in line with the actual access in use and is more dynamic and continuous than the first type of access flow model. Depending on the arrival rate of each time slot, this type of access flow model can also be divided into several categories, as shown in Figure 1. At the same time, it also pays attention to the improvement of the comprehensive quality and practical ability of innovation and entrepreneurship,


Figure 1: IoT adaptation mutation framework.

especially the expansion of self-entrepreneurship awareness and innovative operation ability, so that students can find and solve problems independently, and then put forward their own new views and opinions, for the life of students The continuous development of learning and the individual has laid a solid foundation.

In the IoT mass access scenario, for periodic services such as the regular reporting of sensor data is suitable for uniformly distributed or Poisson distributed access flow model, while for bursty services such as alarm-like services is suitable for beta distributed access flow model, IoT as an emerging application in the communication industry, driven by big data and artificial intelligence, the market scale will further expand, with technological progress [14]. With technological advancement, government support, and increasingly improved industry standards, China's IoT industry will continue its good development momentum and provide new impetus for sustained and stable economic growth. The wave of expansion of mobile Internet to the Internet of everything will create larger market space and industrial opportunities compared to the Internet [9]. IoT has become an important technical support for many high-tech enterprises in China, such as cloud computing, mobile payment system, bicycle-sharing, and other IoT-related industrial chains, and have achieved great success in the Chinese market, bringing good economic benefits while also bringing great convenience to our travel and work.

Network sizing estimation is usually a comprehensive analysis of both coverage and capacity to determine the size, i.e., the number of sites, required for network planning in each area. On the one hand, the coverage estimation combines the link budget with the propagation model to calculate the coverage radius of the base stations to find the number of base stations required to cover the planning area; on the other hand, the capacity estimation calculates the number of base stations required to meet all the service demands by processing various actual services into some virtual equivalent services based on the resources provided by individual base stations. The larger of the coverage estimate and the capacity estimate are used as the number of sites for the size estimate.

$$
\begin{aligned}
R_{\text{SBS}} &= \left\{ d_{sll} | \text{PL}\left(d_{su}\right) = \chi_{\text{PL}}^2 \right\}, \\
N_{\text{cap}} &= \sum_{k=1}^{N_{\text{region}}} N_{\text{cap}}^k \chi_{\text{PL}}^2.
\end{aligned}
\tag{1}
$$

Among the various types of artificial neural networks, multilayer feedforward networks can not only solve the heterogeneous problem and the arbitrary function approximation problem but also the classifier constructed based on this network has a strong classification recognition ability. BPNN is a typical feedforward neural network, but it has slow convergence and weak generalization ability. Many practical problems have many local minima due to the complex multidimensional nature of the problem itself, and because the BP algorithm itself uses the gradient descent method to find the optimal value will also lead to local minima, resulting in the overall design of the network is more likely to fall into local minima. To solve the above problems of convergence and local minima in BPNN, this paper proposes to optimize the training neural network with the help of a particle swarm algorithm.

The PSO algorithm optimizes the BPNN by replacing the gradient descent method to correct the network weights and thresholds. The key point to consider in this process is to construct a mapping between the neural network weights and thresholds and the particle dimensions of the PSO algorithm. The key to the training of the BPNN is the continuous correction of the weights and thresholds, while the PSO algorithm is the iteration of the individual particle positions and velocities [15]. Therefore, when the two

algorithms are combined, the weights and thresholds of the BP algorithm correspond to the particle positions of the PSO algorithm, and the total number of weights and thresholds is the dimensionality of the particle population. The fitness function of the particles is generally chosen as the objective function, so the fitness function of the particles is determined as MSE according to the end condition of the BP algorithm as the reference minimum mean square error (MSE).

$$\text{MSE} = \frac{1}{P} \sum_{p=1}^{P} \sum_{k=1}^{m} \left(T_k^p + Y_{k+1}^p \right)^2. \quad (2)$$

In this paper, the principle of the PSO-BPNN algorithm is to optimize the parameters of BPNN by particle swarm algorithm training, mainly optimizing the weights and thresholds, which can effectively solve the problem of BPNN falling into local miniaturization and slow convergence, and improve the training efficiency of the network. PSO algorithm in training optimization of BPNN, the weights, and thresholds of BPNN is derived from the position vector of particles. In the search process of the particles, the minimum is reached using the following equation:

$$\text{Fitness}_i = \frac{1}{N} \sum_{i=1}^{P} \sum_{j=1}^{m} \left(W_{ij}^d - W_{ji}^p \right)^2. \quad (3)$$

Innovation and entrepreneurship education is oriented to all students, emphasizing not only the cultivation of basic literacy, innovation spirit, entrepreneurial consciousness, and entrepreneurial ability but also the improvement of comprehensive quality and practical ability of innovation and entrepreneurship, especially the expansion of self-entrepreneurial consciousness and innovative operation ability, so that students can independently identify problems and solve them, and then put forward their new views and opinions, which lay a solid foundation for students' lifelong learning and individual. The weights and thresholds of the BP algorithm correspond to the particle positions of the PSO algorithm, and the total number of weights and thresholds is the dimension of the particle swarm. This provides students with a solid foundation for lifelong learning and sustainable development [16]. The purpose of innovation and entrepreneurship education is not to let every student start a business, but the core is to cultivate students' innovation spirit, entrepreneurial consciousness, and entrepreneurial ability, focus on the cultivation of students' independent learning and practical ability, closely combine the cultivation of talents with scientific research and the needs of society, and change from the traditional classroom focus on knowledge transfer to the emphasis on ability and comprehensive quality cultivation, which can effectively improve the quality of talent cultivation in colleges and universities, as shown in Figure 2.

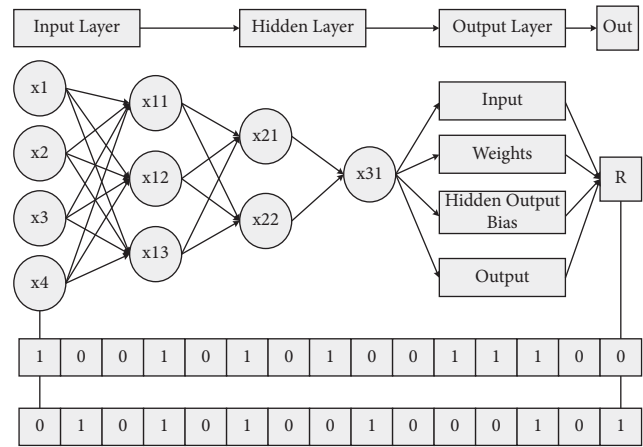
Educational evaluation should be as impartial and objective as possible to make the results of the evaluation have a greater reference value. In the development of educational evaluation activities, objective facts should be used as the


Figure 2: PSO-BPNN algorithm framework.

basis, and the reference standard for evaluation should be used as the yardstick, eliminating as far as possible the interference of the evaluator's subjective factors and external objective factors in the evaluation. Both the methods and means of evaluation and the standards of evaluation should be in line with the norms of ethics and morality. Once the evaluation criteria have been established, they should be strictly enforced from the beginning to the end. In addition, access to evaluation information should be justified and the use of evaluation results should be legal to avoid harming those being evaluated. To explore how to cultivate students' creativity in academic assessment, which is a topic that spans two research fields, it is natural that the research on creativity cultivation is inseparable. There are many research results, both theoretical and practical, on creativity education and creativity cultivation. Analysis of the components of creativity and its characteristics can provide a more scientific theoretical basis for carrying out academic assessment reform.

3.2. Design of Entrepreneurship Evaluation Model for College Students in Higher Education. The innovation of this research lies in: first, the innovation of research perspective. There have been studies on the cultivation of creativity, mainly from the perspective of optimizing curriculum structure, integrating learning resources, enriching learning experience, reforming teaching methods and approaches to talk about the cultivation of creativity, but this study starts from academic assessment to discuss the issue of creativity cultivation, which is an innovation in terms of research perspective. Second, it is an innovation in research content. Using the modern educational evaluation theory and the theory of creativity education, this study provides a systematic and comprehensive discussion on the promotion of creativity cultivation by academic evaluation in colleges and universities, clarifies the correlation between the five major elements of academic evaluation and the subjective and objective factors of creativity cultivation, as well as the mechanism of their influence [17]. Through theoretical analysis and empirical research, it is pointed out that strengthening the orientation of academic evaluation on

creativity cultivation is of great significance to creativity cultivation, summarizing the academic evaluation reform strategy of "five guides," constructing a framework system for academic evaluation of college students, and proposing specific operational suggestions for the reform of evaluation contents and evaluation methods of different types of coursework. In the analysis of the problem by AHP, the relevant influencing factors and solutions are listed according to the overall objective of the problem, and a hierarchical model is constructed. The constructed hierarchical model generally consists of three levels, namely, the objective level, the criterion level, and the solution level. The criterion layer, also known as the intermediate layer, represents the factors that need to be considered and the guidelines for decision making to achieve the overall objective and is the intermediate link to achieve the overall objective, as shown in Figure 3.

The elements of the evaluation of graduate students' innovation and entrepreneurship education initially formulated in this study are mainly analyzed in terms of top-level design, teachers, students, and educational environment and forms. After consulting experts and synthesizing their opinions, the top-level design mainly designed two evaluation dimensions, namely, the incentive support policies related to graduate students' innovation and entrepreneurship and the evaluation of universities' attention to graduate students' innovation and entrepreneurship education. The study explores the influencing factors of postgraduate innovation and entrepreneurship and then designs a framework of postgraduate innovation and entrepreneurship education evaluation system with high realistic guidance value. Moreover, the classifier based on this network has strong classification and recognition capabilities. Therefore, exploring the optimization problem of feedforward neural networks has practical significance for the research in many fields.

The support of graduate student innovation and entrepreneurship education and the teaching methods of graduate student innovation and entrepreneurship education, coded as DA1, DA2, and DA3 in order; the measurable indicators of faculty provision are the faculty provision of graduate student innovation education and the faculty provision of graduate student entrepreneurship education, coded as IF1 and IF2 in order; and the measurable indicators of implementation methods are the practical forms of graduate student innovation education and the practical forms of graduate student entrepreneurship education. Based on the questionnaire survey, to further explore the relationship between the influencing factors, a theoretical model on graduate innovation and entrepreneurship education was constructed with the help of structural equation modeling, as shown in Figure 4.

After running the standardized estimates calculation, the results of the unstandardized path coefficients of the model show that all the path coefficients except the 11 path coefficient reference indicators reach a significant level of 0.05, the measurement errors are positive, the absolute values of the critical ratios are greater than 1.96, and the significance probability values are less than 0.001, indicating that all the

path coefficients are significant and the constructed [18]. The structural equation theoretical model constructed is not problematic. The overall index of graduate students' information literacy is 52.4, which is consistent with the current situation of graduate students' innovation and entrepreneurship education, indicating that the indexes of the influencing factors of graduate students' innovation and entrepreneurship education selected in this study are more effective. However, the value of the total index is only slightly greater than 50, which is not a high index, reflecting that the current situation of the development of innovation and entrepreneurship education for graduate students is not optimistic. The existing evaluation structure of entrepreneurial competency of college students is mainly derived from the evaluation model of entrepreneurial competency of Western entrepreneurs, which is thinly localized on the one hand; and on the other hand, it is difficult to apply the entrepreneurial competency model of general entrepreneurs to college students' entrepreneurs.

Moreover, the current entrepreneurial competency research not highly differentiated from the competency research, which makes it difficult to reflect the theoretical depth of entrepreneurial competency research. Such a research pattern is not conducive to the scientific development of entrepreneurship among college students in science and technology, nor is it conducive to the scientific decision making of management agencies [19]. To determine the scale required for network planning in a given area, that is, the number of sites. Coverage estimation should combine the link budget with the propagation model, calculate the coverage radius of the base station, and find the number of base stations required to cover the planned area. This study precisely seeks to make a breakthrough in this field, deepen theoretically the understanding of entrepreneurial competence, dig deeper into the influencing factors of entrepreneurial competence and countermeasures of cultivation from the theory of college students' entrepreneurship, and strengthen the theoretical explanatory power of evaluation research with vivid cases and an appropriate amount of quantitative research methods to form a theoretical research structure combining depth and breadth, as shown in Figure 5.

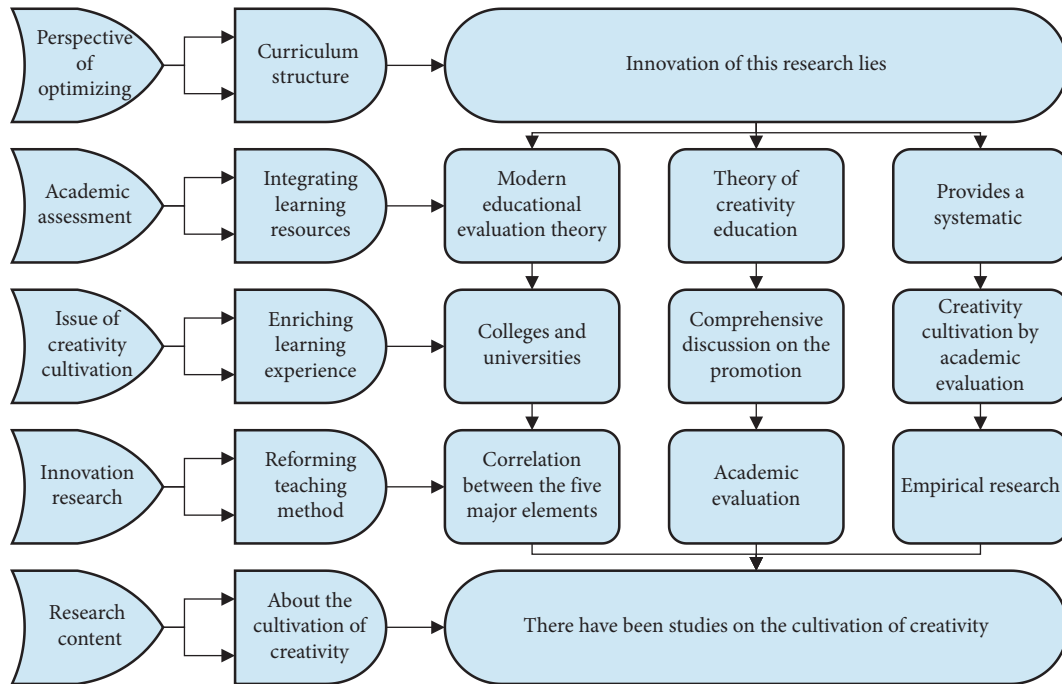
This study takes the evaluation of the ability of science and technology students' entrepreneurship as the research theme, studies the current operation mechanism of entrepreneurship education, constructs a system of ability characteristics based on the comprehensive use of scientific methods, relies on field research and quantitative analysis to process, and organize the system, finally constructs an evaluation index system and mathematical model, and verifies it through empirical methods. The main research methods used include literature research method, questionnaire survey method, statistical analysis method, case study method, expert interview method, etc. Each method is not applied independently, but fully cooperated, repeatedly used, and mutually corroborated. Through this study, we can deepen the theoretical depth of college students' entrepreneurial ability evaluation research, expand the field of college students' entrepreneurial ability evaluation research to the


FIGURE 3: Evaluation hierarchy model.

FIGURE 4: Structural distribution of the questionnaire sample.

Guiding and encouraging members to let go of their psychological burdens, delegating a certain degree and scope of authority, and focusing on nurturing team members' responsibility, sense of mission, and trust are the main focuses of team leaders. In terms of mechanism design for implementing the path, a reasonable and effective system of incentives, constraints, and penalties should be gradually established and improved.

4. Analysis of Results

4.1. IoT Adaptation Mutation PSO-BPNN Algorithm Results. In the initialization of the particle swarm, the particle swarm size $M = 60$, the particle swarm size is too small will not be obvious for the optimization of the later BPNN, when M is less than 50, PSO optimization of BPNN will still exist easy to fall into the condition of local minima, when M is greater than 50 then PSO optimization of BPNN is obvious. The scale of the market will be further expanded. With technological progress, government support, and increasingly perfect industry standards, the Internet of Things industry will continue to maintain a good momentum of development and provide new impetus for sustained and stable economic growth. The sum of the number of weights and thresholds in BPNN is 305, so this particle population has dimension $D = 305$, and usually the fitness function is the training error function MSE of the BPNN. The number of iterations is defined as 200, the learning factors c, and care both 2, and the inertia weight is 0.5. The output of the PSO algorithm is stored as weights and thresholds to facilitate the training of the BPNN in the next step. The PSO algorithm is selected instead of the gradient descent method to correct the weights and thresholds and start training the BPNN so that the training accuracy reaches 0.00001 or the defined

group of science and technology college students, and propose a model of evaluation of college students' entrepreneurial ability in science and technology with the characteristics of the times, reflecting the spirit of China and in line with the reality of science and technology college students and verify it [20]. The biggest potential problem at this stage is that some team members may have palpitations about the difficulties of the turbulent period and cannot express their opinions and insights effectively and sincerely.

Figure 5: Theoretical path diagram of the structural equation model.

number of training times 1000 times ends with a training learning rate of 0.1. When the net training is learned, the feature vectors of any 30 groups of samples for each Chinese character are mixed for training, the total number of training sample images is 960, and the final training samples are built for the next test recognition. The PSO algorithm optimizes the iterative fitness values for BPNN, as shown in Figure 6.

Figure 6 shows that the performance is only improved by about 3% compared to randomly selecting a single relay for transmission, which is much lower than the QL-RSA algorithm under DF protocol. It can be seen from Figure 7 that the performance of the QL-RSA algorithm is not much optimized with random selection as the total transmit power increases. Specifically, the arrival amount of each time slot can conform to different distribution rates. This type of access flow model is more in line with the actual access situation and is more dynamic and continuous than the first type of access flow model. This is because the amplified forwarding protocol amplifies the transmit power of the useful signal at the second hop in addition to the amplified noise power, thus resulting in the received signal-to-noise ratio at the destination of each node is not very different, and the received signal-to-noise ratio is used as a reward for Q-learning, then the difference in the Q-value of each node is not too big, and the Softmax selection strategy is precisely based on the corresponding Q-value of each node. The Softmax selection strategy is based on the corresponding Q-value of each node to make a decision. This is the reason the performance of the QL-RSA algorithm is not much optimized than that of R-RSA.

This is because when the signal-to-noise ratio required at the receiving end is not high, anyone relay node can meet the requirements at the receiving end, so the number of nodes for the three algorithms does not differ much. When the total number of relays is larger, the number of relays
Figure 6: Iterative adaptation degree value graph.

required for cooperative transmission is smaller, because the more densely distributed the relays are, the better the combination of the selected set of relays can be, so that a larger signal-to-noise ratio can be achieved at the receiving end, which in turn means that fewer relays can be used to achieve the upper bound on the signal-to-noise ratio at the receiving end. The optimal single-relay selection and the multirelay selection are discussed separately for the two forwarding protocols. The data transmission process is generally arranged after the allocated access resources are obtained. Random-access methods can be divided into contention-based random-access methods and noncompetition-based random-access methods according to different resource allocation methods. As a comparison of simulation
FIGURE 7: Percentage of ideal throughput accounted for by different algorithms.

results, this paper also simulates the results of the R-RSA algorithm and analyzes the performance of the QL-RSA algorithm from different perspectives of average throughput, the probability distribution of selected nodes, and accounting for the ideal average throughput, the simulation results show that the performance of QL-RSA is obvious compared to R-RSA when DF forwarding protocol is used, but the effect is not so obvious for AF forwarding protocol.

4.2. Results of the Evaluation of Entrepreneurship among College Students in Higher Education. In general, the entrepreneurial ability of science and technology college students is at a good level, among which entrepreneurial management ability and entrepreneurship are equal, and entrepreneurial technology ability is relatively low. The entrepreneurial technology ability of science and technology college students is the center of gravity in their entrepreneurial ability structure, but it is also a relative shortboard that still has room for improvement. The above phenomenon can be tentatively explained by referring to Timmons' entrepreneurial process theory. While solving its own employment, it creates more opportunities and jobs for the society. The participation of college students in entrepreneurship is an important means to enhance their own comprehensive quality and improve their social viability, and it is also an effective way to promote employment through entrepreneurship and relieve social employment pressure. In the early stage of entrepreneurship, entrepreneurs are required to have deep and good professional abilities. For science and technology undergraduates, the level of technical ability can largely influence their quality of exploring and grasping opportunities, while the improvement of technical ability is quite difficult. The influence of scientific and technological ability on entrepreneurial management ability and entrepreneurial

spirits, such as resource application and team management, is weak, and such management ability and entrepreneurial spirit are less required in the early stage of entrepreneurship, and college students can basically reach the initial response after a few years of systematic higher education, so the evaluation is good. However, it should be noted that in the midstage of entrepreneurship, the requirements for resource application and management skills are substantially increased, and the reorganization of resources, the recreation of opportunities, and the operation of teams are raised to a strategic level. The subjects observed in this study are mainly university students, which are in line with the competence performance of subjects in the early or even pre-entrepreneurial stage of entrepreneurship, as shown in Figure 8.

Teaching induction requires teachers to accept and adopt new teaching methods. In entrepreneurship teaching activities for science and technology college students, teachers can use task-driven and typical demonstration teaching methods to induce students to spontaneously generate entrepreneurial views and consolidate entrepreneurial enthusiasm to develop entrepreneurial ability. In the task-driven segment, teachers set specific tasks with technical points and difficulties of technology-based entrepreneurial activities, ask students to complete the tasks in groups and give comments and scores according to the process and results of the groups' completion of the tasks, which induces students' enthusiasm for competition and teamwork, and gains professional knowledge and experience in the process of completing the tasks.

In the typical demonstration, session teachers introduce skilled entrepreneurs or R&D leaders in enterprises into the school to teach the more practical and operational aspects of the teaching. These entrepreneurs are successful models of real entrepreneurship, and interactive exchanges with entrepreneurs can induce students' entrepreneurial enthusiasm perceptually, effectively stimulate students' sense of imitation, consolidate students' enduring interest in entrepreneurship, and enhance the bonding of entrepreneurship education. To enhance the effectiveness of teaching induction, we can consider organizational restructuring by establishing a special entrepreneurship center or entrepreneurship college to cooperate with the technological innovation centers, product development centers, and employment counseling agencies that are currently prevalent in universities, to bring into play the entrepreneurship education and counseling functions of these organizations. It has very important theoretical value and innovative significance for enriching and perfecting the evaluation theory of graduate students' innovation and entrepreneurship education. For example, the Entrepreneurship Center is responsible for providing resources for research and development of entrepreneurship courses, strengthening links with engineering and technology-related industries and academia through cooperation with science and technology transformation departments, and publishing horizontal research topics on innovation and entrepreneurship. It can also cooperate with on-campus
FIGURE 8: College students' entrepreneurship scores.

FIGURE 9: Path coefficients of the modified entrepreneurial opportunity capability structure model.

employment counseling agencies to provide students with entrepreneurial counseling and practical platform services in terms of industry and career development prospects to enhance students' confidence in entrepreneurship, as shown in Figure 9.

To further illustrate the relationship between the factors of entrepreneurship development resources and entrepreneurial competencies, a structural equation model was conducted separately in this chapter to test the relationship between entrepreneurship development resources and entrepreneurial generic competencies, entrepreneurial professional competencies, and entrepreneurial opportunity competencies, and the results showed that the effects of the factors on entrepreneurship generic competencies and

entrepreneurial professional competencies were social network resources, practical training resources, education and teaching resources, and policy and cultural resources, respectively. How to improve the systematic response to practical problems such as college students' entrepreneurial ability has become a major issue that cannot be avoided in the field of entrepreneurship research. The results showed that the effects of the factors on entrepreneurial general ability and entrepreneurial professional ability were social network resources, practical training resources, education and teaching resources, and policy and cultural resources, respectively, and the effects of the factors on entrepreneurial opportunity ability were social network resources, education and teaching resources, and practical training resources, respectively, and policy and cultural resources did not have an effective effect on entrepreneurial opportunity ability.

5. Conclusion

This paper outlines the principle, structure, and implementation process of BPNN and its properties. The PSO-BPNN algorithm is proposed to optimize the BPNN with the PSO algorithm for the defects of slow convergence and easy to fall into the local minima of BPNN. And the prediction feasibility of the optimized algorithm is verified by function simulation fitting, and the optimized PSO-BPNN algorithm has the advantages of high prediction accuracy, fast convergence, and fewer training times than the original BPNN algorithm. Based on the predicted value of the application volume and based on the principle of the maximum number of successful next time slot accesses, the leading code grouping threshold and the ACB control parameters are adjusted, and then the newly arrived service types are identified according to the QoS requirements and the size of the data volume, and the previously derived parameters are used, the access method of time slot Aloha is adopted for the services with insensitive delay and small effective data volume and the cultivation of entrepreneurial ability of college students. The purpose is to build a set of competency theoretical models that conform to the characteristics and laws of college students' entrepreneurial development by referring to existing research results and empirical research. This study shows that the effect of the factors on entrepreneurial general ability and entrepreneurial professional ability is social network resources, practical training resources, education and teaching resources, and policy and cultural resources, respectively; the effect of the factors on entrepreneurial opportunity ability is social network resources, education and teaching resources, and practical training resources, respectively.

The way by which artificial intelligence is implemented is similar to the thinking process of the human brain. People obtain information about external conditions through five senses, namely, vision, hearing, smell, taste, and touch, and, through the further processing of the brain, it forms meaningful decision-making elements. Then, through the process of analysis and reasoning, further decisions are made. In the information age, the application of intelligent management information systems in various fields has promoted the modernization and intelligence of social development. From the perspective of intelligent decision-making, this paper analyzes the requirements of intelligent information systems and designs an intelligent information system based on mobile Internet management optimization, including system management optimization, and proposes an environment-based layer, network transport layer, and the three-tier system architecture of the smart service application layer. Finally, this paper considers the problem of data fusion after system expansion. According to the existing fuzzy fusion algorithm, a weight-based fuzzy fusion algorithm is proposed. The simulation analysis shows that the algorithm can be effectively applied in intelligent information systems.

1. Introduction

Artificial intelligence (AI) is an important branch of computer science. It attempts to understand the essence of intelligence and produce a new intelligent machine that can respond in a similar way to human intelligence. The research in this field includes robot, language recognition, image recognition, natural language processing, and expert system. Artificial intelligence can simulate the information process of human consciousness and thinking. Artificial intelligence is not human intelligence, but it can think like people and may exceed human intelligence. It is also considered as one of the three cutting-edge technologies in the 21st century. In the past few years, some computer systems with artificial intelligence have been established to control spacecraft and underwater robots [1]. Through the program, people can make some thinking reasoning, so that they have certain advanced intelligences such as environmental adaptation, automatic learning, and automatic decision-making [2]. In addition to the application of artificial intelligence to sensory simulation, a more important application is to simulate the thinking and analysis process of the human brain, namely, game and logical reasoning, the application of information sensing, and processing. In games or simulation systems, the application of such artificial intelligence is extraordinarily rich. Some techniques, applied in the chess program, such as looking forward a few steps and breaking down complex problems into some easy subproblems, are developed. It evolved into the basic technology of artificial intelligence such as search and problem summarization. At present, the project technology is developing rapidly and amazingly [3]. The next generation of artificial intelligence system will

affect our life more widely. Artificial intelligence will make more critical and personalized decisions for human beings through interaction with the environment.

The research goal of "3S Smart Service System" [4] is to build a universal access system based on technologies such as Internet of Things, cloud computing, and big data, which can accept intelligent industry, intelligent agriculture, intelligent logistics, intelligent transportation, smart grid, intelligent environmental protection, intelligent security, intelligent medical treatment and smart home, etc. Different types of IoT specific applications [5] provide common solutions for different application scenarios of IoT technology and achieve unified management and control. Considering that the system will be built into an intelligent system with massive data, scientific control, intelligent services, etc., the system is particularly important for the storage, management, processing, and transmission of data. The secure storage, specification management, intelligent processing, and reliable transmission of service environment data will provide reliable guarantee for data volume and data accuracy for system computing and decision-making.

Aiming at the problems existing in intelligent products or systems, this paper intends to adopt a support system model based on intelligent decision-making to design an intelligent information system based on Internet management optimization. The research focuses on intelligent information systems to integrate different intelligent products into the same system and, through big data and cloud computing technology, provide users with truly intelligent, personalized, automated full-service, without the need to control the system through user behavior. Considering the massive data characteristics of the system expansion, according to the existing fuzzy fusion algorithm, a fuzzy fusion algorithm based on weight is designed to provide more accurate and reliable raw data for the decision module of the system.

The remains of this paper are organized into four sections. Section 2 contains related works of our research field. In Section 3, we give the design of system model. Section 4 covers on the experimental and results. In the last section, we draw the discussion and conclusion over our research.

2. Related Work

Decision support system (DSS) is a computer application system that assists decision-makers to make semistructured or unstructured decisions by human-computer interaction through data, model, and knowledge [7]. It is an advanced information management system produced by the development of management information system (MIS) to a higher level. It provides an environment for decision- makers to analyze problems, establish models, simulate decision-making processes and schemes, and call various information resources and analysis tools to help decision-makers improve decision-making level and quality. Because DSS requires decision-makers to participate, man-machine dialogue is used to manipulate data through models. What is supported is only the structured

and clearly procedural part of the decision-making process. The core content of decision support system is human-computer interaction. In order to help decision-makers deal with semistructured and unstructured problems, identify objectives and environmental constraints, further clarify problems, generate decision schemes, and comprehensively evaluate decision schemes, the system should have stronger human-computer interaction ability and become an interactive system. As the decision-making environment becomes more complex, the limitations of DSS in decision support are becoming more prominent:

(1) Decision support system uses a static model to operate the data through the model. DSS is a system that makes comprehensive use of a large amount of data, organically combines many models, and assists decision-makers at all levels to realize scientific decision-making through human-computer interaction. The role of the system in decision support is passive and cannot be based on the decision environment. Changes provide active support [8, 9].

(2) Decision support system is modeled by the decision-makers and requires decision-making problems with procedural and clear computability [10, 11], which cannot support the unstructured problems that are common in decision-making.

(3) Decision support system is not a general product, but a solution. Each enterprise should combine its own situation, clarify the management difficulties to be solved, and then analyze, design, develop, and implement the decision support system, so as to truly meet the needs of enterprise management decision-making. DSS is based on quantitative mathematical models and lacks corresponding support methods for qualitative, fuzzy, and uncertain problems in decision-making [12, 13].

Intelligent decision support system (IDSS) is a combination of artificial intelligence (AI) and DSS and applies expert system (ES) technology to enable DSS to more fully apply human knowledge, such as descriptive knowledge about decision-making problems and procedural knowledge in the decision-making process. Introducing AI technology into DSS is mainly through the combination of expert system and DSS and adding inference engine and rule base to DSS system. In the decision-making process, many knowledge amounts cannot be expressed by data or described by models, so there is no fixed way of expertise and historical experience. Researchers integrate AI technology into DSS, mainly through the combination of expert system and DSS, and add inference engine and rule base to DSS system. The rule base introduced by IDSS can store these knowledge amounts and provide important reference and basis for decision-making. IDSS can have many types of information bases: text base (TB), database (DB), arithmetic base (AB), model base (MB), and rule base (RB). The text library stores a large number of documents written in natural language. The database stores the field form of

the key factors of things. Various models reflecting the essential relationship of information are stored in the model base. Rule base is the most refined form of knowledge. From the original unprocessed data to the processed information and then to the extracted knowledge, this evolution relationship of information is called evolution chain.

From the viewpoint of system level, IDSS can be technically divided into three levels:

(1) The application layer is directly oriented to IDSS users. In this layer, decision-makers can determine the status and constraints of IDSS according to their own needs. Decision-makers conduct system dialogue and input relevant information through the user interface; DSS understands user requests and commands through information conversion, carries out system reasoning operation, and reflects the results to users through the output interface. The whole process is transparent to users.

(2) Control and coordination layer, for the chief designer of IDSS: its basic unit is the control and coordination module of the system central library. The system engineer establishes the relationship between them through the standard interface of each library.

(3) The basic structure layer is for professional programmers. Professional programmers implement each library through this layer, specifically defining the organizational structure and communication mode of each library, so as to complete the department management and external communication tasks of each library.

During the operation of IDSS, each module needs to call the upper bridge repeatedly, which is less efficient than using the low-level call directly. However, considering that IDSS only operates when senior managers make major decisions, its operation frequency is much lower than that of other information systems, and the environmental conditions of each operation are very different; it is completely worth sacrificing part of the operation efficiency in exchange for the efficiency of system maintenance [14–16].

With the development of computer and artificial intelligence technology, the research focus of IDSS has gradually shifted from expert IDSS to the research of IDSS model system, man-machine interface, knowledge processing unit, and distributed IDSS. Distributed IDSS introduces distributed artificial intelligence (DAI) technology on the basis of knowledge-based IDSS. Its main idea is to use agent and multiagent system technology in Da; that is, agents playing different roles are designed as intelligent agents of modules according to the main functional modules in IDSS [17]. Through the self-learning mechanism, it simulates the different steps of human intelligence to complete the decision-making task, so as to make scientific decision-making. Distributed IDSS mainly designs and establishes large-scale and complex intelligent decision support system supported by Internet [18].

Expert system tools and technologies can be integrated into decision support system to provide users with consulting environment to improve decision quality and complete functions that conventional decision support system cannot complete. However, expert system is different from decision support system. When using decision support system, users must have certain professional knowledge and skills for the problems they deal with; that is, users should know how to reason about the problems, what questions should be put forward, how to get the answer, and how to proceed to the next step. At this time, the decision support system can only assist users to make decisions. However, the expert system is different. It itself has the professional knowledge of experts in a certain field to solve problems. Users only need to put forward the facts and appearances of the problem to the expert system.

3. System Model Design

3.1. Intelligent Decision Support System. Since the emergence of the intelligent decision support system, due to the great potential of expert system technology in the field of management decision-making, researchers at home and abroad have conducted a lot of research, integrating tools and methods such as computer science and artificial intelligence with human decision-making processes [19]. Intelligent decision system supports structure and function [20]. Holsapple summarized the system's support ability and learning ability for decision-making process and divided IDSS into 4 categories [21]: no adaptive, passive support; no adaptive, which can provide active support; adaptive, passive support; adaptive, active support.

3.1.1. Active Decision Support System. The traditional decision support system provides the corresponding data and model, and the user chooses the corresponding method and model. The decision process is completely controlled by the user. The system only completes the auxiliary computing function. Like many developing things, active decision support system (ADSS) is a developing concept. The intelligent decision support system has part of the domain expert knowledge. Human intelligence has the ability of actively supporting decision-making. ADSS can change its behavior with the user's decision-making process, which is an important milestone in the research of decision support system, which is generated by intelligent decision support system [7]. Active decision-making is an important feature of ADSS. By establishing a human cognitive model, ADSS can provide decision-makers with different choices in different problem solving stages, thus forming different problem solving paths. ADSS provides decision-makers with different method choices at different stages of decision-making problem solving by establishing human cognitive model. ADSS is based on human prior knowledge, but its premise is that the system runs in a static decision-making environment. Therefore, ADSS still has the limitation of poor adaptability in practical application.

However, the research on ADSS lays a foundation for the proposal of adaptive decision support.

3.1.2. Adaptive Decision Support System. ADSS relies mainly on human prior knowledge. The operating environment of the system is static. The domain knowledge and reasoning knowledge required for decision-making are known in advance. In fact, the decision-making environment is usually changeable, and the problem solving process is closely related to the decision-making environment. In relation to this, the knowledge that humans possess and can use for reasoning is also limited. Therefore, the above ADSS knowledge structure and function have many limitations. Adaptive decision support system is an important step toward better support decision. Adaptability is based on the environmental changes of the system and improves the ability of the system of dealing with problems. In order to overcome the limitations of ADSS in knowledge structure, data mining, data warehousing, case-based reasoning, and other data-driven decision support methods and machine learning techniques are adopted. Algorithms such as ANN, GA, and ROUGH SET attempt to discover knowledge that is critical to decision-making from a large amount of historical data and past experience, so that the system has the ability of adjusting its behavior over time and decision process changes, thus generating adaptive decision-making support system (ADSS) [22].

The researchers try to find the knowledge related to decision-making problems from a large number of historical data and past experience by using machine learning and case-based reasoning, so as to make the system have the ability of adjusting its behavior with the change of time and decision-making process. On this basis, people have carried out a lot of research on ADSS, including system structure adaptation, domain knowledge adaptation, and user interface adaptation. Adaptability and self-learning ability have become a main symbol of intelligent decision support system. ADSS has logic-based reasoning in addition to traditional process calculations and other forms of reasoning and also uses inductive reasoning to implement dynamic knowledge systems. Inductive reasoning is a kind of nonmonotonic reasoning, which can be limited or incomplete knowledge. The state introduces a complete state of knowledge. Through inductive learning, ADSS has a certain ability of innovating and can use inductive assertions as knowledge. When new contradictions are contradictory, the knowledge obtained by inductive reasoning can be overthrown, thus maintaining the consistency of knowledge [23].

3.1.3. Decision Expert System. The decision expert system is a decision support system established by using expert technology. The decision expert system uses deductive reasoning and uses existing knowledge to derive conclusions. The correctness of the derivation process can be guaranteed. The problem of this system is that a complete axiom system is needed for the basis of reasoning. In fact, in the environment of uncertain, abrupt, and fuzzy information, this condition is difficult to achieve, so it is only suitable

for the application of well-defined decision-making tasks. In recent years, the progress of artificial intelligence and expert system technology seems to break through the limitations of traditional decision-making expert systems; the application of nonmonotonic reasoning and qualitative reasoning technology is broadening the application scope of expert systems and has made some progress in combination with human intelligence [24].

3.1.4. Holistic Decision Support System. The integrated decision support system is based on the adaptive decision support system and the decision expert system [7]. In the process of human expert decision-making, it faces incomplete, uncertain, and even conflicting knowledge, and human thinking often has nonprocesses. Sexuality generally leads to decision-making through the synthesis of various knowledge and processes. The integrated decision support system (HDSS) emerges to mimic human advanced intelligence and can make full use of human in process analysis, logical reasoning, and cognition and learning. And it has the advantages of knowledge innovation, so that the system's auxiliary decision-making ability transcends the stage of fact, reasoning, and learning and can support the decision-making problem of ill-structured structure [25].

The application of Internet technology in the field of decision support makes the decision environment have new characteristics; that is, the data in decision analysis are no longer concentrated in one physical location, but scattered in different departments or regions. The above discussion about the types of decision support systems is based on the main characteristics of the system, from the perspective of the development of system intelligence. Several types are mutually contained and complementary. More advanced models reflect the evolution of system intelligence [26, 27], Excluding other types of features. In the big data environment, distributed decision support system will get more and more attention. In fact, the research of intelligent decision support systems is showing a trend of integration [7]. Existing systems are generally hybrid systems formed by a combination of methods, with several models characteristics. Uncertainty is the key problem in the current research of artificial intelligence technology, and it is also the core problem throughout the whole process of big data intelligent decision-making. Table 1 compares several IDSSs from the aspects of system learning ability, intelligent behavior, and decision-making methods.

3.2. Intelligent Information System Requirements Analysis. Since the beginning of the 21st century, the wave of globalization has driven the rapid development of the social economy, and the quality of human life has been continuously improved. Together with the rapid development of information technology, human beings have begun to pursue the information technology and intelligence of the living environment. Such powerful human subjective needs have spawned the birth of intelligent information systems. Although the intelligent information products have been developed over a long period of time, this paper has found

TABLE 1: Comparison of IDSS models.

System	Knowledge base type	Completeness of knowledge	Knowledge innovation ability	Decision process understanding	Main reasoning	Main decision-making tool
Active decision support system	Static	Completeness without conflict	No	Have	Adopt a predefined process	Data, cognitive model
Decision expert system static	Static	Completeness without conflict	No	Maybe do not have	Deductive reasoning	Knowledge base
Adaptive decision support system	Dynamic	Allowing incompleteness and conflict	Yes	Generally have	Deductive and inductive reasoning	Data, intelligent decision model, and knowledge base
Integrated decision support system	Dynamic	Allowing incompleteness and conflict	Yes	Have	Deductive, inductive, and case-based reasoning	Cognitive model, intelligent computing method, machine learning, and knowledge base

that the existing smart products or systems still have the following shortcomings after investigating the existing products or systems in the market:

(1) Manufacturer's products are singularly mass-produced.

The existing smart device manufacturers only carry out mass production of a single product and do not systematically carry out product design and mass production and do not form a unified industry standard or access standard resulting in a mixed market of products and systems. There is poor compatibility between the two; new products are difficult to access the system.

(2) The system control layer does not achieve true intelligence.

In response to the above problems (1), many manufacturers have proposed their own intelligent system solutions, integrating different types of products into the system and providing decision control functions, realizing remote control, security alarm, and other functions. However, the decision-making control layer of the system is not intelligent, but the user behavior is used for control or decision-making; that is, the user needs to manually adjust it.

(3) The pressure on data processing of system servers in the Internet of Things has increased dramatically.

Most of the existing intelligent products use the intelligent gateway for data forwarding, and all the original data is sent to the remote server for analysis, storage, processing, etc. After the user scale is expanded, all the user's original data is processed by the remote server. The pressure on servers is getting bigger and bigger, and the cost of expansion is getting higher and higher.

In view of the shortcomings of the above existing intelligent products or systems, the intelligent system studied in this paper hopes to make improvements and finally build a gateway that can provide a unified device interface, realize decision control intelligence, and include local data storage and processing functions. The intelligent information system of the device provides users with systematic, automated, intelligent, and personalized services.

3.3. Hierarchical Structure Design of Intelligent Information System. The structure of the Internet of Things itself is complex and diverse. The current structure of an Internet of Things is divided into three levels: the perception layer, the network layer, and the application layer.

The bottom layer of the Internet of Things is the perception layer, which is the basis for realizing the comprehensive perception of the Internet of Things. RFID, sensors, two-dimensional code, etc., are mainly used to collect device information with sensors and use radio frequency identification technology to achieve transmission and recognition within a certain range. The main function is to identify objects and collect information through sensing devices.

The network layer is located above the sensing layer and is a network device and platform that serves the aggregation, transmission, and preliminary processing of IoT information. Through the existing three-network or next-generation network NGN, the huge amount of data collected from the sensor network is seamlessly transmitted over long distances; it is responsible for the secure transmission of the information collected by the sensor and the analysis of the collected information, processing and providing the results to the application layer.

The application layer is the top layer of the Internet of Things architecture. It mainly solves the problem of information processing and human-machine interface and provides the information services that people need through data processing and solutions. The application layer directly contacts the user and provides users with rich service functions. The user customizes the required service information, such as query information, monitoring information, and control information, on the application layer through the smart terminal.

The application of Internet of Things technology in the service environment mainly focuses on home appliance

automation and intelligent security systems. Home appliance automation is installing sensors in traditional household electrical appliances (such as air conditioners, TVs, and refrigerators), making them intelligent, nodding them, and accessing the Internet, so that users can realize remote control of home appliances in the sky. The intelligent security system is equipped with sensor nodes for monitoring fire, gas concentration, etc., at home, so that the user gets the first time alarm feedback when there is a fire in the home and can timely handle the danger or escape in time to avoid personnel casualties.

The basic framework of an intelligent information system can be divided into three layers: the environment-awareness layer, the network transmission layer, and the smart service application layer as shown in Figure 1.

3.3.1. Environment-Aware Layer.
The environment-aware layer is the bottom layer of the system. If an analogy is made by one person, the environment-aware layer is like a human tactile nerve, which is composed of a large number of environmental information sensors. These sensors are like a neural node, distributed in every corner of the environment, collecting environmental information and sending the collected data to the upper layer of the intelligent information system through a certain short-range wireless transmission technology.

From the perspective of network technology, the sensor of the environment-aware layer constructs a WPAN network within a certain range. The so-called WPAN is a network proposed to solve the "last few meters of wireless communication connection". Generally, this refers to short-range wireless networks with coverage within a radius of 10 m, especially for self-organizing networks that can be connected shortly between portable consumer appliances and communication devices. WPAN is a network that is parallel with wireless wide area network (WWAN), wireless metropolitan area network (WMAN), and wireless local area network (WLAN) but has a smaller coverage. The corresponding relationship is shown in Figure 2.

3.3.2. Network Transport Layer.
The network transport layer is the middle layer of the intelligent information system of the service environment, which assists network communication and data transmission between the entire system levels. It includes communication between environmental information collection sensors, communication between environmental information collection sensors and terminals, and communication between terminals and smart cloud platforms.

3.3.3. Smart Service Application Layer.
The intelligent service application layer is the uppermost layer of the system and is the concentrated expression of the intelligence of the information system oriented to the service environment. It mainly includes the following functions:

(a) Cloud data storage and management

(b) Inducting user habits and building user knowledge base

(c) Smart decision based on user habits

(d) Sending control commands to the lower layer of the system

If one person is used as an analogy, the intelligent service application layer is equivalent to the human brain, which can store memory, intelligently think, make optimal decisions, and control other parts of the human body through neural networks. The intelligent service layer learns knowledge through machine learning algorithms and makes decisions to control the underlying devices of the system.

3.4. Improvement of Data Fusion Algorithm.
The limitations of the fuzzy fusion algorithm in the current environment are mainly reflected in the two aspects of time efficiency and energy consumption. The improvement of the algorithm will also start from these two aspects: first, it reduces the amount of data to be fused by setting a reasonable threshold to improve the fusion algorithm by setting weights for data that fails to pass the threshold.

In an intelligent information system, assuming that there are n sensor nodes, they can form $2n - 1$ sensor groups. As the number of nodes n increases, the number of sensor groups increases exponentially. Each sensor group performs the calculation of the tolerance function and the fuzzy measure function, which will generate a huge amount of computation and take a lot of time. Correspondingly, if we can reduce the number of n participating in the operation by a certain method, the calculation amount and time consumption of the algorithm will decrease exponentially. Therefore, reducing the amount of data with fusion is an effective way to solve the above problems.

Assuming that the system enters a stable data transmission phase, if the monitoring index does not fluctuate significantly over a period of time, then this part of the data is relatively small for system decision-making. The method designed in this paper is to record the result of each fusion and set an appropriate threshold. The data to be transmitted is compared and decided to be retained or deleted. The results of the reservation are directly involved in the final fusion, and the data to be deleted is given a weight, giving it the opportunity to reengage. The main process of the algorithm is as follows:

Suppose that the output set of n sensors is

$$X = [x_1, x_2, \ldots, x_n]. \tag{1}$$

After performing a fusion, the result of the fusion is recorded as C_0, and, in addition, the threshold is set as

$$Thr = [C_0 - \mu, C_0 + \mu]. \tag{2}$$

In the next fusion, the node output x_i is compared with Thr. If $x_i \in Thr$, the data is deleted and the change output is $x_1, x_2, \ldots, x_m, m \leq n$. There are three key points here: the selection of thresholds, the processing of deleted data, and the improvement of weight-based algorithms.
FIGURE 1: Intelligent information system hierarchy diagram.

FIGURE 2: Correspondence between WPAN and other wireless networks.

3.4.1. Threshold Selection. Choosing the appropriate threshold is especially important in the improvement of the algorithm. If the threshold is selected to be too large, it will not be able to mask invalid data, and the accuracy of the data will be greatly reduced. If the threshold is selected to be too small, it will cause the data to be deleted and screened out in the next comparison, which will result in the algorithm. The amount of calculation and time consumption are not much different from those before the threshold is taken, and the meaning of the improved algorithm is lost. According to the above formula (2), the selection of the threshold in this paper is based on the result of the previous fusion C0. Here, we consider the fusion of temperature data.

Assume the following scenario: after the user enters the service environment, the room temperature is 8°C. The intelligent information system sets the air conditioner temperature to 25°C according to the user's habit. After the air conditioner is turned on, the room temperature rise curve is shown in Figure 3.

From the figure, we can see that, in the first few minutes, since the main engine has just started running after the air conditioner is started, the heating effect is not obvious and the temperature is almost changed. With the normal operation of the air conditioner main unit, the heating effect

begins to appear and the temperature rises faster; later, as the room temperature has risen, the temperature rise requires more heat, so the temperature rise tends to be slow.

In this scenario, the fuzzy fusion of the temperature data is carried out. Obviously, the data in the first few minutes and the last few minutes shows a lot of redundancy, and some data can be eliminated by setting the threshold. After repeated experiments and measurements, this paper selects $\mu = 0.5$, which is the threshold of

$$Thr = [C_0 - 0.5, C_0 + 0.5]. \tag{3}$$

3.4.2. Delete Data Processing. In the above threshold elimination process, the data within the threshold range is directly deleted, but if the amount of data deleted is large, it will also cause distortion of the final fuzzy fusion result. In order to prevent this from happening, this paper introduces a processing mechanism for deleting data, which is to give the data a weight value to reflect its importance in the system.

The weight value mechanism of this paper is to assign a weight W to each data to be fused. The default value is
Figure 3: The room temperature rise curve.

$W = 1$. W represents the number of data amounts similar to the data and $W = 1$ means that the data can only represent itself.

According to the above, assuming that the result of the last fuzzy fusion is C_0, a weighted data to be merged x_i is compared with the threshold value (3), and if $x_i \in Thr$, whether it is the first data entering the threshold Thr, then, C_0 is assigned to x_i, and the weight W is still 1; the data that enters the threshold Thr again can be directly deleted, but each time a data enters the threshold the weight W of C_0 is increased by 1, indicating that the number of data amounts similar to C_0 is increased by one. If $x_i \notin Thr$, the data is not adjusted, participating in the next fusion, and the weight W is still 1. This process can be represented in Figure 4.

3.4.3. Weight-Based Algorithm Improvement. Since the weight of the data to be merged is introduced, the fuzzy measure function of the traditional fuzzy fusion algorithm cannot be directly used, and corresponding improvement is needed. The following describes the improvement of the fuzzy measure.

The fuzzy measure function reflects the reliability of the sensor group participating in the calculation. The range is between [0, 1]. The more the number of sensors participating in the fusion, the larger the fuzzy measure value and the higher the reliability. Otherwise, the number of participating sensors is less than the fuzzy measure value and thus the reliability is lower.

Assume, that in the home service environment, the number of sensors in the sensor group is n. When the number of participating sensors is m when a data is fused, the reliability can be expressed as m/n.

The result of the previous fusion is C_0. After the next fusion, all data is compared with the threshold T, and the weight of C_0 is $W = i$.

If C_0 is not included in the sensor group data to be calculated, m/n is still used as the result of the fuzzy measure. If C_0 is included in the sensor group data to be calculated, the fuzzy measure of the sensor group can be expressed by

$$\frac{(m + i - 1)}{n}. \tag{4}$$

The improved fuzzy measure guarantees the integrity of the data and makes the fusion result more accurate.

4. Designs and Analysis

4.1. System Architecture Design. This paper participates in the design of the presidential architecture of a service-oriented intelligent information system, as shown in Figure 5.

The intelligent information system is divided into functional modules, and the specific functions are designed. The functional modules include information collection template, data processing module, knowledge management module, decision control module, and device adjustment module. Their relationship to each other is shown in Figure 6.

The data collected by the information acquisition module is the most primitive data prototype obtained by the data processing module. It is the nerve ending of the entire intelligent information system and collects the information of the surrounding environment as accurately as possible for system processing, calculation, and decision-making.

The data processing module is a template for the intelligent information system. First, data is collected as input, then stored locally, and then preprocessed to provide a more accurate and reliable data prototype for the knowledge management module and decision control module.

The knowledge management module is a positioning in the intelligent information system, which is equivalent to a memory module in the human brain. Its input mainly comes from the data prototype provided by the data processing module, and the output is the user habit obtained by massive data accumulation and data mining. These data are stored in the database together with the data prototype and, on the other hand, as decision control. The data also can be input to the module for reference by the decision control module.

The decision control module is mainly responsible for making comprehensive decision judgments based on the information transmitted by the data processing module and
FIGURE 4: Data processing process that introduces weight values.

FIGURE 5: Intelligent information system architecture diagram.

the knowledge management module and producing control instructions.

The device adjustment template is one of the ends of the intelligent information system, receives the control command of the decision control module as an input, and performs input information to control the device parameters.

4.2. Experimental Analysis of Improved Data Fusion Algorithm. In this section, by setting the specific application scenarios, the data is simulated by MATLAB, and the traditional fuzzy fusion algorithm and the improved algorithm are compared and analyzed.

4.2.1. Comparison of the Number of Participating Nodes. First of all, this paper separately compares the number of sensors participating in each fusion of the two algorithms and obtains the results of Figure 7 as follows.

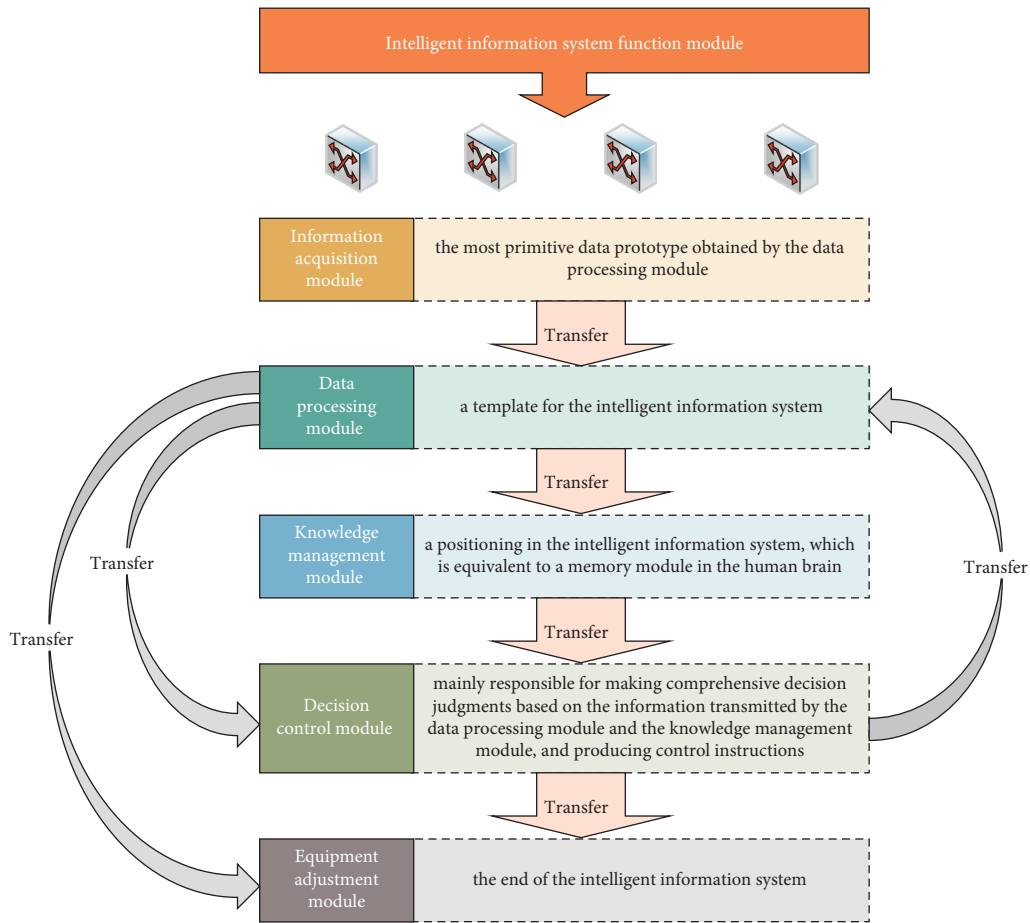
In Figure 7, the blue dot curve represents the traditional data fusion algorithm, and the orange dot curve represents the improved fuzzy fusion algorithm. As can be seen from the figure, in the traditional algorithm, the number of nodes participating in the fusion has been fluctuating around 90~100; this means that, in every fusion process, almost all the data collected by the nodes will participate, which will cause huge calculations and consume system resources and time. The improved fusion algorithm has dropped significantly by half since the second fusion and then basically maintains a stable fluctuation around 50. This shows that, from the second time, the number of nodes participating in the fusion is significantly reduced. That is, setting a reasonable threshold makes the number of nodes participating in the fusion greatly reduced. From the previous analysis, we already know that when there are n nodes participating in the fusion, $2n - 1$ kinds of node combinations will be generated. When n is reduced, the number of node combinations will decrease exponentially, which will greatly reduce the calculation amount of the system and improve


FIGURE 6: Intelligent information system function module diagram.
FIGURE 7: Comparison of the number of participating nodes.

the timeliness of data processing. Therefore, in the improved fuzzy fusion algorithm, it is feasible and effective to reduce the amount of data to be fused by setting a reasonable threshold.

4.2.2. Comparison of Fusion Results. At the same time, the fusion results of the traditional fuzzy fusion algorithm and the improved weight-based fuzzy fusion algorithm are compared. The comparison results are shown in Figure 8.
FIGURE 8: Comparison of fusion results.

In Figure 8, the blue dot curve represents the temperature fusion result of 50 fusions by the traditional fuzzy fusion algorithm, and the orange dot curve represents the temperature fusion result of the improved weight-based fuzzy fusion algorithm. It can be seen from the figure that the curve of the improved algorithm is more consistent with the curve of the improved algorithm and the error is smaller. This shows that the improved algorithm can still accurately integrate the data and the improved algorithm is accurate and reliable.

5. Conclusions

Since the introduction of the concept of intelligent decision-making information system, after years of research and development, it has gradually entered the practical stage of the market. With the rapid development of technologies such as Internet of Things, big data, and cloud computing, its research has gradually focused on the wisdom of the system level. In view of the shortcomings of existing intelligent products or systems, this paper designs a data processing module of intelligent information system, considers the problem of data fusion after system expansion, and improves the data fusion algorithm. According to the analysis of requirements, the intelligent information system is designed, and the three-layer architecture of the system based on intelligent decision-making is proposed, including the sensing layer, the network transmission layer, and the intelligent service application layer. The module construction is decomposed to explain how the modules interact with each other to cooperate in work. Considering the massive data problem after the expansion of intelligent information system, the data fusion algorithm is compared and improved according to the traditional fuzzy fusion algorithm. A weight-based fuzzy fusion algorithm is proposed to make it more adaptable to massive data and improve the accuracy and reliability of system data. Through the simulation diagram, the improved algorithm and the traditional algorithm are compared and analyzed, and the effectiveness of the weight-based fuzzy fusion algorithm is verified.

This paper provides an in-depth study and analysis of robot vision features for predictive control and a global calibration of their feature completeness. The acquisition and use of the complete macrofeature set are studied in the context of a robot task by defining the complete macrofeature set at the level of the overall purpose and constraints of the robot vision servo task. The visual feature set that can fully characterize the macropurpose and constraints of a vision servo task is defined as the complete macrofeature set. Due to the complexity of the task, a part of the features of the complete macrofeature set is obtained directly from the image, and another part of the features is obtained from the image by inference. The task is guaranteed to be completely based on a robust calibration-free visual serving strategy based on interference observer that is proposed to complete the visual serving task with high performance. To address the problems of singular values, local minima, and insufficient robustness in the traditional scale-free vision servo algorithm, a new scale-free vision servo method is proposed to construct a dual closed-loop vision servo structure based on interference observer, which ensures the closed-loop stability of the system through the Q-filter-based interference observer, while estimating and eliminating the interference consisting of hand-eye mapping model uncertainty and controlled robot input interference. The equivalent interference consisting of hand-eye mapping model uncertainty, controlled robot input interference, and detection noise is estimated and eliminated to obtain an inner-loop structure that presents a nominal model externally, and then an outer-loop controller is designed according to the nominal model to achieve the best performance of the system dynamic performance and robustness to optimally perform the vision servo task.

1. Introduction

The ability of humans to observe things in the outside world with both eyes and manipulate what we see is the result of a long evolutionary process that is important for us to adapt to and make use of the outside world. Inspired by this phenomenon, visual sensing was introduced to robot control systems to sense the state of the system and the task. This type of information is collected from the outside of the control system, compensating for the information fed back from within the system, relaxing the requirements for mechanical accuracy and joint tightness of the robot components, and allowing the robot system to enhance its flexibility in an uncertain external environment for various automatic control functions, such as robotic assembly, robotic surgery, and remote-control tasks. As a result, visual

servo control, that is, the introduction of visual information into the control closed loop to guide dynamic system motion, has received a great deal of attention. The development of robotics is changing rapidly; robots are more functional and more versatile; not only traditional robots for industrial applications but also more military and medical robots along with the wave of artificial intelligence robots are making a splash in various fields [1]. Whether the information contained in the macro- and microfeatures is complete affects the completion of the task. Therefore, the complete visual feature set of the visual servo task is defined to describe the feature set that meets the needs of completing the task. The feature set consists of a complete macrofeature set and a complete microfeature set. The wide application of robots makes robotics products form a huge industry. At the same time, the development of robotics will have a huge and far-

reaching impact on the country's comprehensive national power and its ability to develop sustainably. Therefore, robotics is not only seen as a frontier technology but also taken as a national strategy by many developed countries in the world, which gives strong support to the research in this field. As the most important class of robots, mobile robots will be used in industry, agriculture, national defines, scientific research, and other industries to partially or completely replace the work of people as human society continues to develop and the degree of information technology and intelligence continues to increase.

Vision-based mobile navigation is a research hotspot, and research in this area can currently be divided into three parts: visual simultaneous localization and mapping (VSLAM), path planning, and navigation control. Over the past decades, a large amount of research has focused on VSLAM, which is the study of environmental modelling. The process requires the system to build the environment while using the known local environment to achieve self-localization and then incrementally model the environment [2]. Research in this area, often without considering the command generation for its movement control, but only how to achieve environment reconstruction as well as real-time localization is given the information, is essentially a real-time version of structure from motion (SfM) in the field of computer vision [3]. In the visual navigation process, the captured image sequences are used to achieve online incremental environment perception and autonomous localization using VSLAM. The concept of feature completeness for robot vision servo tasks is proposed, and the complete feature set is defined to consist of a complete microscopic feature set and a complete macroscopic feature set. For an arbitrary vision servo task, a criterion is given to judge whether a microscopic feature set is complete or not, and three metrics are proposed to evaluate the performance of a complete microscopic feature set. The task of grasping a brush by a humanoid robot is taken as an example to study the acquisition and application of the complete microfeature set in the robot vision servo task [4]. According to the proposed definition and discriminative quasi-discrimination of the complete feature set, the complete feature set is designed. The camshaft algorithm is used to detect target points and actuator ends in the video stream captured by the system camera, and then the complete feature set is obtained.

Mobile robots often work in unstructured and unknown environments and need to autonomously sense and perceive the environment according to specified task goals and plan their behaviour efficiently and intelligently to accomplish specific tasks. To accomplish tasks more efficiently, mobile robot systems contain a central decision-making system and several subsystems that are responsible for different subtasks [5]. Among them, autonomous navigation technology for mobile robots is a fundamental module. The navigation system is the minimum complete system integrating environment modelling, scene understanding and reasoning, autonomous decision-making and execution, and human-robot interaction, corresponding to a complete processing process of information representation, association, fusion, reasoning, and management. Therefore, the level of

intelligence of a robot navigation system also determines the complexity of the environment it can adapt to and the complexity of the navigation task. The intelligence level of robot autonomous navigation systems is closely related to the corresponding methods of information processing, feature expression, and autonomous cognition. In recent years, the leap in technologies such as high-speed cameras, image processing hardware, and high-performance mobile computing platforms has provided mobile robots with the assurance of perceptual information and computing efficiency for autonomous navigation. The rapid development of information intelligence processing technology also keeps pushing the robot autonomous navigation system towards the direction of intelligence, which makes the robot gradually improve its adaptability and autonomy to the environment. This paper focuses on the effect of different feature sets on the completability and completion performance of an uncalibrated visual servo task. Feature completeness is proposed to examine whether a feature set provides enough information to make a task complete. Evaluation metrics are proposed to examine whether a completeness feature set enables optimal task completion. The humanoid robot grasping brush task and the robot writing Chinese calligraphy task are used as examples to investigate how to select, extract, and use the complete feature set for different visual servo tasks, respectively. Based on this, a robust calibration-free visual servo control method based on the complete feature set is proposed to improve the task completion performance.

2. Status of Research

Since the control commands of the vision servo system are calculated based on the hand-eye mapping relationship, the transient performance, steady-state performance, and stability of the system are affected by the hand-eye relationship [6]. The calibration-free vision servo system uses visual information to guide the robot's motion when the camera parameters are not calibrated. How to obtain an accurate hand-eye relationship in uncalibrated vision servo control is an important research problem [7]. The hand-eye mapping relationship for visual servo systems is strongly nonlinear and can be approximated by a series of linear relationships within each local domain, such as the use of image Jacobian matrices. There are two main ways to calculate the image Jacobian matrix, indirectly or directly, to estimate the matrix take values. One way to estimate the image Jacobian matrix indirectly is by estimating the unknown parameters in the model. The literature [8] represents the uncalibrated visual servo problem as a multiple-input, multiple-output adaptive control problem and accomplishes visual servo control using a Lyapunov adaptive control method based on SDU decomposition with online calibration of the camera parameters through a cascade control strategy. The literature [9] investigates how a system with unknown camera and robot parameters can accomplish calibrated control. The algorithm uses a depth-independent image Jacobian matrix to establish a mapping of visual deviations to the joint angle space of the robot arm so that the unknown camera and

robot parameters appear linearly in the closed-loop dynamic structure of the system, which in turn estimates the unknown parameters online using an adaptive algorithm [10]. Another approach estimates the image Jacobian matrix directly using a different method.

The spatial projection of image pixel points using multiview geometry as well as feature point matching and optical flow tracking is used to obtain a spatial point cloud, and the matching of this point cloud map with the current image and the PnP algorithm is used to localize the robot system [11]. Its localization optimization is performed with the reprojection error or image error as the optimization term for the pose solution. The method is characterized by high operable accuracy and intuitive map representation [12]. The basic dual-view geometric relative pose solution usually uses feature points to represent the image and calculates the basis matrix or single response matrix between two frames by matching the feature points and then obtains the relative pose between two frames by decomposing the singular values of the matrix [13]. The method has a deep theoretical foundation and can obtain pose calculation results with high accuracy under the premise of having ideal data matching [14]. This kind of reprojection method is usually implemented based on feature points, so this kind of method relies on the information of individual pixels in the image for localization, and this kind of matching method with local information often limits the reliability of data matching due to the limitation of its observation window size; in addition, the amount of information used in the selection and expression of pixels is limited, so this method has a weak ability to overcome changes in environmental conditions. In addition, due to the limited amount of information used, the ability to overcome changes in environmental conditions is weak, resulting in problems such as data matching errors or insufficient effective matching [15]. These problems also lead to the inability of visual navigation based on these methods to achieve reliable localization output and stable navigation under a long period or harsh working environment, which reduces the robustness of the visual navigation system.

Real-time modelling for the unstructured environment in the human-robot collaboration scenario can provide global process information for subsequent motion planning, which is a key technology for visual perception. It mainly studies the influence of different feature sets on the accomplish ability and completion performance of an uncalibrated visual serving task. The feature completeness is proposed to investigate whether a feature set provides enough information to make a task complete. According to the above comparison, the depth camera based on the principle can calculate the depth information in real-time and fast, with moderate accuracy and a large field of view, which can fully meet the robot's needs for motion planning in a large working space. However, after analysis, in unstructured working scenes, the field of view of a single depth camera is affected by obstacle occlusion, so it is necessary to introduce multiple depth cameras to form a high real-time global vision system to obtain more complete environmental information and improve the success rate and safety of

motion planning. Therefore, efficient modelling of unstructured environments is one of the main research directions of this paper.

3. Predictive Control for Robot Vision Feature Completeness Analysis and Global Calibration Analysis

3.1. Predictive Control for Robot Vision Feature Completeness Design. Visual servo tasks require optimization of the overall performance of the task from a macroscopic perspective and the achievement of planned control goals at each step from a microscopic perspective. Both macroscopic optimization and microscopic control require description and feedback of the task in terms of visual features [16]. The completeness of the information contained in the macro- and microfeatures affects the completability of the task. Therefore, the complete set of visual features for a visual servo task is defined to describe the set of features needed to satisfy the task completion, which consists of a complete macrofeature set and a complete microfeature set. Macrofeatures are often built on top of microfeatures, so this section discusses the complete microfeature set first. Robot vision servo control is an interdisciplinary research field, involving multiple disciplinary elements such as image processing technology, computer vision, control theory, and real-time computing. However, the purpose of its task execution is to achieve control goals in the task space. Microscopic visual features play a role in visual servo control to characterize and feedback the control condition of the system. Therefore, evaluating the merit of a microscopic visual feature set for a visual servo task examines whether the hand-eye relationship adequately links up control and visual features. That is, the microscopic visual features should be sufficiently informative to ensure that every control degree of freedom is characterized and fed back by the visual features.

$$f = \frac{\partial H(q)}{\partial q}\dot{q},$$
$$f = J \cdot U^2. \tag{1}$$

The image Jacobian matrix varies with robot poses, so for a particular set of microscopic features, it is important to ensure that the image Jacobian matrix is a full rank within the robot motion range involved in the task. Based on ensuring that the visual servo task can be completed, the feature set with the best properties is selected so that the task completion effect is optimized. First, the mapping relationship between the image space and the task space should be as stable as possible, changing substantially as the relative poses between the target object and the camera change so that the feature set can avoid the system converging to local minima or having unintended motions in the task space [17]. Second, the rate and magnitude of change of the microscopic visual features should be as consistent as possible with the control volume to better characterize it. The microscopic features are chosen to avoid singular values and local

minima as much as possible. When singular values or local minima are present, both visual feature changes and control volume changes will be extremely inconsistent. At singularities, it is known from the hand-eye mapping relationship that a nonzero velocity vector at the end of the actuator corresponds to a visual feature deviation that may be zero, and thus, the visual feature does not correctly reflect the condition of the controlled robot. At local minima, the feature deviations belong to the zero space of the generalized inverse matrix of the image Jacobian matrix.

$$f + f^* = \operatorname{Ker} J^+. \tag{2}$$

The visual feature bias is not zero, and the robot control speed command is calculated to have a value of zero, so the visual feature cannot be used to guide the control either. In addition, good decoupling of the hand-eye relationship facilitates control and planning to avoid control of individual degrees of freedom causing undesired operations in other degrees of freedom, resulting in reduced control efficiency or actuator end motion out of the field of view, as shown in Figure 1.

For the human-machine collaborative operation system, there is a state that the human-machine is not in the same space at the same time; then the robot's working space is an unstructured environment occupied by static obstacles. Unlike the free space or structured environment where the state is known, the work objects and obstacles in the unstructured environment are irregular and randomly placed, especially for the customized and small-batch operations where the human-robot collaborative production method is applicable; the work objects are of many types and often change production. The navigation system is the smallest complete system that integrates environment modelling, scene understanding and reasoning, autonomous decision-making and execution, and human-computer interaction. It corresponds to a complete processing flow of information expression, association, fusion, reasoning, and management. In the actual operation process, the robot first needs to identify the target workpiece among multiple types of work objects, that is, to achieve the position estimation of the target workpiece, which is the basis for completing the subsequent operation tasks and is exactly what was studied in the previous section of this paper [18]. In the process of executing subsequent tasks, the robot calculates the corresponding end tool posture based on the workpiece posture and moves safely and autonomously to the target posture in

an unstructured environment, which is an important manifestation of the robot's intelligence capability, and motion planning is one of the key technologies to realize the robot's autonomous motion, which is also the focus of this chapter. Since robots for human-robot collaboration usually have six or seven degrees of freedom, their planning space is a complex high-dimensional space, which leads to complex space modelling and increased computational effort for collision detection, affecting the efficiency and success rate of motion planning. To solve the above problems and quickly plan feasible motion paths, this chapter first introduces the planning principle of the classical fast extended random tree algorithm and then proposes a heuristic-guided fast extended random tree algorithm for its problems of randomly scattered sampling points and slow convergence, which uses a guided search strategy to accelerate the convergence of the algorithm, and heuristic functions are used to optimize the motion paths to make the optimal motion path length.

$$J = \begin{bmatrix} \dfrac{\lambda_1}{z_1} & 1 & -\dfrac{f_1}{z_1} \\[2ex] 1 & \dfrac{\lambda_1}{z_1} & -\dfrac{f_2}{z_1} \\[2ex] \dfrac{\lambda_1}{z_1} & 1 & -\dfrac{f_3}{z_1} \end{bmatrix}. \tag{3}$$

The camera of a specific focal length can be selected according to the range of features in the actual experiment to avoid singular Jacobian matrices when the inverse matrix zero space of the image Jacobian matrix contains only zero vectors and avoids local minima. Thus, the feature set consisting of the pixel coordinates of the marker points is the complete feature set for this task. With the feature set complete, its performance is discussed. The image Jacobian matrix does not change rapidly with the relative positional change of the hand-eye, so the linear nature is acceptable. Good consistency of hand-eye variation is obtained by avoiding singular values and local minima with a suitable choice of camera focal length. There are three zero terms in the image Jacobian matrix, so the hand-eye relationship under this feature set is well decoupled. The simplicity of the points makes the feature set acquisition efficient and satisfies the requirement of processing speed in human-computer interaction.

$$\theta_0 = \arctan\left(\frac{2\left((M_{11}/M_{00}) + x_\lambda y_\lambda\right)}{\left((M_{11}/M_{00}) + x_\lambda^2 y_\lambda^2\right) + \left((M_{11}/M_{00}) - x_\lambda y_\lambda\right)}\right), \tag{4}$$

$$f(k-1) = f(k) + J(q(k)) \cdot \Delta q\left(k_k^2\right).$$

The autonomous navigation behaviour of a mobile robot is first based on stereo vision sensors to obtain information about the surrounding environment and construct an

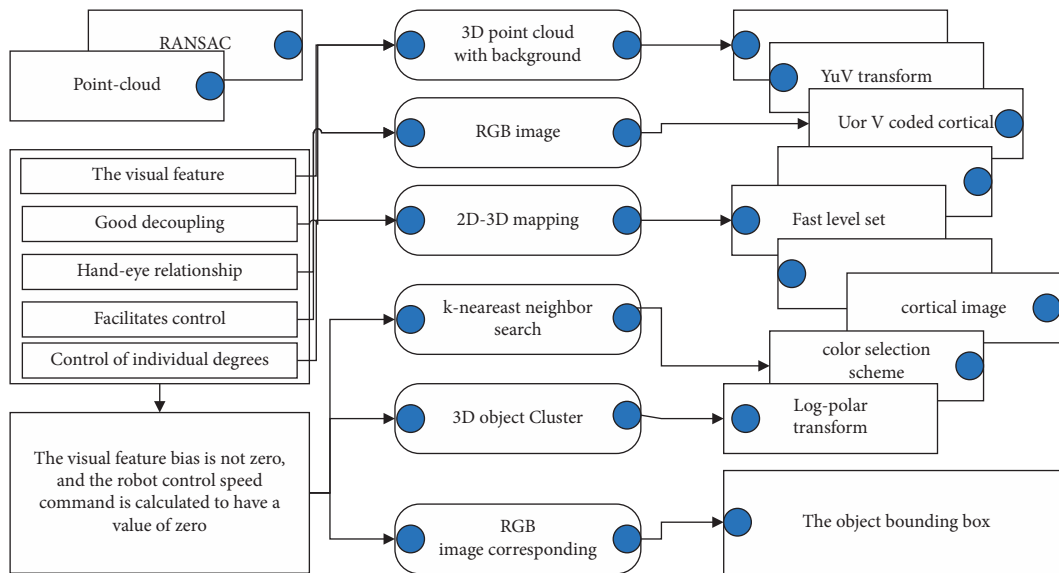
environmental possibility map and plan a reasonable executable path under the a priori information of the possibility map, and finally, the robot follows this executable path to


FIGURE 1: Robot vision feature completeness framework.

complete the obstacle avoidance navigation task [19]. The key to the robot navigation problem is to be able to find a safe and smooth path in the process of moving towards the target point while enabling the mobile robot to accomplish the task of dynamic obstacle avoidance. The existing mobile robots have a certain autonomous navigation capability, but because the characteristics of the field environment are more complex and dynamic, the control error and measurement error of the mobile robot is greater; therefore, it is necessary to conduct further in-depth research on the key technology motion planning of the autonomous navigation behaviour of the mobile robot in the field environment, as shown in Figure 2.

For the visual tracking constraint, since this kind of constraint is performed between the current frame and the previous keyframe with a short visual tracking baseline, it can be assumed that the relative motion between the two images is small, and it is feasible to use the optical flow method for data matching alignment in that case. Three indicators are proposed to evaluate the performance of a complete microfeature set. Taking the task of a humanoid robot grabbing a brush as an example, the acquisition and application of a complete set of microfeatures in the task of robot visual serving are studied. Also, it is appropriate to use the optical flow-based method to handle the visual tracking constraint calculation with a higher establishment frequency because of the simple and efficient data matching process. Based on the matching results of the optical flow method in the keyframe selection stage, pixel matching between two frames can be simply obtained to complete the data association establishment of visual tracking constraints.

To avoid the computationally expensive problem of too many candidate regions due to probabilistic sampling, the sampling mode of other traditional tracking algorithms is replaced by a local search cantered on the location of the target, which reduces the search range and improves computational efficiency. The advantage of local search is

that it considers the continuity of the target's motion trajectory and the smoothness of the appearance transformation during the tracking process. The previous frame filter model, obtained by using the filter template update method, is correlated with the local search region of the current image frame to locate the position of the tracking target in the current frame.

$$y = F^{-1}\{Z \oplus F^*\}. \tag{5}$$

To introduce multiscale estimation in the algorithm to obtain an accurate extraction of the region where the target is located, but not to lose the rapidity of tracking efficiency due to the increase in computational complexity, an incremental estimation strategy is used. The strategy separates the position estimation from the scale estimation, forming a cascading relationship. After relying on position estimation to capture the location of the target from the image, scale estimation is enabled to extract the extent of the target's region in the image. This estimation strategy does not affect the computational process of location estimation but also relies on its results to reduce the scale estimation range and reduce the computational cost.

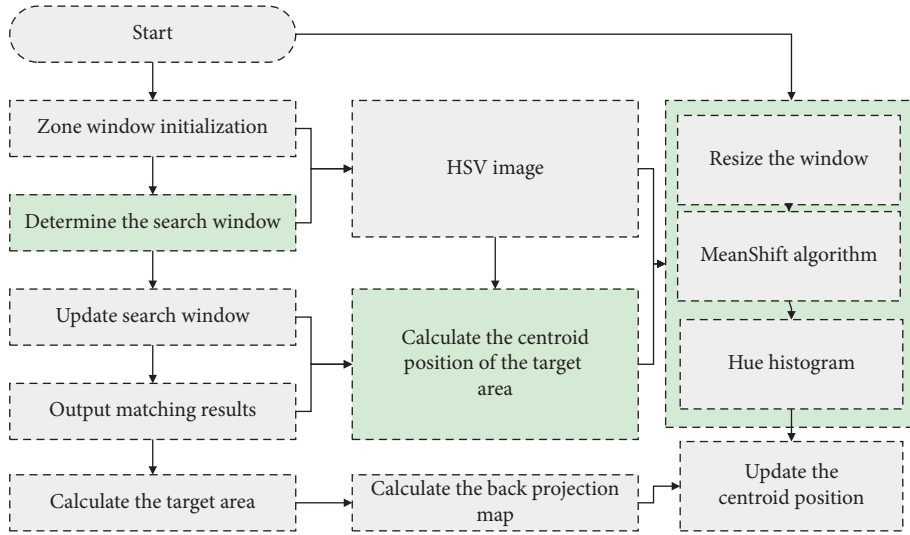
3.2. Experimental Analysis of Visual Feature Completeness Bureau Calibration. Based on the positional information of the operation object, the robot needs to plan a feasible path in the unstructured environment. Since in unstructured scenarios such as human-robot collaboration, there is a situation where the human and the robot are in the same workspace at the same time when the robot is in a dynamic unstructured scene, the state changes of the human, the robot, and the environment are random, so the robot needs to intelligently sense the state changes of the obstacles in the workspace through vision sensors, and when the obstacles may interfere with its normal operation, the robot needs to react in time, that is, plan its motion trajectory online to


FIGURE 2: Predictive control steps.

achieve obstacle avoidance to avoid potential collision hazards [20]. Therefore, this chapter proposes an online real-time trajectory planning method for robots in dynamic unstructured environments.

First, to solve the problems of the limited single-camera field of view and real-time dynamic obstacle avoidance, a visual perception method is proposed to establish an offline mapping and online fusion model of multicamera depth images and robot workspace 3D raster, determine the occupation state of the occluded 3D raster by the robot and obstacles, and obtain the nearest distance and relative velocity between the stable robot and obstacles in real-time based on Kalman filtering algorithm. It often does not consider the generation of commands for movement control but only considers how to achieve environmental reconstruction and real-time positioning under given information, which is essentially a real-time version of the field of computer vision. Then, based on the improved artificial potential field method to calculate the attractive and repulsive forces, the trajectory avoidance strategy is adjusted according to the relative position and velocity of the obstacles, and the potential field forces are converted into robot joint velocities to control the robot from the velocity level to complete the obstacle avoidance task so that the robot can avoid obstacles and ensure the operational efficiency at the same time. Finally, the effectiveness of the trajectory avoidance algorithm is verified in scenarios with different dynamic obstacles, as shown in Figure 3.

Unlike current path planning methods that optimize the path search approach to improve efficiency, this chapter improves the efficiency of path search by reconstructing the environment representation model. The multilevel graph model-based environment representation method can describe the multilevel topological structure information of the environment more effectively, which in turn improves the efficiency of using environment-inspired information in the path search process. This experiment further validates the idea that building a task-oriented environment
FIGURE 3: Path planning.

representation model can improve the efficiency of retrieving and utilizing information during task execution. However, in the path tracking process, to track the feature paths, the mobile robot needs to accurately identify the global features of the environment, thus requiring higher performance of global localization. The mobile robot needs to globally localize not only its pose but also the features of the environment.

Based on the above description, the definition of a visual tracking failure of the system is given here: a keyframe with an empty set of constraints is considered to have a tracking failure at that point. When a tracking failure occurs, the system considers this keyframe as the first keyframe in a new subgraph at the back end and reestablishes the subgraph coordinate system based on this frame so that future visual tracking is maintained in this new subgraph. It is important to note that in contrast to the first keyframe initialized by the system that is cured and not involved in the optimization

adjustment, the first node of the newly created subgraph here is not cured and will be involved in the future global graph optimization adjustment process. With this subgraph mechanism, the system will always be in two states: maintaining visual tracking in a subgraph or creating a new subgraph and trying to track maintenance in that subgraph. Thus, the system can run all the time without running out. The flow diagram of the back end of this subgraph is shown in Figure 4.

During the visual tracking of a particular subgraph, the poses of the nodes are given according to the motion model. The pose estimate of the current image frame is determined by the known pose of the related frames within the same subgraph and the constraints between the two frames. Also, nodes that are within the same subgraph will be influenced by other nodes that are constrained by another subgraph, thus achieving an overall alignment of the subgraph. Mobile robots are the most important category of robots. With the continuous development of human society and the continuous improvement of informatization and intelligence, mobile robots will surely replace human work partially or completely in industries such as manufacturing industry, agriculture, national defense, and scientific research. Thus, visual tracking always operates within a certain subgraph, and the operation of that visual tracking is always a two-view geometric operation based on two frames of images. With such a strategy, it is possible to maintain the operation of the system in the face of visual tracking failure in this system, despite the loss of information about other existing nodes.

When building a workstation for human-robot collaboration, the area of interest to be observed needs to be set and multiple cameras need to be arranged according to the scope of the working scene regarding the above method to obtain more complete environmental information [21]. Although two cameras can acquire more complete environmental information, the amount of data acquired by two depth cameras at the same time is large, and they need to be updated and fused in real time, which requires more computational effort and time, resulting in the robot's intelligent perception and trajectory planning performance in dynamic unstructured environments being affected by the online updating efficiency of the environmental model. Therefore, to speed up the fusion and update of dual-camera data, this paper draws on the idea of offline modelling and online updating, builds a model of the projection relationship between 3D raster and depth image in the offline stage based on the projection principle of 3D space and 2D image, calculates the projected pixel points of each 3D raster centre in the robot workspace on the depth image, and constructs the mapping data structure of 3D raster to depth map pixels to the data set that is saved offline.

4. Results and Analysis

4.1. Predictive Control Results for Completeness of Robot Vision Features. Figure 5 depicts the entire process of right-hand tracking for the NAO robot. In this task, the binocular vision system takes pictures of the workspace and the vision servo system uses the Camshafts algorithm to detect the end of the actuator and the quill. In this way, this process of the task can be described in vision space. At the beginning of the task, the NAO robot's left and right cameras capture images with a difference of 111 pixels in the horizontal and 163 pixels in the vertical direction. A Kalman–Bucy filter-based visual servo controller is used to estimate the image Jacobian matrix, which in turn derives control quantities to act on the robot. The NAO robot eventually reaches the quill within 17 steps, and the deviation between the two centres is within 10 pixels. The experimental results show the robustness of the algorithm proposed in this paper to image noise, motion disturbances, and irregular motion of the target object.

Task-oriented evaluation of visual feature sets examines the impact of feature sets on task completability and completion performance. First, a definition of a complete feature set for a visual servo task is proposed, and a complete feature set includes a complete microfeature set and a complete macrofeature set. This section focuses on the complete microfeature set and proposes a criterion to determine whether a feature set is a complete microfeature set for a visual servo task. On this basis, if the visual feature set is complete, its performance needs to be further examined in terms of the linear nature, change consistency, and decoupling of the complete feature set. Taking a humanoid robot grasping a brush as an example, the acquisition and use of the complete microscopic feature set is investigated, and a visual servo system is proposed, which is built based on the calibration-free Kalman–Bucy filter visual servo method and the Camshaft detection algorithm. Using this system, the NAO robot accomplished the grasping of brushes well in the calligraphy task. The experimental results verify the validity of the theory of complete microscopic feature sets proposed in this chapter and the robustness of the complete feature set extraction algorithm to image noise, humanoid robot return error, and an irregular motion of the target object.

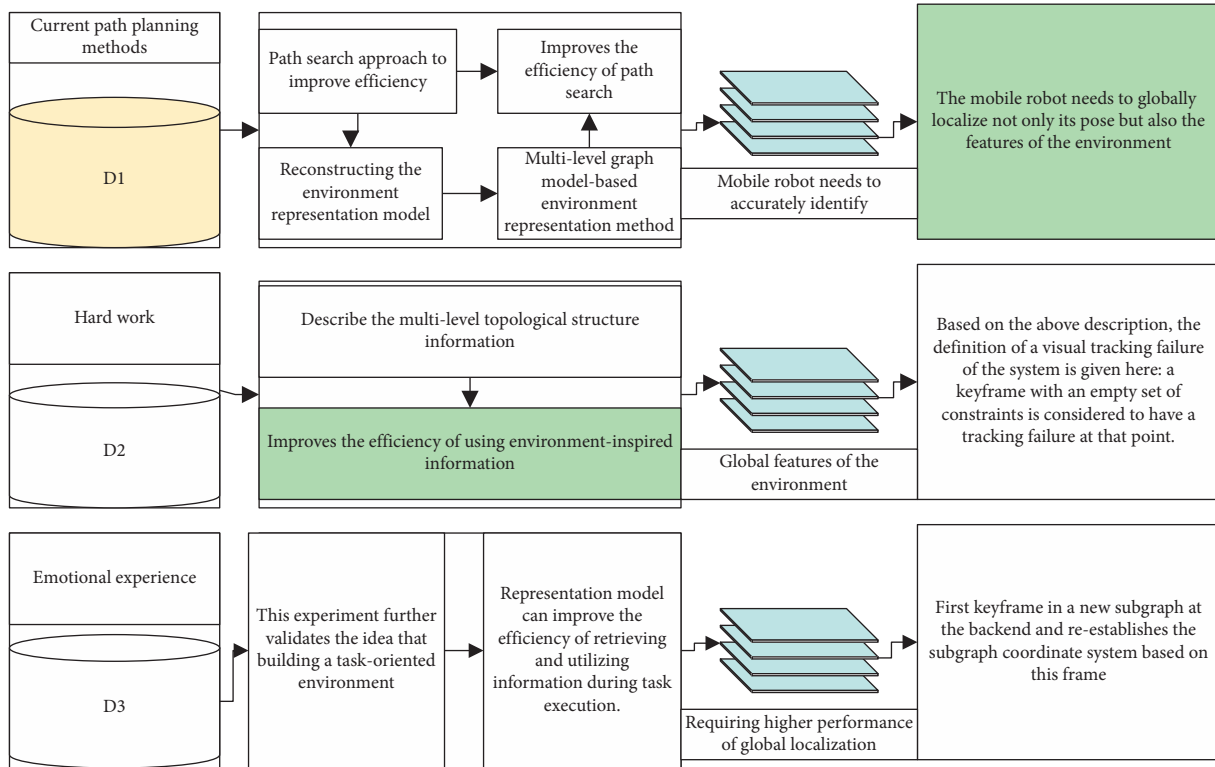
In terms of quantitative evaluation for the multisugar back end, to demonstrate the improved enhancement of this back end design for fault recovery, we recorded the timestamps of the occurrence of tracking loss and closed-loop detection during the experiment, as well as the localization error at the corresponding time points. The results are shown in, Figure 6, where the difference between the true bit poses recorded by the red grasping system is obtained, the light blue line is the response marker for the moment of tracking loss, and the red line is the response marker for the occurrence of closed loop. During the figure, visual tracking, as well as map construction, can always maintain operation in either subgraph, and when mutual constraints are detected between the subgraphs, the error curve decreases due to the alignment between the subgraphs. Furthermore, the trend of the error curve shows that after a certain time of environmental exploration, the error curve stops rising, and any new keyframe always finds a relevant reference frame in the map, which in turn establishes a constraint and achieves successful localization. Such curve results quantify the ability of the system in tracking lost fault recovery.


Figure 4: Back-end flow diagram based on multiple subgraphs.
Figure 5: Observed tracking bias.

The decreasing trend in the number of particles employed in the process indicates that the robot positional uncertainty is reducing the influence of its fluctuation process by the environmental structure. In the algorithm of this chapter, the number of effective particles is always maintained at a low level, which makes the algorithm require a low amount of computation. As the mobile robot moves, it collects enough information about its environment, and the uncertainty in its positional estimation decreases. However, to still ensure the robustness of the positional estimation, the algorithm still maintains a certain number of particles for the estimation of the positional pose.

The convergence rate is low in the corridor scenario because only the boundary information of the motion model is provided and the inner content is not fully described. Also, due to the use of omnidirectional observation particles, while obtaining as many possibility regions as possible, it introduces correlation uncertainty that needs to be fused with more observations for elimination. From the comparison experiments, the initial likelihood region calculation has an important impact on the convergence speed of the global localization algorithm. In the corridor scenario, it is difficult to make an accurate estimate of the region in which the initial poses are located. However, in the results of the

FIGURE 6: Analysis of positioning error accuracy at the back end of multisubgraph.

method in this chapter, despite the large deviation of the initial moment's positional estimation, the algorithm is still able to converge to the correct region after a period of motion, which fully verifies the robustness and stability of the method in this chapter in the process of global localization. It compensates for the information fed back from the system, relaxes the requirements for the mechanical accuracy and joint tightness of the robot components so that the robot system can also improve flexibility in an uncertain external environment, and realizes various automatic control functions. Through simulation experiments, this chapter verifies the effectiveness of the proposed method in terms of global localization accuracy and further verifies the effectiveness of this chapter's method in terms of global localization efficiency and global localization robustness through online experiments.

4.2. Experimental Results of Visual Feature Completeness Bureau Calibration. Geometric features in scenes are pervasive features, less affected by texture, more robust to changes in perspective, and so on. Geometric features can improve the ability to represent space. Establishing a mapping model of geometric feature descriptors to their spatial locations and constructing a method to retrieve their corresponding geometric features for a given spatial location are essential to improve the ability of geometric features to represent space. There are two main types of geometric features. One is the features corresponding to geometric primitives, such as line segments, planes, and other features. The second is local geometric features of dense surfaces, which do not have a specific form of expression but describe geometric information of the corresponding surface and can generally be modelled using surface elements. Single features have limited ability to characterize spatial information and are more dependent on environmental conditions. Exploring global localization methods for multiple features is important for improving navigation system stability and environmental adaptability.

Line segment features are pervasive features in the environment and are the main environmental features in

weakly textured scenes. Their number is generally small, but the feature descriptors are relatively expressive. In this chapter, a visual global localization method based on multivariate geometric features is proposed, which can better reason about feature associations by using the relationship between multivariate features. Furthermore, since the dense geometric information of the environment can greatly improve the screening quality of the positional hypothesis, this chapter explores more efficient dense map representation methods that enable the robot to quickly retrieve location-specific geometric distribution information to speed up the screening efficiency. A schematic diagram of visual relocation based on multivariate geometric features is shown in Figure 7.

In the interference observer-based visual servo control, the tracking results observed from both cameras are shown in Figure 8. It can be seen from the figure that the system can track the target object well using the interference observer-based algorithm even in the presence of image noise and external interference. It can be concluded that the visual servo method based on interference observer can suppress the effect of image noise and external interference well while ensuring the closed-loop stability of the system. At the same time, there is no steady-state error.

The experiments were first conducted using a pioneer robot equipped with vision sensors to collect training data and test data in a laboratory scene and a corridor scene. The lab scene contains richer texture information, while the corridor scene is a typical weak texture scene. Line segment features are the main feature type in the corridor. The data sequences collected in the static laboratory scene are Official and Office 2. To test the robustness of the method in this chapter to dynamic objects, pedestrians are set to walk during the test, and the corresponding data sequences are Office-D and Corridor-D. The method in this chapter is compared with the DBoW2 method, which is a global localization method widely used in current SLAM systems. It can be seen from Figure 8 that the method in this chapter can obtain more successful localization frames, in which, the indexes of the training and test sequences are given in the table. The experimental indexes are the number of frames with localization error less than 5 cm and the number of frames less than 10 cm. In the laboratory scenario, more correct localization frames can be obtained due to the richer features. Comparing the localization results of ORB-SLAM2 in Office and Office-D, the robustness of the method in this chapter is higher for dynamic objects. Although the method in this chapter obtained fewer successful localization frames with errors less than 5 cm in the corridor scene, most of the frames were localized with errors of 10 cm, indicating the robustness of the method in this chapter for dynamic, low-texture scenes.

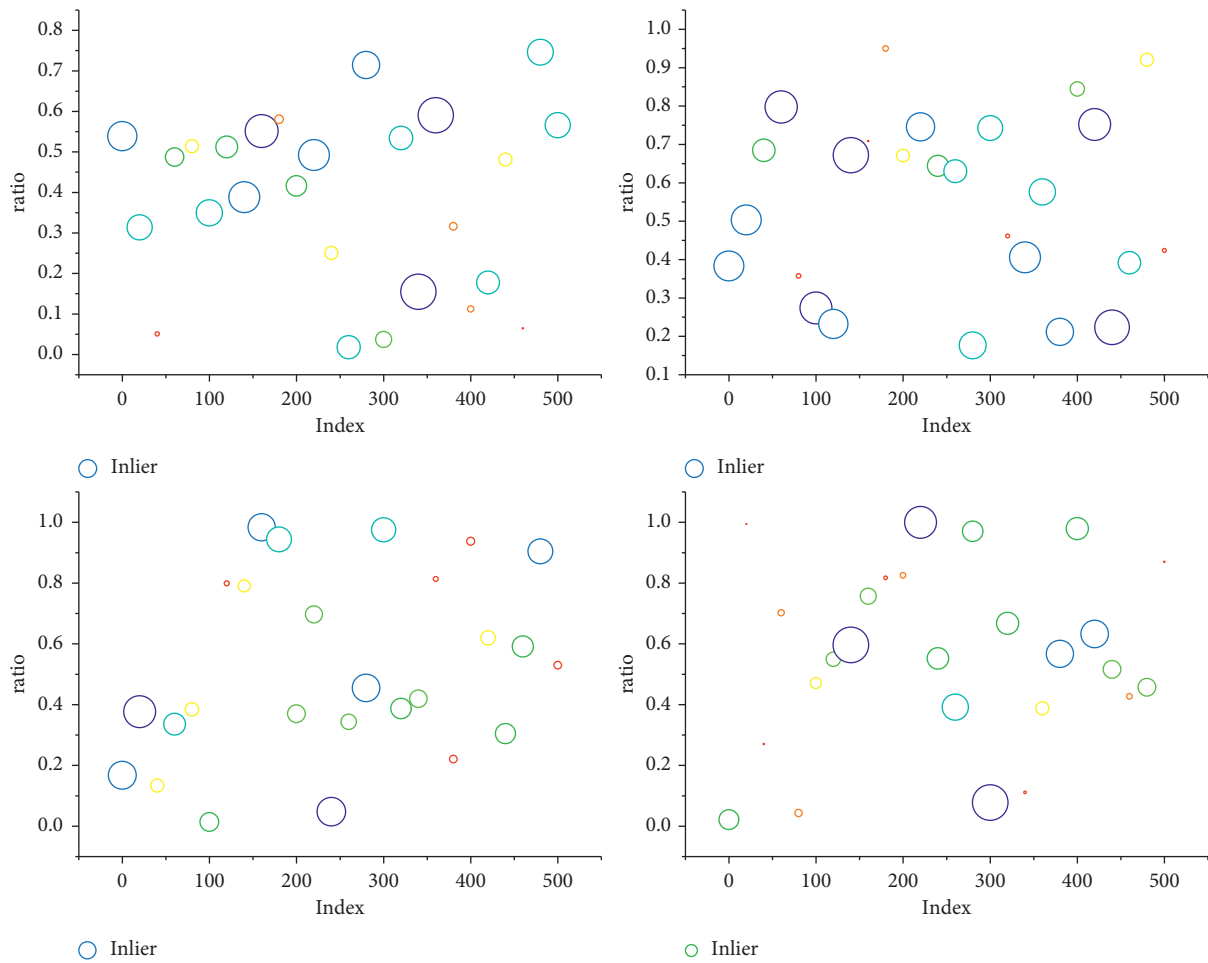
The feature point maps, line segment feature maps, and dense point cloud maps learned through regression trees, which greatly improve the efficiency of feature-based retrieval of space and spatial information-based retrieval of features. In the process of global localization, the camera poses are estimated by combining the applied point information and line segment information, and stable point


FIGURE 7: Results of point matching within the test image.
FIGURE 8: Tracking trajectory obtained using interference observer-based vision in a workspace.

pair matching is constructed using point-to-linear projection to realize the computation of positional assumptions. The stacked RANSAC method is constructed to address the problem of insufficient sampling efficiency due to the low proportion of interior points in the matched pairs. Compared to the traditional RANSAC method, the stacked RANSAC method uses the results of the previous sampling information to guide the new sampling process to

be more biased towards meaningful samples. At the same time, a more efficient method of assuming a quality metric for the poses is utilized to constrain the current observation to match the environmental surface in a more efficient manner using the dense geometric information of the environment.

5. Conclusion

The concept of a complete feature set is proposed from the perspective of visual servo task completability; the determination method of a complete microscopic feature set is given; and the extraction and use of a complete microscopic feature set are investigated using a humanoid robot grasping a brush as an example. In this paper, the hand-eye relationship of the feature-based 2D visual servo task is described by the image Jacobian matrix, and the completeness of the microscopic feature set is examined by finding the rank of the image Jacobian matrix to see whether the microscopic feature set completely characterizes the robot control degrees of freedom, that is, the completeness of the microscopic feature set is examined. The camshaft method is used to track the target object, obtain the microscopic feature set, and complete the task based on the complete microscopic feature set using a Kalman–Bucy filter-based visual serving method. Through the experiments based on the NAO robot, it is confirmed that the feature set proposed in this paper can guarantee the completion of the task, the microscopic feature set acquisition method has good robustness in the presence of image noise and irregular motion trajectory of the target object, and finally, the visual serving task can be completed with good performance according to the whole visual serving strategy. Based on the Q-filter to construct the interference observer, the equivalent interference consisting of model uncertainty, high-frequency detection noise, and low-frequency input interference is estimated and eliminated through the input and output signals of the controlled object so that the part consisting of the controlled object and the interference observer externally exhibits the given nominal model, and then the visual servo controller is designed according to the nominal model to achieve robustness under the premise of closed-loop stability of the system high-performance control effect under the premise of closed-loop stability of the system. Finally, the effectiveness of the calibration-free visual servo method proposed in this paper is verified by comparing the algorithm with the proportional-integral method and the divisional Brayden method in the simulation environment and comparing the method with the proportional-integral method in the experimental conditions.

With the rapid development of the economy and society, geological disasters such as landslides, collapses, and mudslides have shown an intensifying trend, seriously endangering the safety of people's lives and property, and affecting the sustainable development of the economy and society. Aiming at the problems of merging different data layers and determining the weighting of data stacking in the statistical analysis model based on GIS technology in the evaluation of the risk of geological disasters, this study proposes a logistic regression model combined with the RBFNN-GA algorithm, that is, the determination of the occurrence of geological disasters. The fusion coefficient (CF value) with the RBFNN-GA algorithm model, and with the help of SPSS statistical analysis software, solves the problem of factor selection, heterogeneous data merging, and weighting of each data layer in the risk assessment. In the experimental stage, this study adopts the method of geological hazard certainty coefficients to carry out the sensitivity analysis of the geological hazards in the study area. Using homogeneous grid division, the spatial quantitative evaluation of the risk of geological disasters is realized, and at the same time, the results of the spatial quantitative evaluation of the risk of geological disasters are tested according to the latest landslide points in the region. The existing classification mainly depends on the acquisition of land use/cover information or the processing method of the acquired information, but the existing information acquisition will be limited by time, space, and spectral resolution. The results show that the number of landslide points per unit area in the extremely unstable zone and the unstable zone is 0.0395 points/km^2 and 0.0251 points/km^2, respectively, which is much higher than 0.0038 points/km^2 in the stable zone, indicating the evaluation results and actual landslide conditions.

1. Introduction

According to statistics, in the past 50 years, landslides, collapses, and mudslides have caused more than 20,000 deaths, with hundreds to more than 1,000 deaths every year. Among the many natural disasters, the death toll is second only to earthquakes and floods. In particular, landslides, collapses, and mudslides that erupt in densely populated areas such as towns and mining areas often cause a disaster event that kills hundreds of people [1]. Geological disasters such as landslides, collapses, and mudslides are one of the natural disasters that cause the loss of people's lives and property [2]. In order to effectively prevent and reduce

geological disasters, it is first necessary to have a more comprehensive understanding of regional geological disasters. When formulating regional geological disasters, they can be more targeted. At the same time, research on geological disaster forecasting and early warning is based on the division of geological disasters. The foundation has also become a hot issue in the field of geological disaster research [3]. There are many domestic studies on the mechanism of single geological disasters such as landslides, but the research progress on the development and distribution of regional geological disasters is relatively slow [4]. Exploring and forming a set of scientific, complete, and practical research methods for the development and distribution of regional

geological disasters, and evaluating the risk of regional geological disasters, is of great practical significance for the prevention and control of regional geological disasters [5].

The geological hazard evaluation method adopted at the beginning has inherited the evaluation of geography in many methods, and the methods used can be summarized as follows: dominant factor method, multifactor single-factor item-by-item overlay method, geographic correlation analysis method, and theoretical derivation method [6]. After the 1980s, the degree of quantification increased, the application of mathematical knowledge in geosciences developed vertically and horizontally, and the geological hazard evaluation and zoning research gradually tended to quantify [7]. The extensive application of linear regression prediction, mathematical model analysis, gray theory, neural network, GIS, etc. is gradually introduced to further improve the degree of quantification [8]. In the study of slope geological hazards in an urban development planning project in Australia, Mai [9] integrated the risk, vulnerability, and risk assessment of slope hazards, using GIS software as the technical platform, and using two-dimensional and three-dimensional evaluation systems, respectively, for research on the danger and risk zoning of slope geological disasters in Cairns area. He et al.'s [10] probabilistic analysis and forecasting models show that these models have their own advantages but also have certain shortcomings. For example, the models established by index analysis methods, probability statistical methods, and fuzzy prediction methods are generally only suitable for specific research. At the same time, it is difficult to extract information related to the geology, mechanics, and other environmental conditions of the sliding mass. Liu [11] applied a genetic algorithm to the neural network to form the GA-ANN method to collaboratively solve optimization problems in complex engineering. This method not only uses the functions of neural network's nonlinear mapping, network reasoning, and prediction but also uses the global optimization characteristics of genetic algorithm. It can be widely used in many complex projects where the objective function is difficult to express in the form of explicit function of decision variables. Peng [12] applied the genetic algorithm to the artificial neural network model to determine the maintenance strategy of the parts and analyzed it in combination with examples. After experimental verification, the system selected the maintenance strategy and the actual value is in full compliance with the relative error between the predicted value of the maintenance cost and the actual value. Within the allowable range, the model is credible. Afan [13] applied the genetic algorithm to optimize the parameters of the controller based on the neural network structure and used the controller to control the objects with pure lag. The experiment proved that the control system optimized by the genetic algorithm has good static performance and dynamics. Performance has made a new exploration for solving this problem in the control field. The background factors include engineering rock formations, topography, geological structure, seismic intensity, human engineering activities, and atmospheric precipitation [14–16].

This study takes the regional geological disaster survey project of the autonomous region as the background, based on abundant actual data, deeply researches various factors affecting the occurrence of geological disasters, comprehensively analyzes the relationship between the distribution of geological disasters and various factors, and explores the determination of regional geological disasters. They should have the same or similar spectral information features and spatial information features, so the feature vectors of the pixels of the same type of features will be clustered in a unified feature space area, and different features will be due to different spectral information features or spatial information features. The method of risk has established a risk assessment system for regional geological disasters. Studies have shown that the regional layered soft phyllite intercalated with hard sandstone rock formations, a slope of $20°–40°$, and an elevation range of 320–800 m above sea level are most prone to geological disasters. The key factors affecting the risk of geological disasters are elevation, rock formations, road construction, and slope. According to the calculated cell geological hazard probability value, the regional geological hazard risk is divided into 4 levels, namely, extremely unstable, unstable, basically stable, and stable.

2. GIS Technology Based on RBFNN-GA Algorithm in the Delineation Model Construction of Geological Hazard Prone Areas

2.1. GIS Technology Level Classification. Geographic information system (GIS) is a decision support system that collects, stores, manages, analyzes, and reproduces information related to geographic spatial distribution and has various characteristics of an information system [17]. The main difference between geographic information system and other information systems is that the information stored and processed by it is geocoded. Geographic location and related feature information become an important part of information retrieval. Figure 1 shows the hierarchical topology of GIS technology.

The most important part of the geographic information system is spatial data. Spatial data can effectively express spatial location information and attribute data, while GIS spatial database is a collection of spatial data reasonably stored. The spatial database management system developed on this basis can effectively provide spatial query and analysis [18–20]:

$$p(x(1), x(2), \ldots, x(n)) = \prod_{i=1}^{n} p\{x(n)|x(n-i+1)\}. \quad (1)$$

In MapX, all the features in a layer constitute a feature set. Each graphic element is a feature object (Feature), and many methods of the layer object (Layer) return the feature set of the layer. You can search and locate geographic features such as lines, symbols, or regional characteristics [21–24]. In order to be able to use this method, there must be an index field in the MapInfo table of the search layer:
FIGURE 1: Hierarchical topology of GIS technology.

$$f(x) = x(i) + \frac{x(i) \times x(j)}{x(i) + x(j)},$$

$$T^2 - \frac{1}{n} \times \sum_{i=1}^{n} (p(i) - p(x))^2 = 0. \qquad (2)$$

The basic building blocks of MapX components are a single object and a collection. The collection includes objects, which is a combination of multiple objects. Each kind of alignment and collection is responsible for processing a certain aspect of the map. In the model structure of MapX, the Map object exists at the top, and each MapX object, attribute, and method are derived from the Map object.

$$\begin{cases} x(i,0) = a - x(j,0), \\ x(i,1) = b - x(j,1), \\ x(i,j) = \sqrt{\dfrac{x(j,i)}{a+b}}. \end{cases} \qquad (3)$$

Each attribute and method under the Map object will have an impact on the generation of the entire Map object. Each Map object is mainly defined by DataSets, Layers, and Annotations objects. Among them, Layers are mainly used to manipulate the layers of the map, DataSets are used to access spatial data tables, and Annotations are used to add text and symbols on the map:

$$S(x,m) - \frac{(1/2) \times x(m)p(n) + (2/3) \times x(n)p(m)}{p(m) + p(n)} = 0,$$

$$I = \{C(x,y), x \in (0,1,2,\ldots,n), y \in (0,1,2,\ldots,n-1), n \in N\}. \qquad (4)$$

The basic idea of GIS is to divide the main functional modules of GIS into several components, and each component performs different functions. Various GIS components, as well as between GIS components and other non-G1S components, can be easily integrated through visual software development tools to realize the final GIS application [25–27]:

$$L(x,y) = \sqrt{\sum [C_a(x,y) - C_b(x,y)]^2}. \qquad (5)$$

Each map has a data set. Through the data collection, the user's attribute data can be connected with the map spatial data. Data binding is the process of introducing external data into MapX. External data can be multiple types of databases.

$$K(x,y) = \begin{bmatrix} k(x) \times \cos x & 1 \\ 1 & k(y) \times \sin y \end{bmatrix}. \qquad (6)$$

After data binding, you can browse the data on the map as primitives or create a thematic rendering map based on these data. The learning process consists of three stages. The first stage uses unsupervised methods to determine the center of the RBF; the second stage determines the width of the RBF based on the determined center of the RBF; and the third stage determines the distance between the intermediate

layer and the output layer. Generally speaking, these stages are carried out separately.

2.2. The Composition of Geological Hazards. Geological disaster refers to a disaster related to geological action caused by natural factors or human engineering economic activities, which damages the ecological environment and endangers the safety of human life and property. It is in the shape of an inverted stone cone, with a loose and disorderly structure. The dangerous rock mass is a dangerous mountain mass that is cracking and deforming, and may collapse. Landslide refers to the phenomenon that the rock and soil on the slope lose the original balance condition and move downward along a certain weak surface as a whole or scattered along a certain weak surface under the influence of river erosion, groundwater activity (heavy rain), earthquake, and artificial slope cutting. The tendency of the weak structure surface is consistent with the slope direction, and the slope angle is most likely to occur when the slope angle is greater than the inclination angle of the weak surface. The material can be a loose layer, soft rock, and hard rock. A complete landslide should have a sliding surface (slide bed), landslide surface cracks and steps, trailing and lateral sliding walls, cracks, and front bulging. The influencing factors and formation conditions of geological disasters are extremely complex. They act independently, but also influence and overlap each other. According to their active forms, they are summarized as influencing factors and basic conditions; influencing factors include atmospheric rainfall, hydrogeology, neotectonic movement, and human activities; the basic conditions include topography and geomorphology conditions, stratum lithology conditions, and geological structure conditions. The spatial database of this project includes spatial databases of engineering geology and geological disasters. Figure 2 shows the fan chart of the factors of geological hazards.

This database system is constructed in accordance with the relevant provisions. The system includes geological hazard field survey data, result data, its spatial graphic database, and database structure, and the naming of format, layer, view project file, and the structure of primitive number are all carried out in accordance with regulations. The research area has a relatively complete range of disasters. Based on the geological environmental conditions formed in the area, the degree of disaster susceptibility, the degree of harm, and the integrated social development plan, a comprehensive analysis is made. The research area is divided into key prevention and control areas, subkey prevention and control areas, and general prevention area. We adopt measures such as restoring vegetation, cutting slopes, clearing dangerous rocks, strengthening supports, monitoring and forecasting of ground collapse disaster areas, strengthening of the survey of building foundations, assessment of the risk of geological disasters in disaster areas, and dredging of debris flow disaster areas. For river courses, excavation of water-cutting ditches around mountains, construction of slope protection, valleys, blocking dams, etc., the long term should be based on biological engineering and engineering treatment. According to geological survey data, the probability of geological disasters on concave slopes in the

Figure 2: Fan-shaped diagrams of geological hazard factors.

study area is low, and the probability of geological disasters on linear and convex slopes is greater. When the slope of convex slopes in the area is more curved, the relatively concentrated stress of the slope ultimately affects the stability of the slope. Therefore, the shape of the slope directly affects the possibility of geological disasters in the study area.

2.3. RBFNN-GA Algorithm Design. The RBF neural network is a forward neural network that combines a parameterized statistical distribution model and a nonparametric linear perceptron model. The essence of the RBF neural network is the combination of unsupervised clustering method and supervised single-layer linear perceptron to realize the neural network model of nonlinear mapping. The RBF neural network is composed of 3 layers, namely, the input layer, the middle RBF layer, and the output layer. For hyperspectral images, it is difficult to get so many pixels in a limited space for certain classes, and as the dimensionality of the feature space increases, the accuracy degradation called the Hughes phenomenon also requires more training samples. Generally, the number of nodes in the input layer is equal to the dimension of the selected data in the application field, and the number of nodes in the output layer is equal to the number of categories to be classified. For a specific application, the number of nodes in the input layer and output layer is determined. Therefore, the design of the RBF network structure is mainly to determine the number of nodes in the middle RBF layer. It uses the connection strength and the nonlinear input-output relationship of neurons to realize the nonlinear mapping from the input state space to the output state space. Feedforward networks are widely used in pattern classification and feature extraction. Another mode of operation is evolutionary, in which the input is equivalent to the initial state, and the final state of network evolution is the output. This kind of network is similar to a dissipative nonlinear dynamic system.

Figure 3 shows the RBFNN-GA algorithm architecture. The state space shrinks continuously during evolution and finally shrinks to a small attracting subset, and each attracting subset has a certain attraction domain. The energy function is a basic quantity of this type of network. Using the
Figure 3: RBFNN-GA algorithm architecture.

local minima of the energy function, operations such as associative memory, information compression, and coding can be performed: only the global minima of the energy function can be used to solve combinatorial optimization problems, such as TP problems, visual matching, and problem-solving. Output layer learning is a kind of supervised learning. In supervised learning, the attributes of the pattern samples to be classified are known, and for each sample input and output, there is a corresponding guidance signal that matches its nature. Based on the network output supervision, the various objective function criteria of the signal and the actual output adjust the weights accordingly until the accuracy reaches the best requirements. The database is based on the implementation project, the standard map sheet is the spatial index, and the geological disaster professional data are classified as the first-level processing object. According to the storage form, it is divided into two parts: the graphic database and the attribute database. Respective graphic elements and associated fields of records (or unified numbers) realize the two-way dynamic connection, combined with multimedia database and graphical legend data, to lay the foundation for environmental geological survey and evaluation as the application goal. The specific operation is carried out in strict accordance with the input direction and input sequence in the technical requirements of spatial database construction and the method of distinguishing different line elements with different colors to form a comprehensive graphic line file in order to facilitate the hierarchical extraction of line files.

2.4. Delineation of Regional Features.

The Permian and Triassic strata are the most widely distributed in the area. Among them, the Triassic strata are the most well developed.

Carbonate rocks account for about 68% of the total thickness of the strata. Carbonatite and clastic rocks are multilayered in vertical distribution and are also called interbedded carbonate rocks. The interbedded carbonate rocks are distributed in a strip-like plane. That is to say, except for the Yanshan Movement, which is an obvious fold orogenic movement, the rest of the crustal movement is slowly ascending and descending. Therefore, the regional crust is relatively stable. In order to apply the projection transformation of GIS, we first transform the data format in the database. Figure 4 shows a quantitative histogram of the susceptibility of geological disasters.

The grid map of the susceptibility of geological hazards is obtained through spatial analysis and superposition based on the changing trend of geological hazard points. The stability of regional landslides, avalanches, ground subsidences, and unstable slopes is divided into three categories: unstable, basically stable, and stable using expert assessment methods; for debris flows, the integral method is used, and the evaluation factor is determined to be 15 items. The integral value method is used to assess the susceptibility of debris flow geological hazards. Taking the 1 : 100,000 topographic map of the study area as the basic base map, it is divided by the raster data processing method. Taking into account the geological environment and disaster development status of an area, the standard area grid is 2 km × 2 km. The area is divided into 66 rows and 6l columns, with a total of 1,856 cells. Compared with traditional computer remote sensing classification, its classification accuracy is significantly improved, providing technical reserves and references for land use dynamic monitoring and land use management. Using the face-to-point intersection function of GIS spatial analysis, the face-to-point intersection calculation is performed between the surface file of the divided grid and the point file of various disaster points (with the attribute of
FIGURE 4: Quantitative histogram of the susceptibility of geological disasters.

proneness degree) to obtain different levels of disasters. Each cell is assigned a value based on the highest level of a type of disaster point that appears in the range. Using the method of GIS spatial analysis, the surface files of the divided grid and the point files of various geological disaster points (with the attribute of proneness degree) are calculated to obtain the partition files of different levels of various disasters. The partition files of different levels of various disasters obtained above are superimposed according to the following formula, which is the result of the scoring area. First, we superimpose the files in various unstable or high-prone areas. When there are two or more geological hazard high-prone areas overlapping, the value is 5. Second, we intersect all kinds of basically stable or medium-prone surface files with the merged unstable or high-prone surface files, subtract the common parts, and superimpose and merge according to the above formula to obtain the medium-prone layer. Third, we intersect all kinds of stable or low-prone surface files with the merged high- and medium-prone files and subtract the intersecting part, superimpose, and merge according to the above formula to get the low-prone layer. Finally, we subtract the high-, medium-, and low-prone areas from the whole picture, and the remaining areas are less prone areas. After merging, the zoning grid map of the susceptibility of the whole area can be obtained.

3. Application and Analysis of GIS Technology Based on RBFNN-GA Algorithm in the Delineation Model of Geological Hazard Prone Areas

3.1. RBFNN-GA Algorithm Data Extraction. The hardware requirements of this system are as follows: CPU Pentium 1.5 GHz, memory 512 M, hard disk 20 G and above

running on computers, Windows 2000/XP/2003 operating system, and software platforms that mainly include ERDAS IMAGINE 8.7, MATLAB 6.5, and Visual Studio 2005. Through field surveys and referring to the current land use map, we select typical land use plots and record their latitude and longitude coordinates. We use the remote sensing image file and text file conversion tool provided by ERDAS IMAGINE to convert the established training sample area into a text file; use the text file reading function provided by MATLAB to write the band values of each land use type into the matrix; and build a network model through the newrb function. The results of the network simulation are output in the form of a matrix, and when the accuracy analysis and classification results are evaluated, the image map is used as the basic data. Therefore, the classification results in the matrix form should be converted and restored into remote sensing images. This work can be done through remote sensing.

Figure 5 shows the normalized comparison line chart of RBFNN network evaluation indicators. We integrate the normalized results of the aforementioned various evaluation index data analysis and then use all the indicator inputs by the spatial overlay and analysis function in ArcGIS to obtain the digital matrix result; in ArcGIS, the Raster Calculator distributes the index data in the study area according to the weight. After the stacking calculation, the results need to be reclassified. Using the natural discontinuity grading method in the classical tool in ArcGIS, the stacking results are divided into three levels, and the regional geological hazard risk assessment result map is obtained. The system function mainly includes the selection of training sample area and the establishment of RBFNN algorithm and simulation. According to the scores in the result map superimposed by various indicators of the region, the geological hazard risk is
FIGURE 5: RBFNN network evaluation index normalized comparison line chart.

divided into three levels, namely, high, medium, and low, and then according to the actual situation, the repeated operation of grid or merging small redundant areas is performed. Finally, an artificially modified and integrated geological hazard risk zoning map can be obtained. The data calculated by GIS technology have been obtained by statistics of 16 villages and towns in the region. The requirement of consistency requires the establishment of a new judgment matrix through the relationships at all levels until the calculation and judgment results are reasonable. According to the principle of checking the consistency of the judgment matrix, matrix 1, matrix 2, matrix 3, and matrix 4 are calculated and tested, respectively, and the average CR < 0.1 is obtained. It is known that the constructed regional geological disaster risk assessment judgment matrix meets the consistency requirements.

3.2. Realization of GIS Delineation in Areas Prone to Geological Hazards. In this study, the neural network was set with 6 input nodes and 1 output node, and the initial value of the hidden node was 20. We used the control force to train the network parameters. The number of SGA implicit function nodes is fixed as 6, and the crossover probability is 0.7. The probability of variation is 0.05. The maximum fitness value changes during the training process as described in the text. As the core part of the geographic information system, the design quality of the database will not only affect the cost and quality of the system construction but also affect the operation, maintenance, and data update of the system. At the same time, the content and structure of the database determine the quality of the

system and will have a direct impact on the integration of GIS and other application technologies. When designing the system, we fully consider the scalability and compatibility of the system. In terms of the encoding of disaster-type information, the selection of the base map coordinate system, the design of the database, and the system interface functions, as much as possible, there is room for further development to facilitate the expansion of the system. With database migration, when new modules are added, the functional structure of existing modules and the entire system will not be greatly affected.

Figure 6 shows the distribution of curvature of geological hazards in the GIS system. According to the survey of geological disasters, the probability of geological disasters on concave slopes is relatively small, while the probability of geological disasters on straight and convex slopes is greater. The more curved the slopes of convex slopes are, the more concentrated the stress on the slope is. Therefore, for the slope curvature, when the curvature of a certain area is less than 0, the possibility of geological disasters is smaller. A large number of human engineering activities have a direct or indirect impact on the formation and development of landslides, collapses, and unstable slopes in the study area. Considering that traffic construction such as roads and railways is the most representative human engineering activity in the region, it has the most impact on geological disasters. Obviously, it has the characteristics of penetration and full coverage, so the analysis of human engineering activities in this study takes the regional secondary road as the baseline and makes buffer analysis. A value close to 0 means that the prior probability is very close to the conditional probability, and the certainty of the occurrence of
Figure 6: TheGIS system geological hazard influence curvature distribution.

the event is close to the regional average. When the curvature is greater than 0, the possibility of geological disasters is high, and the greater the curvature is, the more unstable the slope is. We use the Raster Calculator in ArcGIS to do the difference to calculate the slope height index map of the study area. Finally, it can be normalized by Raster Calculator in ArcGIS. Table 1 shows normalized processing of GIS disaster indicators.

The improved HANHGA-trained neural network controller and the SGA-trained neural network controller were used to control the double-stage inverted pendulum, and the simulation block diagram of the entire control system was built in Simulink using MATLAB. It can be seen that the improved HANHGA has a faster convergence speed and higher accuracy. The improved HANHGA training neural network has an error of 4.2% when it is trained for 100 generations, while the error of the SGA training neural network is only at the end of 200 generations. It reaches 1.2%, so the improved genetic algorithm has greater advantages than a simple genetic algorithm in convergence speed and in finding the global optimal solution. As a comparison between the improved HANHGA's RBFNN control method and the SGA neural network control method, it can be seen that the improved RBFNN control method can restore the inverted pendulum to a stable state faster, which proves the superiority of the improved algorithm. The data in the figure represent the control effect of the improved algorithm. It can be seen that it has a smaller overshoot and a shorter settling time, which proves the superiority of the improved algorithm.

3.3. Example Application and Analysis. On the ERDAS IMAGINE platform, using the Image Interpreter function provided by it, in the Utilities menu, the layer overlay module completes the overlay of each monochrome band,

Table 1: Normalized processing of GIS disaster indicators

Indicator index	Raster calculator	Weight	Curvature (%)
1	Landslides	0.32	13.5
2	Collapses	0.17	22.1
3	Slopes	0.42	31.2
4	Mudslides	0.09	26.4
5	Cracks	0.11	19.6

the data type is output as unsigned 8-bit data, and image fusion is mainly performed in the Spatial Enhancement menu. The fusion method uses a principal component (principal component analysis), and the resampling aspect is cubic convolution sampling. The key technologies for image geometric correction mainly include the selection of digital geometric correction calculation models and ground control points. For the determination of the gray value of the digital image and the resampling of the gray value of the digital image, the selection of the resampling method is particularly important. The commonly used gray value resampling methods mainly include the nearest point method, the bilinear interpolation method, and the cubic convolution method. The essence of the nearest point method resampling is to take the gray value of the known pixel point closest to the conjugate position in the original distorted image as the gray value of the output pixel. Figure 7 shows the gray value interpolation of the output pixel fitting.

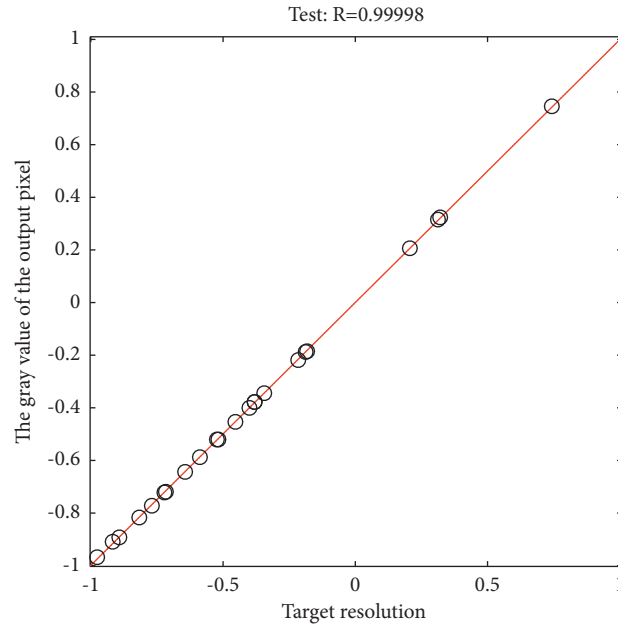
Based on the powerful spatial analysis capabilities of GIS, for various geological disaster risk evaluation indicators in a certain area, it is necessary to normalize each indicator to achieve the final comprehensive risk evaluation. In this study, DEM images are downloaded from the geospatial data cloud of the National Academy of Sciences. We use the ArcGIS automatic stitching function to get the DEM map. After SPSS software completes logistic regression analysis,


FIGURE 7: Gray value interpolation of output pixel fitting.
FIGURE 8: The standard deviation line chart of the RBFNN network band.

the output digital matrix can also be converted into raster graphics in GIS software, thus solving the problem of mutual import of data in GIS and professional statistical analysis software. In order to unify the coordinates and facilitate the postprocessing, the DEM is converted into general coordinates. According to the distribution of geological hazards, we use Spatial Analyst in ArcGIS density tool to designate a circular area and use a field radius of 1,000 m to analyze the point density of geological hazards. The higher the point density in the area is, the more it reflects, the higher the probability of geological disasters in this area, and the greater the risk of geological disasters is. The data sample set is divided into two parts: the modeling sample set (1,056 data

samples) used to build the RBF neural network model and the test sample set (168 data samples). Through calculation, the performance value convergence curve can be drawn when constructing the network. It can be seen that it can converge to the target value after 126 generations.

Figure 8 shows the standard deviation line chart of the RBFNN network band. The data show that the order of the standard deviation of each band is shown in the figure. It is generally believed that there is good agreement between the amount of information of remote sensing images and the image standard deviation; that is, the larger the standard deviation is, the richer the information is. The standard deviation of each band of the image is greater than 3, the

largest is 18, the smallest is 3.4, and the average is 9.4, indicating that the information contained in the features is more enriched, and it is feasible to extract land types. The social attribute factors mainly include important engineering facilities such as reservoirs and a small number of oil extraction plants. In some areas, there are a small amount of urban construction and roads, and human engineering activities are relatively weak, so its social attributes are low. The development density of geological disasters and landslides in this area is about 0.3 places/$100\,km^2$. Among them, there are only 11 unstable slopes in the southern part of the area, which are of low risk. Considering various factors, the geological hazard risk in this area is positioned as medium, which is the risk area in the regional risk assessment.

4. Conclusions

This study comprehensively analyzes the main influencing factors that induce regional geological disasters. Based on the theoretical experience and field investigations, the evaluation index system for geological hazards and the regional geological environment quality evaluation index system are established, and the quality characteristics of the regional geological environment are determined. According to the characteristics of the regional geological disaster risk assessment problem, two simple and practical mathematical methods, GIS technology and neural network, are selected to establish the RBFNN-GA algorithm evaluation model, and the final evaluation results are analyzed and compared. Based on ArcGIS as the underlying platform, a spatial graphic database is established. The attribute database is linked by an external database. The evaluation is obtained through secondary development on the basis of the geological spatial database. The analysis module realizes the spatial analysis function. Finally, the fuzzy comprehensive judgment method is used to optimize and select the evaluation index, and the neural network method is used to determine the weight of the evaluation index. A set of scoring standards based on quantitative indicators is formed, and membership functions are used to obtain values; qualitative indicators are evaluated using expert scoring methods to quantify indicators. At the same time, the main geological disasters in the region are the evaluation objects, combined with GIS technology to comprehensively evaluate the susceptibility and zoning of regional urban geological disasters, and the study area is divided into four levels: excellent, good, medium, and poor. The result shows that the evaluation model is reasonable and the system has strong practicability.

As a human brain-like computational model that can reflect the cognitive function of the brain, the problem of dynamic analysis of associative memory neural networks has attracted the attention of scholars. This paper combines associative memory neural networks with enterprise financial management risks, studies the synchronization control and stability analysis problems of unidirectional associative memory-like human brain amnestic neural networks with perturbation and mixed time-varying time lags, proposes a bidirectional associative memory-like brain stochastic amnestic neural network model with mixed time-varying time lags, designs a discrete-time sampling control strategy based on the model, and studies various types of recent financial risks. Based on the early warning research, based on the associative memory neural network method, we propose to reconstruct the risk categories, including improving the enterprise risk management system, enhancing the awareness of financial risk management from top to bottom, and strengthening the core competitiveness of the enterprise itself and control measures for financing, investment, operation, and cash flow risks.

1. Introduction

Associative memory neural network is by imitating the working pattern of neuronal cells in the human brain; firstly, the pattern to be memorized is stored in the form of weight network of the neural network; when receiving the information of incomplete or defective pattern from outside, the neural network at this time makes the input pattern continuously change its value and converge to the memorized pattern by massive parallel computation. The neural network has a good robust performance, which means that the associative memory neural network has a good fault tolerance performance. The patterns to be memorized are first stored in the form of a network of weights of the neural network. When receiving information about incomplete or fragmented patterns from outside, the neural network then continuously changes its values and converges to the memorized patterns through massive parallel computation. Associative memory neural networks are now widely used in pattern recognition, image processing, etc. Self-associative memory means that the input aberration patterns are equal

to the remembered patterns; in contrast to heteroassociative memory, the input aberration patterns are not the same as the remembered patterns but show corresponding mapping relationships. Self-associative memory refers to the application of associative memory in which the initial pattern of input is identical to the remembered pattern of output. The first step in self-associative memory is to deposit the desired memorized pattern (e.g., the word computer) in a specific form into the network weights through the learning algorithm of a neural network [1]. Then, it is possible to input the pattern with cue information, and the neural network performs continuous iterative operations to give the correct output, and this cue information is not the complete word but has noisy information, but the neural network is still able to calculate to get the remembered word information; i.e., this associative memory neural network has a certain degree of fault tolerance. In fact, fault tolerance is one of the criteria to judge whether the application of associative memory is feasible. The memory process of the neural network, that is, the setting of the weights of the neural network, needs to translate the memorized patterns into the form of the state

values of each neuron when the neural network is in a stable state; that is, generally, a stable point of the neural network can store a pattern, and the determination of the value of the stable point needs to be set according to the necessary conditions required by the associative memory neural network model adopted in this chapter, generally by substituting the memory pattern into the set of differential equations of the neural network, then listing the corresponding inequality based on the above necessary conditions, and relating this inequality to the system of differential equations coupled to solve a specific set of solutions and eventually determine a more suitable weight [2]. This process is also performed using specific training algorithms (e.g., through network self-feedback). Since the self-associative memory input and output patterns are identical, meaning that both have the same dimensionality, this is a characteristic of self-associative memory.

Under the conditions of market economy, enterprises must be aware of the objectivity of financial risks, and at present, enterprises generally have a weak awareness of financial risks, blind fund-raising, imprudent investment, inadequate financial risk management system, and state-owned enterprises, which have weak points such as imperfect financial risk evaluation mechanism and lack of risk control measures. Thus, studying the characteristics of enterprise financial risks and taking certain measures to prevent and manage them has become an important issue facing us now. Although the rapid development of various industries also brings many risks, the industry frequently appears in the financial crisis and even eventually leads to bankruptcy of enterprises [3]. The determination of the stability point value is set according to the necessary conditions required by the associative memory neural network model adopted in this chapter, generally by substituting the memory model into the set of differential equations of the neural network and then listing the corresponding inequalities according to the above necessary conditions. This inequality is then combined with the set of differential equations to solve a series of specific solutions and finally determine a more suitable weight value. Therefore, the financial risk management of enterprises is very important and can determine whether the enterprise can develop in a high speed and sound manner. In recent years, scholars have also increased their research on the financial risk management of enterprises, but a systematic theoretical system has not yet been formed for the study of the financial risk of enterprises. Furthermore, the focus of existing research is to analyze the financial risks of enterprises and put forward financial risk control opinions, and there are relatively few studies that analyze the steps of financial risk management of enterprises, i.e., the identification, evaluation, and control means of financial risks, in-depth. Based on associative memory neural network, this paper combines the relevant theoretical literature on enterprise financial risk control with the specific case of financial risk control of the Storm Group and researches the identification, analysis, and evaluation of financial risk and control of enterprises, hoping to play a supplementary verification role to the current theoretical research on financial risk control in enterprises.

2. Status of Research

Artificial neural networks have been intensively studied in recent decades due to their wide application in many fields such as pattern recognition, associative memory, signal processing, and optimization. Some applications, such as those in optimization theory, require neural networks to have only a single stable point. However, some other applications such as associative memory and pattern recognition require the existence of multiple stable equilibria in the neural network itself.

The multistability of two recurrent neural networks with phase plane origin symmetric activation functions is studied in the literature [4]. Multiple μ-stability of neural networks with unbounded time-varying time lags is considered in the literature [5]. The multistability of recurrent neural networks with nonmonotonic activation functions and unbounded time-varying time lags is discussed in the literature [6]. In the literature [7], the multistability of fractional-order neural networks in the Mittag-Leffler sense with segmental constant parameters is discussed. The multistability of a class of Hopfield neural networks with stochastic time lags was studied in the literature [8] by applying Schauder's immobility point principle and the related stochastic time-lag theory, where there exist $2n$ rectangular invariant set regions under certain conditions and at least one of these regions has an equilibrium point, and by proposing two sufficient conditions to ensure that these equilibrium points are stable. A new condition that is less restrictive relative to the Lipschitz continuum condition in complex-valued activation functions is proposed in the literature [9], and a series of criteria are presented to guarantee the existence, uniqueness, and numerical examples of global asymptotic stabilization points of complex-valued recurrent neural networks. In the literature [10], the stability of recurrent neural networks with time-varying time lags is analyzed using FTM (Flexible Edge Method), and several new stability criteria are proposed to describe the stability of this neural network by constructing a new type of Lyapunov function. In the literature [11], a novel design idea for CVHAMs (complex-valued multistate Hopfield associative memory) is proposed to analyze the stability of CVHAM systems utilizing the energy function method and finally obtain that the network can converge to an immobile point for an arbitrary input value, and the projection geometry of the GPR (generalized projection rule) is discussed. According to the literature [12], Internet enterprises have the financial characteristics of the "flow economy" model, asset-light operation model, cost-light and expense-light, fast product replacement, and equity financing. The financial risk of Internet enterprises has both the characteristics of general enterprises and its special characteristics. Compared to the general enterprises, the risk of capital shortage of Internet enterprises is the most significant. The literature [13] introduced the EVA valuation model to explore the link between financial risk and an enterprise value of Internet enterprises, used the EVA model and the traditional valuation model to assess the company value of the case company NetEase, and

concluded that the EVA valuation model is more accurate. The literature [14] argues that Internet enterprises mainly have risks in profitability model, cash flow, financing, investment, and government regulation. It also suggested that Internet enterprises should establish a sound financial risk early warning mechanism, set up a professional auditing institution and audit system, strengthen comprehensive budget work, improve the accounts receivable control mechanism, and strengthen financing and investment risk management. The literature [15] argues that the assurance of asset profitability and the control measures proposed to prevent unexpected losses are accomplished through risk management. Literature [16] argues that companies should first establish a sound internal control system when making business decisions, which can, to a certain extent, avoid suffering financial risks and causing operational difficulties when financing activities. Literature [17] studies the origin of the risk, the financial risk mechanism of action as the goal to explore, and more targeted risk identification, evaluation, and control, eliminating the hidden financial risk factors.

3. A Risk Model for Corporate Financial Management Based on Associative Memory Neural Networks

3.1. Associative Memory Neural Network Model. The basic steps of the current recurrent neural network training algorithm are to first preprocess the samples to be recognized to obtain numerical feature vectors, input these vectors sequentially into the network, then compare the output of the network with the going output by a difference, and use this difference as negative feedback to correct the network weights. The advantage of this algorithm is that it is simple to operate and the training process is unsupervised learning, while the disadvantage is also evident in that it needs to be retrained once every time a new sample pattern is remembered, which may consume more time in the case of larger network dimensions. The neural network model is built by adjusting the weights of its neurons after it receives data, and the input variables of the model can change according to the actual needs, such as market factors and financial indicators. The neural network model can be automatically trained to filter the best variables and adjust the weights according to their implied relationships to build a nonlinear model and improve the model accuracy. The training method is used to correct the network weights by continuously feeding in training samples so that the sample patterns to be remembered are embedded in the network weights; i.e., the network "remembers" the samples. It is possible to use algebraic methods to solve the weights directly, because the network has a large number of attractors and can remember a large number of samples, by using the samples as input, assuming that the output is the desired output, representing both as vectors, and substituting them into the differential equations of the system, using the knowledge of linear algebra to solve a set of weights network, then using other samples for input, and finally solving the

corresponding number of analytical solutions. The intersection of these analytic solutions is the network of weights to be determined if these solutions do not intersect. Then, it means that the memory capacity of the network is not sufficient and a new model needs to be redesigned to ensure that it has sufficient memory capacity [18]. Next, an example of the design of associative memory will be given, as shown in Figure 1 for an example of the associative memory process.

Here is an example of the detailed steps of associative memory design; a recurrent neural network can be described by the following set of differential equations:

$$\frac{\partial}{\partial W_{ij}^l} J(w, b) = \frac{1}{b} \sum_{i=1}^m J(w, b; x^i, y^i) + \lambda W_{ij}^l. \tag{1}$$

The network is a more classical model of a memetic recurrent neural network. Several character samples are used for the training of this network until the network is given a network of weights that satisfy the conditions that make the network remember the characters to be remembered. For the sample image data to be recognized, the image first needs to be subjected to a series of preprocessing steps, which are graying, smoothing, denoising, and finally, transforming into an input vector. All samples of data are grayed out, smoothed, denoised, and then transformed into an array of vectors of the following form:

$$f_\phi(p, x) = d_p\left(x - \frac{\lambda_{\theta_1}}{d_p(x)}\right) + d_p\left(x - \frac{\lambda_{\theta_2}}{d_p(x)}\right). \tag{2}$$

And the output vector of the network can be represented as an array of vectors of the form

$$(\alpha, \beta, \gamma) = \frac{1}{r} \sum_{i=1}^k \left(\frac{\alpha_i + \beta_i + \gamma_i}{3}\right). \tag{3}$$

Substituting the above two sets of vectors into the system equation (1), we get

$$\nabla_{b'} J(w, b; x_i^*, y) = \delta^{l+1} \frac{\partial J(w, b)}{\partial b_{ij}^l} + \lambda \alpha_{ij}^l, \tag{4}$$

where $x_i^* x_i *$ is the stable equilibrium point of the system with the i-th set of samples as input, and this value is chosen according to conditions such as the form of the activation function. A sufficient condition for this equation to have a solution is that the number of stable equilibrium points of the neural network is greater than or equal to the number of samples to be memorized by the claim; that is, the number of attractors should be large enough to be able to remember a sufficient number of patterns. The equation can be solved using singular value decomposition, the solution of the equation is also the vector of connection weights of the network, and these weights imply information about the patterns to be remembered. The above form is generally a self-associative memory weight solving process that can be specifically applied in the fields of character recognition, face recognition, etc. Then examples will be given to illustrate the design and the weight solving process of recurrent neural
Figure 1: Example of the associative memory process.

network-based heteroassociative memory applications. Traditional character recognition algorithms include template matching and OCR [19]. For unbalanced sample data, you can start with downsampling and upsampling methods. The downsampling method, also known as the random downsampling method, refers to the random removal of the class of data with the most categories by the sampling method. The advantage is that the sampling method can improve the model accuracy when the deleted samples contain noisy data, and the disadvantage is that some important samples may be deleted. Oversampling method refers to synthesizing a part of small sample data by an algorithm. Compared with these character recognition algorithms, the recurrent neural network-based associative memory mentioned above is characterized by low design cost, simple processing logic, fast network convergence, less dependence on external conditions, and easy practical implementation. The most important point is that this associative memory system has good fault tolerance performance; high fault tolerance means that when there is more noise or disturbance in the sample, it can also correctly identify the target pattern, so if this associative memory method is applied to image recognition, although the current application is simple and the idea is more basic, after a little development, I believe there will be a use for it. The design steps of recurrent neural networks for associative memory are summarized as follows.

(1) Determine the model characteristics of the neural network to be used

(2) Convert the patterns to be remembered into vectors as inputs to the system as well as outputs to be substituted into the system equations

(3) The solution to the system of equations is obtained by appropriate choice of coordinates of the equilibrium point and by singular value decomposition

(4) Store the solutions of the system of equations as the weights of the neural network

(5) Build an associative memory neural network system and perform recognition tests.

The associative memory-based reconfigurable amnestic network circuit consists of four parts: the associative memory-based amnestic network circuit, the PRMC with input binary signals, the synaptic circuit block, and the control circuit. In the associative memory-based amnestic network circuit, the synaptic weights indicate the strength of the synaptic connections and thus only positive weights. The PRMC of the input binary signal can only be trained by the algorithm to achieve the corresponding function, so the synaptic circuit needs to represent negative weights, zero weights, and positive weights. In the associative memory-based reconfigurable memetic neural network circuit, the PRMC with input binary signals and the associative memory-based memetic neural network circuit uses the same synaptic circuit, and the synaptic circuit in the associative memory-based memetic neural network circuit is restricted to vary within the positive weights by a control circuit [20]. The synaptic circuits in the synaptic circuit block are shared, and these synaptic circuits can be used to construct both PRMCs with input binary signals and the associative memory-based memetic neural network circuits. As can be seen in Figure 2, the two subnetworks operate independently, so they can work in parallel.

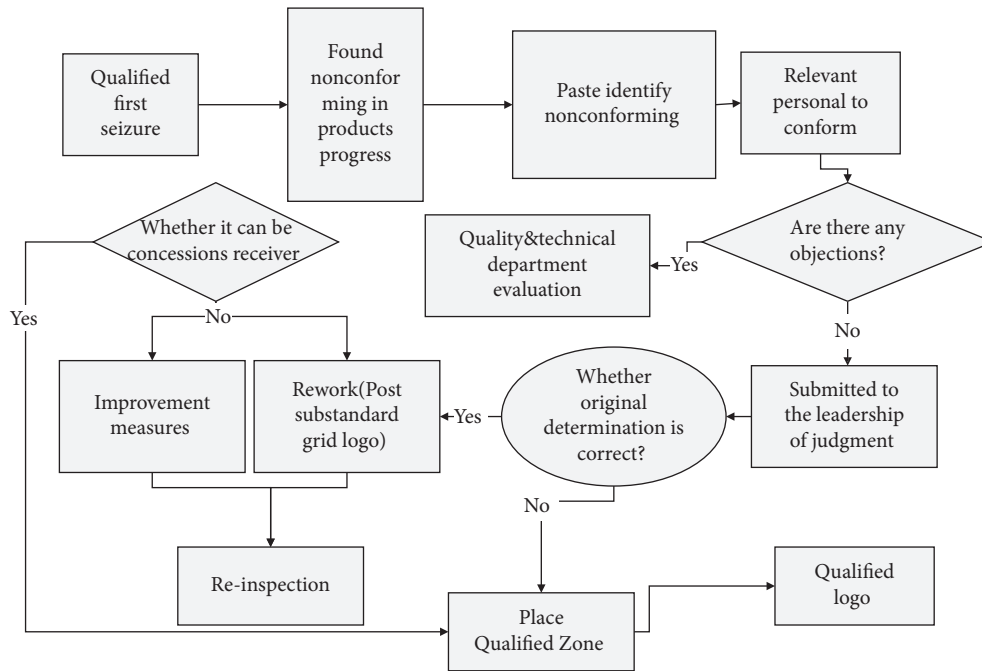
By simulating learning and forgetting in associative memory, the reconfigurable memristor neural network


Figure 2: Structural diagram of reconfigurable amnestic network circuit based on associative memory.

circuit based on associative memory can dynamically change the circuit structure to achieve reconfiguration, corresponding to the following process: when the unconditioned stimulus signal and the conditioned stimulus signal are simultaneously input to the memristor neural network circuit based on associative memory, associative learning between the two is induced, so that the synaptic weight corresponding to the conditioned stimulus gradually increases. After the learning process is over, if the conditioned stimulus signal is kept input, the forgetting process is induced. During forgetting, the synaptic weight corresponding to the conditioned stimulus gradually decreases until it fails to activate the corresponding neuronal circuit. After the end of the forgetting process, the circuits of the associative memory-based amnestic network do not activate regardless of whether the conditioned stimulus signal is input [21]. And then, the synaptic circuits corresponding to the conditioned stimulus can be disconnected from the neuronal circuits, and these synaptic circuits can be fed into the synaptic circuit block. The synaptic circuits in the synaptic circuit block can be used to construct either PRMC or associative memory-based amnestic network circuits with input binary signals. In this way, circuit reconfiguration is achieved.

4. An Associative Memory Neural Network-Based Risk Prediction Model for Corporate Financial Management

Financial risk is a type of business risk that exists in financial activities such as raising, investing, spending, recovering, and allocating activities of funds in the process of social reproduction. And the risk is the deviation of expectations from reality. There is a distinction between financial risk in a narrow and broad sense. Financial risk in the narrow sense refers to the financial risk arising from the debt operation in the process of raising funds for the enterprise. Financial risk in the broad sense refers to the uncertainty of obtaining the expected financial results in the process of conducting the financial activities of the enterprise. Therefore, the financial risk exists in every enterprise and in the business activities of the enterprise and has a significant impact on the profit and loss situation and business conditions of the enterprise. Financial risk management is the prevention, control, and management of risk in enterprise financial management and is also a part of comprehensive enterprise risk management [22]. Internal diagnosis is a way for the enterprise itself to find out various problems in the business process through self-analysis and finally to solve them in a targeted manner. External diagnosis means that the enterprise hires an external third-party organization to analyze the financial operation of the enterprise. As a new management science theory, it is a management theory mainly developed by scholars according to the previous experience in risk management and financial management for all kinds of risks in the operation of enterprises. Financial risk management includes risk identification, assessment, analysis of causes, and control of various financial activities of the enterprise. To ensure the normal operation and capital movement of the enterprise and to avoid negative impact on the economic interests of the enterprise, the management process of financial risk management includes risk identification, assessment, analysis of causes and control of various financial activities of the enterprise, and timely and effective prevention and control measures based on its early warning role.

The most commonly used methods for financial risk evaluation include hierarchical analysis, efficacy factor method, and factor analysis. The basic principle of factor analysis is to group indicators with strong relevance into one category and replace each category with a factor, thus replacing all the original indicators with a few factors.

In this paper, the analysis of corporate financial management risk prediction is carried out by combining the associative memory neural network model with factor analysis. Factor analysis is chosen for the following reasons: firstly, factor analysis can reduce the number of original variables, by extracting and naming the main factors instead of the vast majority of the original information; secondly, the sample can be ranked and compared. According to the score of each main factor and the comprehensive score, the sample can be ranked, which not only shows the ranking of individual factors and clarifies which factors have a greater impact on the financial situation of the enterprise but also analyzes the comprehensive ranking of the factors after weighting, which is beneficial to the enterprise to clarify its strengths and weaknesses [23].

The steps of the factor analysis method are as follows:

(1) KMO and Bartlett's test were performed to determine whether the original variables were suitable for factor analysis; KMO was used to describe the magnitude of the correlation coefficient between variables, and the larger the value, the more suitable for factor analysis; while the smaller the value of Bartlett's test, the more suitable for factor analysis.

(2) Constructing factor variables and extracting principal component factors in place of all initial variables, the mathematical model for factor analysis is

$$f\left(\{x_1, x_2, \ldots, x_n\}\right) = g\left(h\left(x_1\right) + h\left(x_2\right) + \cdots + h\left(x_n\right)\right). \tag{5}$$

(3) Interpretation of the principal component factors is named, generally using the orthogonal rotation method to obtain the maximum loading values of the principal factors and clarify the meaning of what each factor represents.

(4) The expressions of each principal factor are derived from the component score matrix, and then a comprehensive evaluation model is constructed according to the respective weights, and the samples are ranked and analyzed.

$$C_{ij} = \sum_{i=1}^{n} x_i^2 \sigma_i + \sum_{j=1}^{n} x_j^2 \sigma_j + \sum_{k=1}^{n} x_k^2 \sigma_k. \tag{6}$$

Associative memory neural network is built based on decision tree model using histogram algorithm which is easier to segregate the data. The difference from previous decision tree models is that the associative memory neural network is oriented vertically, i.e., generating the leaves of the decision tree, whereas other decision tree models generate the levels of the tree, so the associative memory neural

network algorithm runs faster and stores fewer data. Its main feature is to traverse the entire training set and to make the attributes discrete for floating-point continuous variables; these k discrete data are constructed into a histogram with a specific width of k. The number of discrete values converged within each histogram is calculated. Since there are many components of financial risk, various factors and financial indicators will interact with each other to form a complex relationship. In this paper, relevant indicators are extracted, factors are extracted by significance test, and factors suitable for model building are obtained by sphericity test, principal component extraction, and other steps. Based on the obtained factors, the logistic model of stepwise regression is used to model the financial early warning. The modeling process gradually analyzes the factors of risk composition, using the advantages of the model to provide a more intuitive basis for the future decision-making of managers. The selected early warning indicators should be comprehensive; i.e., indicators should be selected from the traditional aspects of solvency, profitability, development capability, and operating capability, and indicators should be selected from the aspects of research and development capability that reflect the characteristics of the industry, making the range of indicators selected for the communication equipment manufacturing industry more comprehensive. The company invests capital in the production of products and recovers the capital and profits through the sales of the products. Inventory turnover can only be increased if sales are successful and inventory is cleared quickly, so inventory turnover indicates how quickly money can be recovered from the sale of goods. In general, a company can improve its liquidity by increasing its inventory turnover. The inventory turnover ratio indicates the level of inventory, while the current asset turnover ratio reflects the speed of turnover of current assets, which is the most liquid of all the assets of a company. A lower level of current asset turnover can have a greater impact on a firm's short-term repayment ability. The higher the current asset turnover ratio, the lower the relative financial liquidity risk. A slow turnover rate will require supplementary liquidity to participate in the turnover, which will create a waste of funds and reduce the profitability of the enterprise. Based on the above theory, in the subsequent classification, the optimal cut-off point can be found only according to the width of the histogram. The idea of the histogram algorithm is mainly reflected in the conversion of floating-point data into binary data, and the specific operation is to determine the number of buckets contained in each feature, update the data of each bucket separately after equal division, and substitute the features of enterprise financial management risk prediction into the associative memory neural network model, which is represented graphically as shown in Figure 3.

Compared to other models built on decision tree algorithms, associative memory neural networks are faster mainly in terms of running speed, while consuming less memory, and accuracy is not compromised, perfectly combining both fish and bear's paw. With the desire to go to the next level, the model can be optimized in the following two ways: to speed up the running speed, the original data
FIGURE 3: Flow chart of an interactive product styling model.

can be simply processed; reducing the number of features and data, converting feature variables into category features, or saving the data files as binary files, changing the training method of the model to parallel can also speed up the running speed of the model; to improve the accuracy of the model and reduce the model learning rate, starting from the model, mesh tuning the parameters of the model, choosing the best combination of parameters, increasing the learning times of the model, and making the model better understand the laws between the data can improve the accuracy of the model. Starting with the data, increasing the number of training data and preprocessing the data to solve the missing values and imbalance in the original data can also train the model better and improve the performance of the model.

4.1. Experimental Verification and Conclusions. The CART decision tree model with prepruning and postpruning design will be trained, and the decision tree graph and variable importance graph will be generated after the model training to better interpret the CART decision tree model discriminant results. Firstly, the discriminant results and ruleset of the overall financial risk assessment model of the enterprise are constructed. Because there are too many values of assessment features in the overall financial risk assessment of the enterprise, the variable importance graph in the overall financial risk assessment of the enterprise takes the top 5 importance variables, and the overall financial risk assessment model of the enterprise generates the variable importance graph as shown in Figure 4.

As can be seen from Figure 4, among the 18 characteristics of the CART decision tree model, "interest earned multiple," "total assets return," "accounts receivable turnover," "total assets turnover," and "weighted return on net

assets" ranked the top five in importance, with "interest earned multiple" being the most important indicator with the importance of over 0.5. Operating capacity reflects the efficiency and effectiveness of an enterprise's capital operation with different assets, and the turnover efficiency of different types of assets is usually used to determine the operating level of an enterprise. This indicates that enterprises should focus on "interest earned multiple" when assessing the overall financial risk, and the sum of the top five importance scores exceeds 90%; therefore, it also indicates that listed companies should focus on these five index characteristics in the process of assessing the overall financial risk of enterprises. The interpretation of the rule set generated by the decision tree model will provide quantitative evidence for the listed company to assess the overall financial risk of the company, which will help the listed company to measure whether it has overall financial risk.

The importance of the variables generated by the enterprise operational risk assessment model is shown in Figure 5. As can be seen from Figure 5, the importance of the six characteristics of the CART decision tree model is the same, with the importance of "operating profit margin" becoming the most important assessment indicator. Therefore, the model results indicate that listed companies should focus on these 6 indicators in the process of enterprise business risk assessment. Rule 1: when the "operating profit margin" is ≤−6.151, the enterprise has business risks. Rule 2: when "operating profit margin" >−6.151 and "accounts receivable turnover ratio" >3.203, the company does not have financial risk. Rule 3: when "operating profit margin" >−6.151, "accounts receivable turnover" ≤3.203, and "cost margin" ≤7.552, the enterprise, there is financial risk. Rule 4: when "operating profit margin" >−6.151, "accounts receivable turnover" ≤3.203, and "cost margin"
FIGURE 4: Importance of variables for assessing the overall financial risk of an enterprise.
FIGURE 5: Importance of business operational risk assessment variables.

>7.552, the enterprise does not have financial risk. The interpretation of the rule set generated by the decision tree model will provide the listed company with quantitative evidence to assess the degree of the business risk of the company, which will help the listed company to measure whether it has business risk.

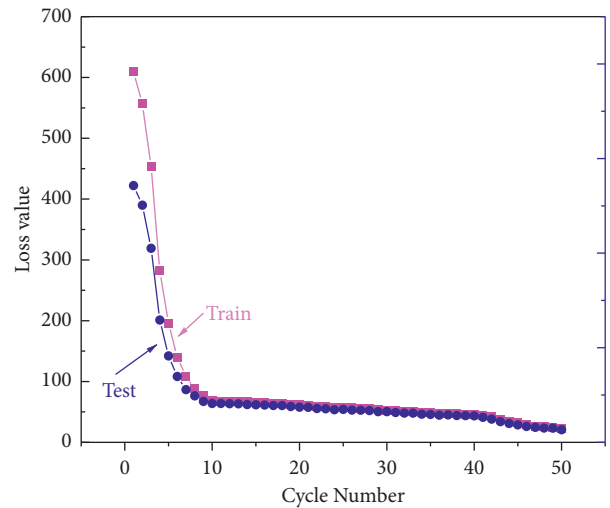
The importance diagram of the variables generated by the enterprise financing risk assessment model is shown in Figure 6. For the decision result of the CART decision tree model, among the three characteristics of financing risk, the importance of "interest multiples earned" becomes the most important evaluation indicator, and the importance score of

FIGURE 6: Importance of variables generated by the enterprise financing risk assessment model.

FIGURE 7: Model accuracy validation.

FIGURE 8: Loss curve of sample size set for associative memory neural network.

its indicator is close to 0.8. Therefore, the model results indicate that listed companies should focus on the following characteristics in the process of enterprise financing risk evaluation. The year-over-year revenue growth rate, net asset per share growth rate, and total asset growth rate are important indicators of a company's growth ability. The model results suggest that listed companies should focus on the indicator characteristic of "interest multiples earned" in the process of corporate financing risk assessment. The set of rules for the determination of the CART decision tree for corporate financing risk is as follows. Rule 1: when the "interest earned multiple" is ≤1.249, the enterprise has financing risk. Rule 2: when the interest earned multiple is >1.249, the firm is not at risk. The interpretation of the rule set generated by the decision tree model will provide the listed company with quantitative evidence to assess the level of funding risk of the company, which will help the listed company to measure whether it has funding risk.

From Figure 7, it can be seen that this paper's model based on associative memory neural network achieves 83% accuracy for the discriminative effect of the training set and 76% accuracy for the validation set, which is a better result. At the same time, this paper combined the GBDT model with the logistic regression model for the combined prediction, and the prediction results showed that the combined model improved the prediction accuracy of the training set to 91% and the validation set to 78%, in terms of both accuracy and stability; the combined model warning effect is more significant compared with the single model, so it proves the feasibility of the combined model. Compared with the single model logistic regression model, the ROC curve of the associative memory neural network model regression financial risk warning model is closer to the upper left axis, and its AUC value is 0.79, which is significantly higher than the logistic regression model AUC value of 0.60. The advantages of the associative memory neural network financial risk warning model can be seen directly from the ROC curve and AUC value. From the experiment, it can be concluded that GBDT for feature combination can better mine the information in the financial data of listed companies, and the logistic model has fast processing speed, which can solve the problem of slow processing speed that


GBDT cannot be processed in parallel, and the model fused with GBDT and logistic model can be effectively used in the field of financial risk early warning of listed companies for modeling.

The learning rate is the rate at which the input variables are updated at each iteration during training and determines how far the weights have to move in the direction of the gradient in a small batch, through many iterations, eventually moving to a position that matches the training accuracy of the network. The process of learning the features of a sample dataset by an associative memory neural network is the process of constantly iterating forward. A lower learning rate makes the training process more reliable, but optimization will take longer. Higher learning rates, on the other hand, lead to nonconvergence of training and may cause very large weight changes, making the loss function very poor. Optimizing the rate of matrix multiplication and improving memory utilization can be achieved by increasing the number of batches in a certain region, which reduces the number of updates needed to complete the training of the

entire dataset and speeds up the process somewhat for data of the same capacity. Stochastic gradient descent updates only one sample information at a time, which speeds up the training, but because only one sample is used at a time, it does not represent the entire training sample, making it more difficult to converge the training results to some minimum value. For a company to achieve sustainable development, it must attach great importance to its R&D and innovation capabilities. Only through continuous innovation and continuous inventions can a company gain a competitive advantage. With the development of deep learning, it was shown that the training results could be converted to a local minimum by slowly decreasing the learning rate. After adjusting the parameters several times, the expected training results were finally obtained, and the average absolute error of the model on the samples during training finally converged. The loss curves for the sample dataset are shown in Figure 8.

The blue line in the figure represents the training set loss curve and the orange line represents the test set loss curve; the horizontal axis presents the number of iterations of the samples in the training process, and the vertical axis presents the change of the average error value during the training process. According to the parameters set in this paper, the Spyder window can display the losses of the training and test samples in each iteration and calculate the root mean square error of the model at the end of training. During the training process, the more iterations, the smaller the sampling error, with local fluctuations in a small range. At the beginning of the training, the error drops quickly, and in the training interval from 10 to 50 iterations, the error drops at a rapid rate, indicating that the model is being fine-tuned locally, and from 100 training iterations onwards, the error drops more gently, indicating that the model has converged to an optimal process. The trend of the loss curve of the training sample and the loss change of the test sample are integrated, and the error of the training sample finally converges with a better fit; the error of the test sample converges to a local minimum, and its fit is not as good as that of the training sample, but the effect of using gradient descent for optimization is obvious and will not affect the performance of the whole model.

Based on the associative memory neural network model, the early warning indicator system that can reflect the risk characteristics of listed agricultural companies is established by combining the risk characteristics of the company and the causes of its generation: it contains financial and nonfinancial indicators, covering solvency, operating capacity, development capacity, profitability, and other capacity indicators. To improve the convergence speed and stability of the model, SPSS software is used to conduct factor analysis on the data of the primary selected indicators and calculate the factor scores of the samples as the input layer data of the model. In this way, the accuracy of the financial crisis model is further determined and a part of the sample is selected to test the model. Finally, the model is applied to the actual company to identify its problems and optimize them to reduce the possibility of its financial crisis.

5. Conclusion

Associative memory neural network models are generally constructed based on data about the characteristics of the industry in question to make predictions about various aspects of demand points. Associative memory neural network model predictions are not only limited to daily life preferences, food, clothing, housing, etc. but now also almost permeate in financial industry development, financial forecasting, etc. In this paper, by analyzing the subsequent development capability in conjunction with the industry characteristics and competitive landscape of the company, it is found that the model can reflect the situation of the company well through early warning indicators and provide a reference for the future development of the company. If only the data model fitting of financial indicators is introduced, it will be too single and will not be able to judge the situation of finance comprehensively. In the study, it was found that the number of samples in the high financial risk category was too small compared to the samples in the low and medium financial risk categories, and if the sample data were not balanced, it might lead to the early warning model not learning the characteristics of the samples in the high financial risk category during training, which eventually led to a low prediction accuracy of the samples in this category. Since factors such as company composition and equity can also have an important impact on finance, this paper adds nonfinancial indicators to improve the generalizability and accuracy of the model. Nowadays, companies are in an increasingly complex market environment and social activities, and big data simulation by quantifying the relevant indicators of companies in the industry can reflect the current situation of the industry comprehensively and extensively, and the reasonable inclusion of industry-specific indicators can also improve the effectiveness of the early warning model. By combining the company indicators and the established early warning model, the principal components that can be identified by the model are used to analyze the situation in which the company risks arise while providing opinions that incorporate the details of Company B. Using this financial early warning model, one can adjust the company structure, do strategic planning and crisis prevention in advance for the changing market, organize training for financial early warning talent, strengthen the communication between financial early warning talents, and ensure a reasonable shareholding structure to avoid one share being dominant; secondly, one can improve the information construction of the financial system and establish a set of the financial system applicable to the company on this basis. At the same time, we should comply with the choice of the market, and the development of diversified markets can ensure their competition and at the same time focus on product quality.

Correspondence should be addressed to Su Zhang; zhangsu@tourzj.edu.cn

From the time dimension, this paper analyzes the characteristics of the scale, industrial structure, employment flexibility, and comprehensive employment effects of regional tourism employment based on the three-level criteria of the scope of tourism employment based on the regional Internet of Things. From the spatial dimension, we take the regional city as the basic research unit, adopt multiple indicators, and conduct a comprehensive evaluation of the regional development of regional tourism employment through horizontal and vertical comparisons. This paper uses multiple linear regression analysis to establish the relationship between the development level of the county tourism economy and the influencing factors; in order of magnitude of influence, they are tourism resource endowment, location traffic conditions, and economic development. Using a combination of a single indicator and multiple indicators, the county tourism economy is evaluated and analyzed for differences in time and space. We select the total tourism revenue as an indicator and use methods such as range, standard deviation, coefficient of variation, and coefficient to analyze the time difference of the tourism economy in each county. We adopt the Granger causality test and other methods to analyze the factors affecting tourism employment in the area and the growth mode. Through the establishment of a structural model of the tourism employment growth dynamics system, causality test and other methods are adopted to analyze the regional tourism employment influencing factors and growth methods, and the results show that the regional tourism employment growth mode is an investment-driven tourism employment growth mode.

1. Introduction

In recent years, the development speed of the tourism industry based on the regional Internet of Things has been accelerating, and the level of development has also been increasing. Compared with other regions, especially the developed tourism regions, there is still a relatively large gap, and the overall development level is still relatively low [1]. The travel rate can reflect the number of tourists and tourism income in a region, as well as the tourism development status of a region. There are obvious temporal and spatial differences in the travel rate of cities and states in the same area [2]. In addition to the improvement of people's living standards and scientific and cultural quality, tourism has become a sunrise industry for regional economic and social development [3]. The development of the

tourism industry has greatly increased regional national income and effectively increased the gross national product and fiscal revenue; the tourism industry has a relatively large degree of relevance and a strong development driving effect, which can promote the development of related industries and the economy and promote structural optimization and adjustment [4]. The tourism industry is a labor-intensive industry that can accommodate and absorb more labor, create abundant employment space, and help solve social employment problems; the development of the tourism industry improves the quality of life of the people. Not only it can improve people's physical and mental health but also can improve people's quality and accomplishment and enrich people's spiritual world, promote the all-round development of people, and help build a harmonious society [5].

Domestic research studies on the spatial and temporal distribution characteristics of tourism flows have more research on the spatial distribution of inbound tourism flows [6]. Talari et al. [7] divided the regional inbound tourism flow into spatial divisions. For the research on the spatial pattern of tourism flow, in the horizontal pedigree, more emphasis is placed on the study of the circle structure, and in the vertical pedigree, more emphasis is placed on the single-point level study [8]. At present, the conceptual models of the spatial structure of tourism flow mainly include leisure vacation mode, travel mode, spatial layered movement mode, international tourism flow mode, urban tourism flow mode, and tourist travel spatial structure mode [9]. Piccialli and Chianese [10] conducted a research on the theory of tourism flow spatial pattern and divided the basic theory of tourism flow spatial pattern into three theories, namely, circle structure theory, core edge theory, and spatial diffusion theory. And on this basis, some problems existing in the study of tourism flow are put forward. Perles et al. [11] studied the spatial structure optimization of the regional outbound tourism flow and optimized it from the two aspects of the destination and the source of tourists by studying the characteristics of the regional outbound tourism flow and its spatial structure. Foreign scholars have mainly studied tourists' travel preferences, travel motives, travel behavior, travel demand, and the analysis and prediction of travel flows [12]. Zsarnoczky [13] analyzed five factors that directly affect the bilateral flow of tourism flows, namely, political factors, economic factors, private enterprises, intangible factors, and diplomatic and health factors. Weber et al. [14] emphasized the seasonality of tourism flows. From a macroperspective, it uses register-based data to analyze the spatial structure and analyzes the recent impact of tourist flow and migration flows and the flow of foreign property ownership. Jha et al. [15] carried out research on the comparative advantages of tourism flows. The article pointed out that tourism and international trade flows have similarities. The results are usually supported by two aspects: supply-side variables and the comparative advantages of exporting countries. In addition, western geographers are also committed to the study of the interpretation mode and spatial distribution mode of tourism flow, but they are mostly based on hypotheses, so they are of little practical significance, and they have made useful contributions to the research methods of tourism flow [16]. Some scholars analyzed five factors that directly affect the bilateral flow of tourism flows, namely, political factors, economic factors, private enterprises, intangible factors, and diplomatic and health factors [17]. Researchers emphasize the seasonality of tourism flows [18]. An article pointed out that tourism and international trade flows have similarities, and the results are usually supported by two aspects: supply-side variables and the comparative advantage of exporting countries [19]. In addition, Western geographers are also committed to the study of interpretation models and spatial distribution models of tourism flows, but most of them are based on assumptions, which are of little practical significance and have not made useful contributions to the research methods of tourism flows. The study of tourism flow is an important basis for formulating tourism development plans, determining source markets, and formulating external publicity strategies [20, 21].

At present, the research on the difference of tourism economy based on the regional Internet of Things is slightly insufficient. The existing research results are limited to large regions or intercity areas, and most of them are still qualitative analysis, lacking quantitative empirical analysis. This article uses quantitative, qualitative, and spatial analysis methods to study the spatial and temporal differences of the tourism economy based on the regional Internet of Things, analyzes the influencing factors of the differences, and then proposes countermeasures for the development of the county tourism economy on this basis. In view of the characteristics of the temporal and spatial differences in the travel rate, the reasons for these characteristics are analyzed from the aspects of politics, society, tourism resources, transportation, and short-term crises. This method of calculating how much labor input is needed to reverse the output of the tourism industry believes that the employment capacity of tourism characteristic industries mainly depends on two major factors. Based on the actual situation, suggestions are made to increase the travel rate and promote the sustainable development of the regional tourism industry: establish the concept of grand tourism and innovate the concept of tourism development, which is conducive to accelerating the system reform; strengthening the government's leadership in the tourism industry is conducive to regional tourism; focusing on the training of tourism professionals is conducive to improving the quality of tourism services.

2. Construction of a Model for the Evolution of Temporal and Spatial Differences in Tourism Economy Based on the Regional Internet of Things Technology

2.1. Regional IoT Spatial Hierarchy. In a type of real-time system such as the Internet of Things, Time Computation Tree Logic (TCTL) can represent a large number of naturally occurring normative attributes, such as security and time response, and is especially suitable for research on time reachability. Because of its powerful functions, it can capture many routine inspections and can perform verification more effectively. Since the state space of the underlying model is basically uncountable, the analysis of accessibility must use symbolic technology to describe the continuity of the clock through a finite quotient. Figure 1 shows the spatial hierarchical nesting of regional IoT.

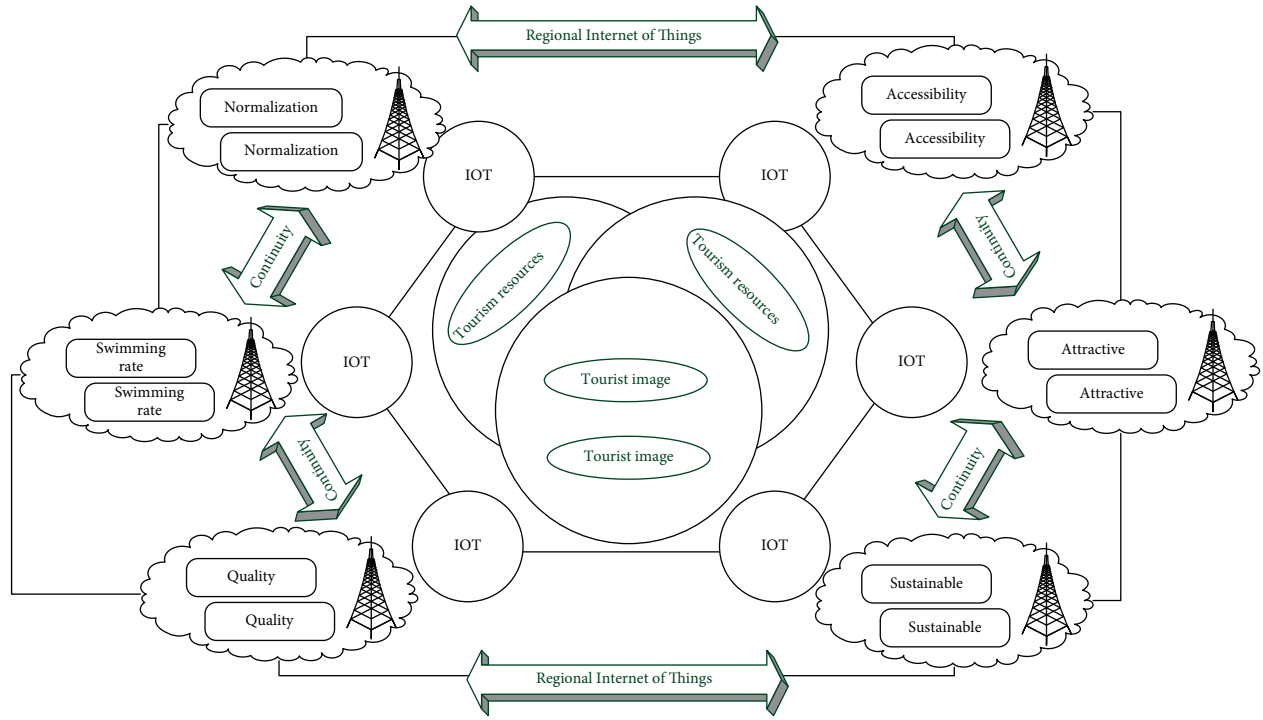
Due to the real-time and concurrent characteristics of the Internet of Things system, based on exhaustive search for multiplying the state space and the clock band, the number of states generated tends to increase exponentially, which greatly increases time and space consumption. When the number of concurrent systems is large, searching the state space directly will exceed the memory limit of the computer, and the verification result will not be obtained.


FIGURE 1: Spatial nesting of regional IoT.

$$p(x(1), x(2), \ldots, x(n)) = \prod_{i=1}^{n} p[x(n)|x(n-i+1)],$$

$$C = 2 \times \frac{(p(x) \times p(n))^{1/2}}{(p(x) + p(n))}. \tag{1}$$

The direct consumption coefficient, also called the input coefficient, is recorded as i, j, which refers to the direct consumption of the unit's total output of the j product (or industry) sector in the production and operation process. The value of the goods or services consumed in the i product sector is represented by the direct consumption coefficient of each product (or industry) sector in the form of a direct consumption coefficient table or a direct consumption coefficient matrix, usually represented by the letter T.

$$f(x) = x(i) + \frac{x(i) \times x(j)}{x(i) + x(j)},$$

$$T^2 - \frac{1}{n} \times \sum_{i=1}^{n} (p(i) - p(x))^2 = 0. \tag{2}$$

The direct consumption coefficient reflects the basic characteristics of the production structure in the Leontief model and is the basis for calculating the complete consumption coefficient. It fully reveals the technical and economic connections between the various sectors of the national economy, that is, the strength of the interdependence and mutual restraint between the sectors, and provides important economic parameters for constructing input-output models.

$$\begin{cases} x(i,0) = a - x(j,0), \\[2mm] x(i,1) = b - x(j,1), \\[2mm] x(i,j) = \sqrt{\dfrac{x(j,i)}{a+b}}. \end{cases}$$

$$U(x) = (I - C)^{-1} \times C^{T} - \sum_{i=1}^{n} p(x) \times C(i) \sum_{i=1}^{n} p(x) \times Z(i). \tag{3}$$

Range refers to the difference between the maximum value and the minimum value of a certain index. It reflects the largest absolute difference in the change of a certain indicator among various regions. The range index g can indicate the gap between the county with the most developed tourism economy and the county with the least developed tourism economy. The standard deviation is the square root of the square root of the square of the deviation of the standard value of each unit of the population from its mean.

$$g(w(i)|w(i-n+1), \ldots, w(i-1)) = \frac{P(w(i-n+1), \ldots, w(i-1), w(i))}{P(w(i-n+1), \ldots, w(i-1))}. \tag{4}$$

The complete consumption coefficient refers to the sum of the direct and indirect consumption of goods or services in the i product sector for each unit provided by the j product sector for final use. The complete consumption coefficient of each product department is expressed in the form of a table, which is a complete consumption coefficient table or a complete consumption coefficient matrix, usually represented by the letter V.

$$V(x) = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w(i,j) * (x(i) - x) \times (x(j) - x)}{\sum_{i=1}^{n} \sum_{j=1}^{n} w(i,j) \times x(i,j)}. \quad (5)$$

The coefficient of variation is the ratio of the standard deviation to the corresponding average. It can exclude the influence of the difference in units or averages on the comparison of the degree of variation of two or more values. The coefficient of variation $f(x)$ can explain the relative differences in tourism economy among different research units.

$$\exp \sum_{i=1}^{n} x(i) f(s,t) = \exp x(1) f(x) + \cdots + \exp x(n) f(x). \quad (6)$$

2.2. Spatiotemporal Difference Evolution Model.

In this article, the difference in the tourism economy based on the regional Internet of Things means that, under the influence of different factors, there are differences in economic levels between different regions in the development of the tourism economy and the unevenness in the development of tourism industry in different regions within a certain period of time. Figure 2 shows a schematic diagram of the evolution model of temporal and spatial differences. The growth pole refers to a collection of economic units with agglomeration characteristics in space. Economic development will first explode at a certain point in a region and then gradually spread outward from this point, thereby driving the economic development of the entire region. It has a strong economy of scale and it drives the economic development of the entire region through multiplier effects, dominance effects, polarization, and diffusion effects. Some areas developed first to become regional "centers" due to various favorable factors, while other areas became "peripheries" due to lagging development. The center is in a dominant position, while the periphery depends on the center for development, and peripheral funds, materials, and labor will be continuously transferred to the center.

Generally speaking, the lower the level of tourism development is, the lower the consumption level of tourists is, and the higher the proportion of basic tourism consumption expenditure in total consumption expenditure is. At present, as the regional tourism industry is generally in the early stage of development, tourism supporting facilities and services are not yet complete, and the products are single, tourism consumption is mainly used for transportation, accommodation, catering, sightseeing, etc., and the proportion of nonbasic tourism consumption is very small. The change curve of employment elasticity is basically similar to that of the tertiary industry, and the fluctuation range shows a trend of gradual convergence. The employment elasticity of tourism industries showed almost the same changes as the employment elasticity. The purpose of statistical testing is to test the reliability and accuracy of estimated values. Table 1 shows the statistical test results of tourism characteristic industries. Goodness of fit refers to the degree of fit of the regression line to the observed value. The regression parameter estimation shows that the model fits the sample well.

The tourism characteristic industry belongs to the tertiary industry. There are two main methods for measuring the difference of the tourism economy: relative difference and absolute difference. It shows that the regression equation is significant; that is, the combination of variables such as tourism resource endowment, location and transportation conditions, economic development level, and industrial structure does have a significant impact on the tourism economy. When other variables remain unchanged, the explanatory variables such as the endowment of tourism resources, location and transportation conditions, and the level of economic development have a significant impact on the tourism economy, while the industrial structure has no significant impact on the tourism economy.

2.3. The Distribution of Tourism Economic Weighting Factors.

The establishment of an indicator system of factors influencing the tourism economy based on the regional Internet of Things requires that the indicators have scientific and clear characteristics and can accurately reflect the main aspects and essential characteristics of factors affecting tourism economy in the county. Based on the correct understanding of the county tourism economy, the influencing factors are classified, and each category corresponds to specific indicators so as to construct the county tourism economy influencing factor index system. Therefore, it is of great significance to develop the tourism industry, to further utilize the potential of tourism characteristic industries to absorb labor, to adjust the regional employment structure, to optimize and upgrade the employment structure, and to achieve the coordinated development of the employment structure and industrial upgrading.

Based on the proximity of counties (cities and districts), the binary adjacency weight matrix is used, and Geoda software is used to calculate the global spatial autocorrelation coefficient of the comprehensive development level of the regional tourism economy. The adjusted goodness of fit was 0.918, indicating that there is a significant linear relationship between the dependent variable and the independent variable. The statistical t values are all positive, and the significance level is less than 0.05, indicating that the standard regression coefficient is significant. Figure 3 shows the two-dimensional scatter point distribution of the goodness of fit of the temporal and spatial differences. Therefore, the equation has a good fitting effect on the whole, indicating that the level of regional economic development can reflect the development of the regional tourism economy to a certain extent. Therefore, when constructing indicators for the comprehensive development level of the tourism economy, this article constructs it from two aspects: tourism
FIGURE 2: Schematic diagram of the evolution model of temporal and spatial differences.

TABLE 1: Statistical test results of tourism characteristic industries.

| Unit index	Coefficient of elasticity	Goodness of fit	Return parameters
1	0.03	0.97	1.44
2	0.07	0.96	3.71
3	0.05	0.89	2.36
4	0.08	0.87	2.53

FIGURE 3: Two-dimensional scatter point distribution of goodness of fit of temporal and spatial differences.

industry development level and regional economic development level.

The selected index system needs to be able to scientifically reflect the actual situation of the county tourism economy and faithfully reflect the connotation of the corresponding influencing factors by selecting indicators with strong relevance and high representativeness. The establishment of the index system is ultimately to implement each specific data, so the availability and calculation of the selected index data are required to be strong. Because it is relatively difficult to collect county data, it is necessary to ensure the availability of indicators. The principle of operability is one of the indispensable conditions for establishing a complete index system. The full consumption coefficient refers to the sum of the direct and indirect consumption of goods or services in the i-th product sector for each unit provided by the j-th product sector for final use. Based on the characteristics of county tourism economy and the principles of influencing factor index system construction, and drawing on some of the latest results of current regional tourism economic research, this article focuses on the four aspects of tourism resource endowment, location and transportation conditions, economic development level, and industrial structure. They are tourism resource endowment, location traffic conditions, economic development level, and industrial structure. Therefore, we can

conclude that the endowment of tourism resources affects the tourism economy of the county to a greater extent. The location and traffic conditions are greater than the level of economic development and the industrial structure. This is basically consistent with empirical judgment.

3. Results and Analysis

3.1. Extraction of Tourism Economic Data. We use SPSS19.0 software to analyze the selected indicators using the orthogonal rotation method with maximum variance. The KMO test result was 0.819, indicating that the principal component analysis method is suitable. Mathematical statistics cannot explore the evolution of economic differences from a spatial perspective. Therefore, this article uses the natural fracture method in ArcGIS software to classify counties and visualize them to analyze the development of the county tourism economy in terms of time. The characteristics of spatial evolution are to make up for the limitations of mathematical statistics in spatial analysis and also reflect the characteristics of geographic research—analyzing the differences in the distribution of things from a spatial perspective. The research needs to use the relevant data of county-level administrative districts. Table 2 shows the statistics of tourism economic data. This article is to obtain the relevant data in a complete and comprehensive way. By visiting statistical websites of various counties, relevant effective data are collected from statistical yearbooks, statistical reports, or annual national economic and social development reports to reflect the county's tourism economy as comprehensively and accurately as possible.

Through calculations, in the past ten years, the employment scale of the regional tourism industry has shown an overall growth trend, but the volatility is relatively large. The number of employees in the regional tourism industry has reached 961,300, an increase of 24.31% compared to 773,300, and an average annual growth of 2.03%. The proportion of employees in tourism characteristic industries in the total number of employees in the society has increased, from 3.20% to 3.43%, but the proportion of employees in the tertiary industry has declined, from 14.45% to 11.35%. The growth rate of employment is faster than the growth rate of the number of employees in the whole society but obviously lags behind the growth of the number of employees in the tertiary industry. Traditional labor-intensive industries such as the postal industry have become the main industries for absorbing labor in the tertiary industry in the region, with an employment ratio of more than 10%. It can be seen that the selected index data reflecting the level of regional tourism economic development have been subjected to principal component analysis and dimensionality reduction, and four principal components have been extracted. The characteristic value of principal component one is 5.665, and its principal component contribution rate is 47.206%. The characteristic value of principal component two is 1.737, and its principal component contribution rate is 14.472%. The characteristic value of principal component three is 1.319, and its principal component contribution rate is 10.992%. The characteristic value of principal component

four is 1.178, and its principal component contribution rate is 9.819%. Its cumulative variance contribution rate has reached 8.489%. Figure 4 shows the statistical distribution of the contribution rate of tourism economic variance. The eigenvalues of the four principal components are all greater than 1, indicating that the extracted four principal components can well describe the comprehensive difference of tourism economic differences.

We use multiple linear regression to analyze the correlation between tourism economic development level and tourism resource endowment, location traffic conditions, economic development level, industrial structure, and other factors and judge the degree of influence of different factors on dependent variables. From the analysis of the causality test results of the two variable combinations composed of each influencing variable and the employment elasticity of tourism characteristic industries, there is a certain one-way relationship between labor factors and the employment elasticity of tourism characteristic industries. Both the differences between prefectures and cities and the differences within prefectures and cities show a downward trend in fluctuations. The decline from 0.934 to 0.469 shows that the regional differences in total tourism revenues within cities are gradually decreasing.

4. Simulation of Temporal and Spatial Difference Evolution Model

In order to further comprehensively study the regional differences in regional tourism, this article extracts $X1$ domestic tourism income, $X2$ tourism foreign exchange income, $X3$ domestic tourists, and $X4$ international tourists. As an explanatory variable of the effect of regional tourism employment, it is not only necessary to analyze it from the scale of employment but also to grasp it from the quality of employment. Therefore, the absolute amount of tourism employment and the elasticity of tourism employment are selected for measurement. Here, GH, TH, GT, and TT are used to denote the employment scale of tourism core industry, the employment elasticity of tourism core industry, the employment scale of tourism characteristic industries, and the employment elasticity of tourism characteristic industries. Such a statistical caliber is obviously not enough to reflect the actual situation and overall picture of the tourism industry, and it cannot reflect the corresponding status and role of the tourism industry in the national economy. Figure 5 shows a line chart of the proportion of the tourism economy in the total value. This article uses international and domestic tourist visits (TP) and international and domestic tourism revenue (TC) to characterize tourism demand factors, selects fixed asset investment (FAI) and tourism institutions (TS) in industries that are highly related to tourism economic growth to characterize tourism supply factors, and uses gross domestic product (GDP), the proportion of tertiary industry gross product (TIG), and per capita income (PCI) to characterize economic environmental factors.

It is difficult to select appropriate variables for the influencing factors of county tourism spatial differences. In

TABLE 2: Tourism economic data statistics.

| Area code	Employed population ($\times 10^4$)	Growth rate (%)	Variance contribution rate (%)
1	91.13	22.13	37.56
2	64.71	18.52	39.07
3	82.02	19.17	18.84
4	77.52	26.03	24.57
5	79.72	9.42	47.06

FIGURE 4: The statistical distribution of the contribution rate of tourism economy variance.

FIGURE 5: Line chart of the proportion of tourism economy in the total value.

order to better measure each influencing factor, it is necessary to rationally sort and process the original data. This article has made many adjustments to the selection of data through multiple calculations of SPSS. The contribution index of the county tourism economy to the national economy is the proportion of the county's total tourism revenue to the regional GDP. According to the calculation results, the county tourism industry with a contribution index between 0 and 0.10 is named a general industry, the county tourism industry with a contribution index between 0.10 and 0.20 (including 0.10) is named as a pillar industry, and the county-level tourism industry with a contribution index between 0.20 and 0.30 (including 0.20) is named an important pillar industry, and the contribution index is at 0.20. County tourism industries above 30 (including 0.30) are named as strategic pillar industries. Figure 6 shows a fan chart based on the contribution index of the regional Internet of Things. And through ArcGIS software, these four levels of counties are presented in different colors to analyze the spatiotemporal evolution analysis of the difference in the contribution of the county tourism economy to the national economy. The total tourism income of the counties (cities and districts) in the district is extremely poor, and the standard deviation is increasing. The coefficient of variation and Theil coefficient show a downward trend in fluctuations, indicating the absolute value of the total tourism income of the counties (cities and districts) in the district. The difference shows an accelerated growth trend, and the relative difference in total tourism revenue is gradually shrinking.

We divide the total swimming rate into three levels: in the first level, the total swimming rate is extremely low, which is less than 100%; in the second level, the total swimming rate is low, which is 100% to 200%; and in the third level, the general swimming rate is high, which is between 200% and 300%. We can see that the travel rate anomalies of the cities and states in the region are obvious differences in the value. In some areas, the anomaly values are positive and some are negative. According to the data, we divide the total travel rate anomalies of each city and state into three categories: in the first category, the total travel rate has an anomaly value greater than 50%; the second category refers to areas where the total travel rate is close to the average level, and the total travel rate anomaly is lower than 50%; and the third category refers to areas with a large proportion of total employment in tourism, tourism is also the main area for absorbing labor in the region, accounting for a large proportion of total employment in the region, and the proportions of the cities and districts are basically the same. The inbound travel rate anomaly is divided into two categories: the first category is the inbound travel rate level and the second category is areas where the inbound travel rate is lower than the average level, and the anomaly value is negative. The global index of the total tourism revenue of each county (city and district) in the region is positive and shows a trend of increasing in fluctuation, indicating that there is a significant spatial correlation in total tourism revenue.

FIGURE 6: Fan chart of contribution index based on regional IoT.

4.1. Example Application and Analysis. We divide the inbound travel rate into four levels. The first level refers to areas with an inbound travel rate of less than 0.1%, the second level refers to areas with an inbound travel rate of 0.1% to 1%, the third level refers to areas where the inbound travel rate is between 1% and 2%, and the fourth level refers to areas where the inbound travel rate is greater than 2%. By comparing the number of tourism employment driven by unit income, it reflects the contribution of tourism to the employment of various regions and cities in the region and at the same time measures the imbalance in the development of this indicator between regions. Its size depends on the growth rate of the tourism economy and labor productivity. From a spatial comparison, the better the economic foundation is and the stronger the comprehensive strength of tourism economy development is, the smaller the number of jobs driven by tourism income is, basically between 0.10 and 0.15. Both the extreme value ratio and the coefficient of variation show an obvious growth trend, which can be seen intuitively. Figure 7 shows the histogram of the average annual growth rate of the tourism economy. From the comparison of the number of tourism employment driven by tourism income, the tertiary industry GDP, and the unit income of the regional GDP, the number of employment driven by tourism income per labor is the smallest. These reflect that, from the perspective of industry comparison, the output level of unit tourism labor is relatively high; from the perspective of prefecture and city comparison, the tourism labor productivity of economically developed regions is relatively high. In other words, the tourism economy of underdeveloped regions has a relatively high strong labor-absorptive capacity.

Counties with a ranking improvement of more than 10 places are named rapid development type, and counties with a ranking improvement between 0 and 10 places (including 0 and 10) are named development type, and counties with ranking regressed by 1 to 10 places (including 10) are named lagging type, and counties with ranking regressed by more than 10 places are named significantly lagging type. And we use ArcGIS software to make a spatial visualization map to explore the law of spatial change. The scale of fixed asset
FIGURE 7: Histogram of average annual growth rate of tourism economy.

FIGURE 8: Line chart of growth rate of tourism economy scale.

investment in the region has shown the characteristics of continuous increase, with an average annual growth rate of 18.25%, which is nearly 5 percentage points higher than GDP. The contribution rate of fixed asset investment to economic growth has reached 58.40%, which has risen to around 70% in recent years. Fixed asset investment has the dual function of regulating supply and demand. The long-term growth of accumulation and investment is the most basic condition for a large amount of surplus labor to be absorbed by the economy. On the one hand, continuous

large-scale investment balances the original labor and capital. The relationship is broken, which promotes employment growth; on the other hand, it indirectly drives the expansion of investment and employment in other related sectors through the multiplier effect. The range increased from 149.54 to 718.83, and the average annual growth rate reached 20.4%. And in recent years, the growth has been particularly obvious, and the range has grown rapidly from 483.87 to 718.83, a growth rate of 48.56%. The growth of the standard deviation is very similar to that of the extreme

deviation, but the growth rate is faster. Figure 8 shows a line chart of the growth rate of the tourism economy.

Through the analysis of the correlation between regional tourism employment effect variables and various influencing factors, it can basically be judged that the employment scale of core tourism industries and characteristic industries has a strong same-directional relationship with various influencing factors, and the significance level is obvious. The employment elasticity of characteristic industries has a weak and inverse relationship with various influencing factors, and its significance level is not obvious. It can be found that regional tourism can have an impact on almost all industrial sectors in terms of employment, but the employment effects of different industrial sectors are affected by tourism. The focus of this method is to explore the distribution of spatial data, so it is necessary to measure the correlation coefficient between the data. According to a comprehensive analysis, the accommodation and catering industries are most affected. The comprehensive employment coefficient of each tourism characteristic industry is 2.0015, that is, every characteristic industry gains 10,000 yuan of added value, which can lead to 20,015 employment opportunities in the accommodation and catering industry. This is followed by the manufacturing industry at 1.9477 and the tourism core industry at 1.4686.

5. Conclusion

This paper analyzes the statistical data of tourism economy based on the regional Internet of Things and concludes that the absolute difference in the unbalanced development of the county tourism economy is expanding, the relative difference is constantly shrinking, and the degree of concentration of the county tourism economy is decreasing, and it is developing in a balanced direction. This article analyzes the temporal and spatial evolution characteristics of county tourism economic differences from three aspects: the difference in the total county tourism income, the difference in the contribution of the county tourism economy to the national economy, and the difference in the ranking changes of the county tourism economy in the province. This paper follows the structural model of the tourism development dynamic system, combines the theoretical ideas of employment growth, considers the unique attributes of the tourism industry, and establishes an interactive type composed of tourism demand and tourism element supply and connected by the economic environment and labor conditions. The focus of this method is to explore the distribution law of spatial data, so it is necessary to measure the correlation coefficient between the data to determine whether the data has a spatial relationship and the strength of the relationship. From the spatial dimension, we take the regional city as the basic research unit, take the number of employment in tourism characteristic industries as the research caliber, adopt multiple indicators, and conduct a comprehensive evaluation of the regional development of regional tourism employment through horizontal and vertical comparisons. We use SPSS19.0 to establish a multiple linear regression model of important factors affecting regional tourism economy to analyze the factors affecting regional tourism economic differences. Finally, the countermeasures and suggestions for promoting the sustainable development of the regional tourism economy are put forward, with a view to narrowing the difference of the regional tourism economy and promoting the coordinated development of the tourism economy.

A Study of Piano Timbre Teaching in the Context of Artificial Intelligence Interaction

Cui Wei (ID)

Academy of Music, Hebei Normal University, Shijiazhuang, Hebei 050000, China

Correspondence should be addressed to Cui Wei; cuiwei@hebtu.edu.cn

This paper provides an in-depth analysis and research on piano timbre teaching in the context of artificial intelligence interaction, a bold vision of piano teaching, proposes a feasible solution in terms of teaching modules in intelligent piano teaching for senior teachers, and proposes an implementation path for the integration of intelligent piano and piano teaching from the four main blocks of piano teaching. Based on the multiplicative harmonic model of monophonic signal, combined with the variability of timbre characteristics, an audio synthesis model with editable timbre is proposed, and the experimental results show that editing the timbre parameters in the model can realize timbre modification, and the synthesized timbre conforms to the piano timbre characteristics. Based on the timbre analysis and the timbre synthesis model, a piano timbre library generation system is designed. The detailed design of the software modules such as audio file reading and writing, audio information analysis, timbre parameter acquisition, timbre synthesis, and simulated performance is given. The system can generate piano timbre libraries of different qualities flexibly and meet the requirements of timbre realism. The teaching experiment designed for teaching practice from solo teaching, and the practice target is first-year undergraduate students in the university, and the practice period is six weeks, and finally, the feasibility of intelligent piano teaching application is analysed by combining the experimental results. Through the teaching objectives, teaching content, and teaching methods, teaching environment reflects intelligent piano teaching to make up for the limitations of traditional piano teaching. Analyse the development trend of intelligent piano teaching in the context of artificial intelligence interaction, and explore the value of intelligent piano teaching.

1. Introduction

With the continuous development of contemporary art, the combination of musical art expression and modern computer technology is becoming increasingly widely used. Analysing the situation of major international musical instrument exhibitions in recent years, the musical instrument manufacturing industry in developed countries has started the research and development of intelligent pianos and has made great progress. Some internationally renowned piano brands have started to display sample pianos equipped with modern technological functions, which gradually attract the attention of the international music and musical instrument industry [1]. The imported audio file needs to be parsed to obtain audio data information. Then, the audio data is frequency spectrum transformed, and the timbre characteristic information is analysed; the timbre parameters are obtained through the human-computer interaction interface, and the piano timbre is generated. Play the generated timbre in simulation, if the timbre effect is satisfactory. Some experts predict that intelligent pianos will be the direction of development in the piano industry. For digital pianos and smart pianos, the sound source is an important factor that affects their quality and grade. An intelligent piano with high-quality sound sources and characteristics can form good and continuous competitiveness in the market [2]. The intelligent digital piano series launched by Helen Piano has very high requirements for the sound source, taking the Helen Intelligent Piano Angel Series DUAII model as an example, it adopts a dual sound source system, a high-quality digital electroacoustic sound source, and a high-quality soundboard physical sound source, which is the same as the traditional piano sound, pure sound collection of 9 kinds of famous European piano quality tones, up to 7 layers

of tone performance, 128 realistic tones [3]. With the tone synthesis system to simulate the real tone of the instrument and the flexibility to modify and create new tones by editing the tone, it can enable smart and digital instruments to obtain a richer expression of the instrument. In the field of art, visual art and auditory art are the most common forms of art, each of which can bring both physical and psychological aesthetic experiences to people [4]. Traditionally, auditory art can only be experienced through the auditory senses, and the form of experience is relatively single.

With the development of multimedia technology, people put forward higher requirements for the aesthetic experience of auditory art and seek more diverse forms of artistic expression. Taking the theory of wisdom education as a guide and exploring improvement countermeasures based on reflecting on the problems in today's intelligent piano-assisted basic piano teaching in colleges and universities are both a deepening of the theory of basic piano teaching and an application and deepening of the theory of wisdom education in music education [5]. This study helps to clarify the status of intelligent piano-assisted basic piano teaching in colleges and universities. Although digital piano classes in colleges and universities have been offered for many years, there are still various problems and confusions in the actual teaching for various reasons. To reflect the advantages of this new combined teaching mode, take piano solo teaching as an example, and use the traditional piano individual lessons for teaching arrangements. This research study will reflect on these problems and their causes, using the theory of wisdom education, which will help the healthy development of intelligent piano-assisted basic piano teaching. The exploration of countermeasures for intelligent piano-assisted basic piano teaching also helps to improve the efficiency of intelligent piano-assisted basic piano teaching at the same time [6]. The visualization of sound provides people with a new form of visual and auditory expression for the appreciation of auditory art. The new visual interpretation of auditory art adds to the expressiveness of auditory art, providing people with the dual beauty of the combination of visual and auditory senses, and the visualization of sound is conducive to people's deep understanding of the formal structure and emotional content of artworks. For example, in the live performance of the Czech Philharmonic Orchestra, the designer graphically designed the performance rhythmically and displayed it in 3D synchronously with the performance, bringing a visual feast to the audience.

This paper has an in-depth study of piano timbre. Through the piano pronunciation principle and the actual piano signal, the factors that affect the piano timbre are deeply studied. In addition, various existing audio analysis and synthesis techniques have been studied in depth. This paper studies common pitch recognition algorithms and fast pitch recognition algorithms for computer processing. The piano tone is reconstructed through the basic model of the piano mono signal. According to the factors that affect piano timbre, a timbre synthesis model with timbre parameters and editable timbre is designed. We design a synthesis method based on the timbre synthesis model, which can meet the requirements of timbre accuracy and real-time timbre synthesis by computer. We carried out the software and hardware design and equipment selection of the piano sound library generation system. In addition, the language used for software system development is C#. The system can realize the functions of piano audio acquisition, timbre editing, and timbre synthesis. It is experimentally verified that the timbre synthesized by using the existing timbre model is not realistic enough and has the characteristics of obvious electronic synthesized timbre, which cannot meet the requirements of digital piano and electric piano for high-quality timbre. By establishing an audio synthesis model, timbre editing can be realized, and the timbre can be synthesized to meet the requirements of piano sound realism. If the agent chooses from these actions, this action is called developing what is currently known about the value of the action. Conversely, if the agent chooses nongreedy actions, it is called temptation because it can improve the estimation of the value of nongreedy actions. Define appropriate timbre parameters to meet the dual requirements of timbre modification and timbre realism. Design a timbre synthesis method that enables rapid computer synthesis of timbres in real time while satisfying timbre realism and high accuracy. Design and implement a piano timbre library generation system to meet the common audio processing and timbre library synthesis functions. Several existing timbre synthesis models are introduced and simulated, but the synthesized timbres are not ideal; an audio synthesis model with editable timbres is proposed and the timbre synthesis steps are introduced; experiments show that timbre modification can be achieved by editing the timbre parameters of this model, and at the same time, the synthesized timbres meet the requirements of authenticity and high fidelity of piano timbre synthesis.

1.1. Status of Research. Pitch, timbre, intensity, and length are the four most important basic characteristics of music, and they lay the foundation for the entire piece of music. Pitch indicates the frequency of vibration of a sound; timbre refers to the different characteristics of a sound and represents different instruments; intensity, also known as loudness, indicates the size or strength of a sound; and length refers to the duration of a note from its beginning to its end [7]. In addition to the basic characteristics, there are complex characteristics like intervals, melody, rhythm, and overall characteristics like style, emotion, and category. Music features are an important basis for the study of music using computer technology, and the extraction of music features is an essential step for research in areas such as music retrieval and music signal processing. Music has many storage formats, and MIDI is a structured music data format that is widely used in research in the field of computer technology [8]. The total score of the work is excellent in the range of 90–100, good in the range of 80–89, average in the range of 70–79, qualified in the range of 60–69, and effort is needed in the range of 0–59. The design of piano fingering is closely related to the musical notes and piano keys, and the note information includes information such as pitch, pitch length, and pitch intensity, among which the pitch is associated with the piano keys; therefore, the pitch will be an

important musical feature for the automatic generation of piano fingering research in this paper [9]. As piano fingering is closely related to the key position of the fingers, and the key position information represents the pitch information of the notes in the concrete form of piano playing, if we know the key position of each note on the piano keyboard, then we can follow the fingering rules to complete the performance of the music [10]. Therefore, this paper will directly use the MIDI file of the music and extract the key information contained in it as the musical characteristics.

The positions and forms of hands and fingers are represented as HMM states, and the resulting sequences of executed notes are modelled as emissions associated with HMM transitions, and a search is performed using the Viterbi algorithm to find the most likely sequence of state transitions [11]. Zioga et al. proposed an HMM-based piano fingering annotation method for both hands that can handle both single notes as well as chords [12]. In most of these results, machine learning is used to automatically generate piano fingering sequences based on hidden Markov models, since piano fingering sequences are to be generated based on the note sequences of music [13]. The rule-based knowledge base system approach mainly refers to music composition relying on symbolic operations and rule constraints. The advantage of this type of approach is that it has accurate logical reasoning and every act made by the system can be interpreted. A genetic evolutionary algorithm is a method that imitates the process of the genetic evolution of species in biology, first constructing a suitable adaptation function, and then deciding the evolutionary direction of candidate chromosomes through the adaptation function to perform global optimization, which is considered a very effective method in the field of music generation [14]. Being able to imitate production works and even make innovative works proves the applicability of the design. The questionnaire was used to collect frontline teachers' attitudes and opinions on the design of interactive learning resources and the learning effects of students using interactive learning resources. Most teachers gave positive evaluations to the design and production of interactive learning resources. The main problems of neural network-based music generation are as follows: the main problem of neural network-based music generation is that the music features are more complex and the training method is too single, so the quality of the generated music is not guaranteed. However, the neural network-based music generation method has less human involvement and does not require professional knowledge of music theory, and once the model is trained, the generation speed is fast and music can be generated [15]. Therefore, in this paper, after studying the existing music generation techniques, we choose the neural network-based music generation method.

To make the model fully consider the real music composition process, this paper reviewed the information about music composition and interviewed music composers about the specific process of composing music. After further research, these abstract conceptual constraints are converted into computer language, and a chord progression reward mechanism and a music theory rule reward mechanism are constructed and introduced into the critic network constructed in this paper.

2. Analysis of Piano Tone Teaching in the Context of Artificial Intelligence Interaction

2.1. Artificial Intelligence Interaction Background Design. There are two directions in the music generation problem, monophonic music generation, and multitrack music generation. There is no good solution so far on how to represent the connection between different tracks with mathematical models in multitrack music generation, and multitrack music generation requires more stringent training data compared to monotrack. The existence of these problems causes the music tracks generated by multitrack music algorithms to be confusing, of low quality, and lacking in artistic aesthetics; therefore, the music generation in this paper is mainly aimed at monotrack music generation [16]. There are many fields involved in deep learning and many types of network models have emerged during the development process, convolutional neural networks (CNNs), RNNs, LSTMs, etc. Among the abovementioned network types, CNN is mainly used in the field of image processing to extract feature information in images utilizing convolutional kernel, and it can build multi-layer convolution to extract higher dimensional information features, which is beneficial to image recognition and classification. Hoch Reiter and Schmid Huber proposed the LSTM network framework, whose structure is shown in Figure 1. RNN adds three gates, namely, a forget gate, an input gate, and an output gate. Through the gate to control the information, and protect and control the state of the cells, the effect of learning long-term dependence on information is achieved.

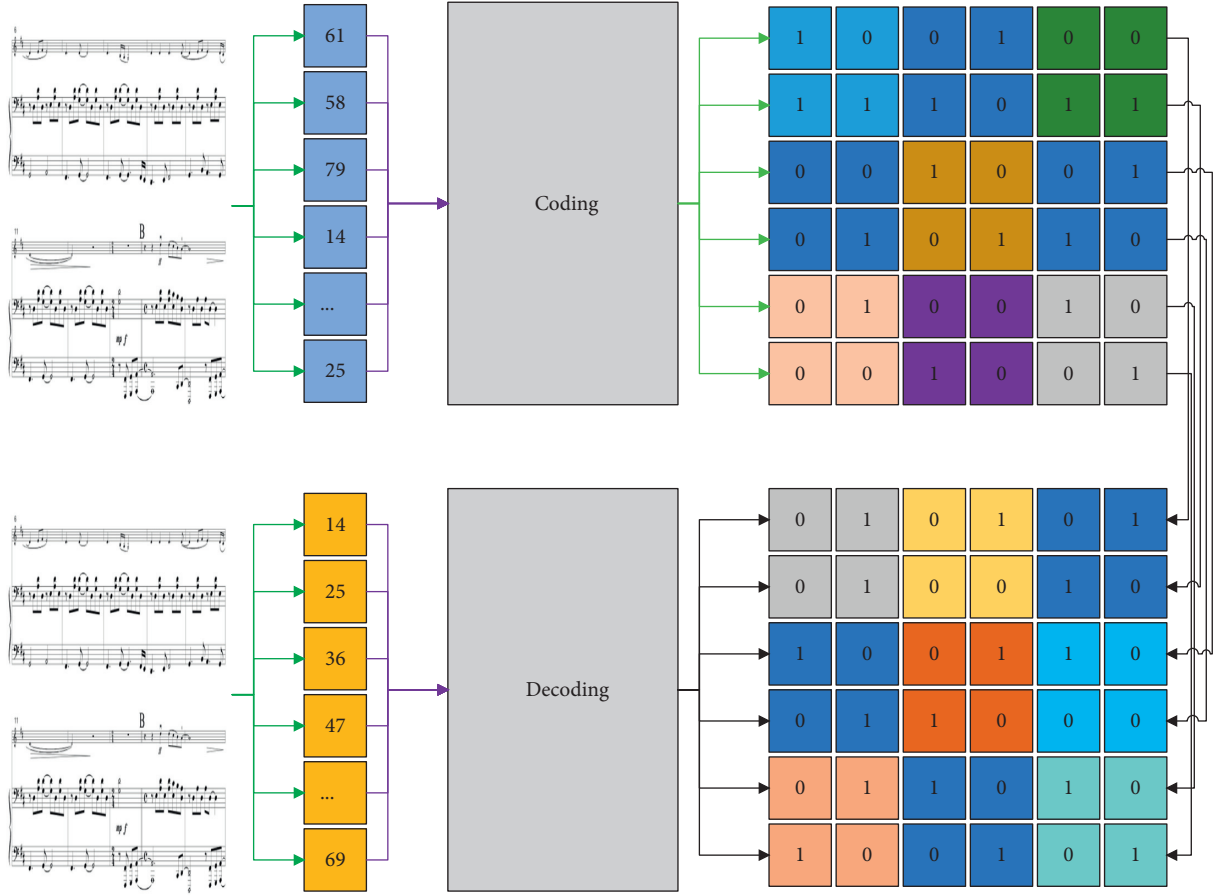
In the implementation of interactive sound visualization, what determines the final visual representation of sound is the transformation patterns and association rules between sound and visual information, and the final visual representation presents a wide variety of variability due to different transformation patterns and rules. Conducive to image recognition and classification. RNN is mostly used in the field of natural language processing. Unlike the feedforward neural network, RNN introduces a self-loop structure, which is characterized by being able to deal with issues related to the input information. Randy and Ben define this way of transforming sound information to visual information through some attribute of association rules as "mapping," where different modes of transformation and association rules are different mappings. The term "mapping" is originally a mathematical term that refers to the unique correspondence between elements in a set of two elements [17]. In the mapping of sound visualization, sound information and visual information form two source bases for information matching, and some association rules are used to correspond to the information in the source bases and finally realize the transmission and transformation between audiovisual information.


Figure 1: Generating a music framework.

It is different from mathematical mapping, and the "mapping" in this paper emphasizes some overall connection and transformation rules between audiovisual information from the macroscopic aspect, rather than referring to the unique correspondence of each element in it.

$$f_t = \sigma\left(W_f \cdot [h_t, X_t] - b_f\right). \tag{1}$$

The adaptation of learning resources to learners is manifested by the fact that learners can choose the learning content and the presentation of the learning content according to their own needs. The adaptation of learning resources to learners is manifested by giving immediate response and intelligent processing according to the dynamic information generated in the learning process of learners, such as providing different learning contents for learners according to the different answer situations of learners; recording students' learning; simulating problem situations in life, etc. And finally. realize the transmission and conversion between audiovisual information, which is not completely equivalent to mathematical mapping. The "mapping" in this article emphasizes a certain overall connection and conversion rule between audiovisual information from a macro perspective. Therefore, the support of learning resources for operational interaction can be summarized in five aspects: learner control, adaptivity, convenience, learning to monitor, and contextuality.

$$i_t = \sigma\left(W_i \cdot [h_t, X_{t-1}] - b_i\right), \tag{2}$$

$$o_t = \sigma\left(W_o \cdot [h_{t-1}, X_{t-1}] + b_o\right), \tag{3}$$

$$C_t = \coth\left(W_c \cdot [h_{t-1}, X_{t-1}] - b_c\right). \tag{4}$$

This stage is not an isolated existence, from aesthetic intuition to aesthetic understanding can produce relevant emotional and affective experience, it is the central outlet of various psychological content and form network structure in the aesthetic process, throughout the entire aesthetic process. When people are assimilated by the content and melody of sound work, they will integrate their body and mind into the sound art and produce the corresponding emotional experience, as in Gestalt psychology's mind-object isomorphism. This emotional experience unfolds along with the perception and understanding of the work and is an involuntary and intense psychological experience, which will be retained in the aesthetic memory for a long time even after the aesthetic process is over.

Sound is a type of wave and therefore has the common properties of waves. Frequency, amplitude, and period are three important physical quantities that can describe the properties of sound waves. Frequency is the number of periodic regular changes per second, and for the frequency of sound, it is the number of sound waves that produce

periodic vibrations in a second from the source. Amplitude is the maximum of the range of vibrations that a vibrating physical quantity can reach, and the amplitude of a sound determines the size of the sound. Sound waves exhibit periodic changes in their vibrational state during propagation, which describes the arrangement of individual repeated pressure changes of sound waves. The motion of the molecules of the medium is not visible to people, but according to the process of physical sound generation and physical properties, the conversion of the audiovisual mapping of physical sound can be achieved in three directions. Sound waves can be represented numerically and precisely by physical quantities such as frequency and amplitude, and through the perception of the extremely physical properties of the physical sound generation process, sound waves in physics are usually described and calculated mathematically in terms of the commonality of their generation principles, that is, a curved sonogram describing the periodic changes of sound energy at different moments experiencing different displacements utilizing mathematical number axes, as shown in Figure 2. The sonogram can accurately show the numerical variation of physical quantities of sound waves such as frequency and amplitude with time, which is important for the analysis of sound waves.

According to the physical nature of sound waves, a mapping transformation can be performed utilizing visual description, at which point the sound map becomes another form of sound existence, a visual feature of physical sound in human perception of sound, an external representation of sound that is based on objective knowledge of the physical characteristics of sound with unique certainty. Professional sound processing and editing software are based on this form of audiovisual conversion.

$$L(\theta_M) = \frac{1}{I}\sum_{i=1}^{I}(Y \ln Y - (1 + Y)\ln(1 + Y)). \qquad (5)$$

Software table technology uses algorithms to replace the hardware timbre library on the sound card and playback MIDI instrument sounds via CPU calculations in real time. The advantages of software table technology are that it produces high-quality sounds, is inexpensive, and is easily upgradeable [18]. Corresponding emotional experience is generated, such as the same shape of mind and object in Gestalt psychology, and psychological emotions will be generated with physical perception. However, the software table synthesis algorithms of different companies in the market are all trade secrets and cannot be obtained for free, and the synthesis results of software table synthesis algorithms vary from company to company, and their levels vary greatly. Therefore, an in-depth analysis of tone synthesis algorithms is needed.

$$P[S_{t+1} \mid S_t] = PP[S_{t+1} \mid S_1, \ldots, S_1]. \qquad (6)$$

There is a reason for the creation of new things, and humankind has never stopped searching and innovating in the field of art. Studies of the piano's development have shown that it is a product of the fusion of music and science

Figure 2: Sonogram.

and that it has become progressively more robust because of the improvement of science and technology. The piano is a keyboard instrument that produces sound by striking the strings through the power of the wrist, hand, and fingertips, so it also belongs to the category of percussion instruments, combining the attributes of a harmonious and dazzling instrument and a percussion instrument. But whatever changes this instrument underwent as it moved forward, it ultimately had a purpose around it, one to fill in the scraps of the age for the aural world with the finest sounds or combinations of different kinds of sounds, from which it gradually changed into aesthetic satisfaction.

$$\text{Notes Accuracy} = \frac{\sum_{m=1}^{M}\sum_{i=1}^{N} p(y_{im}, y_{im}^2)}{M + N}. \qquad (7)$$

Human language as instruction has two different forms of material bearing, namely, speech and writing. Speech belongs to the formal expression of language in the human body, and writing belongs to the symbolic form of the external presentation of language. The two belong to the expression of language in different spatial dimensions. Under the structured system of human linguistic knowledge, speech and text correspond to each other, and text is the visual representation of speech. Human beings have a special function of converting speech and words in real time and accurately, which is done according to human speech perception. Pure Tone collects the high-quality timbres of 9 famous European pianos, up to 7 layers of timbre performance, and 128 realistic timbres. The reading centre in the brain is responsible for linking the visual and auditory symbols of words according to the intentional requirements of the words, thus allowing the person to establish the audiovisual link of words, i.e., to hear the pronunciation and write the words. Usually, such recognition is uniquely deterministic within the same linguistic structural system. The audiovisual transformation between the two bearer forms of language is based on the accepted standard of decoding instructions for human linguistic knowledge, has a broad agreement in human society, and produces a visual commonality in people.

2.2. Experimental Analysis of Piano Tone Teaching. In the timbre composition analysis, we have concluded that all frequency components in the frequency domain work together to form a full and rich piano tone, and that overtone frequency components alone cannot be used for piano tone synthesis. The next step is to investigate the different effects of different frequency components on the formation of piano timbre [19]. In piano timbre, the fundamental and its overtone series play a major role in forming the timbre, and the timbre synthesized using only this frequency component can simulate the main timbral qualities of the piano. The frequencies of the telharmonic play an essential role in forming a full and rich piano tone, and the more interharmonic frequencies used in synthesis, the closer the synthesized tone is to the original piano tone. The part of the frequency spectrum whose frequencies are below the fundamental frequency forms the sound of a piano key struck now it is pressed. The intervals are divided into concordant and discordant intervals according to the auditory perception that the harmonic intervals give to the human ear. Every art form can bring people a dual aesthetic experience of physical and psychological. In the traditional sense, auditory art can only be experienced through auditory senses, and the form of experience is relatively simple. The interval's harmony is a characteristic that reflects the basic nature of the interval and is determined by the ratio of the vibrational frequencies of the two tones forming the interval. An interval that sounds pleasant and blends are called a concordant interval, while an interval that sounds harsher and does not blend is called a discordant interval. Consonant intervals include very fully consonant intervals, fully consonant intervals, and imperfectly consonant intervals. The relationship between the degree of interval harmony is shown in Figure 3.

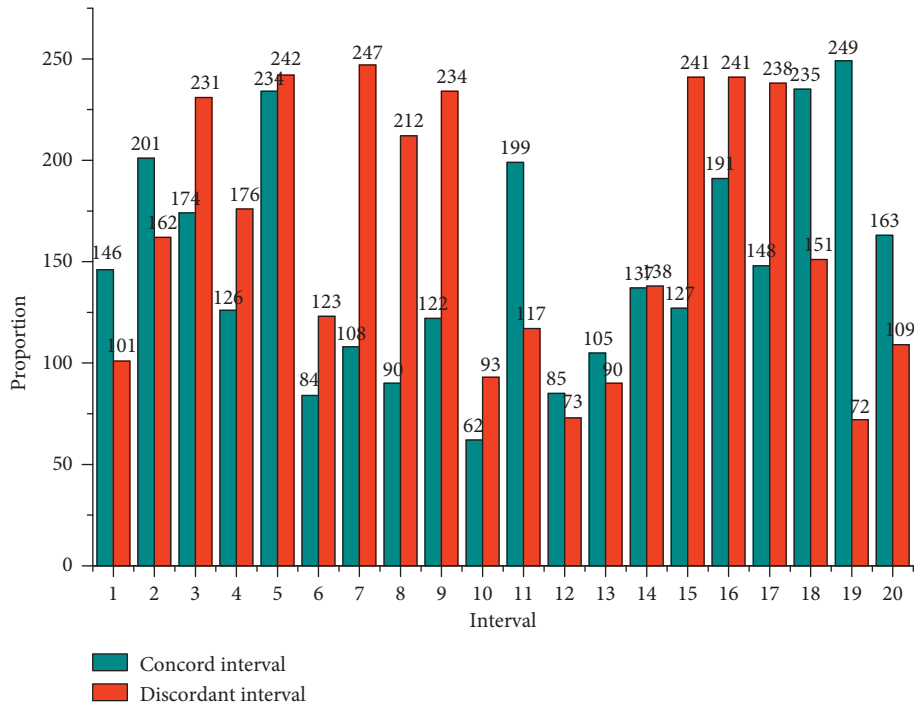
From Figure 3, the time-domain waveforms of the three synthesized timbres differed among the three sets of experimental parameters, indicating that the parameters of the synthesis model can effectively change the time domain waveforms of the timbres. At the same time, the time-domain waveforms of the synthesized timbres are very similar in terms of the general characteristics of the waveform changes, and they all satisfy the three phases of piano articulation: onset, decay, and fade [20]. The frequency-domain waveform plots of the three synthesized timbres are different for the three sets of experimental parameters, indicating that the parameters of the synthesis model can effectively change the frequency domain waveforms of the timbres. Sound visualization provides a new form of expression that combines audiovisual art for people to appreciate auditory art. The new visual interpretation of auditory art adds the expressive power of auditory art, provides people with the dual beauty of audiovisual sensory, and visualizes sound. Performance is conducive to people's deep understanding of the form, structure, and content emotions of artistic works. At the same time, the frequency-domain waveforms of the three timbres have the same characteristics: the frequency distribution is clean and clear, the frequency amplitude is larger at the octave, and the rest of the frequency amplitude is smaller, and there are more

frequency components with smaller amplitude at the lower frequency band, which form the percussive sound of the piano now of pressing. Therefore, it can be judged that it belongs to the same category of piano tone.

The synthesized model timbre parameters can be set to change the time domain waveform and frequency domain waveform of the timbre and combined with the factors affecting the timbre, the timbre parameters must be changed to change the synthesized timbre; at the same time, the synthesized timbre retains the characteristics of the piano timbre in the time domain and frequency domain, in the time domain: it has three phases: onset, decay, and fade, and the sound rapidly decreases in the waveform and then continues to oscillate; in the frequency domain: the frequency distribution is clean. In the frequency domain, the frequency distribution is clean and clear, with larger frequency amplitude at the octave and smaller amplitude at the rest of the frequencies, and more frequency components of smaller amplitude at the low-frequency band that form the piano percussion. The synthesized timbre is a piano timbre, which satisfies the requirements of the piano timbre library generation system for timbre authenticity and high fidelity. Tone editing experiments can prove that using the audio synthesis touch pattern of editable tones in this paper for tone synthesis can change the synthesized tones by adjusting the tone parameters, and at the same time can meet the high-fidelity requirements of the piano tone generation system.

The main steps of piano tone library generation using tone library generation software include: source input, parameter editing, tone library generation, and the software displays audio/tone information and supports simulated playback of synthesized tones to assist the user in generating satisfactory tones and tone libraries. Explore the basic model of piano monophonic signal, reconstruct piano timbre through the basic model; design timbre parameters and an audio synthesis model of editable timbre according to the factors that affect piano timbre. The flowchart of tone library generation is shown in Figure 4.

The software supports two types of audio input methods: piano sound acquisition and import of existing audio files, which requires denoising of the audio after piano sound acquisition and audio file parsing to obtain audio data information. Then, the audio data spectrally transformed and the timbre characteristics are analysed; the timbre parameters are obtained through the human-computer interaction interface and the piano timbre is generated. If you are satisfied with the sound effect, you can save it as an audio file or directly generate and save the piano sound library in batch; if you are not satisfied with the sound effect, you can re-edit the sound parameters through the HMI to generate the sound.

With the combination of smart piano and traditional piano teaching, the teaching arrangement is divided into individual and group lessons crossed by piano solo teaching as an example. Six weeks as a systematic teaching cycle can be based on the intelligent feedback of the intelligent piano and the feedback of the manual teacher as experimental data, to do a summary analysis of the course progress, quality. The first and second weeks are in the form of group lessons on


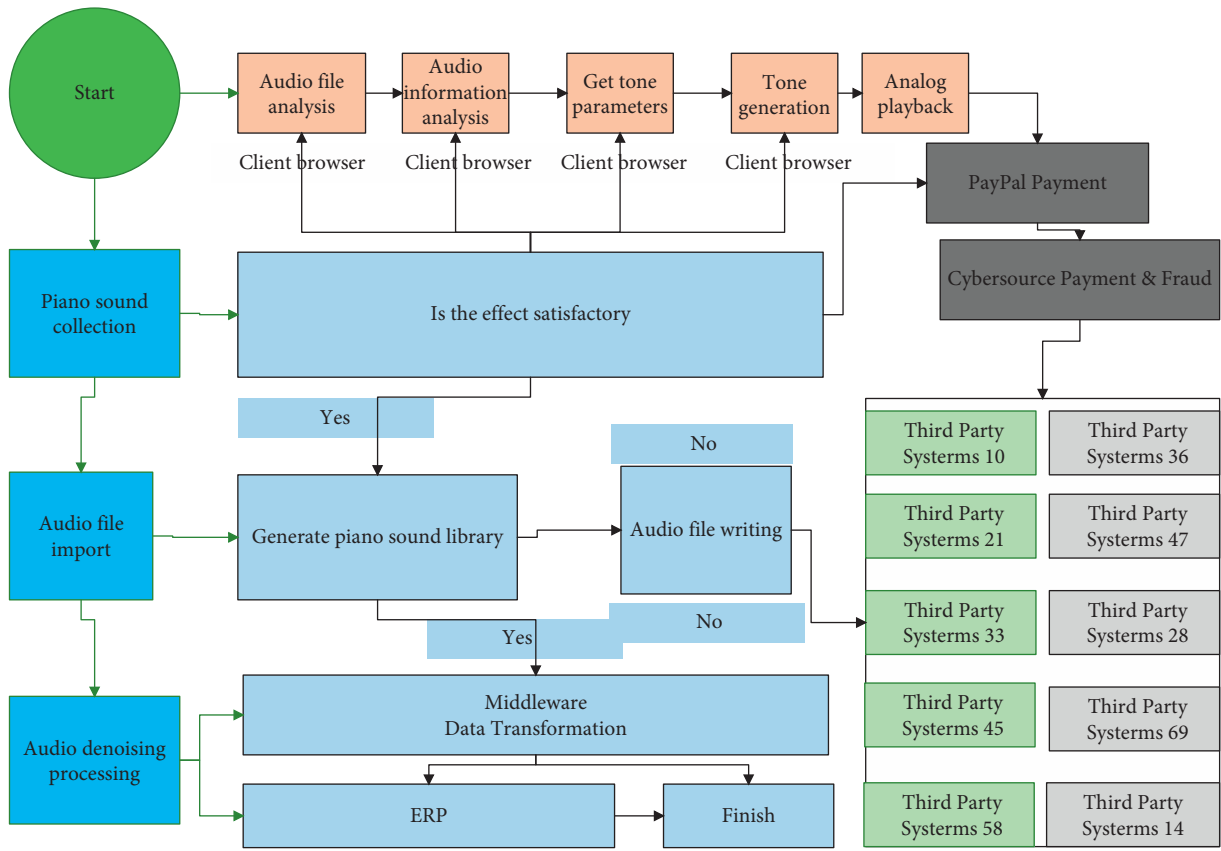


Figure 3: Interval concordance relationship.

Figure 4: Flowchart of tone library generation.

smart piano, the third and fourth weeks are in the form of individual lessons of smart piano, and the fifth and sixth weeks are in the form of individual lessons of a traditional piano. Taking the example of "Chopin's Narrative in G minor" as a case study, we started teaching from the first week to the sixth week, based on the combination of students' receptiveness, basic piano ability, and the difficulty level of "Chopin's Narrative in G minor," from the regular step-by-step teaching process the course is based on the combination of students' receptiveness, basic piano ability, and the difficulty level of the "Chopin's G minor." Each week, student's feedback is combined with the final assessment of student completion, thus demonstrating the advantages of this new combined teaching model. The system can realize the functions of piano audio collection, timbre editing, and timbre synthesis. It has been verified by experiments that the timbre synthesized by the existing timbre model is not real enough and has obvious characteristics of electronically synthesized timbre, which cannot meet the high-quality requirements of digital pianos and electric pianos. As an example, solo piano instruction is arranged in the form of a single traditional individual piano lesson [21]. The six weeks are used as a systematic teaching cycle, and the weekly lessons are summarized and analysed based on the combination of manual teacher feedback and intelligent feedback from the smart piano in the sixth week as experimental tracking data. The first six weeks were spent in the form of traditional individual piano lessons. Taking the "Chopin narrative in G minor" as a case study, the first week to the sixth week, based on the combination of students' receptiveness, basic piano ability, and the difficulty of the "Chopin narrative in G minor", each week combined with the data obtained from students' feedback, and finally checked students' completion. The final check of the students' completion is based on the data obtained from their feedback each week.

The two cases of the six weeks were compared in terms of different lesson formats and teaching methods, and the comparison shows that the combination of smart piano and traditional piano teaching is feasible and replicable. It is possible to try to incorporate "smart piano" into the existing piano teaching. Piano lessons with the "smart piano" application use both individual and group lessons, which are no longer mechanical and monotonous when combined with the traditional individual lessons. This new form of teaching is mainly based on intelligent technology, which can use pictures and audio to teach the students what they need to teach in oral and written form. Compared with the traditional teaching model, this is more stringent for students' learning quality, widens the path of students' knowledge acquisition, and improves teaching efficiency and quality.

3. Results and Analysis

3.1. Artificial Intelligence Interaction Performance Results. During the process of reinforcement learning, the intelligence will continuously estimate the value of states and actions, which is the basis for making action selection. When training reaches a mature stage, then the intelligence will mostly choose the action with the highest estimated value to perform, which will maximize the total gain and achieve our goal. However, at the beginning of training, the intelligence does not know which actions are really "good actions," so the problem of how to make action selection is called the action selection mechanism. The intelligence continuously estimates the value of an action so that at any given moment there is at least one action with the highest estimated value, and these actions are called greedy actions. If the intelligence chooses from these actions, this behaviour is called exploiting (exploit) the currently known knowledge about the value of the action. Conversely, if the intelligence chooses a nongreedy action, it is said to explore, because this improves the estimation of the value of the nongreedy action. "Exploitation" is correct for maximizing the desired benefit in the current moment, but "exploration" may maximize the overall benefit overall. And in an active choice, exploitation and probing cannot be performed simultaneously.

The average gain rate comparison statistics were obtained from the piano fingering generation experiments based on the constructed Q learning network using the key sequences of three music clips respectively, as shown in Figure 5. The average gain rate is the average of the ratio of the total gain to the optimal gain of a training ground, which reflects the superiority of the learning effect and the goodness of the result of the intelligence averaged over a certain range of training steps.

From Figure 5, when the number of training steps is relatively small, the average gain rate of each music fragment is unstable, the results are not satisfactory and fluctuate greatly, and as the number of training steps increases, the bits of intelligence learn to acquire better and better fingering rules, and the total gain gradually increases. The average gain rate stabilized earlier and later due to the different number of keys in each segment, and the segments with more keys require a larger number of training steps to ensure a better experimental result. The fingering sequences with larger yields were selected as the final output fingering sequence results in the training step interval where the average yield of each music fragment stabilized, respectively.

In terms of the cumulative score trend, the machine-generated fingering may be slightly lower than the professional fingering in the intermediate steps, but in general, the scoring trend of the machine-generated fingering for the three music clips is consistent with the professional fingering; in terms of the score rate trend, the scoring rate of the machine-generated fingering for clip 1 and clip 2 is consistent with the professional fingering, and the scoring rate of the machine-generated fingering for clip 3 shows some fluctuations. This indicates that there is still some room for improving the stability of the generated fingering results for music fragments with many notes, but for music fragments with a small number of keys, it can generate high-quality, stable fingering, as shown in Figure 6.

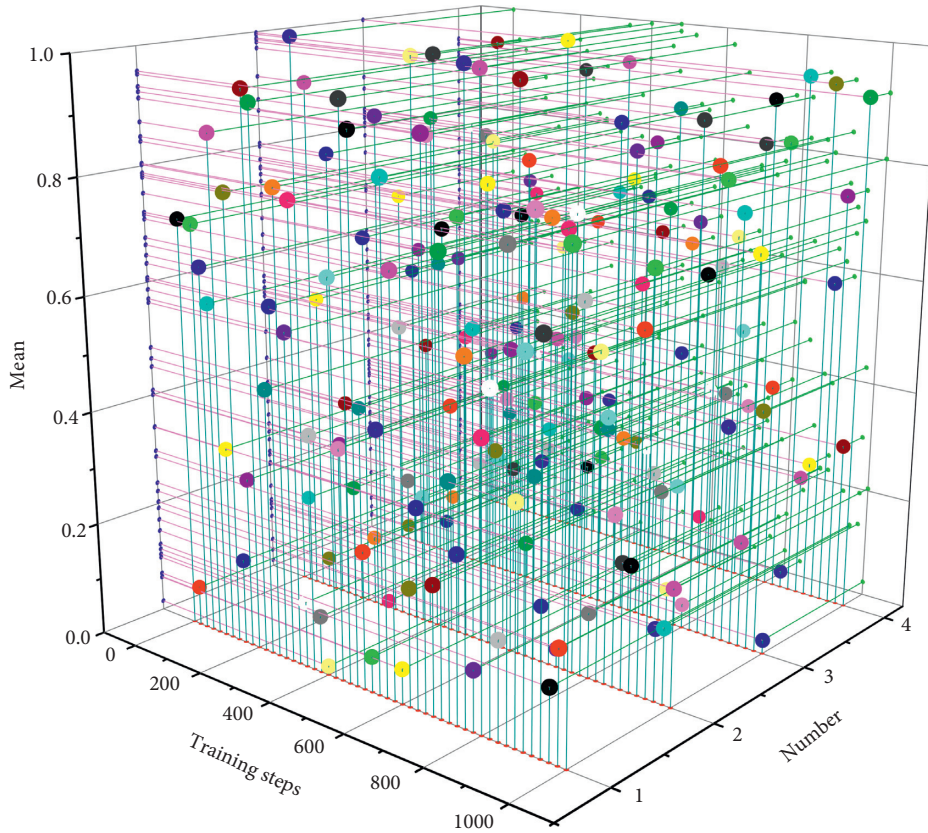
After the above experiments, the character-level music generation network Melodists constructed in this paper can accomplish the end-to-end music generation task and can learn the dependencies of notes on the time scale from the training data, but the Melodists network only uses pure LSTM


Figure 5: Comparison of average yield across music segments.

Figure 6: Plot of generated music versus sample music and difference sound spectrum.

units and the structure is too simple that it cannot learn such complex data as music well. In this paper, we analyse many generation results and find that the generated music often contains many duplicate fragments, the generated music lacks structure, does not follow the rules of music theory, and lacks artistic aesthetics, and we also find that these problems exist in existing music algorithms. Therefore, this paper improves on the Melodists network constructed above and introduces a reinforcement learning algorithm to solve the above problems by combining deep learning and reinforcement learning.

3.2. Results of Teaching Piano Tone. To test whether students achieve a deeper level of conceptual interaction when using interactive learning resources for learning, the teacher should evaluate the mind maps drawn by students during the course, referring to the evaluation criteria for scholarly mind maps in terms of whether the mind maps meet the cognitive level of the students, the appropriateness of the choice of keywords, the connection of relationships between key objects, the presence of scientific errors, aesthetics, etc. The statistics of the evaluation levels of the student-drawn mind maps were obtained as shown in Figure 7.

Through the above evaluation of the students' mind maps, most of the students' mind maps were able to reach the level of C and above, and the mind maps were in line with the student's cognitive level, with appropriate keywords, accurate hierarchical relationships, and no scientific errors, but the aesthetic aspects of the mind maps were still lacking. Students were able to make correct connections between the new content learned in this lesson and the mind maps are drawn in the previous lesson, clarify the hierarchical relationships between concepts, and make correct connections between the new content and the content they had already learned in their minds in the previous lesson.

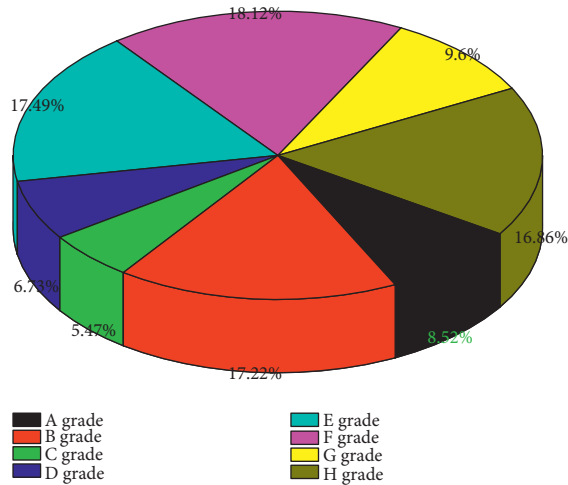
To test the effectiveness of students' learning using the interactive learning resources, and intelligent design work evaluation gauge is designed to evaluate the completion of students' classroom exercises in each lesson. Moreover, the multitrack music generation requires more stringent


FIGURE 7: Thinking maps evaluation results statistics.

FIGURE 8: Comparison of the time-domain waveforms of the synthesized tones of the four sets of experimental parameters.

training data than the single-track music. The existence of these problems causes the confusion, low quality, and lack of artistic aesthetics of the music tracks generated by the multitrack music algorithm. The evaluation gauge evaluates the work in three dimensions: hardware assembly, pictorial programming, and work completion, with ten dimensions and a score of 10 points for each dimension. The total score of the work is excellent in the range of 90–100, good in the range of 80–89, fair in the range of 70–79, pass in the range of 60–69, and needs work in the range of 0–59. The work of 10 students within the AI club was evaluated according to the scale, resulting in the student work evaluation grade statistics shown in Figure 8.

The Smart Design Work Evaluation Scale evaluates students' classroom practice work, and the applicability of the design is demonstrated by the fact that students met the learning objectives after learning with the interactive learning resource and were able to imitate and produce work or even make innovative work. The questionnaire collected frontline teachers' attitudes and opinions about the design of the interactive learning resources and the learning effects of students' use of the interactive learning resources. Most of the teachers gave positive comments on the design and production of the interactive learning resources and believed that the use of the interactive learning resources could guide students to actively control their learning progress, independently assess their learning status, promote the independent construction of learners' knowledge, and realize the deep active interaction between learners. The use of interactive learning resources can guide students to actively control their learning progress, assess their learning status, promote the independent construction of learners' knowledge, and achieve deep active interaction between learners and learning resources.

Most surveyors say that smart pianos mostly used in group lessons and the equipment is old, and students rarely use smart pianos in their daily piano training. In the scenario of basic piano teaching, smart pianos are useful for technique teaching and psychological teaching; in the more complex and high-end teaching scenario involving
performance teaching, smart pianos are not suitable for this purpose. In the current educational environment, the use of intelligent pianos is still very limited. In the current situation of intelligent pianos to assist in basic piano teaching, the author first analyses the causes of the problem from the results of the survey and the literature, including the pressure of teachers to research, the uneven level of students, the lack of professional orientation for students, the lack of contact with intelligent piano courses and the lack of continuity in learning, and the lack of investment in hardware in schools.

4. Conclusion

In this paper, an audio synthesis model with editable timbre is proposed, in which the timbre parameters: maximum octave, amplitude modification coefficient, synthesis parameters, and modification type are set to realize the editable timbre. The synthesis and editing experiments show that the timbre synthesized by this model can meet the high-fidelity requirements of the piano timbre generation system. The model can be used to synthesize timbres to meet the flexibility and authenticity requirements of the piano timbre generation system. The existing piano timbre synthesis model is analysed and experimented with, and the difference between the synthesized timbre and the actual piano timbre is very large, which cannot meet the high-fidelity requirement of the sound source. In this paper, based on the multiplicative harmonic model of monophonic signal, combined with the variability of timbre characteristics, an audio synthesis model with editable timbre is proposed, and the editable timbre is realized by modifying each timbre parameter of the model. The experimental results show that the piano timbre synthesized by this model can meet the system's requirements for flexibility and realism of timbre library generation. The system software includes audio file reading and writing touch block, audio information analysis module, timbre parameter acquisition module, timbre synthesis module, and simulated performance module.

Compared with the traditional methods, the use of this system to generate piano timbre libraries is inexpensive and simple to operate, and it meets the demand for authenticity and personalization of sound sources for digital pianos and smart pianos.

Data Availability

The data used to support the findings of this study are available from the corresponding author upon request.

Conflicts of Interest

The author declares that there are no conflicts of interest regarding the publication of this paper.
